Study and exploration. The Red Sea is one of the first large bodies of water mentioned in recorded history. It was important in early Egyptian maritime commerce (2000 BC) and was used as a water route to India by about 1000 BC. It is believed that it was reasonably well charted by 1500 BC, because at that time Queen Hatshepsut of Egypt sailed its length. Later the Phoenicians explored its shores during their circumnavigatory exploration of Africa in about 600 BC. Shallow canals were dug between the Nile and the Red Sea before the time of Christ but were later abandoned. A deep canal between the Mediterranean and the Red Sea was first suggested about AD 800 by the caliph Hārūn ar-Rashīd. It was not until 1869 that Ferdinand Marie de Lesseps completed the Suez Canal connecting the Red and Mediterranean seas. (B.C.S./W.B.F.R.)

Early use as a route to India

TIGRIS AND EUPHRATES RIVERS

The two greatest rivers of southwestern Asia have widely separated sources in the mountains of eastern Turkey and travel in a southeasterly direction through north Syria and Iraq to the head of the Persian Gulf. The total length of the Euphrates (Akkadian Purattu; Turkish Firat; Arabic Furāt; Biblical Perath) is approximately 1,700 miles (2,700 kilometres). The total length of the Tigris (Akkadian Idiklat; Biblical Hiddekel; Turkish Dicle; Arabic Dijla) is about 1,180 miles (1,890 kilometres). Both rivers traverse two-thirds of their courses before reaching the fringes of the Mesopotamian Plain—the silt-filled depression that must be regarded as their combined delta. To the north of this an upper and a middle course is usually distinguished for each river; each upper course is restricted to the valleys and gorges of east Anatolia, at altitudes diminishing from those of their sources at 6,000–10,000 feet (1,830–3,050 metres) above sea level; each middle course proceeding more tranquilly through the uplands of north Syria and Iraq at elevations varying from 1,200 feet at the foot of the so-called Kurdish Escarpment to 170 feet where the alluvium begins at the head of the delta.

The Tigris and Euphrates derive the bulk of their water from the winter rains and snow of the Güneydoğu Toroslar and Zagros mountains. Both, in their middle courses, are joined by substantial left-bank tributaries. Tributary streams of the Tigris, the Great and Little Zab, which are fed in the spring with snow-melt waters from the high ranges of Iraqi and Iranian Kurdistan, are both more powerful and more unpredictable than the Balīkh and the (western) al-Khābūr, which flow into the Euphrates from springs beneath the Escarpment. The Tigris, therefore, is a more copious and swifter stream than the Euphrates, its character being reflected in the Arabic name Dijla, meaning arrow. Geologically, the most striking feature of both streams is the heavy content of silt which they carry in flood-time. At this season their mean discharge in Iraq is reckoned at about 175,000 cubic feet (4,960 cubic metres) per second, and their water carries as much as 3,000,000 tons of eroded material from the highlands in a single day. The fact that little of this sediment reaches the sea explains the vast tract of alluvial soil of which the Mesopotamian Plain is composed.

Physical features. After reaching the Syrian frontier 250 miles apart, the rivers in their middle courses gradually converge until they are separated only by a triangle of barren limestone desert, known as al-Jazīrah (the Island). On either side of this they have cut deep and permanent beds in the Tertiary rock, so that their courses have remained virtually unchanged since prehistoric times and are punctuated at frequent intervals by the ruins of ancient cities. The Tigris here traverses the homeland of the Assyrians, whose three great capitals—Nineveh, Calah (modern Nimrūd), and Ashur—still overlook the river. By contrast, when the alluvial plain is reached, the rivers are found to have so frequently bifurcated or altered their beds that their earlier courses, and the canals dependent upon them, can sometimes be traced only by the lines of *talls* ("mounds") representing ancient settlements. The *talls* increase in number as the territory of Babylonia is reached,

Tigris–Euphrates river system.

and the mounds marking the sites of the great Sumerian cities in the extreme south suggest a pattern of occupation almost unrelated to the present system of waterways.

Use of embankments

The two rivers, in their lower courses, tend to build up their beds to a level considerably above the plain across which they flow. They are, furthermore, confined between artificial bunds (embankments) to prevent the inundation of the adjacent agricultural lands in the highwater season. Consequently, when, in the past, these bunds have proved ineffectual or have been damaged intentionally, not only have vast areas of surrounding country been flooded but on occasion the rivers have changed their main courses. The high level of the rivers has nevertheless made possible the system of irrigation to which the country owes its prodigious agricultural potential.

The Euphrates has no major right-bank tributaries in its delta, but is joined on its left bank by the Gharrāf Channel, which branches off from the Tigris at al-Kūt. The Tigris has two major left-bank tributaries. It is joined near Baghdad first by al-'Uzaym and then by the even larger Diyālā. This produces a volume of water in excess of the river's capacity, which dissipates itself in extensive marshes on either side of its lower course. To the west the marshes merge into the waters of a great shallow lake, the Hawr al-Ḥammār. The Euphrates flows through this lake before uniting with the Tigris in a single channel, the Shaṭṭ al-'Arab, which reaches the sea over 100 miles further south.

The Euphrates

Physiography. The headwaters of the Euphrates comprise two confluent streams known as the Murat and Kara Su. From their sources near Erzurum, Turkey, they traverse the high lava plain to the northwest of Lake Van and meet eventually at Keban, near Elâzığ, where the rockfill Keban Dam, completed in 1974, spans a deep gorge. The stream, after breaking through the range of Güneydoğu Toroslar, drops down through the foothills of the ancient

district of Commagene. Approaching to within 100 miles of the Mediterranean, it flows by Birecik in Turkey, where it is spanned by road, and Jarābulus on the Syrian side of the frontier, where it is crossed by the Iraqi Railway. From here its southeasterly course across Syria is through barren and thinly populated country, where its cultivable valley is no more than a few miles wide. After the western al-Khābūr joins the Euphrates, it flows through a broader agricultural province until it reaches Abū Kamāl, near the Iraqi frontier, after which the valley narrows again to a strip of alluvium between limestone escarpments. At intervals in the reach between the frontier and Hīt, small towns such as ʿĀnah and Rāwah occupy islands in mid-stream, subsisting upon a riparian system of cultivation that uses ingenious waterwheels for irrigation. Below Hīt, the river cliffs recede and from this point onward irrigation begins on a large scale. Just south of the river below ar-Ramādī lies Lake Ḥabbānīyah, a large depression, enclosed on three sides by low hills, that has been converted into a controlled escape, to minimize the danger of floods and to be used for storage during the low-water period. Between ar-Ramādī and al-Hindīyah, over a distance of about 140 miles, the mouths of all the main controlled irrigation canals as well as most of the pumping installations are to be found. At al-Hindīyah itself, until early in the present century, the river split into two branches, al-Ḥillah and al-Hindīyah, each of which, over the centuries, had alternately assumed importance. In 1908 a barrage was built to canalize and control al-Ḥilah branch, thus making al-Hindīyah the main river channel. Below al-Kifl the river enters an unstable area where effective control is difficult. It bifurcates twice before reappearing above as-Samāwah as a single stream, which still maintains its elevation above the surrounding marshes. Below an-Nāṣrīyah, numerous channels dispose of the waters, which make their way into the Hawr al-Ḥammār, from which, in turn, the outflow finds its way to the Shaṭṭ al-ʿArab.

The Tigris

The Tigris rises in a small mountain lake, Hazar Gölü, southeast of Elâziğ, Turkey. Minor tributaries, flowing into it, drain a wide area extending eastward into Hakkâri *il* (province). Passing beneath the great basalt walls of Diyarbakir, and by a troglodyte settlement at Hasankeyf, it reaches the Syrian frontier at its junction with the eastern al-Khābūr near Cizre (Jazīrat ibn ʿUmar), entering Iraq a few miles beyond at Faysh Khābūr. After passing Mosul, with the ruins of Nineveh on its left bank, the Tigris is joined by its two main tributaries, the Great and the Little Zab, which drain the mountain area of Iraqi Kurdistan. During the season of melting snows, the Zabs, laden with silt, double the volume of the main stream. The river next passes through the al-Fatḥah gorge, where rapids impede navigation, after which a further reach of 60 miles brings the Tigris to the head of the alluvial plain near Sāmarrāʾ. Here there is a barrage and a regulated escape that diverts surplus water into the Tharthār Depression to the west. From Baghdad onward, after receiving the waters of al-ʿUẓaym and the Diyālā, the Tigris is increasingly confined between artificial embankments, from which the southward overspill keeps the great Hawr Dalmaj (Dalmaj Marsh) almost perennially supplied with water. At al-Kūt, 200 miles downstream from Baghdad, there is a barrage and the channel of the Shaṭṭ al-Gharrāf (Shaṭṭ al-Hai) branches off southward. The Shaṭṭ al-Gharrāf is a very ancient bed of the river, irrigating a wide interfluvial area before merging its surplus water with that of the Euphrates where it enters the Hawr al-Ḥammār. The main stream, meanwhile, both above and below al-ʿAmārah, again splits into a number of channels that disperse their water over rice-growing areas and extensive marshes on either bank. At al-Qurnah it joins an old bed of the Euphrates, now fed by the outflow of these same marshlands to become Shaṭṭ al-ʿArab. At Qarmat ʿAlī, a little above Basra, the main stream is joined by more waters from the Euphrates that have filtered through the Hawr al-Ḥammār.

From Baghdad to Basra

Shaṭṭ al-ʿArab

On either side of the Shaṭṭ al-ʿArab, both above and below Basra, close settlement is limited to a belt of cultivation between one and three miles wide. These lands are irrigated by a network of creeks that fill with water from al-ʿArab when the sluices are opened at high tide and are famous for their groves of date palms, from which the fruit is exported all over the world. At Khorramshahr, al-ʿArab is joined by the Kārūn River, which flows southward from Khuzistan in Iran. From here to the sea an uneasy political agreement gives equal rights of navigation to Iraq and Iran. Basra on the right bank is, of course, the principal seaport of Iraq, while Khorramshahr, on the left bank, is Iranian. Two further ports on the lower course of al-ʿArab, Ābādān (Iran) and al-Fāw (Iraq) are no more than specialized discharge points for exporting oil.

Climate. The countries traversed by the Tigris and Euphrates have a continental sub-tropical climate, with extremes of heat and cold in summer and winter, respectively, and a scanty rainfall. In the alpine regions, where the rivers have their upper courses, winter winds are weak and variable, and much of the light precipitation falls in the form of snow, which lies for four or more months in the higher valleys. At this season the mean temperature is much below freezing, so that agriculture is at a standstill and communications are restricted. After the snowfields melt in the spring the rivers are in spate. The mounting volume of their waters is augmented in their middle courses by seasonal rainfall, which reaches its maximum between March and May. Although in the rivers' lower courses intermittent rains continue during the winter months, the total rainfall rarely exceeds eight inches (200 millimetres) annually, and from May onward rain ceases altogether. In the alluvial plain, the most conspicuous climatic feature is the extreme heat of the summer months, with day temperatures rising as high as 120° F (49° C), and with the relative humidity as low as 15 percent. The fertility of the delta is therefore entirely dependent upon the seasonal flooding of the Tigris and Euphrates.

Plant and animal life. Dense communities of common reed and the narrowleaf cattail are found in the wide areas of marshland through which the rivers flow in south Iraq. The young shoots of both are used by Marsh Arabs for fodder. Along the rivers themselves in their lower courses the Euphrates poplar and a species of willow grow in small belts. The poplar is used for practical purposes such as boat building. Undergrowth in these riverain thickets is composed chiefly of five-stamen tamarisk and mesquite, which also extends northward to the middle course of the Tigris and to its tributaries, up to an altitude of 3,000 feet. It is often accompanied by licorice, from whose roots an exportable product is obtained.

Wild pigs are widespread in the marshes adjoining the rivers throughout their courses. In southern Iraq, jackals and occasional hyenas are to be seen among the riverside gardens, and a very large form of Indian jungle cat inhabits the more remote tamarisk thickets. The smaller Eastern wild cat is less common. Among smaller animals are several species of gerbils and the agile jerboa, which may be seen as far north as central Anatolia. Buxton's mole-rat, which covers the entrance to its burrow with a mound of earth, is also found in the riverbanks. Many birds migrating between Europe and Asia fly along the rivers' course.

Locally resident birds include babblers, bulbuls, scrub warblers, and sandgrouse. Among the larger species that frequent the marshes and occasionally breed there are pelicans, flamingoes, herons (including the huge giant heron), storks, spoonbills, and two kinds of bustard. Winter visitors are geese, white-fronted or graylag, and innumerable ducks, including all the common European kinds as well as the red-crested pochard and marbled duck. Gray cranes breed on the upper reaches of the Euphrates. Brilliant European bee-eaters visit the riverbanks on passage, and Persian bee-eaters remain to breed. Both the European and the Indian rollers nest in the vicinity of the rivers, particularly in the vertical banks of water channels.

Among the freshwater fish characteristic of the Tigris-Euphrates system, the carp family is the most conspicuous. The rivers harbour a variety of genera in this family, including small-scale forms recalling the Indian mahseer. A barbel genus is recorded as attaining a weight of 300 pounds (136 kilograms). Besides carp, there are a few varieties of catfish as well as the spiny eel with its curious tubular nostrils.

The people. With the exception of city dwellers, the Arab population on the rivers' banks live either by stock breeding or by agriculture. Their way of life varies from the nomadism of the desert bedouin to the settled condition of the peasantry (fellahin) in the agricultural districts. Both bedouin and fellahin, together with semi-settled Arabs, may be included within the organization of a single tribe. Over the past half century, however, tribal associations have begun to disintegrate. Among the fellahin an improved system of land settlement and legal reforms are breaking the authority of feudal landlords and encouraging the syndication of small holdings.

The Marsh Arabs

The uniform simplicity of village life among the fellahin extends to the limits of the delta. Almost the only variation is to be found among the Maʿdan, or Marsh Arabs, who occupy the vast triangle of swampland between an-Nāṣirīyah, al-ʿAmārah, and Basra. A distinctive culture emerges from their seminomadic life. They raise water buffalo and hunt wildfowl or pigs from their mashuf canoes. The giant mardi reeds found in these swamps reach a height of up to 25 feet, providing them with building material for their characteristic architecture.

North of al-Fatḥah gorge, the Tigris and its tributaries pass through country in which pure Arabs are increasingly in a minority. In the 17th century this region provided winter pasture for the Kurdish tribes but was then settled with Turkmen by Sultan Murad IV, in order to secure his lines of communication with Baghdad. To the north the Turkmen merge with the Iraqi Kurds, whose orchards and vegetable gardens are found along the Tigris tributaries and their smaller affluents. In their upper courses, both the Tigris and the Euphrates pass through mountain country whose inhabitants were once predominantly Kurdish. Today, however, the Kurds have become assimilated into the Anatolian population. Until recently the highland provinces, where both rivers have their sources, were underpopulated as a result of the departure of the Armenians early in the 20th century.

The economy. The rivers have two well-marked flood periods; the first, an irregular rise mainly due to the rain, that lasts from November to the end of March; the second, that of the main flood in April and May. During the second period, the rivers' combined discharge may reach 175,000 cubic feet (4,960 cubic metres) per second, but the volume drops rapidly in June and rarely exceeds one-tenth of that amount in later summer and autumn. From the point of view of agriculture, the rivers are high at the wrong time of year for most crops (except rice), so that cultivation by direct inundation cannot be generally practiced.

Furthermore, the sheer volume of flood water endangers the bunds within which the rivers are confined in their lower courses. The primary requirement of river control is therefore to maintain an effective system of diversion and storage, both as a precaution against the kind of inundation that threatened the existence of Baghdad as recently as 1954 and as a means of retaining the flood waters for distribution in the hot season. To this end, in the early decades of the present century, barrages were built at al-Hindīyah and al-Kūt, and an important weir constructed on the Diyālā east of Baghdad. The diversionary escapes at ar-Ramādī on the Euphrates and at Sāmarrāʾ on the Tigris were both completed in 1956. An even larger storage basin has been created by the construction of a dam at Dukān on the Little Zab in 1958, and yet another is being built at Bakhma on the Great Zab.

Irrigation. The districts of northern Iraq and Syria, together with the piedmont area of southeastern Anatolia, through which the two rivers flow in their middle courses, have a milder climate than the plains in the south and sufficient rainfall to raise a crop of winter grain without irrigation. North of ʿĀnah on the Euphrates and of Tikrīt on the Tigris date palms disappear and are replaced by vines, olives, tobacco, and temperate fruits. There are no major canal systems in this area, and such irrigation as is required is supplied by mechanical lifts. By contrast, in the south the principal crops are wheat, barley, millet, and rice, as well as dates, all of which are dependent upon irrigation. Irrigation takes three forms. Water is distributed from rivers and canals by direct flow onto the land through small channels; by lifting water mechanically into such channels; and by direct inundation. The second of these methods is limited to land relatively close to rivers and canals; the third is useful only for rice cultivation. The relative importance of each method may be judged by the figures for 1942, an average and comparatively recent year; out of a total area cropped by irrigation, 1,700,000 acres (688,000 hectares) were dependent on lifts, 1,500,000 on canals, and 250,000 on inundation. Canals are of two kinds; controlled canals, which receive water from regulators on the main river at all seasons, and uncontrolled canals, which are fed only when the river level reaches the canal head—an eventuality that unfortunately occurs mainly at the season when water is least in demand.

The three systems of irrigation

While the Tigris, at the northern extremity of the delta, flows at a slightly higher level than the Euphrates, before reaching Baghdad the relationship is reversed, and the Euphrates becomes the higher of the two by about 30 feet. There is a second reversal before the Tigris reaches al-Kūt. In antiquity, advantage was taken of these characteristics, which permitted irrigation from one river and drainage into the other, and the situation is still partially reflected in the operation of the controlled canal zones of the present irrigation system.

Areas dependent upon irrigation

Five areas are dependent upon irrigation from large canals, controlled by barrages and sluice gates. The canal systems are the following: (1) the five left-bank Euphrates canals, running generally eastward between ar-Ramādī and al-Musayyib. Irrigation is perennial and is by free flow. (2) The Euphrates canals, depending directly on the Hindīyah Barrage. (3) The Diyālā canals, whose flow is maintained in summer by the Diyālā Weir. (4) The canal system on the Kūt Barrage, including the Gharrāf Canal, and the Dujaylah (an old bed of the Tigris). (5) Canals and spillways from al-ʿAmārah to Qalʿat Ṣāliḥ, on the left bank of the Tigris. Uncontrolled canal irrigation and inundation are predominantly practiced in rice-growing areas, such as in ash-Shāmīyah district (through which run the two branches of al-Hindīyah channel of the Euphrates) along the lower Euphrates around as-Samāwah, from an-Nāṣirīyah to the Hawr al-Ḥammār, and along the Lower Tigris below al-Kūt. Water-lifting machinery, consisting either of oil pumps or more primitive types of apparatus, is in use throughout the middle and lower courses of both rivers. Among the traditional devices in use, particularly on the middle Euphrates, are tall waterwheels, driven by the force of the current, which raise the water in earthenware jars attached to their rims. On the Tigris the height of lifts vary from six feet in the lowest reaches to 40 feet at Baghdad.

In the great irrigated areas of lower Mesopotamia, where the system of extensive cultivation has traditionally been practiced, a primary threat is the gradual salinization of the soil. The irrigation water from the rivers is slightly saline and the heavy residue left by evaporation in hot weather is augmented by salt forced to the surface by groundwater. The resultant deterioration of the soil has been promoted by the pattern of irrigation canals, whose dikes, created by dredging, have divided the low-lying ground into small units, making it difficult to drain off water before evaporation occurs. Philologists have found evidence in cuneiform texts to suggest that the deterioration of land through salinization was already well understood as early as the third millennium BC, when the centres of agricultural prosperity began to shift northward from the original homeland of the Sumerians.

Navigation. In 1836 a British expedition, led by Col. Francis Chesney, navigated the Euphrates by steamship from an-Nāṣirīyah to al-Qurnah, north of the Hawr al-Ḥammār. Today the Euphrates is not navigable except by local craft. From Basra to Baghdad, however, the Tigris is navigable by steamers with draughts of 4 feet 6 inches in the high water season and 4 feet at low water. Above Baghdad small steamers of three foot draught can, with some difficulty, reach Mosul. Much of the downstream traffic on both rivers consists of *kalaks*—rafts of timber and brushwood supported on inflated skins. *Kalaks* carry loads of up to 35 tons and take three or four days to cover

Types of river craft

the 275 miles from Mosul to Baghdad. Upon arrival, the rafts are dismantled, the timber is sold, and the skins are returned by road to their starting-point. Sailing craft include *muhaylahs* and *safīnahs* 30–80 feet long, with a capacity of up to 50 tons. Carrying smaller loads are *balams*—long, narrow double-ended, flat-bottomed craft with a shallow draft. Until recently *guffahs* —huge circular coracles of basketwork, coated with bitumen and capable of carrying up to 20 men—were in regular use in the vicinity of Baghdad.

The ancient trade route from the Persian Gulf to the Mediterranean followed the right bank of the Euphrates almost to Aleppo. The modern road and railway, after crossing the river at as-Samāwah, are diverted at al-Ḥillah toward Baghdad, but the road returns from Baghdad to the important Euphrates crossing at al-Fallūjah, after which it runs across the desert to Damascus. From Baghdad, with its four modern bridges over the mainstream, the railway follows the right bank of the Tigris to Mosul, then turns northwestward across the corner of Syria known as the "Bec-de-Canard" to follow the Turco-Syrian frontier to the Euphrates crossing at Jarābulus. On its way, it passes near the ruins of Haran (modern Harran), the "crossroads city" of the ancient world, and intersects a road that runs due north from ar-Raqqah to cross the headwaters of Euphrates once more at Samsat.

Among the mountains of east Anatolia, railways follow ancient paths, in part, along the upper course of the Tigris and both confluents of the Euphrates, bridging the Euphrates near Malatya.

Study and exploration. History has little to record regarding physiological changes in the upper and middle courses of the two rivers. In the delta, by contrast, the pattern created by complex hydrological developments over a period of several millennia is available for study, even if it is as yet only partially understood. Different explanations, for example, have been given for the way in which the plains were formed and the present coastline created. Until recently it was thought that the head of the Persian Gulf once extended as far as the apex of the delta but must have receded southward until, in early historic times, it corresponded roughly to a line drawn through al-ʿAmārah and an-Nāṣirīyah. Nearer to the present coastline, meanwhile, the westward outflow from the Kārūn River had built up a barrier of silt, behind which a great lake formed. The lake had then gradually filled with alluvium, until only the Hawr al-Ḥammār and the marshes around it remained. In 1952, this long-accepted interpretation was refuted by geologists who detected a gradual subsidence in the basal rocks beneath the Euphrates estuary at a rate that was enough to maintain the alluvial deposit at a constant level. They accordingly concluded that the coastline had remained almost unchanged since historic times—a contention that still requires to be reconciled with conflicting archaeological evidence.

The tangle of waterways and ancient irrigation channels with which the Mesopotamian Plain appears to be covered, especially when seen from the air, gives an exaggerated impression of ancient prosperity, modified only if one remembers that at no time in the past were all these channels in simultaneous use. Of the major canal systems on which the country depended in early medieval times, for instance, some are today re-used and extended, while others are obsolete and forgotten. The five great Euphrates canals (Isa, Sarsar, Malik, Kutha, and Nil), on which the fertility of central Iraq depended in ʿAbbāsid times, have modern counterparts, but their overflow can no longer drain into the Tigris because of a change in level. East of the Tigris, now long neglected and dry, is the great Nahrawān Canal, which irrigated an area extending almost to the Persian frontier. Leaving the Tigris just north of Sāmarrāʾ and utilizing an ancient bed of the main river, this canal collected the waters of al-ʿUẓaym and the Diyālā, carrying them southeastward almost to al-Kūt. It was abandoned after the Mongol invasions, and only a small part of its former dependent territory is now supplied with water by the Diyālā Weir. The old Ishaqi-Dujaylah Canal that irrigated the farmlands west of the Tigris in the same era also now lies derelict. (S.H.F.L.)

The ancient canals

ARABIAN SEA

The Arabian Sea lies in the northwestern section of the Indian Ocean. Situated within the trade wind latitudes, it forms part of the principal sea route between Europe and India. It is bounded to the east by India, to the north by Pakistan and Iran, to the west by the Arabian Peninsula and the Horn of Africa, and to the south by the remainder of the Indian Ocean. To the north the Gulf of Oman connects the sea with the Persian Gulf via the Strait of Hormuz. To the west the Gulf of Aden connects it with the Red Sea via the Strait of Bab el-Mandeb. Its total area is about 1,490,000 square miles (3,859,100 square kilometres); it has a mean depth of 8,750 feet (2,734 metres). In Roman times its name was the Mare Erythraeum (the Erythraean Sea).

Political units bordering the sea—apart from India, Iran, and Pakistan—are the Sultanate of Oman, Yemen (Aden), and Somalia. Islands in the sea include Socotra (a part of the Yemen [Aden]) off the Horn of Africa, the Kuria Muria Islands off the coast of Oman, and the Laccadive Islands (a part of India), the latter of which are a group of coral atolls lying between 100 and 250 miles (160–400 kilometres) off the southwest (Malabar) coast of India. The Indus River is the principal river draining into the sea.

Physical features. Most of the Arabian Sea has depths that exceed 9,600 feet, and there are no islands in the middle. Deep water reaches close to the bordering lands except in the northeast, off Pakistan and India. To the southeast the Laccadive Islands form part of the submarine Maldive Ridge, which extends farther south into the Indian Ocean where it rises above the surface to form the Maldive Islands. On the western side of the sea, the plateau island of Socotra, about 70 miles long and with an area of about 1,200 square miles, is an insular extension of the Horn of Africa, lying 160 miles east of Cape Guardafui.

Submarine morphology and geology. Stretching southeastward from Socotra is the submarine Carlsberg Ridge, which coincides with the belt of seismic activity in the Indian Ocean that divides the Arabian Sea into two major basins—the Arabian Basin to the east and the Somali Basin to the west. The deepest soundings, 15,900 feet, have been recorded in the Somali Basin. The Carlsberg Ridge is longitudinally split by a central valley that reaches depths of 10,800 feet below the sea's surface. The coastal escarpments of the Gulf of Aden are formed by rift faults that converge toward the southwest to continue into Africa as the boundary scarps of the Ethiopian Rift Valley, which forms part of the East African Rift Valley.

The Carlsberg Ridge

The Arabian Basin is separated from the Gulf of Oman Basin by the Murray Ridge, a narrow submarine ridge that extends northeast to southwest to meet the Carlsberg Ridge.

A deep submarine canyon has been discovered off the mouth of the Indus River, while an abyssal cone (a cone in the lowest depths of the ocean) and an associated abyssal plain occupy much of the northeast floor of the Arabian Sea. To the east of the Somali coast is another large abyssal plain.

The coastal shelf is narrow along the coast of the Arabian Peninsula and is even narrower along the Somali coast. No true coral reefs are found along the Arabian coast. Sediments near Raʾs al-Ḥadd (the easternmost headland of the Arabian Peninsula), where upwelling of deep water occurs in summer, consist of fine greenish mud with a high organic content containing hydrogen sulfide. The region, which contains many fish remains, is known as a fish cemetery. Deposits derived from the land cover the major part of the continental slope bordering the sea, down to a depth of about 8,250 feet. Below this, deposits consist of *Globigerina* (a genus of microscopic animals with calcareous shells belonging to a group known as Foraminifera), while basins lying below 12,000 feet are covered by red clay. Manganese nodules have been discovered in the midst of foraminiferal ooze; a single dredge obtained as much as 275 pounds (125 kilograms) of these nodules. Sediment thickness decreases from 8,200 feet in the north to about 1,600 feet in the south of the Arabian Basin.

The Arabian Sea is believed to have been formed during the Mesozoic and Cenozoic eras (*i.e.*, within the last

225,000,000 years). Geophysical studies conducted in the Gulf of Aden suggest that the continental blocks of Africa and Arabia separated, with new oceanic crust forming in between, in the pre-Miocene epoch (*i.e.*, more than 26,000,000 years ago).

Climate and hydrography. Minimum surface temperatures of about 75° to 77° F (24° to 25° C) occur in the central Arabian Sea in January and February, while temperatures higher than 82° F (28° C) occur both in June and in November. During the rainy season, which occurs when the southwest monsoon winds blow, from April to November, salinities of less than 35 parts per 1,000 have been recorded in the upper 150 feet of the sea, while during the dry season from November to March, when the northeast monsoon winds blow, salinities of more than 36 parts per 1,000 have been recorded at the surface over the entire Arabian Sea north of latitude 5° north, except off the Somali coast.

The Somali Current

The complex Somali Current, which attains speeds of about seven knots off the coast of Socotra, becomes part of a clockwise circulation system that continues to the northeast along the coast of Arabia and thence south along the coast of India to 10° north. At this point it merges with the southwestern drift current, flowing east between 5° and 10° north, that is associated with the southwest monsoon winds. Pronounced upwelling of deeper waters occurs along the Somali and Arabian coasts in summer. Of the five water masses that have been distinguished in the upper 3,000 feet of the north Indian Ocean, three have been identified as originating in the Red Sea, the Persian Gulf, and the Arabian Sea, respectively. The paths of flow of these water masses are to the south and east.

Marine life. High levels of inorganic nutrients, such as phosphate concentrate, which produce a rich fish life, have been observed in the western Arabian Sea and off the southeastern coast of the Arabian Peninsula. Occurring in the euphotic zone (zone of light, which is found in the upper 450 feet of the sea), this concentration of nutrients is undoubtedly due in part to coastal upwelling, which plays a major role in fertilizing the water.

Pelagic fish (*i.e.*, those living at or near the surface far from the land) in the Arabian Sea include tuna, sardine, billfish (a species having a long sharp bill or snout), wahoo (a large, swift game fish), sharks, lancet fish (a large species having dagger-like teeth), and moonfish (a species of silvery fish with very compressed bodies).

A periodic phenomenon in the Arabian Sea, however, is mass mortality of fish. In 1957, for example, in an area of approximately 77,000 square miles about 20,000,000 tons of fish were believed to have perished. Fish mortality is attributed to a subsurface layer of water of tropical origin that is poor in oxygen but rich in phosphate; under certain circumstances this layer is brought to the surface by strong upwelling, resulting in the death of fish from lack of oxygen.

Study and exploration. To medieval Arabs the Arabian Sea was known as the Sea of India or as part of the "Great Sea," from which smaller gulfs such as the Sea of Faris (Persian Gulf) or Sea of Kolzum (Red Sea) were distinguished. From about the 8th or 9th centuries onward.

The early Arabian and Persian navigators

Arab and Persian seafarers learned to use the surface currents propelled by the summer and winter monsoon winds. Detailed navigational instructions for sailing between southern Arabian, East African, and Red Sea ports, as well as ports in India, Malaysia, and China, were written down by pilots from Oman and the Ḥaḍramawt region of southern Arabia between the 9th and 15th centuries. Some of these works, entitled in Persian *rahmangs* (books of routes), contain useful information on navigating by the stars, on winds, currents, soundings, descriptions of coasts, approaches, and islands. Among flourishing medieval ports mentioned in these works are Diu and Surat in India, Hormuz in Persia, and Muscat and Aden on the Arabian Peninsula. Landmarks mentioned included Raʾs (cape) al-Ḥadd and Raʾs Madrak—capes on the southeast coast of the Arabian peninsula—and Cape Guardafui in Somalia, which is the cape of the Horn of Africa.

In recent times the Arabian Sea has been studied by several oceanographic expeditions, of which the most important has been the Mabahiss, or John Murray, Expedition of 1933 to 1934, which reported findings concerning hydrography, chemistry, currents, water masses, bottom topography, and sediments. Further information was obtained during the International Indian Ocean Programme (1960–65) in which British, U.S., Soviet, and German ships participated, studying currents, biological productivity, seismology, and geology. (An.A.A.)

BAY OF BENGAL

The Bay of Bengal, lying roughly between latitude 5°–22° N and longitude 80°–95° E, forms a relatively shallow embayment of the northeastern Indian Ocean. The bay occupies an area of 839,000 square miles (2,173,000 square kilometres) and is bordered by India and Sri Lanka (Ceylon) on the west, Bangladesh to the north, and Burma and the northern part of the Malay Peninsula to the east. According to the definition of the International Hydrographic Bureau, the southern boundary of the bay extends from Dondra Head at the southern end of Sri Lanka to the northern tip of Sumatra. The bay is about 1,000 miles (1,600 kilometres) wide, with an average depth of more than 2,600 feet (790 metres). The maximum depth is 14,764 feet (4,500 metres). A number of large rivers, namely, the Ganges and Brahmaputra on the north, the Irrawaddy on the east, and the Godāvari, Mahānadi, Krishna, and Cauvery on the west, flow into the Bay of Bengal. The Andaman and Nicobar groups are the only islands. Among the principal ports on the bay are the Indian ports of Calcutta, Cuddalore, Kākināda, Machilīpatnam, Madras, Paradip, and Vishākhapatnam.

A number of expeditions have traversed the area since the latter part of the 19th century, and, in connection with the International Indian Ocean Expedition, the "Vityaz" from the Soviet Union, and the "Pioneer" and "Anton Bruun" from the United States, have more recently carried out detailed investigations. Extensive work has been done on the western coast of the bay by research workers of Andhra University.

Physical features. *Physiography.* The Bay of Bengal is bordered to the north by a continental shelf 100 miles wide, but narrower to the south, and by slopes of varying gradient on the west, north, and northeast. Except for the submarine canyons around Sri Lanka, the trough-like valley off the Ganges Delta, and suspected north–south turbidity channels, the deep floor of the bay until recently was believed to be occupied by a vast plain sloping to the south and in places dissected by underwater valleys, perhaps caused by turbidity currents. As a result of the International Indian Ocean Expedition, however, the oceanography is now better understood, and many new physiographic features—mountain chains, submarine canyons, and deep channels—have been brought to light. One of the main submarine features is the north–south Indonesian Trench near the Nicobar-Sumatra mainland, which extends into the bay at a maximum depth of 14,800 feet. A large submarine canyon beginning at the head of the bay and called "Swatch of No Ground" extends across the continental shelf for 100 miles with a uniform breadth of eight miles. It appears to begin at about 60 to 180 feet and to cut into the shelf to depths of as much as 3,000 feet below the adjacent shelf level.

Bottom topography

In 1963 the Andhra, Mahadevan, and Krishna canyons were discovered off the Andhra coast. A number of other canyons have been identified off the Kākināda–Madras (Coromandel) coast and named after rivers in the vicinity of their locations, namely, Swarnamukhi Canyon, Pennar Canyon, Madras Canyon, Nagarjuna Canyon, Godāvari Canyon, Gautami Canyon, and another south of Puri. Some of them are believed to have been formed during the Pleistocene (10,000 to 2,500,000 years ago) and to have been maintained since then by progressive slumps, density flows, and slow creep.

Hydrography. A unique feature of the bay is the extreme variability of its physical properties. Temperature in the offshore areas, however, is very uniform at all seasons, with decreasing temperatures toward the north. Surface densities are considerably greater in spring than in fall. The sea presents alternately slick and ruffled surfaces over

shallow internal waves all along the east-coast shelf. Surface movements of the waters change direction with the season, the northeast monsoon giving them a clockwise circulation, the southeast monsoon a counterclockwise circulation. Severe storms occur at the change of monsoon, particularly to the south in October.

In addition to water-level changes resulting from waves and tide, the average sea level varies throughout the year.

Marine life and bottom deposits. Near its shores the Bay of Bengal is rich in phytoplankton and the related zooplankton. The coastal strips near the outlets of the Vamsadhāra, Nāgāvali, Vasishta Godāvari, and Vainateyam Godāvari rivers have deposits of heavy mineral sands, especially rich in manganese. The source of the manganese has been traced to the rocks in the drainage basins of the rivers emptying their waters and sediment load into the bay. The amount of organic matter present in the continental-shelf sediment of the northern part of the east coast is poor compared with the world's average for nearshore sediments.

Mineral assemblages

On the basis of the available data, the Bay of Bengal can be divided into two areas, one characterized by clay minerals such as illite and kaolinite (Andaman and Nicobar Islands) and the other containing montmorillonite—another clay mineral characterized by swelling in water (eastern and southern parts of the bay). These minerals appear to be derived mainly from the Indian peninsula and from the Himalayas, where they occur abundantly in sedimentary rocks and soils of the river basins. Modern geophysical methods of exploration employed in offshore prospecting are likely to open new vistas into the bay's structure and possible mineral resources under the ocean bed.

The economy. The bay faces on the fertile deltas of many large and navigable rivers: the Ganges and Brahmaputra on the north, the Irrawaddy on the east, and the Mahānadi, Godāvari, and Cauvery on the west. The Deccan coast provides no harbours, Madras having a mere open roadstead; but on the east the drowned coast has given many good ports, such as Sittwe, Moulmein, and Rangoon. (S.B.)

BRAHMAPUTRA RIVER

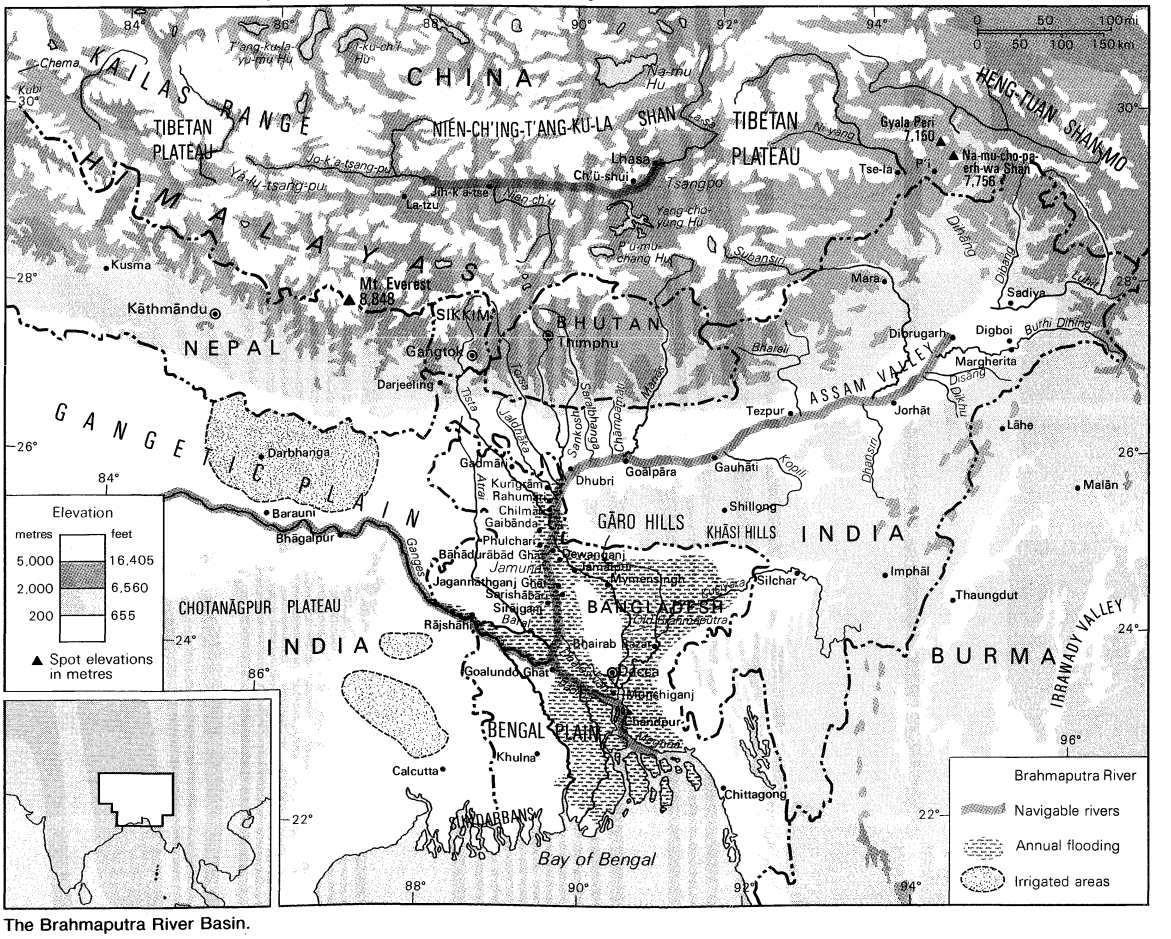
The mighty Brahmaputra River flows for 1,800 miles (2,900 kilometres) from its source in the Himalayas to its confluence with the Ganges, after which the mingled waters of the two rivers empty into the Bay of Bengal. Along its course it passes through the Tibetan Autonomous Region of China; the union territory of Arunachal Pradesh and the state of Assam, India; and Bangladesh. It is known to the Tibetans as the Tsangpo, to the Chinese as the Ya-lu-ts'ang-pu, to the Indians as the Brahmaputra, and to the people of Bangladesh as the Jamuna. For most of its length, the river serves as an important inland waterway; it is not, however, navigable between the mountains of Tibet and the plains of India. In its lower course, the river is both a creator and a destroyer—depositing large amounts of fertile alluvial soil but also causing disastrous and frequent floods.

Physical features. The river's source lies in the Chema-Yungdung Glacier, which covers the slopes of the Himalayas about 60 miles (100 kilometres) southeast of Lake Manasarowar in southwestern Tibet. The three headstreams that arise there are the Kubi, the Angsi, and the Chema-Yungdung. From its source the river runs for nearly 700 miles (1,120 kilometres) in a generally easterly direction between the main Himalayan range to the south and the Nien-ch'ing-t'ang-ku-la Shan (Nyenchen Tangla) to the north. Throughout its upper course the river is generally known as the Tsangpo (the Purifier); it is also known by the Chinese name Ya-lu-tsang-pu Chiang and by other local Tibetan names at various points along its course.

The river's upper course

In Tibet the Tsangpo receives a number of tributaries. The most important left-bank tributaries are the Jo-k'a tsang-pu (Raga Tsangpo), which joins the river west of Jih-k'a-tse (Zhikatze), and the La-sa Ho (Kyi Chu), which

Flooding data from R. Rawson, *The Monsoon Lands of Asia;* irrigation data from L. Cantor, *A World Geography of Irrigation* (1970), Oliver and Boyd, Edinburgh



The Brahmaputra River Basin.

flows past the Tibetan capital of Lhasa and joins the Tsangpo at Ch'ü-shui. The Ni-yang Ho (Gyamda Chu) joins the river from the north at Tse-la (Tsela Dzong). On the right bank the Nien-ch'u Ho (Nyang) meets the river at Jih-k'a-tse.

After passing P'i (Pe) in Tibet, the river turns suddenly to the northeast and cuts a course through a succession of great, narrow gorges between the mountainous complex of Gyala Peri (23,458 feet, or 7,150 metres, in height) and Na-mu-cho-pa-erh-wa Shan (Namcha Barwa) (25,446 feet, or 7,756 metres, in height) in a series of rapids and cascades. Thereafter, the river turns south and forces its way through the eastern extremity of the Himalayas to enter the Assam Valley of northeastern India as the Dihāng River.

At the town of Sadiya, India, the Dihāng turns to the southwest and is joined by the two mountain streams of Luhit and Dibang. After the confluence, about 900 miles from the Bay of Bengal, the river is known as the Brahmaputra (the Son of Brahmā [the Creator]). In Assam the river is mighty, even in the dry season, and during the rains its banks are more than five miles apart. As the river follows its braided, 450-mile course through the valley, it receives several rapidly rushing Himalayan streams, including the Subansirī, Bhareli, Dhansiri, Manās, Chāmpamāti, Saralbhānga, and Sankosh rivers. The main tributaries from the hills and from the plateau to the south are the Burhi Dihing, the Disāng, the Dikhu, and the Kāpili.

The complex lower course

The Brahmaputra enters the plains of Bangladesh after turning south around the Gāro Hills below Dhubri, India. After flowing past Chilmāri, Bangladesh, it is joined on its right bank by the Tīsta River, following a 150-mile course due south as the Jamuna River. (South of Gaibānda, the Old Brahmaputra leaves the left bank of the main stream and flows past Jamālpur and Mymensingh to join the Meghna River at Bhairab Bāzār.) Before its confluence with the Ganges River, the Jamuna receives the combined waters of the Baral, Atrai, and Hurāsāgar rivers on its right bank and becomes the point of departure of the large Dhaleswari River on its left bank. A distributary of the Dhaleswari, the Burhi Ganga, flows past Dacca and joins the Meghna River above Munshiganj.

The Jamuna joins with the Ganges north of Goalundo Ghāt, after which, as the Padma, their combined waters flow to the southeast for a distance of about 65 miles. The Padma reaches its confluence with the Meghna River near Chāndpur and then enters the Bay of Bengal through the Meghna Estuary and lesser channels.

Climate. The climate of the Brahmaputra Valley varies from the harsh, cold, and dry conditions found in Tibet to the generally hot and humid conditions prevailing in the Assam Valley and Bangladesh. Tibetan winters are severely cold, with minimum temperatures below 32° F (0° C), while summers are mild and sunny. The river valley lies in the rain shadow of the Himalayas; there is little rain in the summer, but some snow and rain falls during the winter. In the Indian and Bangladesh part of the valley, the monsoon climate is somewhat modified; the hot season is shorter than usual, and the average temperature is 82° F (28° C). Precipitation is relatively heavy, and humidity is high throughout the year. The annual rainfall of between 70 and 150 inches (1,780 and 3,810 millimetres) falls mostly between June and early October; light rains also fall from March to May.

Plant and animal life. Large areas in Assam are covered with sal (valuable timber trees that yield resin) forests, and tall reed jungle grows in the swamps and depressed, water-filled areas (*jhīls*) of the immense floodplains. Around the settlements in the Assam Valley, the many fruit trees yield plantains, papayas, mangos, and jackfruit. Bamboo thickets abound everywhere.

The most notable animal of the swamps in Assam is the one-horned rhinoceros, which has become extinct in other parts of the world. Tigers and elephants are also found. Numerous varieties of fish include the betki, pabda, ruhi, chital, and mrigal.

Hydrography. Constant changes of the river's course constitute a significant factor in the hydrology of the Brahmaputra; the most spectacular of these changes was the eastward diversion of the Tīsta River and the ensuing development of the new channel of the Jamuna, which occurred in 1787 with an exceptionally high flood in the Tīsta. The waters were suddenly diverted eastward into an old abandoned course, causing the river to join the Brahmaputra opposite Bāhādurābād Ghāt in Mymensingh District. Until the late 18th century the Brahmaputra flowed past the town of Mymensingh and joined the Meghna River near Bhairab Bāzār (the path of the present-day Old Brahmaputra Channel). At that time, the course of the Jamuna River (now the main Brahmaputra Channel) was a minor stream called the Konai-Jenai, which was probably a spill channel of the Old Brahmaputra. After being reinforced by the Tīsta flood of 1787, the Brahmaputra began to cut a new channel along the Konai-Jenai and gradually converted it after 1810 into the main stream, now known as the Jamuna.

Changes in the river's course

Along the lower courses of the Ganges and Brahmaputra and along the Meghna, the land is subjected to constant erosion and deposition of silt because of the shifts and changes in these active river courses. Vast areas are subject to large-scale inundation during the monsoon months from June to September. The oscillations of the Jamuna since 1787 have been considerable, and the river is never in exactly the same place for two successive years. Islands and sizable newly deposited lands (*chars*) in the river appear and disappear seasonally. The *chars* are valuable to the economy of Bangladesh as additional cultivable areas.

In Tibet the waters of the Brahmaputra are clear because little silt is carried downstream. As soon as the river enters the Assam Valley, however, the silt charge becomes heavy. Because of the speed and volume of water in the northern tributaries that flow down from the rain-soaked Himalayan slopes, their silt charge is much heavier than that carried by the tributaries that cross the hard rocks of the old plateau to the south. In Assam the deep channel of the Brahmaputra follows the southern bank closer than the northern. This tendency is reinforced by the silt-laden northern tributaries pushing the channel south.

Another important hydrographic feature of the river is its tendency to flood. The quantity of water carried by the Brahmaputra in India and Bangladesh is enormous. The Assam Valley is enclosed by hill ranges on the north, east, and south and receives over 100 inches of rainfall annually, while in the Bengal Plain heavy rainfall (70 to 100 inches) is reinforced by the huge discharge of the Tīsta, Torsa, and Jaldhāka rivers. This results in heavy annual floods and an estimated discharge during the rainy season of 500,000 cubic feet (14,200 cubic metres) per second. The Assam earthquake of 1950 led to numerous landslides on the Himalayan slopes of the Assam Valley; the resulting enlarged discharge, combined with enormous amounts of silt, caused extraordinary floods. Between 1950 and 1970 there were heavy flood conditions every year except 1951, 1952, and 1958.

The people. The people living in the different sections of the Brahmaputra Valley are of diverse origin and culture. North of the Himalayan rampart, the Tibetans practice Buddhism and speak the Tibetan language. They engage in animal husbandry and cultivate the valley with irrigation water taken from the river.

The Assamese are a mixture of Mongolian–Tibetan, Aryan, and Burmese ethnic origins. Their language is akin to Bengali, which is spoken in West Bengal, India, and Bangladesh. From the late 19th century a vast number of immigrants from the Bengal Plain of Bangladesh entered the valley; they settled there to cultivate the almost empty lands, particularly the low floodplains. In the Bengal Plain itself the river flows through an area that is densely populated by the Bengali people, who cultivate the fertile valley. The hilly margins of the plain are inhabited by the hill tribes of the Garos, Khāsis, and Hajangs.

The economy. *Irrigation and flood control.* Flood-control schemes and the building of embankments were initiated after 1954. In Bangladesh the Brahmaputra embankment running west of the Jamuna River from north to south helps to control floods. The Tīsta Barrage Project is both an irrigation and a flood-protection scheme.

The Tīsta Barrage Project

Little power has been harnessed along the Brahmaputra or the Assam Valley, although the estimated potential is great. The tributaries that drain the Shillong plateau have deep stretches and a series of rapids and falls that are suitable for hydroelectric development. Actual development is so far limited to the Barpani Dam and the Umiam Project near Gauhāti, which have a total capacity of almost 60,000 kilowatts and which serve areas of the Khāsi Hills in Meghalaya. There is little demand for electric power in the Brahmaputra Valley because manufacturing is limited and there is relatively little urbanization. Power needed on the tea estates in the Assam Valley is locally generated by thermal sources, which mainly use crude oil.

Navigation and transport. The river is navigable in Tibet for about 400 miles between La-tzu (Lhatse Dzong) and Lhasa. Coracles (boats made of hides and bamboo) and large ferries ply its waters at 12,000 feet above sea level. The Tsangpo is spanned in several places by suspension bridges.

Because it flows through a region of heavy rainfall in Assam and Bangladesh, the Brahmaputra is more important for inland navigation than for irrigation. The river has long formed a waterway between West Bengal and Assam. It is navigable throughout the Bengal Plain and Assam upstream to Dibrugarh, 800 miles from the sea. Besides all types of local craft, powered launches and steamers may easily ply up and down the river, carrying bulky raw materials, timber, and crude oil. After the conflict between India and Pakistan in 1965, however, heavy traffic was suspended.

The Brahmaputra remains unbridged throughout its course in the plains. Roads and railroads run along the river but never cross it; ferries carry traffic between its banks. Sadiya, Dibrugarh, Jorhāt, Tezpur, Gauhāti, Goālpāra, and Dhubri are important towns and ferry-crossing points in Assam, while Kurīgrām, Rahumāri, Chilmāri, Bāhādurābād Ghāt, Phulchari, Sarishābāri, Jagannāthganj Ghāt, Nagarbāri, Sirājganj, and Goalundo Ghāt are important crossing points in Bangladesh. The railheads are located at Bāhādurābād Ghāt, Phulchari, Jagannāthganj Ghāt, Sirājganj, and Goalundo Ghāt.

Study and exploration. The upper course of the Brahmaputra was unknown until the 19th century. The explorations of the Indian surveyor Kinthup in 1884 and of J.F. Needham in Assam in 1886 established the Tsangpo as the upper course of the Brahmaputra. Various British expeditions in the first quarter of the 20th century explored the Tsangpo upstream to Jih-k'a-tse, as well as the river's mountain gorges.

GANGES RIVER

The great river of the North Indian plains is officially as well as popularly called the Ganga, both in Hindi and in other Indian languages. Internationally, however, it is known by its anglicized name, the Ganges. From time immemorial it has been the holy river of the Hindus. For most of its course it is a wide and sluggish stream, flowing through one of the most fertile and densely populated tracts of territory in the world. Despite its importance, its length of 1,557 miles (2,506 kilometres) makes it only the 15th longest river in Asia, and the 39th longest river in the world.

Rising in the Himalayas and emptying into the Bay of Bengal, it drains a quarter of the territory of India, while its basin supports a concentration of about 300,000,000 people, a population larger than that of any state on earth with the exceptions of China and India. The Gangetic Plain, across which it flows, is the heartland of the region known as Hindustān and has been the cradle of successive civilizations from the Kingdom of Aśoka in the 3rd century BC, down to the Mughal Empire, founded in the 16th century.

For most of its course the Ganges flows through Indian territory, although its large delta in the Bengal area, lies mostly in Bangladesh. The general direction of the river's flow is from north-northwest to southeast. At its delta, the flow is generally southward.

Physical features. *Physiography.* The Ganges rises in the southern Himalayas on the Indian side of the Tibet border. Its five headstreams—the Bhāgirathi, the Alaknanda, the Mandakini, the Dhauli Ganga, and the Pindar—all rise in the Uttarakhand region (the northern mountainous districts), a division of the state of Uttar Pradesh. Of these, the two main headstreams are the Alaknanda (the longer of the two), which rises about 30 miles north of the Himalayan peak of Nanda Devi, and the Bhāgirathi, which originates about 10,000 feet (3,050 metres) above sea level in an ice cave at the foot of the Himalayan glacier known as Gangotri. Gangotri itself is a sacred place for Hindu pilgrimage. The true source of the Ganges, however, is considered to be at Gaumukh, about 13 miles south of Gangotri.

The Himalayan headstreams

After the Alaknanda and Bhāgirathi unite at Devaprayāg, they form a main stream known as the Ganga, which cuts through the outer (southern) Himalayas to emerge from the mountains at Rishikesh. It then flows onto the plain at Hardwār, a place that is held sacred by the Hindus.

Although there is a seasonal variation in the river's flow, its volume increases markedly as it receives more tributaries and enters a region of heavier rainfall. From April to June the melting Himalayan snows feed the river, while in the rainy season from July to September the rain-bearing monsoon winds cause floods. Within the state of Uttar Pradesh, the principal right bank tributaries are the Jumna (Yamuna) River that flows past Delhi, the capital of India, to join the Ganges near Allahābād and the Tons that descends from the Vindhya Range in the state of Madhya Pradesh and joins it soon after. The left bank tributaries in Uttar Pradesh are the Rāmganga, the Gomati, and the Ghāghara.

The Ganges next enters the state of Bihār, where its main tributaries from the Himalayan region to the north are the Gandak, the Burhi Gandak, the Ghugri, and the Kosi and its most important southern tributary is the Son. In West Bengal, the last Indian state that the Ganges enters, the Mahānanda joins it from the north. (Throughout West Bengal in India, as well as in Bangladesh, the Ganges is locally called the Padma). The river then skirts the Rājmahāl Hills to the south, and flows southeast to Farakka, at the apex of the delta. The westernmost distributary of the delta is the Hooghly, on the east bank of which stands the city of Calcutta. The Hooghly itself is joined by two tributaries flowing in from the west, the Dāmodar and the Rupnarayan. In Bangladesh, the Ganges is joined by the mighty Brahmaputra (which for about 150 miles before the junction is called Yamuna) near Goalundo Ghāt. The combined stream, now called the Padma, joins with the Meghna River above Chandpur. The waters then flow to the Bay of Bengal through innumerable channels, the largest of which is known as the Meghna Estuary.

Dacca, the principal city of Bangladesh, stands on the Burhi Ganga, a tributary of the Dhaleswari. Apart from the Hooghly and the Meghna, the other distributary streams which form the Ganges Delta are: in West Bengal, the Jalangi; and in Bangladesh, the Matabhanga, the Bhairab, the Kobadak, the Gorai (Madhumati), and the Ariāl Khān.

The lengths of the major tributaries of the Ganges, in miles, are as follows: the Jumna (860), the Rāmganga (428), the Ghāghara (600), the Son (487), the Gandak (263), the Burhi Gandak (378), the Kosi (450), the Mahānanda (180), the Dāmodar (368), and the Brahmaputra (1,800).

The delta. The Ganges, as well as its tributaries and distributaries, is constantly vulnerable to changes in its course in the delta region. Such changes have occurred in comparatively recent times, especially since 1750. In 1785, the Brahmaputra flowed past the city of Mymensingh; it now flows more than 40 miles west of it before joining the Ganges.

The delta, the seaward prolongation of silt deposits from the Ganges and Brahmaputra river valleys, covers an area of about 22,000 square miles (57,000 square kilometres) and is composed of repeated alternations of clays, sands, and marls, with recurring layers of peat, lignite, and beds of what were once forests. The new deposits of the delta, known in Hindi and Urdu as the *khādar,* naturally occur in the vicinity of the present channels.

The southern surface of the Ganges Delta has been

Silt deposits in the delta

formed by the rapid and comparatively recent deposition of enormous loads of silt. To the east, the seaward side of the delta is being changed at a rapid rate by the formation of new lands, known as *chārs*, and new islands. So much silt is deposited here that the 100 fathom (183 metre) line lies much farther out to sea than it does, for example, off the mouth of the Indus in the Arabian Sea. The western coastline of the delta has, however, remained practically unchanged since the 18th century.

The rivers in the West Bengal area, being sluggish, have been described as dead or dying; little water passes down them to the sea. In the Bangladesh delta region, the rivers are broad and active, carrying plentiful water; they are connected by innumerable creeks. During the rains, from June to October, the greater part of the region is flooded to a depth of several feet, leaving the villages and homesteads, which are built on artificially raised land, isolated above the flood waters. Communication between settlements during this season can be accomplished only by boat.

To the seaward side of the delta as a whole there is a vast stretch of tidal forests and swampland. The forests, which are called Sundarbans (Sanskrit meaning "beautiful forest"), are protected by India and Bangladesh. For conservation purposes, no permanent settlement is permitted in them.

In certain parts of the delta, there occur layers of peat, composed of forest vegetation and rice plants. In many natural depressions, known as *bil,* peat, still in the process of formation, is used as a fertilizer by local farmers. In recent years, it also has been dried and used as a domestic and industrial fuel.

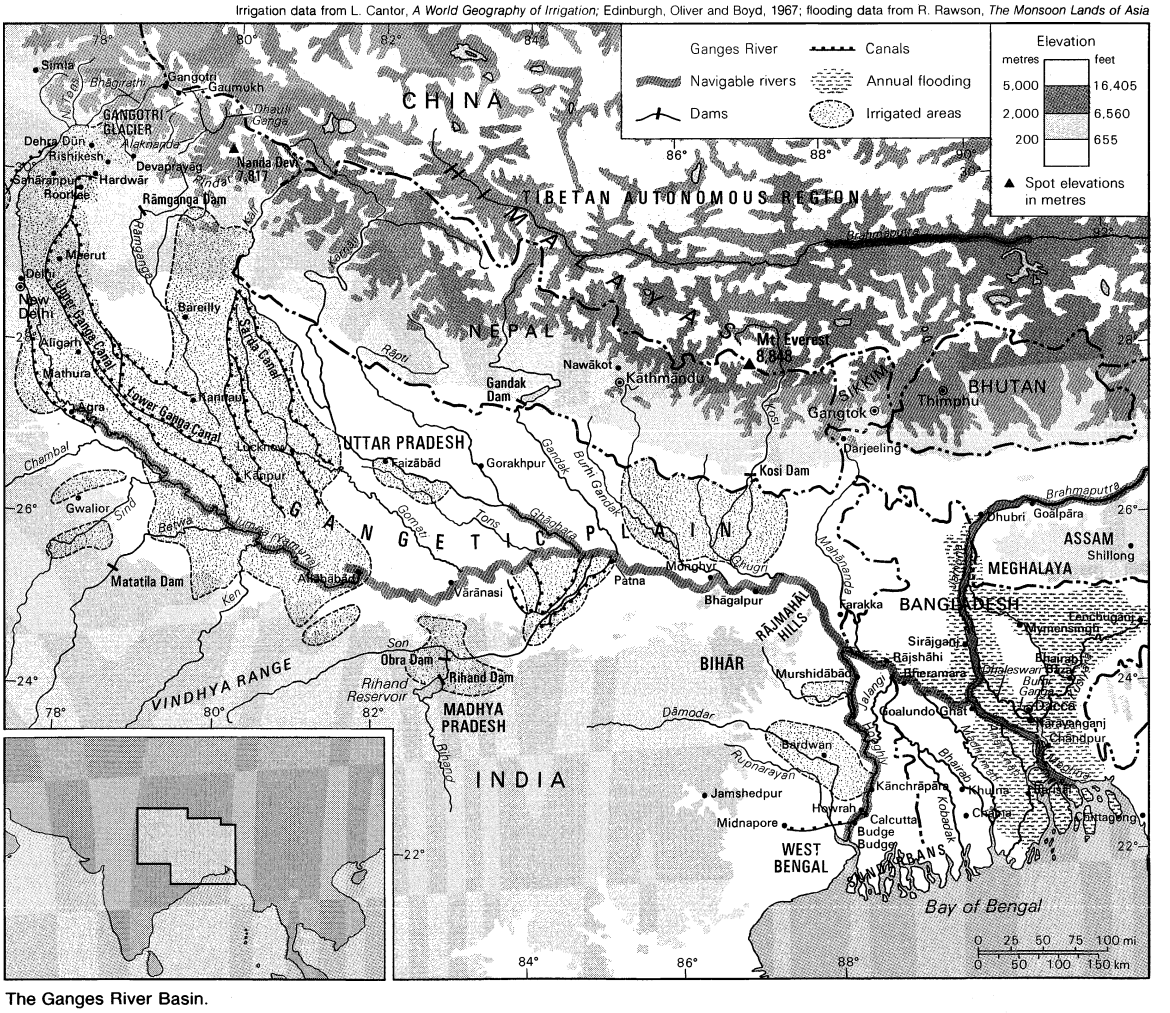
Climate and hydrography. The Ganges Basin contains the largest river system on the subcontinent. The water supply is dependent partly on the rains brought by the monsoon winds from July to October, as well as on the flow from melting Himalayan snows, in the hot season from April to June. Precipitation in the river basin accompanies the southwest monsoon winds, but is also related to cyclones that originate in the Bay of Bengal between June and October. Only a small amount of rainfall occurs in December and January. The average annual rainfall varies from 30 inches (760 millimetres) at the western end of the basin to over 90 inches at the eastern end. (In the Upper Gangetic Plain in Uttar Pradesh rainfall averages about 30 to 40 inches, in the Middle Plain of Bihār from 40 to 60 inches, and in the delta region between 60 and 100 inches.) The delta region experiences strong cyclonic storms both before the commencement of the monsoon season, from March to May, and at the end of it, from September to October. Some of these storms result in much loss of life and destruction of homes, crops, and livestock. One such storm, which occurred in November 1970, was of catastrophic proportions, resulting in deaths of at least 200,000 people.

Since there is little variation in relief over the entire surface of the Gangetic Plain, the river's rate of flow is slow. Between the Jumna River at Delhi and the Bay of Bengal, a distance of nearly 1,000 miles, the elevation drops nearly 700 feet. Altogether the Ganges-Brahmaputra plains extend over an area of 300,000 square miles. The alluvial mantle of the plain, which in some places is more than 6,000 feet thick, is possibly not more than 10,000 years old.

Plant and animal life. The Ganges-Jamuna area was once densely forested; historical writings indicate that in the 16th and 17th centuries wild elephants, buffalo, bison, rhinoceroses, lions, and tigers were hunted there. Most of the original natural vegetation has disappeared from the Gangetic Basin as a whole, and the land is now intensely cultivated to meet the needs of an ever-growing population. Wild animals are few, except for deer, boars, and

Disappearance of original vegetation

Irrigation data from L. Cantor, *A World Geography of Irrigation;* Edinburgh, Oliver and Boyd, 1967; flooding data from R. Rawson, *The Monsoon Lands of Asia*



The Ganges River Basin.

wildcats, and some wolves, jackals, and foxes. Only in the Sundarban area of the delta are some Bengal tigers, crocodiles, and marsh deer still found. Fish abound in all the rivers; especially in the delta area where they form an important item of diet. Many varieties of birds are found, such as mynah birds, parrots, crows, kites, partridges, and fowls. In winter, duck and snipe migrate south across the high Himalayas, settling in large numbers in water-covered areas. In the Bengal area common fish include featherbacks (Notopteridae), barbs (Cyprinidae), walking catfish, gouramis (Anabantidae), and milkfish (Chanidae).

The people. Ethnically, the people of the Ganges Basin are of mixed origin. In the west and centre of the basin they were originally descended from Aryan ancestors. Later, Turks, Mongols, Afghans, Persians, and Arabs came from the west and intermingled with them. To the east and south, largely in the Bengal area, an admixture of Tibetan, Burmese, and miscellaneous hill people has also occurred. The Europeans, arriving still later, did not settle or intermarry to any extent.

Historically the Gangetic Plain has constituted the heartland of Hindustān and has cradled its successive civilizations. The centre of the pre-Christian empire of Aśoka was Patna (Pāṭaliputra), standing on the banks of the Ganges in Bihār. The centres of the great Mughal Empire were at Delhi and Āgra, on the western peripheries of the Gangetic Basin. Kannauj on the Ganges, north of Kānpur, was the centre of the feudatory Empire of Harṣa, which covered most of North India in the middle of the 7th century. During the Muslim era, which began in the 12th century, Muslim rule extended not only over the plain, but over all of Bengal as well. Dacca and Murshidābād in the delta region were centres of Muslim power.

The British, having founded Calcutta on the banks of the Hooghly in the late 17th century, gradually advanced up the valley of the Ganges, reaching Delhi in the mid-19th century.

A great number of cities have been built on the Gangetic Plain. Among the most notable are Roorkee, Sahāranpur, Meerut, Āgra (the city of the famous Tāj Mahal mausoleum), Mathura (esteemed as the birthplace of the Hindu god Krishna), Alīgarh, Kānpur, Bareilly, Lucknow, Allahābād, Vārānasi (Benares; the holy city of the Hindus), Patna, Bhāgalpur, Rājshāhi, Murshidābād, Bardwan, Calcutta, Howrah, Dacca, Khulna, and Barisāl.

In the delta, the area down the Bhāgirathi-Hooghly Channel was urbanized even before the arrival of the British; subsequent growth of commerce and industry resulted in further urbanization. Calcutta and its satellite towns, known as the Calcutta Metropolitan District, stretch along both banks of the Hooghly for about 50 miles, extending from Kānchrāpāra-Kalyāni in the north to Budge Budge in the south.

The holy river

The religious importance of the Ganges may exceed that of any other river in the world. It has been revered from the earliest times, and today is regarded as the holiest of rivers by Hindus. While places of Hindu pilgrimage, called *tirath,* are located throughout the subcontinent, those that are situated on the Ganges have particular significance. Among these are the confluence of the Ganges and the Jumna at Allahābād, where a bathing festival, or *melā,* is held in January and February, during which about 400,000 persons immerse themselves in the river. Other holy places for immersion are at Vārānasi (Benares), or Kāśī, and at Hardwār.

The Hooghly River at Calcutta is also regarded as holy. The places of pilgrimage on the Ganges also include Gangotri and the junction of the Alaknanda and Bhāgirathi headstreams. The Hindus cast their dead upon the river, believing that they will thus go straight to heaven, and cremation ghats (temples at the summit of riverside steps) for burning the dead have been built in many places on the banks of the Ganges.

The economy. *Irrigation.* Use of the Ganges water for irrigation, either when the river is in flood, or by means of gravity canals, has been common since early times. Such irrigation is described in scriptures and mythological books written long before the Christian Era. Megasthenes, a Greek ambassador who was in India, recorded the use of irrigation in the 4th century BC. Irrigation was highly developed during the period of Muslim rule from the 12th century onward, and the Mughal kings later constructed several canals. The canal system was further extended by the British.

The cultivated area of the Ganges Valley in Uttar Pradesh and Bihār benefits from a system of irrigation canals which have increased the production of such cash crops as sugarcane, cotton, and oilseeds. The older canals are mainly in the Ganges-Jumna Doab, a word which means "land between two rivers." The Upper Ganga Canal (which with its distributaries is 5,950 miles long), which begins at Hardwār, was opened in 1856; the Lower Ganga Canal (5,120 miles with distributaries), opened in 1880, begins at Naraura. The Sarda Canal irrigates land in Oudh, in Uttar Pradesh. The land north of the Ganges, being higher, is difficult to irrigate by canal, and water in the subsoil must be pumped to the surface by electricity. The expansion of irrigation into this area has, therefore, depended on the availability of power in the northern part of Uttar Pradesh. Large areas in Uttar Pradesh and in Bihār are also irrigated by channels running from handdug wells.

The Ganges-Kobadak scheme

The Ganges-Kobadak scheme in Bangladesh, largely an irrigation plan, covers parts of the districts of Khulna, Jessore, and Kushtia, lying within the moribund part of the delta where silt and overgrowth choke the rivers.

Total annual rainfall in this region is generally below 60 inches, and winters are comparatively dry. The system of irrigation is based on both gravity canals and lifting devices. Power is provided by a thermal plant situated at Bheramara, on the Ganges in the Kushtia District.

Navigation. In ancient times the Ganges and some of its tributaries, especially in the east, were navigable. According to the Greek Megasthenes, navigation took place on the Ganges and its main tributaries in the 4th century BC. In the 14th century, inland river navigation in the Ganges Basin was still flourishing. In the 19th century, irrigation-cum-navigation canals formed the main arteries of the water-transport system. The advent of paddle-steamers revolutionized inland transport, stimulating the growth of the indigo industry in Bihār and Bengal. Regular steamer services ran from Calcutta up the Ganges to Allahābād and far beyond, as well as to Āgra on the Jumna, and up the Brahmaputra River. Altogether, these services covered about 5,000 miles of waterways; they are still continued today under governmental auspices in both India and Pakistan. Much of the inland water traffic is carried on by various types of rural rivercraft.

The decline of large-scale water transport began with the construction of railways during the mid-19th century. The increasing withdrawal of water for irrigation has also affected navigation. Today, the river traffic is insignificant beyond the middle Ganges Basin around Allahābād.

West Bengal and Bangladesh, however, continue to rely on the waterways to transport jute, tea, grain, and other agricultural and rural products. Principal river ports are Chālna, Khulna, Barisāl, Chāndpur, Nārāyanganj, Goalundo Ghāt, Sirājganj, Bhairab Bāzār, and Fenchuganj, in Bangladesh; and in India, Calcutta, Goālpāra, Dhubri, and Dibrugarh. The partition of India and Pakistan in 1947 produced far-reaching changes, virtually halting the large trade in tea and jute formerly carried to Calcutta from Assam by inland waterway.

In Bangladesh, inland water transport is the responsibility of the Inland Water Transport Authority (IWTA). In India, the comparable authority is the Ganga Brahmaputra Water Transport Board.

The dispute over the Ganges waters

The construction of the Farakka Barrage at the head of the delta, just inside Indian territory in West Bengal, has been a bone of contention between India and Bangladesh. According to the Indian view, the port of Calcutta was deteriorating due to the deposit of silt and the intrusion of saline seawater. In order to ameliorate the condition of Calcutta by flushing away the seawater and raising the water level, India sought to have quantities of fresh water diverted from the Ganges at the site of the Farakka Barrage. The water there is now carried by means of a large canal into the Bhāgirathi River, which joins the Hooghly River, on the banks of which stands Calcutta.

According to Bangladesh, all riparian countries should exercise joint control over the waters of international rivers for the sake of mutual prosperity. The Ganges waters are also vital to irrigation, to navigation, and to the prevention of saline incursions in Bangladesh. Bangladesh has maintained that the Farakka Barrage deprives it of a valuable source of water upon which its prosperity depends. An uneven agreement on the Ganges waters dispute has been reached, however, between India and Bangladesh.

Hydroelectric power. The largest number of streams in the Ganges Basin originate in the Himalayas. Power generation from these rivers depends upon the extent to which, by using water storage, the river flows can be regulated.

The hydroelectric potential of the Ganges Basin has been estimated at about 4,800,000 kilowatts, representing an annual output of 25,400,000,000 kilowatt hours.

INDUS RIVER

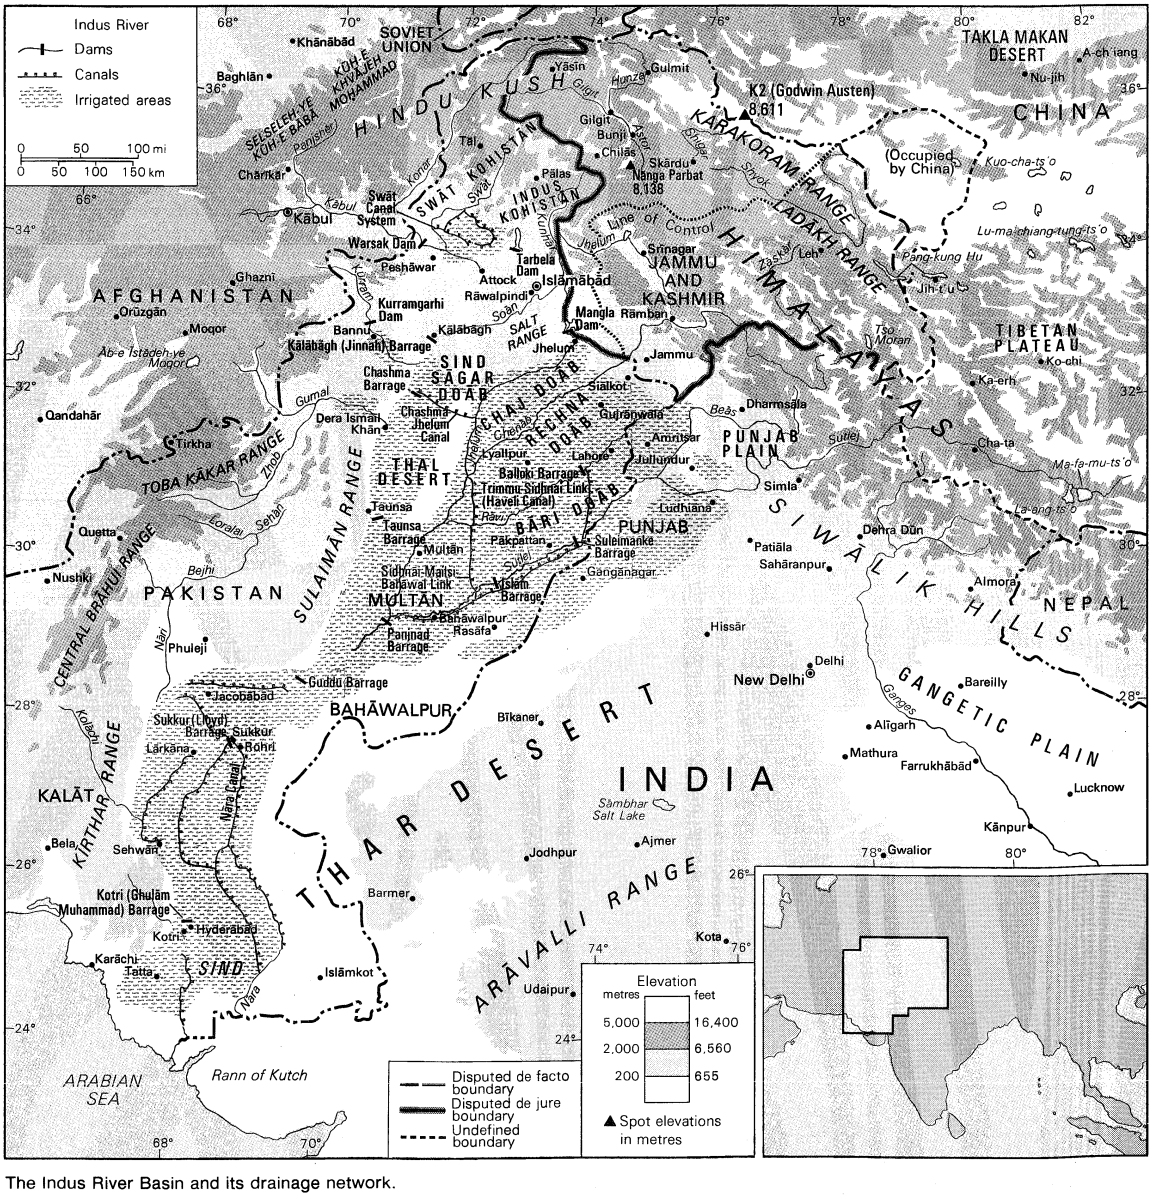
The Indus is a great trans-Himalayan river and one of the longest rivers in the world, having a length of 1,800 miles (2,900 kilometres). It has a total drainage area of about 450,000 square miles (1,165,500 square kilometres), of which 175,000 square miles lie in the Himalayan mountains and foothills and the rest in the semiarid plains of Pakistan. The river's annual flow is about 274,055,000,000 cubic yards (209,542,000,000 cubic metres)—twice that of the Nile and three times that of the Tigris and Euphrates combined. The river's name comes from the Sanskrit word *sindhu.* It is mentioned in the Rigveda, the earliest (*c.* 1500 BC) chronicles and hymns of the Aryan peoples of ancient India, and is the source of the country's name.

Physical features. The river rises in southwestern Tibet at an altitude of 16,000 feet (4,875 metres). For about 200 miles it flows northwest, crossing the southeastern boundary of Jammu and Kashmir at about 15,000 feet (4,600 metres). Eleven miles beyond Leh, in Ladākh, it is joined on its left by its first tributary, the Zāskār. Continuing for 150 miles in the same direction the Indus is joined by its notable tributary the Shyok on the right bank. After its confluence with the Shyok, and up to the Kohistān Mountains, it is fed by mighty glaciers on the slopes of the Karakoram Range, the Nānga Parbat Massif, and the Kohistān Ranges. The Shyok, Shigar, Hunza, Gilgit, and other streams carry the glacial waters into the Indus. Since the present-day precipitation of snow in this region is not sufficient to feed these great rivers of ice, it seems clear that the giant ice streams of the Karakoram are survivors of the last Ice Age of the Himalayas.

Glacial meltwater influx in the Upper Indus

The Shigar joins the Indus on the right bank near Skārdu in Baltistān. The Gilgit, farther down, is another right-bank tributary, joining it at Bunji. Some miles farther downstream, the Astor River joins as a left-bank tributary. The Indus then flows west, crosses the Kashmir border, and turns south and southwest to enter Pakistan. There

Irrigation data adapted from N. Ginsberg (ed.), *The Pattern of Asia* (© 1958); Prentice-Hall, Inc.



The Indus River Basin and its drainage network.

it skirts around the Nānga Parbat Massif (26,660 feet; 8,126 metres) in gorges as deep as 15,000 to 17,000 feet and 12 to 16 miles wide. Trails cling grimly to precipitous slopes overlooking the river from elevations of 4,000 to 5,000 feet.

After emerging from this region of high altitude, the Indus flows as a rapid mountain stream between the Swāt and Hazāra areas in Pakistan until it reaches the reservoir of Tarbela Dam, which was completed in 1975. The Kābul River joins the Indus just above Attock, where the Indus flows at an elevation of 2,000 feet and is crossed by the first bridge carrying rail and road. Finally, it cuts across the Salt Range near Kālābāgh to enter the Punjab Plain.

The Indus receives its most notable tributaries from the Punjab Plains to the east. These five rivers—the Jhelum, the Chenāb, the Rāvi, the Beās, and the Sutlej—give the name Punjab ("land of five rivers") to the land shared between Pakistan and India.

After receiving the waters of the Punjab rivers, the Indus becomes much larger and, during the flood season (July–September), is several miles wide. It flows here at an elevation of 259 feet. Its slow speed at this stage results in its accumulated silt being deposited on its bed, which is thus raised above the level of the sandy plain; indeed, most of the plain in Sind has been built up by alluvium laid down by the Indus. Embankments have been built to prevent flooding, but occasionally these give way, and large areas are destroyed by inundation. Such floods occurred in 1947 and 1958. During heavy flooding the river sometimes changes its course.

The Indus Delta

Near Tatta the Indus begins its deltaic stage and breaks into distributaries that join the sea at various points south-southeast of Karāchi. The delta covers an area of 3,000 square miles or more, and extends along the coast for about 130 miles. The uneven surface of the delta area is marked by a network of existing and abandoned channels. The coastal strip, from about five to 20 miles inland, is flooded by high tides.

Hydrography. The principal rivers of the Indus River system are snow fed. Their flow varies greatly at different times of the year: the discharge is at a minimum during the winter months, there is a rise of water in spring and early summer, floods occur in the rainy season (July–September), and occasionally there are devastating flash floods. The Indus and its tributaries receive all their waters in the upper hilly parts of their catchments. Therefore, their flow is at a maximum where they emerge out of the foothills, and little surface flow is added in the plains, where much loss of water occurs because of evaporation and seepage. On the other hand, some water is added by seepage in the period after the monsoon months. In the main stream of the Indus, the water level is at its lowest from mid-December to mid-February. After this the river starts rising, slowly at first and then more rapidly at the end of March. The high-water level usually occurs between mid-July and mid-August. The river then falls rapidly until the beginning of October, when the water level subsides more gradually. Annually, the Indus carries about 144,283,000,000 cubic yards—one-half of the total supply of water in the Indus River system. The Jhelum and Chenāb each carries about one-fourth as much as the Indus; and the Rāvi, Beās, and the Sutlej combined comprise about one-fifth of the total supply of the system (271,316,000,000 cubic yards).

Shifting course of the Indus

There is considerable physiographic and historical evidence to prove that since the dawn of civilization—at least since the days of Mohenjo-daro culture, 4,000 years ago—the Indus, from the southern Punjab to the sea, has been shifting its course. It is confined between limestone ridges at Rohri-Sukkur, but thereafter it has wandered, shifting generally to the west, particularly in its deltaic sector, so that about 200 years ago it began to flow into the Rann of Kutch. In upper Sind the Indus has shifted westward a distance of about 10 to 20 miles in the last seven centuries. The river is now held back to some extent by higher ground from Sehwān to Tatta at the head of the delta, but the possibility of future shifting cannot be ruled out. There is also evidence of the shifting of the Chenāb, Rāvi, Beās, and Sutlej rivers during the historical period.

Climate. From its source to its mouth, the annual rainfall in the Indus region varies between five and 20 inches (125 to 500 millimetres). Except for the mountainous section of Pakistan, the Indus Valley lies in the driest part of the subcontinent. Northwestern winds sweep the Indus Valley in winter (December to February) and bring four to eight inches of rainfall—vital for the successful growing of wheat and barley. The mountain region of the valley receives precipitation largely in the form of snow. A large amount of the Indus' water is provided by melting snows and glaciers of the Karakoram, Kohistān, and Himalayan mountains. The monsoon rains (July to September) provide the rest of the flow. The climate of the Indus Valley ranges from that of the dry semidesert areas of Sind and lower Punjab to the severe high mountain climate of Kohistān, Hunza, Gilgit, Ladākh, and western Tibet. January temperatures here are below freezing point in the north, while July temperatures reach a maximum of about 100° F (38° C) in Sind and Punjab. Jacobābād, one of the hottest spots on Earth, is situated west of the Indus River in upper Sind and often records summer maximums of 120° F (49° C).

Plant and animal life. There is a close relationship between climate and vegetation in the Indus Valley. In the Lower Indus region of Sind, desert conditions prevail 10 to 25 miles away from the river, and the area is dominated by poor grass and sand. Irrigation by floods or canals permits some cultivation. In upper Sind and Punjab, overgrazing and felling timber for fuel has led to destruction of both trees and vegetation. Further, prolonged human interference with natural drainage and deforestation on the Siwāliks has led to marked deterioration in groundwater conditions and so in vegetation. It appears that in prehistoric and earlier historic times the middle Indus region was more wooded than it is at present: accounts of Alexander the Great's Indian campaigns (*c.* 325 BC) and records of Mughal hunts in the 16th century and after suggest considerable forest growth. Even today, in the Indus Plains not far away from the river, there are thorn forests of open acacia and bush and undergrowth of poppies, vetch, thistles, and chickweed. Near the river are stretches of tall pampa-like grass, and streams and canals are often lined with tamarisk trees and some dense scrub, but there is nowhere a natural forest. In recent years afforestation of some parts of the Thal area in the Punjab east of the Indus has been commenced. Cultivated areas close to the river have many trees, and the strip below the mountains has something of the appearance of parkland. Coniferous trees abound in the Pakistan and Kashmir areas of the mountainous parts of the Indus Valley.

The Indus is moderately rich in fish. The best known variety is called *palla* and is the most important edible fish found in the river. Tatta, Kotri, and Sukkur, all in Sind, are the most important fishing centres. Between the Swāt and Hazāra areas the river is noted for trout fishing. In recent years, since the establishment of Pakistan, fish culture has been practiced in the reservoirs of dams and barrages. Close to the mouth of the Indus—for about 150 miles along the coast—there are numerous creeks and a shallow sea beyond. The area is rich in marine fish, the most important catches including pomfrets and prawns, which are obtained from November to March. A modern fish harbour has been built near the port of Karāchi, providing cold storage and marketing. In recent years an export trade in prawns has developed and sea fish are marketed in different parts of Pakistan.

The economy. *Irrigation.* Irrigation from Indus waters has provided the basis for successful agriculture since time immemorial. Modern irrigation engineering work commenced around 1850, and large canal systems were constructed by the British administration. In many cases old canals and inundation channels of Muslim and Sikh times were revived and modernized; thus the greatest canal irrigation system in the world was created. At partition in 1947, the international boundary between India and West Pakistan cut the irrigation system of the Bāri Doāb and the Sutlej Valley Project, originally designed as one scheme, into two parts. The headwork fell to India while the canals ran through Pakistan. This led to a disruption in the water

The Indus Waters Treaty

supply in some parts of Pakistan. The dispute that thus arose and continued for some years was resolved through the mediation of the World Bank by a treaty between Pakistan and India (1960) known as the Indus Waters Treaty. According to this agreement, the flow of the three western rivers of the Indus Basin—the Indus, Jhelum, and Chenāb (except a small quantity used in Kashmir)—will be utilized exclusively for Pakistan, whereas the entire flow of the three eastern rivers—the Rāvi, Beās, and Sutlej—will be used by India. In accordance with the settlement, Pakistan was permitted to build storage dams, canals, and barrages and to operate a drainage scheme, using tube wells that make underground water available for surface irrigation.

The Mangla Dam on the Jhelum River, near the town of Jhelum, has a crest length of about 11,000 feet and a maximum height of 380 feet and is one of the largest rolled earth-fill dams in the world. The reservoir created by the dam is 40 miles long and has an area of 100 square miles. The project also includes a powerhouse. Mangla Lake is being developed as a fishing centre and a tourist attraction as well as a health resort. The Mangla Watershed Management Organization has been formed to control the silting of the lake by using various techniques of soil conservation and afforestation.

A second gigantic project is the Tarbela Dam on the Indus, 80 miles northwest of Rāwalpindi. The dam, of the rock-filled type, is 9,000 feet long and 485 feet high, and its reservoir is 50 miles long.

Eight new link canals and five barrages have been completed by the Pakistan Water and Power Development Authority. The biggest of these link canals is the Chashma-Jhelum link joining the Indus River with Jhelum, with a discharge capacity of 21,700 cubic feet per second. Water from this canal is used to feed the Haveli Canal and Trimmu-Sidhnai-Mailsi-Bahawal link canal systems, which provide irrigation to the Multān and Bahāwalpur divisions in the lower Punjab.

On the Indus itself, there are five important headworks, or barrages, after the river reaches the plain. In the hilly region, the principal canals west of the Indus are the Swāt Canals, which flow from the Swāt River, a tributary of the Kābul River. These help in the irrigation of the two chief crops of the area, sugarcane and wheat. The Warsak multipurpose project on the Kābul River, about 20 miles northwest of Peshāwar, provides irrigation for food crops and fruit orchards in the Peshāwar Valley and is designed to produce 240,000 kilowatts of electricity. In the plain region, the Kālābāgh or Jinnah Barrage controls the system of canals in the Thal Project, the development authority for which was set up in 1949. The project irrigates a former desert area. It is an integrated project aiming at the extension of agriculture, the development of rural industry, and the settlement of population in villages and towns. Farther downstream in the Dera Ghāzi Khān district is the Taunsa Barrage, designed for the irrigation of land in the Dera Ghāzi Khān and Muzaffargarh districts. It was opened in 1959 and produces about 100,000 kilowatts of electricity. The power helps to operate tube wells. Within the Sind there are three major barrages on the Indus—Gudu, Sukkur, and Kotri, or Ghulām Muḥammad. The Gudu Barrage is just inside the Sind border and is 4,445 feet (1,355 metres) long; it irrigates cultivated land in the region of Sukkur, Jacobābād, and parts of Lārkāna and Kalāt districts. The project has greatly increased the cultivation of rice, but cotton is rapidly becoming the major crop on the left bank of the river and has replaced rice as a cash crop. The Sukkur Barrage was built in 1932 and is about a mile long. Four canals originate on the right bank and three on the left. They serve a cultivable area of about 5,000,000 acres (2,023,500 hectares) of land producing both food and cash crops. The Kotri Barrage, also known as the Ghulām Muḥammad Barrage, was opened in 1955. It is near Hyderābād and is nearly 3,000 feet long. The right-bank canal provides additional water to the city of Karāchi. Sugarcane cultivation has been extended, and crop increases have been achieved in the cultivation of rice and wheat.

Experience in the Indian subcontinent and elsewhere has shown that canal irrigation, unless carefully controlled, can cause much damage to the cultivated land. The water in the unlined canals seeps through the soil and raises the water table so that the soil becomes waterlogged and useless for cultivation. As irrigation by canals has expanded in the Indus and its tributary lands, in some areas underground water has appeared on the surface to form shallow lakes. Elsewhere the water has evaporated in the intense summer heat, leaving behind layers of salt that make crop production impossible. Several careful surveys have been made, including one under the Colombo Plan, and have revealed that, in the past, some of the Indus Plain has been poorly drained or waterlogged and that parts have been affected by salinity. To check this, adequate drainage and the construction of a network of tube wells is necessary. The water drawn out of the tube wells lowers the water table and flushes the surface salts down into the earth. An effective drainage system is therefore essential.

Waterlogging and salinity

Navigation. Until about 1880 the Indus and the other Punjab rivers carried some navigation, but the advent of the railways and expansion of irrigation works has eliminated all but small craft that ply the Lower Indus in Sind. There are fishing boats on the Lower Indus, and the upper reaches of rivers and canals above the first railway crossing are now used for floating timber down from the foothills of Kashmir. (N.A.)

IRRAWADDY RIVER

Irrawaddy, the principal river of Burma and its most important commercial waterway, is about 1,300 miles (2,090 kilometres) long. Its name is believed to have derived from the Hindu *airāvatī* meaning "elephant river." From its sources to its numerous mouths, the river flows wholly within Burmese territory. Its total drainage area is about 158,700 square miles (411,000 square kilometres). Its valley forms the historical, cultural, and economic heartland of Burma.

Physical features. The river is formed by the confluence of the Nmai Hka and the Mali Hka (*hka* being the Kachin word for river). Both branches rise in the glaciers of the high and remote mountains in northern Burma in the vicinity of 28° north. The eastern branch, the Nmai, rises in the Languela glacier and has the greater volume of water but is virtually unnavigable because of its strong current. The Mali, the western branch, has a gentler gradient and, although interrupted by rapids, has some navigable sections.

The river. About 30 miles south of the confluence is Myitkyina, the point of the northernmost limit of seasonal navigation by the Irrawaddy steamers. Bhamo, about 150 miles south of the confluence, marks the northern limit for year-round navigation. Between the confluence and Bhamo, the width of the river during the low-water season varies between a quarter of a mile and half a mile. The depth of the main channel averages about 30 feet (nine metres).

Between Myitkyina and Mandalay, the Irrawaddy flows through three well-marked defiles (narrow passages or gorges). Just south of Sinbo the river enters the upper, or third, defile—a navigational hazard, with a channel only 50 yards wide at its narrowest. Below Bhamo the river makes a sharp westward swing, leaving the Bhamo alluvial basin to cut through the cretaceous limestone rocks of the second defile. The second defile is about 300 feet wide at its narrowest and is flanked by vertical cliffs about 200 to 300 feet high. South of Thabeikkyin the river enters the first defile, which is broader and easier to navigate. Between Katha and Mandalay, the course of the river is remarkably straight, flowing almost due south, except near Kabwet, where a sheet of lava has caused the river to bend sharply westward. Leaving the first defile at Kyaukmyaung, in the Shwebo District, the river follows a broad, open course through the Dry Zone—the ancient cultural heartland—where large areas consist of alluvial flats. From Mandalay, formerly the capital of Upper Burma, the river makes an abrupt westward turn before curving southwest to unite with the Chindwin River in the Pakokku District, after which it continues in a southwesterly direction. It is probable that the upper Irrawaddy originally flowed south from Mandalay, discharging its water through the present

The Dry Zone

Sittang River to the Gulf of Martaban, and that its present westward course is geologically recent. After its confluence with the Chindwin, the Irrawaddy continues to meander through the densely populated Dry Zone to the vicinity of Yenangyaung, after which it flows generally south. In its lower course, between Minbu and Prome, it flows through a narrow valley between forest-covered mountain ranges—the Arakan Yoma ridge to the west and the Pegu Yoma ridge to the east.

The delta. The delta of the Irrawaddy may be said to begin about 58 miles above Henzada. The apex of the delta is about 180 miles from its curved base facing the Andaman Sea. The sides of the delta are formed by the southern extremities of the Pegu Yoma on the east and the Arakan Yoma on the west. The westernmost distributary of the delta is the Bassein River. The easternmost stream is the Rangoon River, on the left bank of which the Burmese capital city of Rangoon is built. As the Rangoon River is only a minor channel, the flow of water is insufficient to prevent Rangoon Harbour from silting up, and dredging is consequently necessary.

Hydrography. The volume of flow of the Irrawaddy and its tributaries fluctuates greatly through the year, chiefly due to the monsoon rains, which occur between June and September, but also to the rapid melting of glaciers during the summer, which adds still further to the volume. The average discharge of the river near the head of the delta varies between a low of 82,000 and a high of 1,152,000 cubic feet (2,300 and 32,600 cubic metres) per second; the annual average discharge is 460,000 cubic feet per second. The range between high and low water is also great. Annual variations between low-water level and flood level of 31.7 feet and 37.3 feet have been recorded at Mandalay and Prome respectively. The lowest water level occurs in February, and the highest in August. In general, from December to March the river varies between the lowest level and five feet above it, while from mid-June to mid-October the river is 20 to 30 feet (six to nine metres) above the lowest level. The river ports therefore find it necessary to have separate high-and low-water landing points.

The people. The peoples living on the river's banks are culturally diverse. On the upper reaches, the Kachins, who practice shifting agriculture, predominate. In the river valley itself, the Burmese are the dominant group, cultivating wheat, cotton, and oilseeds in the Dry Zone, and rice to the south and in the delta region, where rainfall is more plentiful. Also to the south, and particularly in the delta proper, a considerable minority of Karens and some Indians are to be found among the Burmese majority.

The river ports

The economy. *Navigation.* The main river ports on the Irrawaddy, from north to south, are Myitkyina, Bhamo, Katha, Mandalay, Myingyan, Chauk, Yenangyaung, Minbu, Magwe, Thayetmyo, Prome, Henzada, and Yandoon. Of these, Mandalay, Chauk, Prome, and Henzada have good landing facilities. The remaining ports have landing facilities for only one or two barges or lighters—the vessels mooring alongside the riverbank in most places. Despite the fact that Mandalay is the chief rail and highway focus in Upper Burma, a considerable amount of passenger and goods traffic moves by river. The Chindwin valley has no railroad and relies heavily on river transport. Chauk, downstream from the confluence in the oil-field district, is a petroleum port. Prome, about 140 miles to the south, is linked to Rangoon by road and rail. Henzada, near the apex of the delta, is the rail junction for lines leading to Kyangin and Bassein. A ferry operates between Henzada on the west bank and the railway station at Tharrawaw on the east.

Regular steamer service on the Irrawaddy is maintained by the Inland Water Transport Board (IWTB), which has improved service by introducing diesel engines in place of coal-fired ones. Commercial transportation is maintained for about 800 miles. From Henzada to Bhamo (670 miles), commercial traffic is maintained throughout the year, but from Bhamo to Myitkyina (125 miles), for only seven months. Over 2,000 miles of navigable waterways exist in the Irrawaddy delta. On the Chindwin River transportation is carried on by steam or diesel vessels throughout the year up to Homalin—about 400 miles from its confluence with the Irrawaddy. Seasonal navigation is carried on into Tamanthi, which is 57 (river) miles (91 kilometres) above Homalin.

As the Irrawaddy delta is one of the world's major rice-growing areas, rice is a major item of commerce on the river. Also transported are other foodstuffs, petroleum, cotton, and local commodities. Teak logs—of which Burma is the world's major exporter—are floated downstream in the form of large rafts. In the delta region, the rice is carried in small country boats to local markets, from where it is shipped to Rangoon for export.

The Irrawaddy is crossed mainly by the Ava Bridge, which spans the river below Mandalay.

Irrigation. Although the Irrawaddy has been little used for irrigation in the Dry Zone, its tributary, the Mu River, has been used for this purpose since the 9th century. The current Mu Valley Irrigation Project, financially supported by the UN Development Programme, is the largest in the country. It permits the dry-season cropping of maize (corn), groundnuts (peanuts), sesame, millet, and other dry crops.

The soils of the delta are enriched every year by the fertile alluvium carried down by the river. The river waters themselves are used to flood the delta rice paddies. "Irrawaddy" is also the name of an administrative division of the delta, which includes the districts of Bassein, Henzada, Ma-ubin, Myaungmya, and Pyapon. (S.M.B.)

AMUR RIVER

The Amur River (Wade-Giles romanization Hei-lung Chiang; Pinyin Heilong Jiang) in eastern Asia forms part of the frontier between the Union of Soviet Socialist Republics and the People's Republic of China. It rises on the northern border of Northeast China and Inner Mongolia with the Soviet Union and flows generally east and southeast along that border to Khabarovsk, where it turns northeastward and flows to the Tatar Strait, separating Siberia from the island of Sakhalin. It is the longest river in the Soviet Far East. Its Chinese name, Hei-lung Chiang, means Black Dragon River; its Mongol name, Kharamuren, means Black River; among local tribes it is known as Mamu.

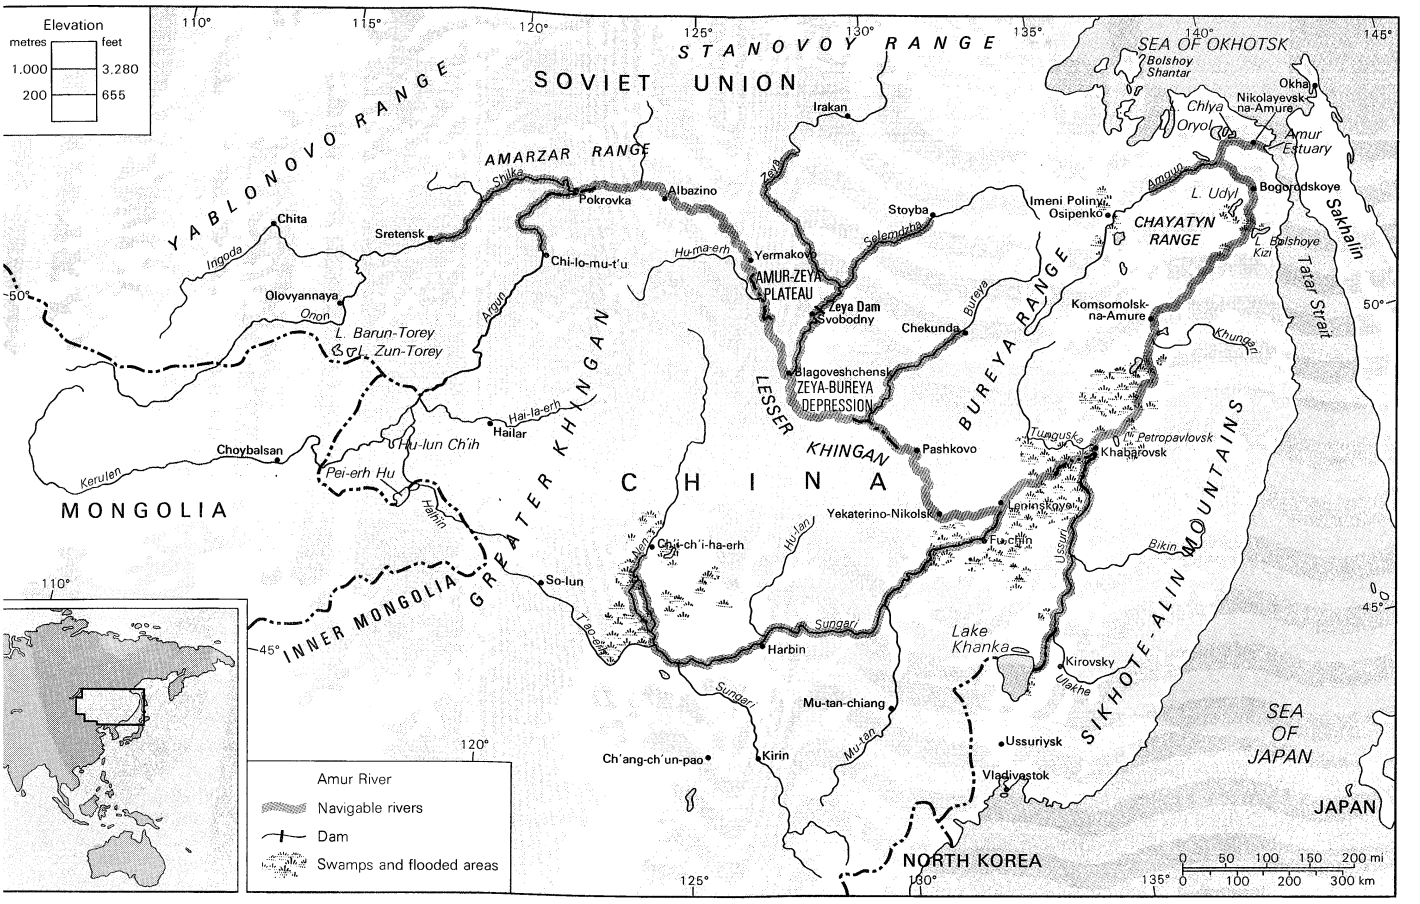
Physical features. *Physiography.* The Amur begins at the confluence of the Shilka and the Argun rivers, at a point 1,755 miles (2,824 kilometres) from its mouth. The Shilka rises more than 340 miles farther inland at the junction of the Siberian Ingoda River and the Mongolian Onon River. The Argun River rises in the Chinese autonomous region of Inner Mongolia, about 1,000 miles from its confluence with the Shilka. The entire river system of the Amur includes numerous rivers and lakes; among the rivers are five major ones—the Zeya, Bureya, Sungari, Ussuri, and Amgun.

It is customary to treat the river as divided into three sections: the Upper, Middle, and Lower Amur. The Upper Amur begins at the juncture of the Shilka and Argun and ends at the mouth of the Zeya (Blagoveshchensk), about 550 miles (880 kilometres) downstream. The Middle Amur extends about 600 miles (960 kilometres) from the Zeya north to Khabarovsk. The Lower Amur, from Khabarovsk to the mouth, is also about 600 miles in length.

The Upper Amur River

The Upper Amur flows through a mountain valley between the spurs of the Greater Khingan, which is covered by thick larch woods, and the pine-clad slopes of the Amarzarsky mountain ridge. Near Albazino the mountains part, and the river enters open-plateau country. The winding river has built up sandbanks, many of them really spits of land formed at looping bends of the river, which in places has cut deeply into the earth. The terraced slopes of the valley testify that in remote times the land was flat and the Amur wandered through wide floodlands. Below Yermakovo lie the Burning Mountains, rocky precipices made up of complex layers of spontaneously igniting carbonaceous, clayey shales that are continually steaming and sometimes give off flames.

Middle Amur flows into the Zeya-Bureya Depression. The left slope of the valley merges imperceptibly with the plain, while the right slope—steep and high—borders the Lesser Khingan Range. Below the Bureya River the plain



The Amur River Basin and its drainage area.

narrows gradually, and near Pashkovo the river runs past spurs of the Bureya Range. Farther on it flows along a narrow ravine-like passage through the Lesser Khingan mountains, its depth and speed sharply increasing.

The Lower Amur runs between low, overflowing banks into a vast marsh, the surface of which is broken by channels and dotted with lakes and ponds; the riverbed branches often, and the channel becomes very wide. Near Novoye the Sungari, the Amur's largest tributary, pours in its yellow, muddy waters. Near Khabarovsk it is joined by the Ussuri. With these accessions to its waters, it overflows widely over the flat, marshy ground of the tidal valley. The riverbed becomes a labyrinth of branches, channels, offshoots, former riverbeds, islands, sandbanks, and spits. During high-water seasons these sections overflow, and the region becomes an enormous lake. At Khabarovsk the Amur is only 230 miles from the shores of the Sea of Japan; but, diverted by the Sikhote-Alin Mountains, it runs northward for 600 miles before it finds the sea. Near Komsomolsk-na-Amure the plain gradually narrows, and the river flows for 90 miles among mountains into a scenic forest valley. It then enters the Udil Kizinsky hollow with wide, flat, marsh-ridden ground. In the hollow lie two large lakes—the Big Kizi and the Udyl. Near Bogorodskoye the hollow is closed in by the Chayatyn Range, and the river flows out onto a low-lying plain, where the Amgun, the last of its important tributaries, joins the Amur on its left bank. It enters the sea through a wide, bell-shaped estuary, which is about 30 miles long.

Climate. The Amur Basin has a monsoon climate—a seasonal alternation of winds from the mainland and from the ocean. In winter the dry, cold air moving down from Siberia brings clear, dry weather with strong frost. Snowfall is generally light. In summer the warm, moist ocean winds predominate, bringing heavy rains and thus raising the water level in the Amur and its main tributaries.

Autumns are warm and dry. Average temperatures, in January, range from −11° F (−24° C) in the south to −27° F (−33° C) in the north. The average July temperature in the south (at Blagoveshchensk) is 70° F (21° C) and in the north about 64° F (18° C). Precipitation in the Amur Basin is uneven, being heaviest in the maritime section, where it ranges between 24 and 36 inches (600 and 900 millimetres) annually. In the middle regions the annual rate does not exceed 24 inches, and in the western, continental regions it averages 12–16 inches. The peak months are July and August, when there are four or five inches of rainfall.

Wide range of precipitation

Marine life. The Amur is rich in fish. The lower river has about 100 species of fish, the upper river 60, surpassing even large European rivers such as the Volga and the Danube. About 25 or 30 species are of commercial value. Northern forms include the Siberian salmon, the sig, and the burbot; southern forms include the Chinese perch and the white amur. There are about 20 indigenous species of carp and broadhead. A biological peculiarity of the Amur fishes is the large number of species that develop in the sea and therefore escape exposure to the sharp changes in water level that occur in the river in summer.

Hydrology. The river is fed principally by the monsoon rains that fall in summer and autumn. The rainwater finds its way quickly into the river, resulting in a period of flooding that extends from May to October. During that period there are usually several times of high water when the river is from 16 to 26 feet (5 to 8 metres) above its usual level. In particularly rainy years the high-water level may be as much as 45 feet above the usual level in the Upper Amur. Farther downstream the variations are less; in the lower reaches, the maximum rise is only about 8 feet. In August and September the floodwaters begin to abate. The lowest level of the river is reached in March and April, before the spring flood, which is fed mainly by runoff of melted snow and which is much smaller than the monsoon floods that occur in summer and autumn. Those floods often cause serious economic loss.

Seasonal flooding

The mean discharge of the Amur is 380,000 cubic feet (10,900 cubic metres) per second. The rate of flow near Komsomolsk-na-Amure is about 348,200 cubic feet (9,860

cubic metres) per second and at the mouth about 383,800 (10,900). The rate varies from as low as 5,300 cubic feet (150 cubic metres) per second to 7,000 (200) in winter near Khabarovsk; the highest rate ever recorded was 1,400,000 (40,000) in 1897.

Ice forms in the Amur in the second half of October. The Upper Amur becomes icebound at the beginning, the Lower Amur in the second half of November. The lower reaches of the river open at the end of April, the upper reaches at the beginning of May. Ice jams often occur in the sharp bends of the river, raising the water level by as much as 50 feet.

At the mouth of the Sungari, the water in the Amur is comparatively clear, but lower down it becomes muddy. In a year the river carries down about 20,000,000 tons of sediments.

The people. The territories of the Amur were originally populated by hunting and cattle-breeding nomadic tribes, such as the Buryats, Yakuts, Nanais, Gilyaks, Udegeys, and Oroks, From the 18th century onward the area north of the Amur was settled by Russians along with Ukrainians, Belorussians, Tatars, Latvians, and others. South of the Amur live Chinese, Mongols, Manchus, and many other peoples.

The Russians began to explore the Amur Basin in the 17th century. Maksim Perfilyev passed through the region in 1638. In the spring of 1644 Vasily Poyarkov set off on a three-year exploration of the Amur; he covered much of the river basin and estuary. Yerofey P. Khabarov followed in 1649–51; Khabarovsk—the second largest city in the Soviet Far East—is named for him.

In 1849–55 an expedition under the leadership of a Russian naval officer, Gennady I. Nevelskoy, made the discovery that Sakhalin is an island and that, therefore, the Amur is accessible from the south and not alone from the north as the Russians had previously supposed. This was the beginning of the systematic study of the water system of the Amur. A series of large expeditions was planned and carried out in the first part of the 20th century (occupying the years 1901–09, 1927–29, 1932, 1935–36). In 1952–58 the Academy of Sciences of the U.S.S.R. sponsored a thorough exploration of the Amur.

The economy. The Amur is navigable throughout its course for about half the year. The large tributaries—the Zeya, Bureya, Sungari, Tunguska, Ussuri, and Amgun—are navigable, as are some of the lakes. The main ports include Pokrovka, Blagoveshchensk, Leninskoye, Khabarovsk, Komsomolsk-na-Amure, and Nikolayevsk-na-Amure. The potential hydroelectric power of the Amur River Basin is estimated at roughly 45,000,000 kilowatts, but little of this potential has so far been developed.

(A.P.M.)

CHINA SEA

The China Sea is that part of the western Pacific Ocean bordering the east-southeast Asian mainland. It consists of two seas, the South China Sea and the East China Sea, which connect through the shallow Taiwan Strait between Taiwan and the People's Republic of China.

East China Sea. The East China Sea, or Eastern Sea, known in Chinese as the Tung Hai (Pinyin Dong Hai), extends northeastward from the South China Sea. Eastward it includes waters out to the Ryukyu Island chain; north to Kyūshū, which is the southernmost of Japan's main islands; northwest to the island of Cheju-do off South Korea; and hence west to the mainland of China. This northern boundary separates the East China Sea from the Yellow Sea.

Boundaries of the East China Sea

Physiography. The East China Sea, which has an area of 290,000 square miles (752,000 square kilometres), is largely shallow, with 71 percent of the area less than 650 feet (200 metres) and an average depth of only 1,145 feet. The deeper part is the Okinawa Trough, extending alongside the Ryukyu Island chain, with a large area over 3,300 feet (1,000 metres) deep and a maximum depth of 8,912 feet (2,717 metres). The western edge of the sea is a continuation of the shelf that extends from the South China Sea up to the Yellow Sea. A large number of islands and shoals dot the eastern boundary as well as the area near the Chinese mainland. The shallow shelf areas are covered with sediments from the bordering landmasses deposited mainly by the Yangtze and other rivers near the northern part of the sea. Coarser sediments of sand occur farther out, and rocks, muds, and oozes are also found in scattered areas. Seismic profiling indicates that the geological subbottom structure comprises nearly parallel folds, with rock ridges near the northern limits of the East China Sea, near the edge of the continental shelf, and along the Ryukyus. These have afforded barriers for sediment brought down by the great Huang (Yellow) and Yangtze rivers. Between the ridges the sediment is up to one mile thick.

Most of the shelf belongs to the stable Neo-Cathaysian Geosyncline (or Cathaysian Platform), dating back at least 300,000,000 years or longer. The Okinawa Trough appears to be perhaps 10,000,000 years old. The Ryukyus are a double island chain, with several volcanic islands on the East China Sea side. Many of the volcanoes are still active. Epicentres of earthquakes are found along the axis of the Okinawa Trough and the Ryukyu Island arc.

Climate. Weather is dominated by the monsoon wind system, the result of differential heating between land and water. In summer, the high Asian landmass is much warmer than the sea; in the winter, it is much colder, particularly in the Plateau of Tibet. Summer heating of air masses over Asia builds areas of low pressure and creates the monsoonal winds, which in this season blow predominantly from the southeast. This brings in warm, moist air from the western Pacific Ocean, producing a rainy summer season that is accompanied by typhoons. In winter the situation is reversed: monsoon winds blow predominantly from the north, bringing with them cold, dry air from the continent.

The China Sea.

Sea currents and tides

Hydrography. Winds also influence water circulation of the Kuroshio (Japan) current, a north-flowing branch of the warm North Equatorial Current that flows near Taiwan. Some of the Kuroshio enters the eastern part of the East China Sea, then diverts eastward back out into the Pacific, and flows east of Japan. Strengthened by monsoon winds, it is at its widest and fastest in summer, and the axis is displaced well into the East China Sea. This warmed surface water varies from 86° F (30° C) in the south to 77° F (25° C) in the north. In winter, northerly monsoon winds modify the circulation, and the north-flowing Kuroshio, though still important, is reduced in strength, while southerly flowing coastal currents are strengthened. This brings in colder water, with temperatures of 41° F (5° C) in the north to 73° F (23° C) in the south.

Because of the constricting nature of the adjoining Yellow Sea and the funnel shape of some of the inlets on the mainland, tidal ranges are especially high along the coast of China. For example, the spring tide range, which is highest in summer and winter, is as much as 23 feet at San-sha Bay and 36 feet at Hangchow Bay.

The economy. The East China Sea is a highly marine-organic productive region, with China, Japan, Taiwan, and North and South Korea actively fishing in the area. Most of the fishing is done by small local boats, although larger trawlers are also used. Tuna, mackerel, shrimps, sardines, milkfish, sea breams, croakers, shellfish, and seaweeds are the main resources harvested. The records of fishing intensity correlate well with the preference of bottom fishes for areas of fine-grain, organic-rich sediments that are probably the result of the greater abundance of worms and other small, mud-digesting organisms in the area.

In addition to the local shipping traffic in and out of Chinese and Korean ports, the East China Sea serves as the main shipping route from the South China Sea to Japanese and other North Pacific ports.

Boundaries of South China Sea

South China Sea. The South China Sea, known in Chinese as Nan Hai (Pinyin Nan Hai), is bounded on the west by the Asian mainland, on the south by the southern limit of the Gulf of Thailand and the east coast of Malay Peninsula, and on the east by Taiwan, the Philippines, and Borneo. The southern boundary is a rise in the seabed between Sumatra and Borneo, and the northern boundary stretches from the northernmost point of Taiwan to the coast of Fukien Province, China (the southern limit of the East China Sea). It embraces an area of about 848,400 square miles, with an average depth of 3,740 feet.

M. Gifford—De Wys Inc.

A portion of the delta of the Mekong River as it flows through southern Vietnam and empties into the South China Sea.

Physiography. The major topographic feature is a deep rhombus-shaped basin on the eastern part, with reef-studded shoal areas rising up steeply within the basin to the south (Reed, Tizard, Nanshan banks) and northwest (Paracel Island and Macclesfield banks). The deep portion, called the China Sea Basin, has a maximum depth of 16,452 feet, and an abyssal plain with a mean depth of 14,100 feet. The continental shelf falls off sharply near Luzon and Palawan islands and forms the Palawan Trough near the latter island.

Along the northwest side of the basin to the mainland is a broad, shallow shelf as wide as 150 miles. It includes the Gulf of Tonkin (maximum depth of 269 feet) and the Taiwan Strait. The large islands of Hainan and Taiwan are situated on this shelf. To the south, off Vietnam, the shelf narrows and connects with the Sunda Shelf, one of the largest in the world, which covers the area between Borneo, Sumatra and Malaysia, and includes the southern part of the South China Sea, the Gulf of Thailand, and the Java Sea. This broad trough is about 130 feet deep at its periphery and up to 330 feet in its central part. On the bottom of the shelf is a network of submerged river valleys that converge into the Sunda Depression and then into the China Sea Basin. These valleys and tributaries vary in width up to three miles.

The Sunda Shelf is covered with littoral sediments contributed by submerged valleys. The inner zone of mud is characteristic of the continental shelf near the Mekong and Red River deltas, while the sediment of the deeper parts of the South China Sea is mainly composed of clay. A characteristic part of the sediments in both deep and shallow water is volcanic ash. This is found in layers, derived from large volcanic eruptions in the East Indies, notably the enormous eruption of Krakatoa in 1883, when ash was transported through the entire area by both wind and currents.

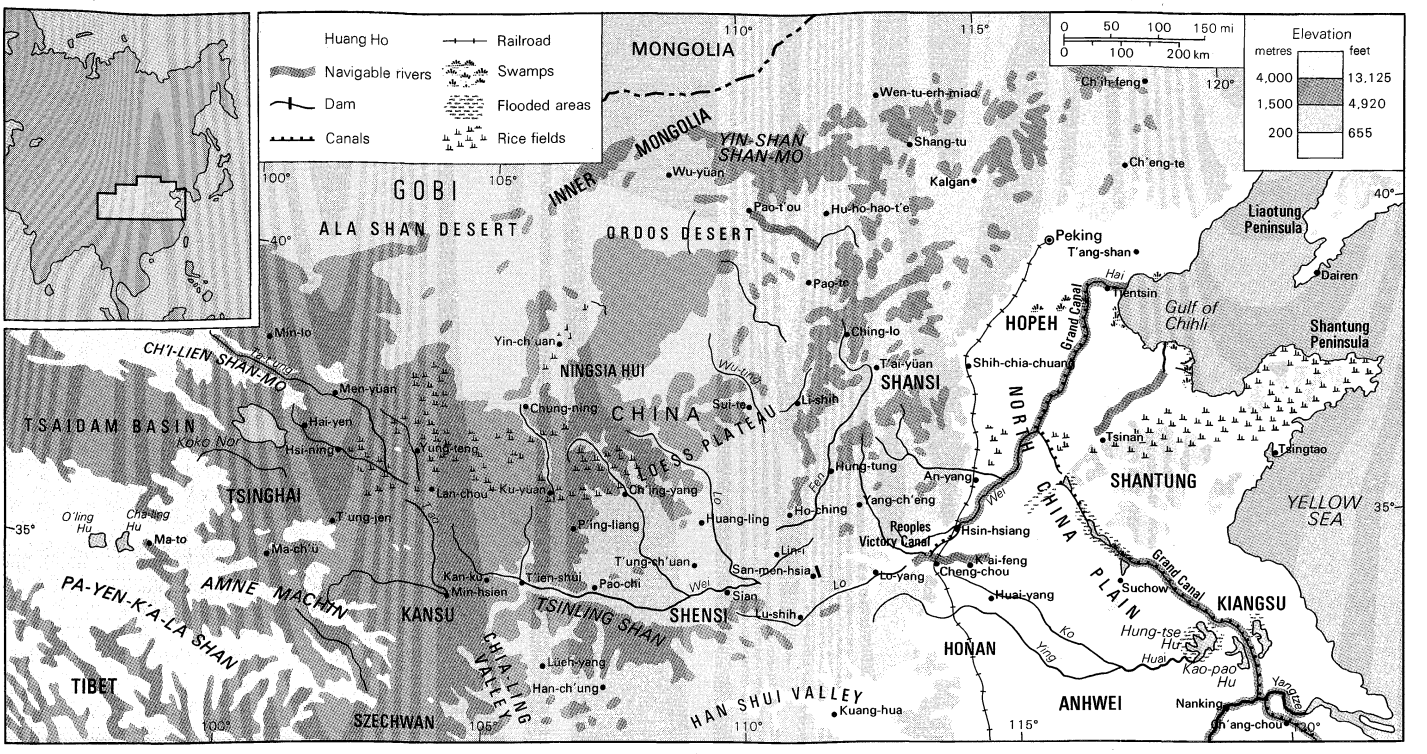
Connecting channels

The South China Sea has connecting channels. The Formosa Strait on the north is about 90 miles wide, with a depth of about 230 feet. The main deep channel connecting the South China Sea with the Pacific Ocean lies between Taiwan and the Philippines and has a depth of about 8,500 feet. Shallow channels are found on the east along the Philippine Island chain and on the south between Borneo and Sumatra. The western connection to the Indian Ocean is the long Strait of Malacca. At its narrowest part it is 19 miles wide and about 100 feet deep. The South China Sea is the largest "marginal sea" of the western Pacific. Some 1,000,000 to 60,000,000 years ago, it was rifted and collapsed as a result of seafloor spreading. The China Sea Basin is believed to have dropped 2.5 miles, leaving residual plateaus studded with numerous coral reefs, islets, and banks, some of which are drowned atolls.

Climate. Weather is tropical and largely controlled by monsoons. In summer, monsoonal winds blow predominantly from the southwest; in winter, winds blow from the northeast. Annual rainfall approximates 12.3 feet (3,750 millimetres), and summer typhoons are frequent.

Hydrography. Monsoons control the sea-surface currents as well as the exchange of water between the South China Sea and adjacent bodies of water. In August, the surface flow into the South China Sea is from the south through Karimata and Kelasa (Gasper) straits. Near the mainland the general flow is northeasterly, passing out through the Taiwan and Luzon straits. There is a weak countercurrent on the eastern side of the sea. In February, the flow is generally to the southwest; the strongest flow occurs along the bulging part of Vietnam, with speeds of up to three knots (nautical miles per hour).

The near-surface waters are relatively warm (about 84° F [29° C] in the summer) because of the low latitude and a tendency for the equatorial current to feed warm water into the area. In early summer, wind from the southwest not only moves the surface water to the northeast but causes it to be displaced off the coast. As a result,



The Huang Ho Basin and its drainage network.

upwelling areas having colder surface temperatures and higher nutrient content are found off central Vietnam. In winter, the general surface temperature is colder, ranging from about 70° F (21° C) in the north to 81° F (27° C) in the south.

The major rivers draining into the South China Sea are the Hsi Chiang, which enters near Macau; the Red River at Haiphong, Vietnam; and the Mekong River, near Ho Chi Minh city (Saigon), Vietnam. The wet summer season causes the Mekong River to triple its annual average flow, and it causes an even greater relative change in the flow of the Red River.

The economy. The heavily fished South China Sea is the main source of animal protein for the people living near its shores, providing as much as 50 percent for the densely populated Southeast Asian area. Most abundant are the various species of tuna, mackerel, croaker, anchovy, shrimp, and shellfish. Nearly the entire catch is consumed locally, either fresh or preserved.

Fishing

The main transport route to and from Pacific and Indian ocean ports is through the Strait of Malacca and the South China Sea. In the main, oil and minerals move up the coast, and food and manufactured goods move down. Some areas in the central South China Sea are not well sounded, and nautical charts bear the notation "dangerous ground." (E.C.LaF.)

HUANG HO

The Huang Ho (Huang He in Pinyin), or Yellow River, one of the most northerly and the second longest of China's rivers, flows from the eastern highlands of the Tibetan Autonomous Region along a course of 3,011 miles (4,845 kilometres) to the Yellow Sea. It passes through the provinces of Tsinghai and Kansu, the autonomous regions of Ningsia Hui and Inner Mongolia, and then into the provinces of Shensi, Shansi, Honan, and Shantung. For much of its length it is a shifting, turbulent, muddy stream that often overflows its banks and sends floodwaters across the North China Plain. For this reason it has been called "China's Sorrow" and "The Ungovernable." The name Huang (Yellow) comes from the fine, loess soil that it brings down with it. More than 110,000,000 people live in the basin of the Huang Ho, which flows past the cities of Lan-chou, Pao-t'ou, Sian, T'ai-yüan, Lo-yang, Cheng-chou, K'ai-feng, and Tsinan. It drains an area of 288,000 square miles (745,000 square kilometres).

Physical features. The Huang Ho is divided into two distinct parts: the mountainous upper basin and the plains section, which is itself subdivided into the middle and lower basins. The broad highlands of the mountainous part rise 1,000 to 1,300 feet (300 to 400 metres) above the river and its tributaries. The highlands are built upon crystalline rocks that are sometimes visible as eroded outcroppings on the surface. On the plateau these rock systems are covered with thick layers of friable deposits, consisting mainly of loess. The loess strata have thicknesses of 160 to 200 feet and in some places as much as 500 feet, extending eastward from the highlands of Tibet all the way to the North China Plain. Through this loose loam the river has cut deep valleys, carrying away with it huge quantities of silt; the easily eroded loess soil accounts for the instability of the riverbed.

Downstream the Huang Ho Basin becomes fan shaped as it broadens out across the North China Plain, which is broken only by the low Shantung Hills. The plain consists of fine silt, brought down by the river, laid over sand and gravel that was deposited when the sea receded in the geological past. Along the river are occasional areas of sand dunes 15 to 30 feet (4.5 to nine metres) in height. The plain, which contains a number of old beds of the river, is China's rice granary.

Physiography. The Huang Ho originates at an altitude of about 15,000 feet in the Pa-yen-k'a-la Shan (Pa-yen-k'a-la Mountains), in the eastern Tibetan Highlands. In its upper reaches the river crosses two large lakes, Cha-ling Hu and O-ling Hu. These are shallow lakes covering an area of about 40 square miles, rich in fish and frozen in winter. The Huang Ho in this region flows generally from west to east. It enters deep gorges winding its way along the southern slopes of the Amne Machin, somewhat above the city of Lan-chou. With many rapids, its fall exceeds 10 feet per mile. Populated areas are few. Past the gorges it leaves the Tibetan Highlands and flows northward across the Ordos Desert, in northern China, having flowed about 726 miles from its source. The basin upstream from that point covers an area of about 48,000 square miles, consisting chiefly of inaccessible, highly mountainous terrain with a cold climate. The few inhabitants engage in cattle breeding.

The upper basin

The middle part of the Huang Ho consists of a great northward loop through the Ordos Desert and then a southward course through a long trench forming the bor-

The middle basin

der between Shensi and Shansi provinces to the city of Cheng-chou, a distance of more than 1,800 miles. Most of the middle basin is cut through the Loess Plateau at altitudes ranging between 3,000 and 7,000 feet. The plateau contains terraced slopes as well as alluvial plains and a scattering of peaks sometimes exceeding 1,500 feet in height. Within its large loop, the Huang Ho drains an area of about 23,000 square miles. The river at first flows in a northeasterly direction for about 550 miles among bare loess hills; it has many rapids, and in a number of places it narrows. It then turns eastward and flows for another 500 miles through alluvial plains; in this stretch it has many branches, and its fall is less than four inches per mile. If it continued eastward it would flow to Peking, but instead it turns sharply to the south and flows for about 445 miles through narrow gorges with steep slopes several hundred feet in height. The river's width usually does not exceed 150–200 feet in this section. The Huang Ho gradually widens and then turns sharply to the east for another 300 miles. Here it flows through inaccessible gorges between the eastern peaks of the Tsinling Shan. The average fall in this stretch is about 14 inches per mile and increasingly rapid in the last 100 miles before the river enters the North China Plain.

This middle basin of the river, between the Tibetan Highlands and the North China Plain, contains the two longest tributaries: the 537-mile Wei Ho of Shensi Province and the 430-mile Fen Ho of Shansi Province.

The lower basin

The lower part of the Huang Ho is about 435 miles long with an average fall of about three inches per mile. This is an area of great floods because the riverbed in many places lies above the surrounding land. In the section above the city of K'ai-feng, the low-water level is between six and 10 feet above the surrounding countryside; the mid-water level is between 19 and 23 feet; and the high-water level sometimes as much as 33 feet above that of the land. From K'ai-feng to the Grand Canal (Yün Ho), the riverbanks rarely exceed three to six feet in height. Marshes are common. Below the Grand Canal the height of the banks increases to 13–16 feet and in some places to 25. Several centuries ago the Chinese built dikes along the river, which in places are broad enough to accommodate villages.

The delta of the Huang Ho begins approximately 160 miles from its mouth, spreading out over an area of about 950 square miles. Built up by silt brought down by the river, the delta is swampy and covered with reeds. A sand bar at the mouth impedes navigation by boats drawing more than four feet of water at low tide; at high tide the depth on the bar is eight or nine feet.

Hydrography. In the past 4,000 years several radical changes have occurred in the Huang Ho's course; at different times the river has entered the Yellow Sea at points varying by as much as 500 miles. From 2278 BC to 602 BC, when it occupied its northernmost course, it flowed through the city of Tientsin and entered the nearby Gulf of Chihli (Po Hai). From 602 BC to AD 70, both the river and its mouth shifted to the south of the Shantung Peninsula. From AD 70 to 1048 the Huang Ho again shifted north, taking up a course much along its present bed.

From 1048 to 1194 changes in the course of the river occurred farther inland, where the river enters the North China Plain. In 1194 the river occupied its southernmost course, the mouth having shifted to the southern edge of the delta. In that year, as a result of the rupturing of the protecting dikes, a second arm of the Huang Ho was created in the southern part of the Shantung Peninsula. From 1289 to 1324 the river took over the bed of the Ko Ho and a large part of the Huai Ho, later returning to its old bed. It was stable for more than 500 years until 1854, when it again began to move farther to the north of the Shantung Peninsula, where it now is located.

Upstream alterations in course

In the upper and middle sections of the Huang Ho, alterations of the riverbed are comparatively slight; concave banks have been washed away, and the alluvial deposits have formed radiating convex banks, or arms, some of which are under cultivation. Numerous outcroppings of rock on the bottom of the river also cause changes in the bed. In the downstream areas, however, where the riverbed is higher than the surrounding land, changes in the bed sometimes lead to a sudden rupturing of the dikes and the flooding of extensive areas. This flooding, which occurs during periods of high water, covers the surrounding territory with huge amounts of silt.

Breaks in the dikes have occurred throughout history. Between 960 and 1048 there were 38 breaks, and 29 from 1048 to 1194. In later years such breaches were less frequent as a result of systematic construction. The slackening of these efforts during the Taiping Rebellion led to a significant change in the course of the river in 1852–54.

In 1887 the Huang Ho burst the dikes near the city of K'ai-feng and began to flow into the Huai Ho, but engineering efforts succeeded in returning it to its former location in 1889. The flood of 1887 covered 30,000 square miles, completely burying many villages under silt. In 1889 another flooding injured nearly 1,000,000 persons and destroyed 1,500 villages. The next major flood, in 1921, wiped out hundreds of populated places, mainly near the mouth of the delta. In the flood of 1933 more than 3,000 populated places were submerged, 3,600,000 people injured, and 18,000 killed. Other floods occurred in 1938 and 1949.

The delta of the Huang Ho is one of the most active in the world. In the century from 1870 to 1970 it pushed outward into the sea an average of more than 12 miles. Some outlying parts have been expanding even more rapidly: one area grew six miles during the period 1949–51, and another grew more than 15 miles in 1949–52.

The Huang Ho carries an average annual volume of about 11.6 cubic miles (48.2 cubic kilometres) of water down to the sea—as much as 16.8 cubic miles (70 cubic kilometres) in high-volume years and as little as 4.8 to 6.0 (20 to 25) in low-volume years. There are also seasonal variations in its volume. More than half of the annual precipitation falls during the rainy season, July to October. The average annual precipitation for the entire basin is about 18½ inches (470 millimetres), but its distribution is very uneven. In some years the bulk of the river volume comes from its tributaries. In the upriver areas the main source is snowfall in the mountains, with the high-water level (33 feet [10 metres]) occurring in the spring. The highest water levels in the middle and lower parts of the river (10 to 23 feet [three to seven metres]) occur in July and August. The maximum flow of water near Lan-chou is 7,000–8,000 cubic yards (5,350–6,115 cubic metres) per second; near Lung-men, 13,000; and in the lower parts of the river, 47,000 (as recorded in 1943).

The Huang Ho is the world's muddiest river. It carries along about 57 pounds of silt per cubic yard (34 kilograms per cubic metre) of water, as compared with two pounds for the Nile, seven for the Amu Darya, and 17 for the Colorado. Floodwaters may contain up to 1,200 pounds of silt per cubic yard (700 kilograms per cubic metre) of water (70 percent by volume). The river carries down to the sea about 1,520,000,000 tons of silt a year, partly because much of the basin is composed of loess, which is loose and easily moved. Other factors are the steepness of the slopes, the rapidity of the current, and a lack of forested areas and reservoirs to check erosion and allow the silt to settle out. The irrigation system in the plain is not enough to slow the river current.

The Huang Ho freezes over in parts of its middle section for several months a year. On the great plain near K'ai-feng there are 15 to 20 icebound days a year but none at all farther downstream. Ice blockage is broken up with the help of bombs dropped from airplanes or sometimes artillery shelling.

Canals and dams

The economy. The 4,000-year-old irrigation system of the Huang Ho, augmented by recently constructed irrigation and navigation canals, brings water to about 10,000 square miles of land. The Grand Canal, cutting across the lower river, runs for more than 1,100 miles from Peking in the north to Hangchow in the south. The People's Victory Canal, completed in 1953, runs for 30 miles parallel to the Peking–Hankow railroad and links the Huang Ho north of Cheng-chou with the Wei Ho at Hsin-hsiang. It raises the level of the Wei Ho, improving navigation between Hsin-hsiang and Tientsin and also providing a

network of irrigation channels between Hsin-hsiang and the Huang Ho.

A 1,000,000-kilowatt power station and dam is located at San-men-hsia (Three-Gate Gorge) on the Honan-Shansi border, 130 miles west of Chengchou; the reservoir is 120 miles long. Before the construction of the reservoir, navigation by boat was restricted to a stretch of 100 miles or so on the lower reaches of the river. Current plans envisage the construction of new dams and reservoirs, the exploitation of its hydroelectric potential (estimated at 30,000,000 kilowatts), and extension of the navigable length of the river and its tributaries.

Study and exploration. Chinese civilization arose in the lower valley of the Huang Ho, which is mentioned in ancient Chinese writings of the 3rd millennium BC. During the reign of one Yao, runs the record, catastrophic flooding occurred on both the Huang Ho and Yangtze River, inundating all of the North China Plain. Regular records have been kept since the 6th century BC of major floods and also of changes in the river's course. Water levels have been studied since 1736. The first European to explore the upper reaches of the Huang Ho was a Russian traveller, Nikolay Przhevalsky, in 1879 and 1884. Since the 1950s the river has been studied intensively by Soviet scientists as well as by the Chinese. (I.V.P.)

SEA OF JAPAN

The Sea of Japan is a marginal sea of the western Pacific Ocean, bounded by Japan and the Soviet island of Sakhalin to the east and by the Soviet Union and Korea (where it is known as the East Sea) on the Asian mainland to the west. Its area is 389,100 square miles (1,007,800 square kilometres). It has a mean depth of 4,429 feet (1,350 metres) and a maximum depth of 12,276 feet (3,742 metres).

Physical features. *Physiography.* The sea is almost elliptical, having its major axis from southwest to northeast; to the north it is approximately bounded by latitude 51°45′ N, while to the south it is bounded by a line drawn from the Japanese island of Kyūshū westward through the Gotō-rettō (Gotō Islands) of Japan to the Korean island of Cheju (also known as Quelpart Island) and then northward to the Korean peninsula.

The sea itself lies in a deep basin, separated from the East China Sea to the south by the Tsushima-kaikyō (Tsushima Strait) and Korea Strait and from the Sea of Okhotsk to the north by Sōya-kaikyō (Sōya Strait, or La Pérouse Strait) and Tatar Strait, all of which have sill depths of less than about 700 feet. To the east it is also connected with the Inland Sea of Japan by Kanmon-kaikyō.

Component basins

Underwater, the sea is separated into the Japan Basin (about 9,800 to 11,500 feet deep) to the north, the Yamato Basin (8,200 feet deep) to the southeast, and the Tsushima Basin (6,600 feet deep) to the southwest. While a narrow continental shelf with an average width of about 19 miles (30 kilometres) fringes Siberia and the Korean peninsula, on the Japanese side of the sea there are wider continental shelves with depths at the edge of between about 430 and 1,300 feet, as well as groups of banks, troughs, and basins lying offshore. The banks lying off the coasts of Japan are divided into groups, which include Okujiri Ridge, Sado Ridge, Hakusan Banks, Wakasa Ridge, and Oki Ridge.

Geology. Yamato Ridge, which has an average depth of about 1,475 feet (450 metres), consists of granite, rhyolite, andesite, and basalt, with boulders of volcanic rock scattered on the seabed. The top of the Korea Plateau is about 3,000 feet below the surface and has a depression in its central part. Geophysical investigation has revealed that, while Yamato Ridge is of continental origin, the Japan Basin and the Yamato Basin are of oceanic origin.

Bottom deposits in the Sea of Japan indicate that earthborn sediments, such as mud, sand, gravel, and fragments of rock, exist down to depths of 650 to 1,000 feet; hemipelagic sediments (*i.e.,* half of oceanic origin), mainly consisting of blue mud rich in organic matter, are found down to depths of about 1,000 to 2,600 feet; and deeper pelagic sediments, consisting of red mud, are found down to a depth of nearly 13,000 feet.

A number of submarine canyons are found on the continental slope, at depths of more than 6,500 feet on the west side of the basin, while those near the islands of Japan lie at depths of only about 2,600 feet.

Argument over the formation of the Sea of Japan has not yet ended, although there is agreement that the four straits that connect the sea either to the Pacific Ocean or to marginal seas were formed in very recent geological periods. The oldest of these straits are the Tsugaru-kaikyō and Tsushima-kaikyō, whose formation interrupted the migration of elephants into the Japanese islands at the end of the Tertiary Period (about 2,500,000 years ago); the most recent is Sōya-kaikyō, which was formed at the end of the Wisconsin Ice Age (60,000 to 11,000 BP) and which closed the route once used by the mammoths whose fossils have been found in Hokkaidō.

Climate. The Sea of Japan contributes greatly to the mild climate of Japan because of the effect exerted by its relatively warm waters; evaporation is especially noticeable in winter, when an estimated 5,000,000,000 tons of water vapour rise as steam fog near the Polar Front (*i.e.,* the frontier between the cold, dry polar air mass and the warm, moist tropical air mass). From December to March the prevailing northwest monsoon wind carries cold and dry continental polar air masses over the warmer waters of the sea, resulting in persistent precipitation in the form of snow along the mountainous coasts of Japan. In summer the southerly tropical monsoon blows from an area of higher atmospheric pressure over the North Pacific onto the Asian mainland, causing dense fog when its warm and moist winds blow over the cold currents that prevail over the northern part of the sea at that season. The winter monsoon brings rough seas and causes coastal erosion as a result of the heavy surf that breaks along the western coasts of Japan. In summer and fall typhoons occasionally occur.

The northern part of the sea, especially off the Siberian coast as well as in Tatar Strait, freezes in winter; as a result of convection, melted ice feeds the cold currents in that part of the sea in spring and summer.

Hydrography. The waters of the sea generally circulate in a counterclockwise pattern. A striking contrast occurs between the cooler and relatively fresher water in the western part and the warmer and relatively more saline water in the eastern part. A branch of the Kuroshio Current, the Tsushima Current, together with its northern branch, the East Korea Warm Current, flows north, bringing warmer and more saline water, before flowing into the Pacific through the Tsugaru-kaikyō as the Tsugaru Current, as well as into the Sea of Okhotsk through the Sōya-kaikyō as the Sōya Current. Along the coast of the Asian mainland, on the other hand, three cold currents—the Liman, North Korea, and Central (or Mid-) Japan Sea cold currents—bring cooler, relatively fresh, and turbid water southward.

Prevailing currents

The economy. Fisheries and mineral deposits form the main economic resources. Fisheries may be divided into pelagic (oceanic) and demersal (sea-bottom) categories. Pelagic fishes include mackerel, horse mackerel, sardines, anchovies, herring, fishes of the salmon and trout family, sea bream, and squid; the demersal category includes cod, Alaskan pollack (bluefish), and Atka mackerel. Seals and whales are also to be found, as well as such crustaceans as prawns and crabs. The fishing grounds are for the most part on the continental shelves and their adjacent waters, as well as in the Polar Front zone and on the submarine banks.

Herring, sardines, and bluefin tuna have traditionally been caught, but since 1946 the fisheries have been becoming depleted. Squid fishing is carried on in the central part of the sea, salmon fishing in the shoal areas of the north and southwest, and crustacean trapping in the deeper parts.

Mineral resources on or in the sea bottom include magnetite sands as well as natural gas and petroleum deposits off Japan and Sakhalin Island.

As trade increases between Asian countries, the Sea of Japan is being increasingly used as a commercial waterway. While the waters of the sea historically have served to protect Japan from foreign invasions, the southern straits have been the scene of some historical naval battles. On two occasions—in 1274 and 1281—the fleets of Kublai

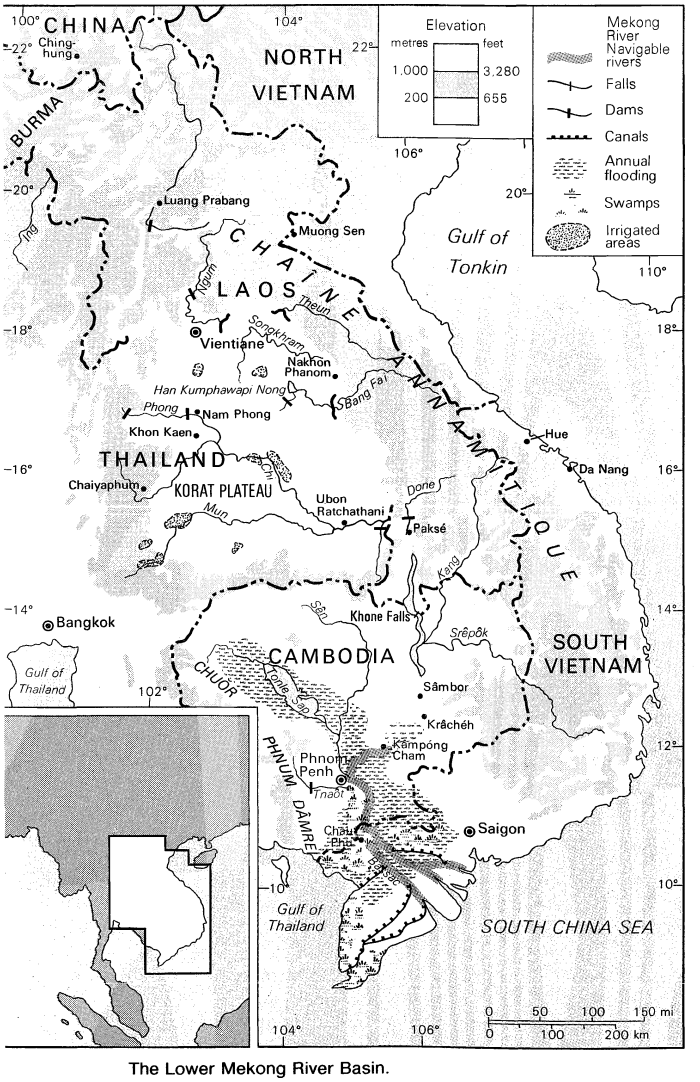
Khan, founder of the Yüan (Mongol) dynasty in China, attempted to cross the straits to conquer Japan, but the conqueror's forces were either destroyed by typhoons or beaten by the Japanese. In 1905, at the battle of Tsushima Strait, the Japanese navy almost completely destroyed the Baltic fleet of the Russian tsar. (M.U.)

MEKONG RIVER

The Mekong, 2,500 miles (4,000 kilometres) long, is the longest river in Southeast Asia and the seventh longest in all of Asia. Rising in Tsinghai Province, China, it flows through Yunnan Province, after which it forms part of the international border between Burma and Laos, as well as between Laos and Thailand, also flowing through Laos, Kampuchea, and Vietnam before draining into the South China Sea to the south of Ho Chi Minh City (Saigon). Vientiane, capital of Laos, and Phnom Penh, capital of Kampuchea, both stand on its banks. About 77 percent of the drainage area of the Mekong lies within the four countries traversed by its lower basin—Laos, Thailand, Kampuchea, and Vietnam.

Physical features. The Mekong River drains more than 307,000 square miles (795,000 square kilometres) of land, stretching from the Tibetan Plateau to the South China Sea. Among Asian rivers, only the Yangtze, Ganges, and Irrawaddy have larger minimum flows. The Mekong River's small width in the first 1,150 miles of its course, and the contrast between the physical conditions that prevail above and below the reach where it flows down off the Yunnan highlands, divide it into two major parts.

The Upper Mekong is a long, narrow valley comprising roughly 26 percent of the total area, cutting through the mountains and plateaus of China. The Lower Mekong, below the point where it forms the border between Burma and Laos, is a stream 1,454 miles in length that claims the drainage from the Korat Plateau of Thailand, from most of Kampuchea, and from the westward slopes of the Chaîne Annamitique (Annamite mountain chain) in Laos and Vietnam before reaching the sea through the distributary channels of its delta.



The Lower Mekong River Basin.

In its upper reaches the Mekong is one of the cluster of great streams rising in the plateau between the Salween and the Yangtze; the streambed has cut deeply into the rugged landscape through which it flows. Where it flows between Burma and Laos, it drains about 8,000 square miles of Burmese territory, all of which consists of rough and relatively inaccessible terrain. In its more gentle lower stretches, where for a considerable distance it constitutes the boundary between Laos and Thailand, it forms a subject of both friction and cooperation among the four countries of Kampuchea, Laos, Thailand, and Vietnam.

Origin of the river

Physiography. The upper sources, known locally as the Pam and the Dzi Chu, rise at elevations of more than 16,000 feet (4,875 metres) in the Tibetan highlands on the southern border of Tsinghai. They flow southeasterly through the Chamdo region of Tibet. The main stream, called the Lan Ts'ang Chiang, descends in a southerly direction across the highlands of Yunnan, which are cut by erosion into hills and valleys, to a point south of Yiinching Hung, where it becomes the border between Burma and China. The river then moves in a southwesterly direction; over a reach of more than 125 miles it forms the Burmese–Laotian border. Although two great roads cross it—the caravan route from the southeast to Lhasa, and the K'un-ming-to-Burma road—much of the river valley in the high plateau and in the Yunnan Mountains is extremely inaccessible and sparsely populated.

Below Burma, the river basin may be divided into six major sections—the northern mountains, Korat Plateau, eastern highlands, southern lowlands, southern highlands, and delta sections. All these sections have somewhat similar landforms, vegetation, and soils. Most of the vegetation in the lower basin is of the tropical broadleaf variety, although the occurrence of individual species varies with latitude and topography.

The northern mountains section has highly folded mountains reaching elevations of about 9,000 feet above sea level, many with slopes slanting at steep angles. As far south as the latitude of Vientiane, these dissected uplands (*i.e.*, cut by erosion into hills and valleys) are covered with dense deciduous forest that has deteriorated as a result of inroads made by shifting cultivation. To the south of the east–west course of the river above Vientiane lies the Korat Plateau, which embraces almost all of the Thai portion of the basin as well as the lower parts of the Mekong's Laotian tributaries. This is an area of flat or gently rolling plains traversed by relatively flat valley bottoms. Soils and deciduous vegetation on the uplands are thin, and much of the original forest has been replaced by grassland as a result of grazing and repeated burning.

The Korat Plateau

The eastern highlands form part of the Chaîne Annamitique of mountains, from which streams drain west into the Mekong. Throughout most of the distance between Muong Sen in Vietnam and Krâchéh in Kampuchea the watershed forms the border between Vietnam to the east and Laos and Kampuchea to the west. There is greater relief in the northern than the southern parts of the watershed, but the highlands in general are characterized by rapid streams that flow through narrow valleys before entering the Korat Plateau or other lowlands. Forest degradation, that has resulted from lumbering, the temporary use of land for cultivation, and grazing, is widespread.

The southern lowlands border both sides of the Mekong below Paksé in Laos. The part of the river that flows through Kampuchea has wide stretches of alluvium in its floodplain. Near Phnom Penh, the Kampuchean capital, a junction occurs between the Mekong and the Tonle Sap river, which connects it to the Tonle Sap lake, sometimes called the Great Lake. The direction of flow of the Tonle Sap river varies according to the season. In midsummer, when the Mekong is in flood, waters flow down the Tonle Sap to the lake, which at this time increases its area from

The Great Lake of Tonle Sap

about 1,000 square miles to about 3,000 square miles. In midwinter when the floods subside, the Tonle Sap reverses its flow to drain southeastward into the Mekong. Tonle Sap lake is one of the most productive fishing grounds in the world, producing as much as 26 tons of fish a year per square mile.

Along the southern border of the basin in Kampuchea, the Éléphant and Cardamon mountains form a string of southern highlands that drain northward into the southern lowlands.

The river divides into two streams—the Mekong and the Bassac—below Phnom Penh. From this point onward the delta spreads out to the sea. The delta, which has a total area of about 25,000 square miles (65,000 square kilometres), has three major sections. The upper section, above Chau Phu, has strong natural levees (embankments built on either side of the river by accumulated deposits of silt) behind which are low, wide depressions. The middle section has some areas that are well drained, others that are poorly drained and swampy. Along the lower section, formed by the river mouths and by the area to the southwest, sediment carried down from the upper river is in the process of being deposited, and the flooding is less extreme than in the upper sections of the delta.

Hydrology. The mean annual flow of the river at Krâchéh in Kampuchea is about 500,000 cubic feet per second (cusecs), making a total annual discharge for the year of about 378,000,000 acre-feet. The recorded minimum at Krâchéh is about one-twelfth of the mean, and the annual peak flow about four times the mean. Below Krâchéh the peak flows diminish as the water spreads out into the distributary channels and backswamps. Flow comes chiefly from rainfall in the lower basin and reflects the variation in seasonal rainfall caused by the monsoon winds; this variation generally forms a regular annual pattern: in April the flow is ordinarily at its lowest; in May or June the flow begins to increase, doing so most rapidly in the eastern highlands and northern mountains; the highest water levels are reached as early as August or September in the upper reaches and as late as October in the southern reaches. The northeast monsoon wind, beginning ordinarily in November in the southern areas, brings dry weather until May.

The annual sediment load is recorded as being highest at Paksé, where it amounts to 132,000,000 tons; it is about half that amount at the Burmese border and about two-thirds at Phnom Penh. The dominant hydrologic fact affecting agriculture is the long dry period in which rice cultivation is impossible without irrigation.

The people. The inhabitants of the lower basin amount to half the population of the four riparian countries. About 80 percent are engaged in agriculture, and rice is the major crop. Heaviest population concentrations are in the delta and on the Korat Plateau. The small urban population has been growing rapidly, chiefly through migration to the capital cities. There is no common ethnic tie among the basin populations. Ethnic groups range from Sino-Tibetan, including Karen and Meo mountain groups, in the Upper Mekong region, to Khmer, Cham, Tai, Mon, and Vietnamese lowland groups in the Lower Mekong Basin. The Vietnamese are heavily concentrated in the delta, and the Khmer and Tai are the most widely distributed in the lower basin.

Ethnic groups

The economy. *Irrigation and flood control.* In the lower basin the management of water offers major opportunities to increase the economic productivity of the tributary lands. Farmers practicing shifting cultivation on the uplands and the rice growers on the rain-fed lowlands are able, under normal conditions, to grow only one crop a year, taking advantage of wet-season precipitation. Half the cultivated land is dependent upon some form of inundation by flood flows. Control of water, however, makes it possible to store water during the dry season, and thus permits the harvesting of a second or third crop. If irrigation is combined with flood control, the losses and delays caused by floods pouring over the river's banks are reduced. Where storage facilities and the degree of downward slope are favourable, hydroelectric power can be generated. If navigational conditions on the Mekong's main stream and on some of its tributaries were to be improved, transport costs for landlocked areas could be reduced.

After the Bureau of Flood Control of the United Nations Economic Commission for Asia and the Far East (ECAFE) had recommended study of the Lower Mekong, surveys were carried out by ECAFE and by the U.S. Bureau of Reclamation. This led to the adoption by Cambodia, Laos, Thailand, and South Vietnam of a 1957 statute creating the Committee for Coordination of Investigations of the Lower Mekong; a 1978 agreement extended the work of the Committee but no longer included Kampuchea, as there was no competent authority to represent it. By the mid-1980s the three riparian countries had sponsored a series of preinvestment and general scientific investigations and had undertaken construction of multiple-purpose water projects. They had continued to cooperate despite the political stresses produced by the war in Vietnam and its aftermath and had enlisted the assistance of other countries.

Investigations undertaken included basic mapping, hydrologic observations, soil surveys, fisheries studies, health studies, engineering-feasibility studies, power-market surveys, agricultural research and pilot farms, and many other inquiries. The engineering studies had provided for reconnaissance appraisal of all of the tributary basins and for more detailed examination of selected projects. Flood forecasting was begun and river navigation was improved. Mineral surveyors explored possible opportunities for bauxite and iron development. Some irrigation and power projects have been initiated or completed.

The focus of the Mekong Development Project as a whole shifted after the Vietnam War to the planning of comprehensive programs for agricultural and community development in areas where water supply was available, with each country working out its individual financial arrangements. No formal negotiations with the two upstream riparian countries, Burma and the People's Republic of China, or with adjacent countries that might be markets for power, had as yet taken place.

Navigation. In the Vietnamese part of the delta there is an elaborate system of canals. Smaller seagoing vessels can sail upstream as far as Phnom Penh and vessls drawing almost 15 feet can reach Kompong Cham during high water. Continuous water transport is blocked chiefly by the barriers of the Khone Falls and other falls between Sâmbor and Paksé, and upstream uses of the river are limited to local traffic. (G.F.W.)

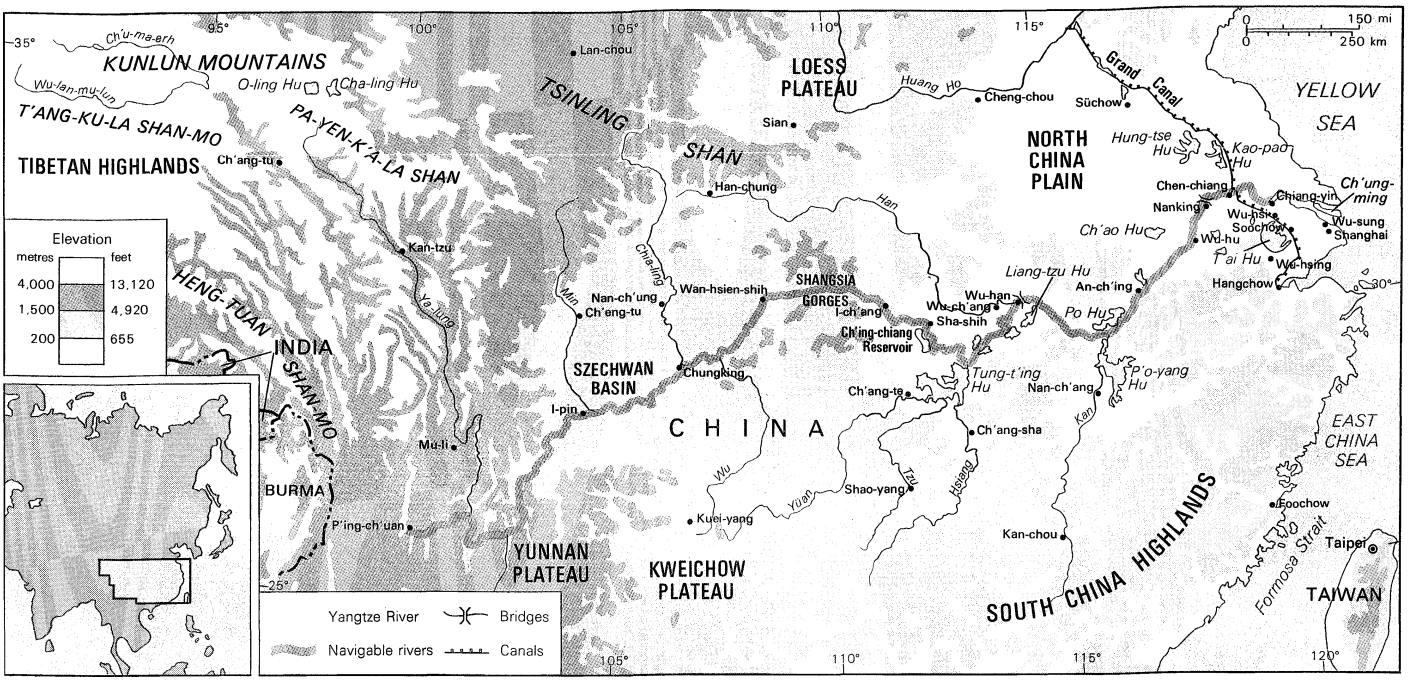
YANGTZE RIVER

The Yangtze River (in Chinese Ch'ang Chiang, in Pinyin Chang Jiang, also spelled Yangtze Kiang, English Blue River) is the longest river in both China and Asia, and is the fourth longest river in the world. Its length is 3,434 miles (5,525 kilometres); its basin extends for 2,000 miles from west to east and is over 600 miles wide. Rising from its source in the west of China, the river, either completely or partially, traverses 12 provinces or regions, including the autonomous region of Tibet. Population distribution in the Yangtze Basin is uneven; it is greatest in the plains that adjoin the banks of the river and its tributaries in central and eastern China and is most sparse in the highland areas to the west of the basin. More than three-quarters of the river's course runs through mountains.

The name Yangtze, which came to be applied to the entire river, is derived from the name of the ancient fiefdom of Yang; it came to be applied by Europeans to the whole river. Among the Chinese people this name is not commonly used; instead the generally accepted name in China for the river is Ch'ang Chiang (Long River); to a lesser extent it is also called Da Kiang (Great River). Yet another name, also given by Europeans, the Blue River, is a misnomer; in its middle and lower course the water of the Yangtze has a brown-yellow hue.

The principal tributaries

The Yangtze has eight principal tributaries. On its left bank, from source to mouth, these are: the Ya-lung Chiang (about 730 miles [1,170 kilometres] long), the Min Chiang (490 miles), the Chia-ling Chiang (700 miles [1,120 kilometres]), and the Han Shui (950 miles); while on the right



The Yangtze River Basin.

bank are the Wu Chiang (630 miles [1,010 kilometres]), the Yüan Chiang (600 miles), the Hsiang Chiang (500 miles), and the Kan Chiang (470 miles).

The Yangtze Basin is the granary of China and contributes almost half of the crops of the country, including up to 70 percent of the total gross volume of rice. In addition, many other crops are grown, among them cotton, wheat, barley, corn (maize), beans, and hemp. Such large cities as Shanghai, Nanking, Wu-han, Chung-king, and Ch'eng-tu are located in the basin, all of which have populations of more than 1,000,000.

Physical features. *The upper course.* The upper course of the Yangtze flows through the Tibetan highlands, where the population consists mainly of persons engaged in cattle breeding and in primitive agriculture. The summers are warm and the winters cold, and the growing season lasts for four or five months. In the most heavily populated points live a small number of Chinese, Dungan, Nepalese, and Indians. In the mountainous regions adjoining the highlands of the southwest, the population is predominately Chinese; like the other minorities, they are primarily engaged in agriculture.

Sources of the Yangtze

The Yangtze initially rises from two sources, which are located in the T'ang-ku-la Shan-mo (T'ang-ku-la Mountains) at an altitude of 18,000 feet (5,500 metres) above sea level. The main (southern) source is known locally by its Tibetan name, Ulan Muren (Wu-lan-mu-lun in Chinese). From the confluence of its source streams, the river flows through a shallow, spacious valley, the bottom of which is studded with lakes and small reservoirs. This part of its course lies in the higher regions of the Tibetan highlands. The river's character changes sharply upon reaching the eastern limits of the highlands. Here, in exiting from Tibet, the river descends from a great altitude, winding its way south of the high Pa-yen-k'a-la Shan and forming a narrow valley between one and two miles in depth. Individual mountain peaks exceed 16,000 feet above sea level and are crowned with glaciers and perpetual snow. The steep, rocky slopes are cut with gorges and deep valleys. For several hundred miles the Yangtze flows in southeasterly direction, before turning southward to flow downward in rushing rapids. For a considerable distance the river flows through passes that are so steep that no room is left even for a narrow path. Villages, which are rarely found, are located high above the river. In this region the Yangtze runs close and parallel to both the Mekong and Salween rivers; all three rivers are within 15 to 30 miles of one another and continue to flow in mutual proximity for a distance of more than 250 miles.

North of latitude 26° N the paths of the rivers diverge, with the Yangtze turning to the east. The Yangtze then flows through mountains to the city of I-pin, passing through a winding valley with steep slopes. Admitting the waters of many tributaries, among which the Ya-lung Chiang is the largest and contributes the most water, the Yangtze widens to between 1,000 and 1,300 feet, reaching depths not infrequently exceeding 30 feet. In the narrow gorges the water width decreases by almost half, but the depth increases sharply.

The Ya-lung Chiang

Toward the end of the upstream part of its course, the Yangtze descends to a level of 1,000 feet above sea level. Thus, the total fall upstream for about 1,600 miles is more than 17,000 feet, or an average of over 10 feet per mile of its course. In the mountains, however, there is a substantial stretch where the fall of the river is several score feet for each mile of its path.

The middle course. The middle course of the Yangtze is characterized by hot summers and not very cold winters, while the precipitation measures from 40 to 60 inches (1,016 to 1,524 millimetres) a year; the growing season lasts for more than half a year. A large part of the rainfall occurs in summer; this is favourable to the development of agriculture, which in this region dominates the economy. The main population is Chinese, with many other national minorities represented.

The river's course between I-pin and I-ch'ang

In its middle course, which stretches for about 630 miles between the cities of I-pin and I-ch'ang, the Yangtze crosses hilly Szechwan Province, where the mountainous region connects the highlands in the southwestern part of China with the mountainous region of Tsinling east of the Himalayas and south of Sian. The river's width here is from about 1,000 to 1,600 feet, and the depth in places exceeds 30 feet. The current is fast; the banks are often high and steep. The fall of the river in Szechwan province is more than 820 feet (about one foot per mile of flow). The people of Szechwan call this area the "Land of Plenty." The soil here is very fertile, and the climatic conditions are entirely favourable to agriculture, since the high mountains associated with the steppe (treeless plain) safely protect the province from the cold north and west winds. The mild climate also favours the development of sericulture (the production of raw silk by raising silkworms). Deposits of various useful minerals are concentrated in this section of Szechwan Province: coal, copper, phosphorus, gold, oil, and gas. The population is especially dense on the plain in the vicinity of the city of Ch'eng-tu. Also located in this area is Chungking, a large-scale industrial centre and river port.

Leaving Szechwan province behind, the Yangtze flows for a distance of 125 miles through a mountainous region where the three narrow gorges of Tsyuytan, U, and Silin are located, before exiting onto the plain. The gorges have steep, sheer slopes composed mainly of thick limestone rocks, rising from 1,300 to 2,000 feet above the river and presenting the appearance of fantastic towers, pillars, or spears. The first gorge—about five miles long—is the shortest, but it is considered the most dangerous for navigation; the river here is very narrow and contains many rapids and eddies. The following gorge, which stretches for about 30 miles, is a narrow, steep corridor with almost vertical walls of heights up to 1,600 or even 2,000 feet. The last gorge is located upstream of I-ch'ang and extends for a distance of 21 miles; in places limestone cliffs rise directly out of the water to heights of hundreds of feet. The gorges are rocky, and the walls speckled with cracks, niches, and indentations. The width of the Yangtze between the gorges is 1,600 to 2,000 feet and about 500 to 600 feet within the gorges; the depth in gorges, however, also increases to between 500 and 600 feet, thus making the Yangtze the deepest river in the world.

The lower course. The lower part of the Yangtze River Basin, situated at the edge of an extensive plain in the lowlands of eastern China, experiences a temperate, coastal climate featuring a warm spring, a hot summer, a cool fall, and a comparatively cold winter. Monsoons (rain-bearing winds) dominate the weather of the region, and in the summer and fall typhoons are experienced periodically. The natural conditions here are exceptionally favourable to agriculture; the growing period continues for eight to 11 months, and in some areas two or three successive crops can be harvested in a single year.

This region is the most industrially and agriculturally developed area in China. A majority of the population of the basin, mostly Chinese, are concentrated here, and the population density is very high. About 1,300 miles downstream, the Yangtze begins its exit from the Shangsia Gorges, flowing into an extensive plain. Here the river forms a complex system consisting of the main river channel, many tributaries, and lakes. The Yangtze flows to the city Wu-han across the flat Liang-tzu Hu Plain, contributing alluvial and lake deposits to the bed of the large Yün-meng Tse (Yun-men Lakes).

The lake region

On the wide terrace-like slopes are situated a number of lakes that begin as small and end as large reservoirs, such as Ch'ang Hu, Hung Hu, and Tung-t'ing Hu. The total area of the lakes exceeds 6,600 square miles (17,100 square kilometres). The lakes are of national economic significance, mainly as fisheries. At the edge of the Liang-tzu Hu Plain the Yangtze widens markedly, the course of its stream wandering in the form of a large loop. The width of the river is up to 2,600 feet, the depth is over 100 feet, and the water current flows at a rate of three to four feet a second. The banks are built up for protection from floods. In the southern part of the plain lies Tung-t'ing Hu, which is the largest lake in the region, having an area of from 1,400 to 1,800 square miles; it shares four tributaries and two canals with the Yangtze, whose flow it serves to regulate. The surrounding area, agricultural and studded with lakes, is called the rice bowl of China.

On the Yangtze, near the mouth of the Han Shui (Han River), are located three cities—Han-yang and Hankow on the left bank, and Wu-ch'ang on the right bank. In the course of time these cities have come to form one huge city—Wu-han, a large metallurgical base and river port. Further east on the Liang-tzu Hu Plain, the Yangtze flows into a narrowing, picturesque valley and then exits onto the plain, in the southern part of which is located another large lake—P'o-yang Hu, which has an area of about 1,000 square miles and which is linked to the Yangtze by a wide tributary. The river then turns to the northeast, flows through a wide, closed valley into which many lakes empty, and exits into the North China Plain. The width of the river increases at this point to between 3,000 and 6,000 feet, and the depth in places approaches 100 feet. In this region there are a number of large cities, An-ch'ing, Wu-hsi, Soochow, and Shanghai among them. The Grand Canal, which, with a length of 1,300 miles, is one of the longest canals in the world, leaves the Yangtze in the vicinity of the city Chen-chiang.

The Yangtze Delta. The Yangtze Delta, which begins beyond the city of Chen-chiang, consists of a large number of branches, tributaries, lakes, ancient riverbeds, and marshes that are connected with the main channel. During major floods the delta area is completely submerged. T'ai Hu, with an area of about 1,300 square miles, is notable as the largest of the many lakes in the delta. The width of the Yangtze in the delta, as far as the city of Chiang-yin, ranges from less than a mile to almost two miles; further downstream the channel gradually widens and becomes a large estuary, the width of which exceeds 50 miles near the mouth of the river.

T'ai Hu

Before emptying into the sea, the Yangtze divides into two arms that drain independently into the East China Sea. The left branch has a width of from three to six miles, the right branch of from six to 15 miles. Between the branches is situated Ch'ung-ming Tao (Ch'ung-ming Island), which has an area of 300 square miles and which was formed over 1,000 years ago as a result of the deposit of alluvium at the mouth of the Yangtze. The depth of the river in places approaches 100 to 130 feet but decreases to several feet near the sea at the mouth of the river due to the presence of sandbars.

The section of river from the mouth to 250 miles upstream is subject to the influence of tides. The maximum range of the tides near the mouth is 13 to 15 feet.

The present bed of the Yangtze in this area is several yards above the plain. Thus, for protection of the surrounding region from floodwaters, the banks of the main and other rivers are built up; the total length of banks on the Yangtze that have thus been diked is about 1,700 miles. Dams have also been built for flood protection on the shores of several lakes; the Ch'ing-chiang Reservoir, for example, built for this purpose near Tung-t'ing Hu, has a capacity of 194,000,000 cubic feet (5,500,000 cubic metres). The delta is protected from the sea by two gigantic parallel banks that are faced with stone in most parts. The extensive area of the delta is used for the planting of rice and cotton.

Hydrology. The Yangtze Basin is comparatively well irrigated; the average yearly rainfall amounts to about 43 inches (1,100 millimetres). Most of the rain is brought by the monsoon winds and falls primarily in the summer months. In the mountainous part of the basin most of the precipitation takes the form of snow. Floods, which result from the monsoon rains in the middle and lower parts of the basin, usually begin in March or April and last for about eight months. In May the water level decreases somewhat, but then sharply increases again, continuing to rise until August, when it reaches its highest level. After that the water level gradually falls to the premonsoon levels, the decrease continuing through the fall and most of the winter until February, when the lowest annual level is reached.

Spring floods

The annual range of water level fluctuations is very great—an average of about 65 feet—with 26 to 35 feet during years of low water. In the gorges, the range of water levels caused by flooding reaches huge proportions—from 130 to 150 feet. Downstream, the impact of the water level variation is lessened by the regulating effect of the lakes; here tides exert the greatest influence on the water level. Near the city of Wu-sung the daily tidal range is 15 feet, and the yearly range is 20 feet.

A breakdown of the water volume delivered to the mouth of the Yangtze shows that the highland part of the basin contributes 10 percent of the flow, while all of the rest of the water in the river is contributed by the middle and downstream parts of the basin, with the Tung-t'ing Hu and P'o-yang Hu being responsible for about 40 percent of the volume.

The Yangtze carries a tremendous volume of water. Even in the upstream areas the average volume of flow exceeds 70,000 cubic feet a second. For comparison, it may be noted that the second longest river in China, the Huang Ho, has a volume of flow at its mouth of 52,580 cubic feet per second, which is significantly less than that of the Yangtze. After the inflow from the first large tributary—

the Ya-lung Chiang—the volume in the Yangtze sharply increases, approaching an average of 194,000 cubic feet a second. Further downstream the Yangtze admits many tributaries, and the volume gradually increases, reaching 529,000 cubic feet per second at the end of the Shangsia Gorges near I-ch'ang, 847,000 cubic feet per second near Hankow, and 1,100,000 cubic feet per second near Nanking. The average volume at the mouth of the Yangtze equals 1,200,000 cubic feet per second, while the total volume entering the sea annually is 244 cubic miles (1,072 cubic kilometres), ranking it fourth in volume of flow among rivers of the world.

During the seasonal rains the Yangtze widely floods the lower areas, and the maximum volume of water entering the sea can amount to from 1,800,000 to 2,500,000 cubic feet per second. During the dry season the flow decreases, sometimes to 212,000 and 282,000 cubic feet per second. In spite of the fact that the current volume of the Yangtze exceeds that of the Huang Ho, the Yangtze is significantly less muddy than the Huang Ho. This is explained by the fact that in the Yangtze Basin the soil is secured by a greater amount of vegetation. In the mountainous part of the basin, particularly in the Tibetan highlands, the waters of the Yangtze are transparent and contain little silt.

The volume of silt

Downstream, however, the waters become muddy and acquire a coffee colour. It is estimated that the Yangtze carries between 280,000,000 and 300,000,000 tons of alluvium to its mouth, depositing an estimated 150,000,000 to 200,000,000 tons on the river bottom in addition. Thus, the total amount of particle substance carried or deposited is between 430,000,000 and 500,000,000 tons in a year. As a result of the depositing of alluvium at the river's mouth, the delta extends into the sea an average of one mile in 64 years.

During the period of monsoon rains the Yangtze and its tributaries spill over, creating extensive floods. If the floods in the main channel coincide with flooding in one or more of the major tributaries, powerful, destructive flood waves can result, an occurrence that has happened repeatedly in the history of China.

The flooding frequently results from the deposit of silt in the bed of the Yangtze. Upon leaving the mountains and entering the plain, the current in the Yangtze sharply decreases, and thus the flow cannot continue to carry the entire amount of silt. As a result, a significant portion is deposited in the bed, causing the bottom to rise. An analogous situation occurs in many of the Yangtze's tributaries. Flooding thus presents a great danger to the inhabitants of the adjacent plains.

A legendary flood

In ancient literature there is much information about a legendary flood that is thought to have occurred in 2297 BC. The flood occurred as a result of extremely intensive and extended heavy rains. The Huang, Wei, and Yangtze rivers overflowed their banks and submerged almost the entire North China Plain, turning it into a huge sea; in the lowest places the water remained for many years. Since that catastrophe many other major floods have occurred. Historical records indicate that, during the period from 206 BC to AD 1960, China has experienced more than 1,030 major floods. Especially extensive flooding has occurred on the Yangtze more than 50 times and on its tributary, the Han Shui, 32 times; on the average, the Yangtze Basin is the scene of catastrophic flooding every 50 to 55 years. Extensive flooding may also take place in shorter periods of time. This has been the case in the last 100 years, during which time the Yangtze Basin was flooded in 1870, 1896, 1931, 1949, and 1954. Of these, the 1931 and 1954 floods have been general, national disasters. The 1931 flood resulted from heavy, continuous monsoon rains that covered most of the middle and lower parts of the basin. During May and June, six huge flood waves swept down the river, destroying the protecting dams and dikes in 23 places and flooding more than 35,000 square miles of land; 40,000,000 persons were rendered homeless or otherwise suffered. Many population centres, including Nanking, Wu-han, and others, were underwater. In Wu-han, the water remained for more than four months, the depth exceeding six feet, and in places ranging up to more than 20 feet. In the summer of 1954 a new, powerful flood occurred, resulting from continued monsoon rains. The water level sharply increased and at times exceeded the 1931 flood levels by almost five feet. As a result of effective flood-control measures, however, many of the potential consequences of the flood were averted.

The economy. *Navigation.* The Yangtze is the principal river used for transportation in China. Along the river for 1,700 miles there is intensive cargo and passenger traffic. The river serves as a continuation of the sea routes, binding the inland and sea ports together with other major cities into a transportation network in which Nanking, Wu-han, and Chungking play the leading roles. Junks are widely used for transporting cargo, and a small number of sail craft with displacements of 50 to 100 tons are also used. Large ships of up to 10,000-tons displacement can travel as far upriver as Wu-han, which is 700 miles (1,120 kilometres) from the coast, and craft of up to 2,000 tons can reach I-ch'ang, but only smaller craft can reach P'ing-ch'uan. Water routes in the Yangtze Basin total about 35,000 miles (56,000 kilometres). The Yangtze is joined to navigable branches of the Huang Ho and Wei Ho by the Grand Canal, which is further connected with the seaports of Hangchow and Tientsin.

Rivercraft

Two large railroad bridges have been built across the Yangtze at Nanking and Wu-han. Another bridge crosses the river at Chungking.

Resources. The Yangtze River and its associated tributaries and lakes, including the large Tung-t'ing Hu, P'o-yang Hu, and T'ai Hu, abound with fish. The fishing trade is widely developed and is a major livelihood for much of the population of the region. Up to 500 kinds of fish can be found in Chinese rivers, the majority of which inhabit the Yangtze and its tributaries. About 30 kinds of riverine fauna have economic significance, especially carp, bream, Chinese perch, gapers (a species of large burrowing clam), and lamprey; the most valuable economically are white and black amur (large members of the carp family), flatfish, and spotted flatfish. Sturgeon are also important; the gorges are a favourite spawning area. Further downstream great amounts of roe can be found, and these are collected and distributed throughout the country for artificial cultivation. Several billion roe are collected annually. The artificial cultivation of fish for trade involves mainly white and black amur, flatfish, and carp.

In the Yangtze Basin the extensive territory under cultivation—especially for rice, the most important crop—requires man-made irrigation facilities. Even in the areas of highest precipitation severe droughts are experienced, resulting in the loss of crops. This is explained by the extremely irregular distribution of precipitation over the course of the year, with 60 to 80 percent falling in the summertime. Rainless periods sometimes last for six to eight weeks. Irrigation has existed in the Yangtze Basin since ancient times, but many modern irrigation projects have been undertaken.

Hydroelectric power. The resources for the production of energy from the Yangtze are extremely great, although they have not been developed to a large extent. The total potential power is estimated to be 217,200,000 kilowatts, representing 40 percent of the total energy potential of all of the rivers of China. The power resources in the vicinity of the Tsyuytan, U, and Silin gorges are especially great, amounting to about 40,000,000 kilowatts. Many tributaries of the Yangtze that have significant fall and volume, such as the Ya-lung Chiang, Min Chiang, Chialing Chiang, and other rivers that are tributaries of Tung-t'ing and P'o-yang lakes, also have a potential for contributing large amounts of hydroelectric energy. It is anticipated that the prevention of destructive floods, the development of new agricultural territory, and the improvement of conditions for agriculture can be achieved simultaneously by the development of the hydroelectric-energy potential of the Yangtze Basin. (A.P.M.)

YELLOW SEA

The Yellow Sea (in Chinese Huang Hai) is a large inlet of the western Pacific lying between the People's Republic of China and the Korean peninsula. It is situated to the north of the East China Sea, which it bounds on a line running

from the mouth of the Yangtze River, near Shanghai, to Cheju-do (Cheju Island) off South Korea. It measures about 600 miles (960 kilometres) from north to south and about 435 miles from east to west. In the northwest part of the sea, northwest of a line between the Liaotung Peninsula to the north and the Shantung Peninsula to the south, is the Gulf of Chihli (Po Hai). The area of the Yellow Sea proper (excluding the Gulf of Chihli) is 156,000 square miles (404,000 square kilometres), its mean depth is 144 feet (44 metres), and its maximum depth is 338 feet. The Yellow Sea derives its name from the colour of silt-laden water discharged from major Chinese rivers.

Origin of the name

Physical features. *Physiography and geology.* The Yellow Sea, including the Gulf of Chihli and the Korea Bay, forms a partly enclosed, flat, and shallow marine embayment. Most of the sea, which is deeper than the Gulf of Chihli, consists of an oval-shaped basin with depths of about 200 to 260 feet (60 to 80 metres). The sand deposits of the Great Yangtze Bank lie off the Yangtze River to the south, near the East China Sea.

The Yellow Sea as it now exists was formed in the postglacial epoch (*i.e.,* not more than 11,000 years ago). Generally, the east and west coastal regions have a sandy bottom because of the strong tidal currents; the central basin has muddy silt; there is also a preponderance of mud on the side nearer the China mainland because of the vast amount of sediment discharged by the Huang Ho (Yellow River) and other major rivers.

Climate. Generally, the climate is characterized by very cold, dry winters and wet, warm summers. From late November to March, a strong northerly monsoon prevails, which in the Gulf of Chihli is sometimes accompanied by severe blizzards. Typhoons occur in summer, and in the colder season there are occasional storms. Air temperatures range from 82° to 50° F (28° to 10° C) and precipitation from about 20 inches (500 millimetres) in the north to 79 inches in the south. Sea fog is frequent along the coasts, especially in the upwelling cold-water areas.

Hydrography. The warm current of the Yellow Sea is a part of the Japanese Tsushima Current, which diverges near the western part of Kyūshū Island and flows at less than 0.5 knots (nautical miles per hour) northward into the middle of the sea. This warm current is modified by the low salinity of the coastal water but still maintains its relatively higher salinity. On the other hand, along the continental coasts southward-flowing currents prevail, which strengthen remarkably in the winter monsoon period when the water is cold, turbid, and of low salinity.

The tidal range is considerable (13 to 26 feet) along the shallower west coast of the Korean peninsula, with a maximum spring tide of almost 27 feet. Along the coasts of China it amounts to about three to 10 feet (except the Gulf of Chihli, which has more than 10 feet). In the Yellow Sea, the tide rises twice daily. The tidal system rotates in a counterclockwise direction. The speed of the tidal current is less than one knot in the middle of the sea, but near the coasts and in the straits and channels stronger currents of more than two or three knots are recorded.

The innermost coastal sections of the Gulf of Chihli freeze in winter, and drift ice and ice fields hinder navigation in parts of the Yellow Sea. Surface temperature ranges from freezing level in winter in the Gulf of Chihli to summer temperatures of from 72° to 82° F (22° to 28° C) in the shallower parts. Thus, the annual range is very large—from 40° to 50° F (4° to 10° C), a good indication of continentality. In winter, the temperature and salinity in the sea are homogeneous from surface to bottom. In spring and summer, the upper layer is warmed and diluted by the fresh water from rivers, while the deeper water remains cold and saline. This deep layer of cold water stagnates and moves slowly south in summer. Around this mass of water, especially at its southern tip, concentrations of commercial bottom fishes are found. The dominant salinity in the Gulf of Chihli is 30 to 31 parts per thousand (‰), and that in the Yellow Sea proper is 31 to 33 parts per thousand. In the southwest monsoon season (June to August), the increased rainfall and runoff cause a very low salinity in the upper layer in summer.

Temperature and salinity

The economy. The Yellow Sea, like the East China Sea, is famous for its fishing grounds. Since the early 20th century, rich demersal (bottom-dwelling) fishing resources have been exploited by Japanese, Chinese, and Korean trawlers. The annual catch amounts to several hundred thousand tons and consists of sea bream, croakers, lizard fish, prawns, cutlass fish, horse mackerel, squids, flounders, and other species. Overfishing and the consequent decline of fisheries had, by the 1970s, been brought under control. Along the coastal waters, spawning areas and fish nurseries are established. (M.U.)

LENA RIVER

The Lena is, in terms of water volume, the second largest river in the Soviet Union; in terms of length it is one of the largest rivers in the world, flowing 2,730 miles (4,400 kilometres) from its source in a small lake in the mountains west of Lake Baikal, in Central Asia, to the mouth of its delta on the Arctic Laptev Sea. The area of the river basin is about 961,000 square miles (2,490,000 square kilometres).

Physical features. *Physiography.* The Lena (which the Yakuts call Big River) has three main sections, each of about 900 miles (1,450 kilometres): the upper section from the source to the Vitim tributary; the middle course from the Vitim to the mouth of the Aldan; and the lower section from the Aldan to the Laptev Sea.

In the section from the source to the Vitim, the Lena flows in a deep-cut valley, the rocky and steep slopes of which are raised above the river, often up to 1,000 feet (300 metres). These slopes are formed on the right bank by the ledges of the Northern-Baikal Upland. The width of the river valley varies from one to six miles, but here and there it narrows in ravines to only 700 feet. The best known ravine, named Pyany Byk (Drunken Bull), is situated 147 miles below Kirensk.

In the first 110 miles from its source the Lena has a great number of shallow, rocky shoals, which occur as far as the Kirenga tributary. Below the mouth of the Kirenga the depth of the riverbed in the pools increases to 30 feet, and the rate of the flow decreases with a decrease in gradient. In the middle course, from the mouth of the Vitim to the Aldan, the Lena becomes a large, deep river. The water supply increases, especially after the junction with the Olyokma, and the width of the river reaches one mile. From the mouth of the Vitim to the Olyokma, the river skirts the Patom Plateau, on the right bank, forming an enormous bend; the width of the valley increases in places to 20 miles. Its slopes are gentle and green with forests, and along them run well-marked terraces formed by rivers. In this section of the valley there occurs an extensive water meadow, in which small lakes are scattered.

Below the Olyokma, the character of the valley changes sharply. In a stretch of about 400 miles, from Olyokma to Pokrovsk (60 miles above Yakutsk), the Lena flows along the bottom of a narrow valley with sheer, broken slopes. The enormous rocks sometimes resemble the ruins of a castle, or columns, or the figures of people and animals; and the area is a favourite place for tourists and rock climbers. In this section the Lena receives its largest tributaries. In addition to the Vitim aand the Aldan, these include the Great Patom and the Olyokma, flowing in on the right, and the Nyuya, on the left. Below the mouth of the Aldan the width of the valley of the Lena extends 12 to 16 miles, and the width of the water meadow reaches four to nine miles. Here the Lena enters into the borders of the Central Yakut Plain. The water meadow abounds with lakes, often marsh-ridden, and the riverbed divides, forming many islands and branches. The depth is from 50 to 70 feet, but there are many shallow sections with sandbanks.

Scenic attractions

In the lower section between the island of Zholdongo and the beginning of the delta the Lena Valley becomes narrow, its width being about one mile. The islands of the delta are low-lying, and covered with peat bogs; some fossilized ice may be found.

Climate. The climatic features of the Lena Basin are determined by its location well inside the Asian continent. In winter a powerful anticyclone is formed, the spur of which occupies all of Eastern Siberia. Because of the anti-

cyclone the winter is notable for its clear skies and prevailing calm. The frosts reach −76° to −94° F (−60° to −70° C), the average monthly air temperature in January being −22° to −40° F. In July averages range between 50° and 68° F (10° to 20° C). Due to its remoteness from the sea, the amount of precipitation in the basin is slight. Only in the southern mountains does the yearly total reach 24–28 inches (600–700 millimetres); in most of the basin it is 8–16 inches and in the delta four inches. Between 70 and 80 percent of the precipitation falls in the summer in the form of steady rain. In winter, on the average, not more than two inches of snow fall, so that the snow cover is very slight.

The very cold temperatures result in large accumulations of ice in the form of icy knolls. These are formed of groundwaters that accumulate between the layers of soil frozen permanently over many years and layers of seasonally frozen soil. Sometimes the icy knolls disintegrate with considerable force, scattering ice blocks. The riverbeds and floodlands are also covered with permanent ice in some places.

Plant and animal life. The vegetation of the Lena Valley reflects the features of the natural zones across which the river flows. The main part of the river basin is covered with taiga (swampy northern coniferous forest); in the lower reaches are found tundra and scattered forest. Spruce, cedar, birch, and poplar predominate in the moister regions. In the central valley occur some expanses of steppe, a rare occurrence above latitude 60° N. Characteristic of the water-meadow area are peat bogs and swamps and thickets of willow, alder, and dwarfish birches. In the lower valley course appear tundra plants such as mosses and lichens, partridge grasses, whitlow grass, arctic poppy, and cotton grass.

The plankton of the Lena is rather poor and restricted in variety. More than 100 species of animals are found. Commercially important fish include sturgeon, salmon, roach, dace, and perch. The main concentration of these varieties is in the mouth region, where in the summer there is comparatively warm water.

Hydrography. More than 95 percent of the Lena's water is obtained from melting snow and from rain; 1 to 2 percent of the yearly flow comes from subsoil waters. Typical of the Lena Basin are high floods, especially flash floods, in summer, and very little flow in winter. Complete cessation of flow may occur with the freezing of the river through to the bottom. The average volume of the Lena at the mouth is 21,300 cubic yards (16,300 cubic metres) per second; the greatest volume is 260,000 cubic yards per second, and the minimum is 478 cubic yards per second. The total yearly volume approaches 100 cubic miles. During the high-water period the water level rises by an average of 30 to 50 feet, and in the lower course reaches 60 feet.

The river's volume

The highest temperature of the water in the upper course of the river reaches 66° F (19° C) and in the lower course about 57° F (14° C). The river is free of ice in the south for five to six months and in the north four to five months. The breakup of ice in the spring causes significant damage to the shores: the ice floes grind the rocks, pull trees out by their roots, and carry away large sections of the banks.

The Lena carries out into the sea about 12,000,000 tons of suspended alluvium and 41,000,000 tons of dissolved matter a year. The proportion of suspended alluvium in the water is small: even in floodwaters it does not exceed 50 to 60 grams per cubic metre. The mineralization of the water in the lower Lena during low water is from 80 to 100 grams per cubic metre, and in floodwaters 160 to 500 grams per cubic metre.

The people. Among the peoples living in the Lena Basin, mainly on the banks of the river and its tributaries, are Russians, Evenks, Yakuts, and Yukaghirs. There are many industrial and cultural centres, collective farms, and state farms. In the territory of the basin is found the Yakut Autonomous Soviet Socialist Republic, with the capital of Yakutsk.

The economy. The Lena is navigable by small boats in sections below Kachug and from Ust-Kut by larger vessels. The largest wharves are Bulun, Zhigansk, Yakutsk, Vitim, Kirensk, Osetrovo, Zhigalovo, and Kachug; Osetrovo is an important river port, equipped with modern machinery. The largest navigable tributaries are the Kirenga, Vitim, Olyokma, Aldan, and Vilyuy. Wood products, furs, gold, mica, industrial products, and food are the main cargoes.

Within the borders of the Central Yakut Plain various agricultural crops—barley, oats, wheat, potatoes, cucumbers, and others—are grown. The large meadows and pastures present successful livestock raising. Future prospects for the economic development of the Lena Basin are extremely good. The basin is rich in useful fossil minerals, and gold and coal occur in exploitable quantities. In 1955, in western Yakutia, rich deposits of diamonds were discovered in the Vilyuy Basin. To the east of the diamond-bearing region are found vast deposits of natural gas; near Olyokminsk are found salt beds, and to the south of Yakutsk, iron ore and coking coal.

The hydroenergy potential of the Lena and its tributaries is about 40,000,000 kilowatts.

Study and exploration. The first exploration of the Lena was conducted by Russians at the beginning of the 17th century. In 1631 a fortress and a settlement was founded at Ust-Kut. The first scientific research was conducted by the Great Northern Expedition in 1733–43. Cartography was begun in 1910. In 1912, in the icebreakers "Taymir" and "Vaygach," the delta was surveyed and mapped. Further surveying was conducted in the interwar period, and is currently being conducted by the Yakut branch of the Academy of Science of the U.S.S.R. and by other government bodies. (I.V.P.)

OB RIVER

One of the greatest rivers of Asia, the Ob flows across Western Siberia in a twisting diagonal from its southeastern sources in the Altai Mountains to its northwestern outlet through the Gulf of Ob (Obskaya Guba) into the Kara Sea of the Arctic Ocean. It is a major communications artery, crossing territory at the heart of the Soviet Union that is extraordinarily varied in terms of physical environment and the character of its peoples: even allowing for the barrenness of much of the region surrounding the ice-threatened lower course of the river and the inhospitable waters into which it discharges, it drains a region of great economic potential, much of which is being realized under long-term Soviet development plans.

Physical features. The Ob proper is formed by the junction of the Biya and Katun rivers, in the foothills of the Soviet sector of the Altai, from which it has a course of 2,268 miles (3,650 kilometres); but, if the Irtysh River is regarded as part of the main course rather than as the Ob's major tributary, then the maximum length, from the source of the Black (Cherny) Irtysh in China's sector of the Altai, is 3,362 miles (5,410 kilometres) or, if the Gulf of Ob be included, 3,959 miles (6,370 kilometres). The catchment area is approximately 1,150,000 square miles (2,975,000 square kilometres) down to the delta's end or 1,343,000 square miles (3,479,000 square kilometres) if the gulf be included—the aggregate 172,000 square miles (445,000 square kilometres) of undrained land in the south of the basin being included in both totals. The Ob's catchment area constitutes about half of the whole Kara Sea; it is the largest Soviet catchment area and the sixth largest in the world.

The basin. The West Siberian Plain covers about 85 percent of the Ob Basin, the rest of which is occupied in the south by the terraced plains of Turgay (Kazakhstan) and the small hills of northernmost Kazakhstan, and in the southeast by the Kuznetsky Alatau, by the Salair Range (Salairskoye Kryazh), by the Mountains of Shoria, and, behind them, by the Altai Mountains.

There are more than 1,900 rivers within the basin, their aggregate length being about 112,000 miles. The Irtysh, a left-bank tributary 2,639 miles long, itself drains 634,362 square miles (a somewhat larger area than that drained by the Upper and Middle Ob before the Irtysh confluence); and some 70 percent of the whole basin is drained by left-bank tributaries.

The huge basin of the Ob could be taken, geographically,

as a representative cross section of Soviet territory: in the far south, around Lake (Ozero) Zaysan (recipient of the Black Irtysh and source of the Irtysh proper), there is arid semidesert; in the central regions of the West Siberian Plain—that is to say, over more than half of the basin—there is the swampy coniferous forest known as taiga, with very large expanses of marshland; and in the north there are vast stretches of the icy, treeless plains known as tundra.

The mainstream and its tributaries. The Upper Ob runs from the Biya–Katun junction to the confluence of the Tom, the Middle Ob from the Tom confluence to the Irtysh confluence, the Lower Ob from the Irtysh confluence to the Gulf of Ob.

The Biya and the Katun both rise in the Altai Mountains: the former in Lake (Ozero) Teletskoye, the latter to the south, among the glaciers of Mount (Gora) Belukha.

The Upper Ob

From their junction the Upper Ob at first flows westward, receiving the Peschanaya, the Anuy, and the Charysh tributaries from the left; for this reach, the river has low banks of alluvium, a bed studded with islands and shoals, and an average gradient of one foot per mile. From the Charysh confluence the Upper Ob flows northward on its way to Barnaul, receiving another left-bank tributary, the Aley, and widening its floodplain as the valley widens. Turning westward again at Barnaul, the river receives a right-bank tributary, the Chumysh, from the Salair Range: the valley hereabouts is three to six miles wide, with steeper ground on the left than on the right; the floodplain is extensive and characterized by diversionary branches of the river and by lakes; the bed is still full of shoals; and the gradient is reduced, but the depth increases markedly. At Kamen-na-Obi, however, where the river begins to loop northeastward, the width of the valley shrinks to two to three miles and that of the floodplain to less than one mile, and reefs of rock emerge in places from the bed. Just above Novosibirsk another right-bank tributary, the Inya, joins the Upper Ob; and a dam at Novosibirsk forms the great reservoir known as the Ob Sea. Below Novosibirsk, where the river leaves the region of forest steppe to enter a zone of aspen and birch forest, both valley and floodplain broaden notably, till at the Tom confluence they are respectively 12 and three or more miles wide. The depth of the Upper Ob (at lower water) varies between six and a half and 20 feet (two and six metres).

The Middle Ob

The Middle Ob begins where the Tom flows into the mainstream, from the right. Taking at first a northwesterly course, the river henceforth becomes much deeper and wider, especially after receiving its mightiest right-bank tributary, the Chulym, shortly below the confluence of the Shegarka from the left. Successive tributaries of the northwesterly course, after the Chulym, include the Chaya and the Parabel (both left), the Ket (right), the Vasyugan (left), the Tym (right), and the Vakh (right). Down to the Vasyugan confluence the river passes through the southern belt of the taiga (marshy forest country); thereafter it enters the middle belt. Below the Vakh confluence the Middle Ob changes its course from northwesterly to westerly and receives more tributaries: the Tromyegan (right), the Great (Bolshoy) Yugan (left), the Lyamin (right), the Great (Bolshoy) Salym (left), the Nazym (right), and finally, at Khanty-Mansiysk, the Irtysh (left, as has been said). In its course through the taiga the Middle Ob has a minimal gradient, a broadening valley (18–30 miles wide), and a correspondingly broadening floodplain (12–18 miles), through which it flows in a complex network of channels, with the main bed widening from less than one mile on the higher reaches to nearly two miles at the end and becoming progressively free of shoals. Low-water depths vary between 13 and 26 feet (four and eight metres); and at high water there are great floods every year, sometimes spreading from 15 or even 50 miles across the valley and lasting from two to three months.

The Lower Ob

From its start at the Irtysh confluence the Lower Ob flows northwestward as far as Peregrebnoye and thereafter northward, crossing the northern belt of the taiga till it enters the zone of forest tundra in the vicinity of its delta. The valley is wide, with slopes steeper on the right than on the left, and the vast floodplain is much intersected by channels of the river and dotted with lakes. Below Peregrebnoye the river divides itself into two main branches: the Great (Bolshaya) Ob, which receives the Kazym tributary and the Kunovat from the right; and the Little (Malaya) Ob, which receives the Northern (Severnaya) Sosva, the Vogulka, and the Synya from the left. These main branches are reunited below Shuryshkary into a single stream nearly 12 miles wide; but after the confluence of the Poluy (from the right) the river divides itself again to form a delta, the two principal arms of which are the Khamanelskaya Ob, which receives the Shchuchya from the left, and the Nadymskaya Ob, which is the more considerable of the pair. At the base of the delta lies the Gulf of Ob, which represents a 500-mile extension of the river's valley invaded by the sea, with a width reaching 50 miles at certain points and its own catchment area (forest tundra and tundra proper) of more than 40,000 square miles.

Climate and hydrology. The Ob Basin has short, warm summers and long, cold winters. The average temperature for the year ranges from 14° F (−10° C) on the shores of the Kara Sea to 34° F (1° C) and 36° F (2° C) in the forest zone and to 38.8° F (3.8° C) on Lake (Ozero) Zaysan. The absolute maximum temperature, in the arid south, is 104° F (40° C); the minimum, in the Altai Mountains, is −76° F (−60° C). Rainfall, which occurs mainly in the summer, varies between averages of 12 inches (300 millimetres) a year in the north to 20 inches in the taiga zone and 100 inches on the steppes, but the western slopes of the Altai may receive as much as 62 inches a year. Snow cover, which lasts for 240–270 days in the north and for 160–170 in the south, is deepest in the forest zone (24–36 inches) and in the mountains (80 inches), much shallower on the tundra (12–20 inches), and very thin on the steppe (8–16 inches).

Annual flooding

On the Upper Ob the spring floods begin very early in April, when the snow on the plains is melting; and they have a second phase, ensuing from the melting of snow on the Altai Mountains. The Middle Ob, scarcely affected by the Upper Ob's phases, has one continuous spring–summer period of high water, which begins in mid-April. For the Lower Ob, high water begins later in April or early in May. Levels in fact begin to rise when the watercourse is still obstructed by ice; and maximum levels, which will have been attained by May on the Upper Ob, may not be attained till June, July, or even August on the lower reaches. For the Upper Ob, the spring floods are over in July, but autumnal rains bring high water again in September–October; for the Middle and for the Lower Ob, the spring–summer floodwaters gradually recede until freezing sets in (on the lower reaches, flooding may last four or five months). The rising of levels on the Ob proper and on the Irtysh obstructs the drainage of the minor tributaries' individual catchment areas.

The autumnal ice drift on the Ob lasts from about October 31 to November 10; then the lower reaches begin to freeze solid; by November 25 the whole river is frozen; and the upper reaches remain so for some 150 days, the lower for 220. The thawing of the ice, which takes longer than the freezing, lasts from the end of April (upstream) to the end of May; and the spring drift (about five days in duration) produces considerable ice jams.

The difference of level between high water and low is approximately 10 feet on the Upper Ob; 36 feet on the Middle Ob down to Aleksandrovskoye, but only about 28 feet between Surgut and the Irtysh confluence; and at most 39 to 40 feet on stretches of the Lower Ob, but less than 20 feet at the mouth of the river.

The water is warmest in July, reaching a maximum of 82° F (28° C) in the vicinity of Barnaul.

In terms of drainage, the Ob is the third greatest river of the U.S.S.R.—after the Yenisey and the Lena. Every year it pours about 515,000,000,000 cubic yards (394 cubic kilometres) of water into the Arctic Ocean—about 12 percent of that ocean's total intake from drainage.

The volume of flow at Salekhard, just above the delta, is nearly 56,000 cubic yards (42,800 cubic metres) per second at its maximum, 2,600 (2,000) at its minimum, while for Barnaul, on the Upper Ob, the corresponding figures are 12,673 cubic yards (9,690 cubic metres) per

second and 211 (161). Most of the water comes from the melting of seasonal snow and from rainfall; much less of it comes from ground drainage, from mountain snow, and from glaciers.

The waters of the Ob are only slightly mineralized: dissolved substances account for an annual outpouring of 30,200,000 tons of ions into the Kara Sea. The total amount of solid matter brought down by the Ob every year amounts only to 50,000,000 tons.

Plant and animal life. Rich meadows extend in bands one to two miles wide for great distances along the banks of the Ob and cover many of the numerous islands. Pine, cedar, silver fir, aspen, and birch also grow on the banks and occasionally constitute isolated forests on the higher ground of the floodplain; and large areas near the river are covered with willow, snowball trees (*Viburnum*), bird cherry (*Prunus padus*), buckthorn (*Hippophaë*), currant bushes, and wild roses.

Of some 50 species of fish to be found in the river or in the gulf, the most valuable economically are sturgeon, sterlet, and such "whitefish" as nelma (*Stenodus leucichthys nelma*), musksun (*Coregonus muksun*), chir (*C. nasus*), and pelyad (*C. pelea*); pike, burbot, Siberian dace, carp, and perch are also caught. For lack of oxygen in the water, however, many fish die every winter in the reaches between the Tym confluence and the delta.

Fur-bearing mammals of the Ob Valley include European and Siberian mole, Siberian and American mink, ermine, fox, wolf (in the taiga), elk, white hare, water rat, muskrat, otter, and beaver. Among more than 170 species of birds breeding in the floodplain are grouse, partridge, goose, and duck.

The people. Politically, most of the Ob Basin belongs to the Russian S.F.S.R., but the south of it forms the northernmost part of Kazakhstan. Russians, Ukrainians, and Belorussians constitute the majority of the population, but there are, of course, numerous non-Slavic peoples also. These include the Kazakhs in the south, the Altai and Shor peoples of the mountains, the Tatars of the Irtysh Basin, the Khants (Ostyaks) and the Mansi (Voguls), whose *natsionalny okrug* (national area) occupies part of the taiga; and the Nenets, Nganasan, Enets, and Selkup peoples of the north. The valleys of the river are more densely populated than other parts of the basin.

The economy. The earliest known sailing directions for the Lower Ob are those appended to Pyotr Ivanovich Godunov's *Chertyozh* ("Chart") of Siberia (1667); further details were provided by Semyon Ulyanovich Remezov in his *Chertyozhnaya Kniga Sibiri* ("Chart-Book of Siberia"; completed 1701); and the Russian scientists of the Great Northern Expedition (1733–43) investigated the Lower Ob as well as other Siberian rivers. For the next 150 years the river system was investigated chiefly for purposes of communication within the basin. Hydrological studies, however, were inaugurated by the end of the 19th century and were pursued intensively in the 20th; and during the Soviet period the hydroelectric potential of the rivers was not only studied but also developed.

Exploration and development

The Ob's total hydroelectric potential is estimated at 250,000,000,000 kilowatt-hours. There are three main stations: one on the Ob proper, at Novosibirsk, the other two on the mountainous reaches of the Irtysh, at Bukhtarminsk and at Ust-Kamenogorsk.

The Ob, one of Western Siberia's principal means of communication, is navigable for 190 days of the year on its upper reaches, for 150 on its lower. It serves the basin both for importing and for exporting. The Trans-Siberian Railway crosses the Irtysh at Omsk and the Upper Ob at Novosibirsk. Railways going into Kazakhstan from Novosibirsk and from the foothills of the mountains cross the Upper Ob at Barnaul. (L.K.M.)

YENISEY RIVER

One of the world's great rivers, the Yenisey (from the Evenki name Ioanesi, Great River) runs from south to north across the Asiatic heart of the Soviet Union. It traverses a vast region of strikingly varied but generally old landscapes in which are found ancient people and customs as well as enormous programs of economic development.

General course of the river

Physical features. The river begins at the Siberian city of Kyzyl at the confluence of two of its tributaries—the Great Yenisey (Bolshoy Yenisey), or By-Khem, which rises on the Eastern Sayan Mountains of the Tuva A.S.S.R. (Tuvinskaya A.S.S.R.), and the Little Yenisey (Maly Yenisey), or Ka-Khem, which rises in the Darkhat Bowl of the Mongolian People's Republic. From the confluence the Yenisey River runs for 2,167 miles (3,487 kilometres), mainly along the border between Eastern and Western Siberia, before emptying into the icy Kara Sea. If the Great Yenisey is reckoned as the source, then the river as a whole is 2,543 miles (4,092 kilometres) long; if the Little Yenisey, then 2,549 miles (4,102 kilometres). The headwaters of the Selenga River, which rise in eastern Mongolia and flow through Lake Baikal (Ozero Baikal), the world's largest freshwater lake, into the Angara tributary of the Yenisey, may be reckoned as the river's ultimate source, in which case its length totals 3,442 miles (5,540 kilometres) draining a basin that at 996,000 square miles (2,580,000 square kilometres) is larger than all but six of the nations of the world. The system within Soviet boundaries comprises some 20,000 tributary or subtributary streams, with an aggregate length of some 550,000 miles. All the major tributaries of the Yenisey join its right-bank zone, a region constituting 80 percent of the basin area.

Physiography. Extending for some 2,175 miles from south to north and for some 1,060 miles from east to west, the Yenisey Basin exhibits a considerable diversity of features. Lowlands constitute only 6 percent or 7 percent of the total area: a narrow strip on the edge of the West Siberian Plain and part of the North Siberian Lowland (Severo Sibirskaya Nizmennost). In the south, the Western and Eastern Sayan, the Tuva, the Baikal, and the Khentey mountains constitute a larger proportion of the basin's area, with elevations mostly between 2,300 and 7,200 feet (700–2,200 metres), steep valleys, and vast bowls between ranges. In southern Tuva and in the Sayans there are some magnificent higher peaks, culminating in Mount (Gora) Munku-Sardyk (11,450 feet [3,491 metres]). Most of the basin stretches over the western sector of the Central Siberian Plateau, with elevations between 1,640 and 2,300 feet, bordered in the northwest by the Putorana Mountains (Gory Putorana; rising to 5,580 feet), in the west by the Yenisey Ridge (Yeniseysky Kryazh; 3,622 feet), and in the southeast by the Angara Ridge (3,353 feet).

The Yenisey River proper is divisible into three principal sections: the 295 miles from Kyzyl to Oznachennoye on the southern edge of the Minusinsk Basin; the 544 miles from Oznachennoye to the Angara confluence; and the 1,328 miles from the Angara confluence to the sea.

For the first 115 miles from Kyzyl, the Yenisey flows westward through the Tuva Bowl (Tuvinskaya Kotlovina), often divided into branches by gravelly shoals and varying in width between 100 and 700 yards (90 and 640 metres). After receiving the Khemchik River from the left it turns northward to wind through the Western Sayan for some 180 miles down a spectacular narrow canyon (sometimes 100 yards wide) with many rapids—including the cascading Great Falls.

On flowing out of the mountains at Oznachennoye, the Yenisey broadens its valley in the Minusinsk Basin: just below the Abakan confluence the valley is more than three miles wide; the bed, about 500 yards from bank to bank, is studded with islands; the flow velocity is reduced to about two yards per second; and the huge 240-mile stretch of the narrow Krasnoyarsk Reservoir (Krasnoyarskoye Vodokhranilishche), contained on the east by northwestern spurs of the Eastern Sayan, begins. A little way upstream from Krasnoyarsk the valley becomes still broader, but there are submerged ridges of rock in the bed, representing extensions of the Yenisey Ridge; one such ridge causes the rapids near Kazachinskoye.

The Lower Yenisey

Below the Angara confluence, the right bank of the Yenisey remains mountainous and is often precipitous, but the left bank assumes the character of a floodplain. The bed, having been only 870 yards wide above the confluence, is at least 2,000 yards wide below it; depth increases to between 32 and 56 feet, and the flow velocity drops by 50 percent or more. Farther downstream, however,

just above the Podkamennaya Tunguska confluence, the Yenisey cuts through spurs of the Yenisey Ridge; rapids occur at Osinovo, and below them the river plunges down a steep and scenic gorge in which its bed is reduced to a width of 800 yards. The widening and deepening process is then resumed: the valley is about 25 miles wide around the Lower Tunguska (Nizhnyaya Tunguska) confluence and about 93 miles wide around Dudinka and Ust-Port; the bed's width increases to 2,700 and then to 5,500 yards; and depths, from a minimum of 16 feet for the whole of the Yenisey's lower course, reach a maximum of more than 80 feet.

The estuary of the Yenisey begins as far upstream as the confluence of the Kureyka (the next considerable tributary north of the Nizhnyana). Below Dudinka the bed is in places divided by islands, some of them 10 or 12 miles long; and a true delta begins north of Ust-Port, where the numerous Brekhov Islands (Brekhovskiye Ostrova) divide the river into channels, with the westernmost bank about 47 miles from the easternmost. The several channels are reunited in a single wide "throat" down which the river flows into the Yenisey Gulf (Yeniseysky Zaliv) of the Kara Sea.

The largest tributaries of the Upper and Middle Yenisey are the Khemchik and the Abakan from the left and the Tuva from the right. Fed chiefly by rainwater in the mountains and by snow in the foothills and on the plains, they begin their spring high water in May or June and are swollen by summer rain floods. The Angara, on the other hand, being influenced for its whole length by the fact of its rising in Lake Baikal, practically never experiences low water. With a length of 1,105 miles, and with its own basin of more than 407,700 square miles—twice the size of the Yenisey's prior to their confluence—and with a volume approaching 5,900 cubic yards (4,500 cubic metres) per second at its mouth (as against the Yenisey's annual average of about 4,500 before the confluence), the Angara might better have been recognized as the upper course of the main river than as a tributary. The Podkamennaya Tunguska and the Lower Tunguska, with an aggregate volume of more than 5,600 cubic yards per second, also play an important role in the formation of the Yenisey runoff.

Hydrology. About 50 percent of the Yenisey's water comes from snow, between 36 percent and 38 percent from rainwater, and the remainder from groundwater. For the greater part of the system the East Siberian hydrological regime prevails: violent spring floods are followed first by a rapid fall of levels, then by a slower fall, with summer and autumn rain floods punctuating the sequence; in winter the runoff is reduced sharply, but levels remain high as ice jams are formed. In terms of runoff, the Yenisey is the greatest river in the U.S.S.R., with about 150 cubic miles (600 cubic kilometres) annually. It carries about 10,500,000 tons of alluvium into the Kara Sea every year, in addition to nearly 30,000,000 tons of dissolved mineral substances. In midsummer the water temperature varies from 57° F (14° C) to 66° F (19° C), but freezing begins on the Lower Yenisey early in October and affects the whole river by early December; ice jams and underwater ice are characteristic. Thawing occurs toward the end of April on the upper reaches, in May on the middle, and from May to mid-June on the lower. The water of the Middle Yenisey is very turbid in spring and summer and contrasts sharply with the limpid water of the Angara; and in summer the two streams flow in the same bed without mingling for nine miles or so from their confluence.

Ice and alluvium

Climate. The climate of the Yenisey Basin is distinctly continental, affected by cold Arctic Ocean air masses, and its cold season prevails from late September to mid-June in the north and from mid-October to late April in the south. Even summer is cold in the northern basin, with temperatures between 46° and 54° F (8° and 12° C) only in July, when frosts may still occur; but summer is hot in the south, with July temperatures between 64° and 68° F (18° and 20° C). The average temperature for January is below 4° F (−20° C): though it rises to 3° F (−16° C) in the foothills of the Sayan Mountains, it falls to −18° F (−28° C) and in places to −33° F (−36° C) in the Central Siberian Plateau. There is an annual rainfall of about 16 or 20 inches (400 or 500 millimetres) in the west and of 12 or 16 in the east of the Central Siberian Plateau; but in the mountainous south and southeast rainfall generally ranges between 20 and 47 inches a year, while the enclosed bowls of the southwest experience much less (12 inches around Minusinsk and less than eight in Tuva). Most of the rain (from 80 to 90 percent) falls in the warmer season and chiefly in its latter period. Since the snow cover in most of the basin is slight (16 inches in the south, 24 in the north, 35 on the Yenisey Ridge alone), the soil and subsoil are frozen to a considerable depth for long periods over most of the basin and all the year round north of the Lower Tunguska.

Plant and animal life. Most of the basin is covered with taiga (dense, marshy forest), with pine predominating in the south and larch farther north. Siberian cedar grows on the southern mountains. In Mongolia, Transbaikalia, and Tuva there are also steppes, bordered in the extreme south of the Selenga Basin by semi-desert. In the far north of the basin, taiga is superseded by lonely stretches of tundra (marshy, moss-covered plain).

The Yenisey and its tributaries are rich in fish: the mountain streams of the headwaters support grayling, trout, goldilocks (*Brachymystax lenok*), roach, and dace; the middle course has sterlet, trout, goldilocks, several species of whitefish (*Coregonus*), and grayling; the lower course has Siberian lamprey, Siberian sturgeon, sterlet, alpine char, trout, gold and silver carp, pike, and many others. The estuary has fewer species of fish but is rich in the economically valuable sturgeon. The lower reaches of the Yenisey are also much favoured in summer by migrant waterfowl from the south; the small lakes and islands support ducks, geese, and swans; and the muskrat has adapted itself to the channels of the delta.

The people. The peoples of the Yenisey Valley are various. Around the western headwaters (Great and Little Yenisey) Tuvinians predominate, with an admixture of Russians promoting the economy. To the north of Tuva the Krasnoyarksy *kray* (territory) of the Russian S.F.S.R. extends down the whole valley northward to the Kara Sea; its population comprises Russians, Ukrainians, Tatars, and numerous other indigenous peoples. The Khakass people occupy an "autonomous region" southwest of Krasnoyarsk. The vast Evenk "national district," extending from south of the Podkamennaya Tunguska to north of the Kureyka, is inhabited both by the Evenk people and by Russians from the west and Yakuts from the east. In the far north the Taymyr "national district" has a majority of Russians and some Evenks, but also the Yakuts (Sakha) and Dolgan, the Nenets, and the Nganasan peoples.

The economy. Hunting, fishing, the breeding of reindeer, and fur farming are the native occupations of the more northerly peoples, and mining is also important, especially for graphite and coal. Processing and manufacturing industries are pursued in the south. The hydroelectric potential of the Yenisey is estimated at 18,000,000 kilowatts. To exploit it, the Krasnoyarsk Hydroelectric Station was built, with a reservoir area of 810 square miles (2,100 square kilometres), and the Sayan Hydroelectric Station was built farther upstream. On the Angara, the Bratsk and the Irkutsk stations provide power; and on the Khantayka River, the Khantaysk station (operative from 1970) provides power for the Norilsk industrial complex (southeast of Dudinka). By the end of the 20th century, it is predicted, the Yenisey Basin will have 18 hydroelectric stations, with a total reservoir area of more than 17,000 square miles (44,000 square kilometres).

Power and navigation

The Yenisey is regularly navigated between Oznachennoye and the sea. A great elevator capable of lifting ships along an inclined railroad between the upper and lower waters of the Krasnoyarsk Hydroelectric Station was being constructed in 1971 to permit through traffic. The chief ports are Krasnoyarsk, Strelka (at the Angara confluence), Yeniseysk, Igarka, Dudinka, and Ust-Port; seagoing vessels sail up to Igarka. Lumber is the main cargo; some of it going upstream to Krasnoyarsk, but the downstream traffic carries bread, coal, petroleum products, and machinery, as well as lumber. Tourist cruises are the latest innovation on an increasingly important river.

Study and exploration. Russians first settled on the Yenisey in 1607, when a winter station was established on the Turukhan River (a left-bank tributary joining the Yenisey just below the Lower Tunguska confluence). Novgorod merchants, however, may have been trading with peoples of the valley as early as the 11th century. In 1619 a fort was built at Yeniseysk; and in 1628 Krasny Yar (now Krasnoyarsk) was founded. From there roads went eastward into the Buryat country and southward into the fertile Minusinsk Basin. The Russian hold on the line of the Yenisey was definitively secured early in the 18th century. Exploration of the rivers was then initiated, with a detachment of the Great Northern Expedition (1733–43) operating on the Yenisey. Later, the Lower Yenisey was explored by an expedition of 1894–96; and from 1907 to 1912 a party made a more thorough investigation of the whole river. Studies for development plans or for scientific purposes continue. (C.G.T.)

Founding of Krasnoyarsk

BIBLIOGRAPHY. The works cited below represent only a fraction of the extant literature on Asia, the purpose being to provide a highly selective reading list that bears on some of the topics dealt with in the article itself. Additional references to further literature on a large number of special topics may be found in these works. For a detailed description of the land and people of Asia, see GEORGE B. CRESSEY, *Asia's Lands and Peoples: A Geography of One-Third of the Earth and Two-thirds of Its People,* 3rd ed. (1963); FRANK M. LEBAR, GERALD C. HICKEY, and JOHN K. MUSGRAVE, *Ethnic Groups of Mainland Southeast Asia* (1964); борис федорович добрынин *et al., Зарубежная Азия; Физическая география* (1956); and *Общии обзор* in *Советскии Союз* (1972). Works treating the influence of geographical conditions on political, social, cultural, and economic conditions include: J.E. SPENCER and WILLIAM L. THOMAS, *Asia, East by South: A Cultural Geography,* 2nd ed. (1971); C.A. FISHER, *South-east Asia: A Social, Economic and Political Geography,* 2nd ed. (1966); and JOSEPH E. SCHWARTZBERG (ed.), *A Historical Atlas of South Asia* (1978), which illustrates the geopolitical development of the region. OWEN LATTIMORE (ed.), *Silks, Spices and Empire: Asia Seen Through the Eyes of Its Discoverers* (1968), is a readable survey of early travel accounts. TIMOTHY SEVERIN, *The Sindbad Voyage* (1983), a book by a traveller and author, contains thorough accounts of Asiatic ports and maritime adventure; E.L. JONES, *The European Miracle: Environments, Economies, and Geopolitics in the History of Europe and Asia* (1981), is a comparative history; STANLEY WOLPERT, *Roots of Confrontation in South Asia: Afghanistan, Pakistan, India, and the Superpowers* (1982), is a history of culture and politics of the region, from ancient times to the third quarter of the 20th century.

(1977); MASAO MINATO, MASAO GORAI, and MITSUO HUNAHASHI (eds.), *The Geologic Developments of the Japanese Islands* (1965); and RAYMOND FURON, *Introduction à la géologie et à l'hydrogeologie de la Turquie* (1953). See also H.K. GUPTA and F.M. DELANY (eds.), *Zagros, Hindu Kush, Himalaya: Geodynamic Evolution* (1981); JOVAN STOCKLIN, "Structural History and Tectonics of Iran: A Review," *Bull. Am. Assoc. Petrol. Geol.,* 52:1229–1258 (1968); AUGUSTO GANSSER, *Geology of Himalayas* (1964); P.V. RAO, "Geology and Mineral Resources of India," *Int. Geol. Congr.,* 22nd session, New Delhi (1964). Other sources are REINOUT VAN BEMMELEN, *The Geology of Indonesia,* 2 vol. (1949); WARREN HAMILTON, *Tectonics of the Indonesian Region* (1979); F.A. VENINGMEINESZ, "Indonesian Archipelago: A Geophysical Study," *Bull. Geol. Soc. Am.,* 65:143–164 (1954); B.M. GOZON, "Geology of the Philippine Islands," *Petrol. Engr.,* 33:B64–66, 69 (1961).

Physical geography: General works include: PIERRE GOUROU, *L'Asie* (1953); R.R. RAWSON and W.G. EAST, *Asia* (1966); RAOUL BLANCHARD, *Asie occidentale,* and FERNAND GRENARD, *Haute Asie* (1929); J. SION, *Asie de moussouns,* 2 vol. (1928–29); R.R. RAWSON, *The Monsoon Lands of Asia* (1963); and CHIA LIN SIEN *et al., South-East Asia: A Systematic Geography* (1979). Representative photographs of the Asian landscape are presented in MARTIN HURLIMANN, *Asien: Bilder seiner Landschaften* (1956; Eng. trans., *Asia: 289 Pictures in Photogravure,* 1957). The geomorphology of Asia is treated in FRITZ MACHATSCHEK, *Das Relief der Erde,* 2 vol. (1955).

Noteworthy studies of insular areas of the region include: ERNST LÖFFLER, *Geomorphology of Papua New Guinea* (1977); TORAO YOSHIKAWA *et al., The Landforms of Japan* (1981); S.G. BURRARD and H.H. HAYDEN, *A Sketch of the Geography and Geology of the Himalaya Mountains and Tibet,* 4 pt. (1907–08; rev. ed., 1933–34), the first official publication of the government of India on the subject, profusely illustrated with charts, diagrams, cross sections, sketches, and maps; S.P. CHATTERJEE, *Physiography of India* (1968), a systematic study dividing the country into physiographic regions; MILDRED CABLE, *The Gobi Desert* (1942); and SVEN A. HEDIN, *Ater till Asien* (1928; Eng. trans., *Across the Gobi Desert,* 1931, reprinted 1968). Additional sources include ALONZO W. POND, *Climate and Weather in the Central Gobi of Mongolia* (1954); N.K. PANIKKAR and R. JAYARAMAN, "Biological and Oceanographic Differences Between the Arabian Sea and the Bay of Bengal as Observed from the Indian Region," *Proc. Indian Acad. Sci.,* 64:231-240 (1966); M.A. BEEK, *Atlas of Mesopotamia* (1962), a text dealing with salinization and delta formation, including primarily historical or archaeological maps; W.C. BRICE, *A Systematic Regional Geography,* vol. 8 of the "South West Asia Series" (1966), a reliable contemporary work; 21st INTERNATIONAL GEOGRAPHICAL CONGRESS, DELHI, *Mountains and Rivers of India* (1968), a useful guide on the origin, courses, and many special features of the rivers of the subcontinent; HERBERT CHATLEY, *The Yellow River As a Factor in the Development of China* (1939); CH'UAN-CHUN WU *et. al., Economic Geography of the Western Region of the Middle Yellow River* (1958); GEORGE BROWN BARBOUR, *Physiographic History of the Yangtze* (1935).

Contemporary descriptions and current data may be found in the *Annual Reports of the Yangtze River Commission* and in any geography or economic history of China. In Russian, an excellent account of the Yangtze is A. П. Мурaнов, *Река Хуанхэ (Желтая Река)* (1959). The basic maps of resources, with descriptive text, on the Mekong are compiled in the UNITED NATIONS, *Atlas of Physical, Economic and Social Resources of the Lower Mekong Basin* (1968). For oceanographic data on the Yellow Sea, see the *Oceanographic Handbook of the Neighbouring Seas of Korea* (1964), issued by the Fisheries Research and Development Agency of the Republic of Korea.

Plant and animal life: L.S. BERG, *Natural Regions of the U.S.S.R.* (1950; Eng. trans. from the 2nd Russian ed., 1938); H.G. CHAMPION, *A Preliminary Survey of the Forest Types of India and Burma* (1936); PHILIP J. DARLINGTON, JR., *Zoogeography* (1957, reprinted 1980); *Flore générale de l'Indochine,* 7 vol. (1905–52); GUSTAV FOCHLER-HAUKE, "Das Waldkleid un die Pflanzenbezirke Süd-Chinas," *Mitt. Geogr. Ges. Wien,* 78:158–178 (1935); *Forestry in Japan,* issued by the Tokyo Forestry Agency (1964); BUNZO HAYATA, "General Aspects of the Flora of Japan . . . ," in *Scientific Japan, Past and Present,* pp. 77–104 (1926); P. LEGRIS, *La Végétation de l'Inde* (1963); LIOU HO, *Lauracées de Chine et d'Indochine* (1934); PAUL MAURAND, *L'Indochine forestière* (1943); F.J. ORMELING, *The Timor*

Problem: A Geographical Interpretation of an Underdeveloped Island (1955); JULES VIDAL, *La Végétation du Laos* (1956); E.H. WALKER, "The Plants of China and Their Usefulness to Man," *A. Rep. Smithson. Instn.*, pp. 325–361 (1943); WANG CHI-WU, *The Forests of China* (1961); R.O. WHYTE, "The Phytogeographical Zones of Palestine," *Geogrl. Rev.*, 40:600–614 (1950).

Natural resources: E.A. ACKERMAN, *Japan's Natural Resources and Their Relation to Japan's Economic Future* (1953); VIOLET CONOLLY, *Beyond the Urals: Economic Developments in Soviet Asia* (1967); J.A. HODGKINS, *Soviet Power:* (1961, reprinted 1976); M.S. KRISHNAN, *Geology of India and Burma,* 5th ed. (1968); P.E. LYDOLPH and THEODORE SHABAD, "The Oil and Gas Industries in the U.S.S.R.," *Ann. Assoc. Am. Geogr.*, 50:461–486 (1960); A.A. MINC, "Geographische Probleme der Ausnutzung der natürlichen Ressourcen in der UdSSR," *Petermanns Geog. Mitt.*, 114:21–28 (1970); "Natural Resources in Malaysia and Singapore," in B.C. STONE (ed.), *Proceedings of the 2nd Symposium* (Kuala Lumpur, 1969); D.B. SHIMKIN, *Minerals: A Key to Soviet Power* (1953), and *The Soviet Mineral-Fuels Industries, 1928–1958: A Statistical Survey* (1963); WANG KUNG-PING, "Mineral Resources of China, with Special Reference to the Nonferrous Metals," *Geogrl. Rev.*, 34:621–635 (1944); R.O. WHYTE, *Grasslands of the Monsoon* (1968), and *Land, Livestock, and Human Nutrition in India* (1968). See also ROBERT G. JENSEN, THEODORE SHABAD, and ARTHUR W. WRIGHT (eds.), *Soviet Natural Resources in the World Economy* (1983).

Human resources and political geography: A number of Asian countries have published national or development atlases; of particular interest are those of China (1979), India (serially, 1968–), Israel (1970), Japan (1977), Malaysia (1977), Thailand (1969), and Turkey (1977). The *Tübinger Atlas des Vorderen Orients* (1977–) is an authoritative atlas of historical, cultural, and social aspects of the development of the Near East. W.G. EAST, O.H.K. SPATE, and C.A. FISHER (eds.), *The Changing Map of Asia,* 5th ed. (1971), is a general political geography. ALISTAIR LAMB, *Asian Frontiers: Studies in a Continuing Problem* (1968); and JOHN ROBERT VICTOR PRESCOTT, *Map of Mainland Asia by Treaty* (1975), concentrate on the problem of political frontiers. GUY WINT (ed.), *Asia Handbook* (1969), is a current events summary and detailed fact book dealing with the continent. C.G.F. SIMKIN, *The Traditional Trade of Asia* (1968), discusses the history of the growth of trade between the Occidental and the Asian regional zones, often with considerable geographic materials included. W.B. FISHER, *The Middle East: A Physical, Social, and Regional Geography,* 7th ed. (1978), provides complete coverage of southwestern Asia; and GEORGE B. CRESSEY, *Crossroads: Land and Life in Southwest Asia* (1960), is somewhat more thematic in its coverage. J.E. SPENCER and W.L. THOMAS, *Asia, East by South: A Cultural Geography,* 2nd ed. (1971), is a full-scale geography dealing with the region from Pakistan through Japan; whereas C.A. FISHER, *South-East Asia: A Social, Economic, and Political Geography,* 2nd ed. (1966); and DONALD W. FRYER, *Emerging Southeast Asia: A Study in Growth and Stagnation,* 2nd ed. (1979), deal in more detail with the mainland of Southeast Asia and Indonesia–Philippines. RICHARD A. BUTWELL, *Southeast Asia Today—and Tomorrow: Problems of Political Development,* 2nd ed. (1969), concentrates on the problems of political nationalism in the former colonial countries. P.E. LYDOLPH, *Geography of the U.S.S.R.*, 3rd ed. (1977), is a full-scale geography of the Soviet lands, including Central Asia and Siberia. W.H. PARKER, *An Historical Geography of Russia* (1968); and CHANAKYA SEN, *Soviet-Asian Relations in the 1970s and Beyond: An Interpretational Study* (1976), concentrate on the historical geography and political expansion of the Soviet state into Asia. EDWARD ALLWORTH (ed.), *Central Asia: A Century of Russian Rule* (1967), is a political-historical study of Russian control of Central Asia; and LAWRENCE KRADER, *Peoples of Central Asia,* 3rd ed. (1971), is primarily concerned with the historic ethnic groupings of Central Asia. Southeast Asia's political prospects are the subject of several works, including RICHARD BUTWELL, *Southeast Asia: A Political Introduction* (1975); CHAWLA SUDERSHAM (ed.), *Southeast Asia under the New Balance of Power* (1974); and JAY TAYLOR, *China and Southeast Asia: Peking's Relations with Revolutionary Movements* (1976). The political and economic developments of the Middle East are the subject of the annual *Middle East Contemporary Survey.* Economic conditions in Southeast Asia and the Far East and their implications for the Western world are discussed in ROY HOFHEINZ and KENT E. CALDER, *The Eastasia Edge* (1982).

Resource development: For the continent as a whole, the basic, most authoritative, and up-to-date sources of economic data and information are the publications of the United Nations Economic and Social Commission for Asia and the Pacific (ESCAP), formerly the United Nations Economic Commission for Asia and the Far East (ECAFE), and certain other intergovernmental organizations. The *Economic Survey of Asia and the Pacific,* prepared and published annually by ESCAP, is the most comprehensive account of the economic situation in the continent as a whole. The U.S. CONGRESS, JOINT ECONOMIC COMMITTEE, has published a number of studies on the Chinese economy, which include: *China, a Reassessment of the Economy* (1975); *China and the Chinese* (1976); and *Chinese Economy Post-Mao: A Compendium of Papers* (1980). SHIN-YONG CHUN (ed.), *Economic Life in Korea* (1978), addresses Korea's striking economic growth.

Also valuable is *The Political Economy of the Middle East* (1980), published by the U.S. CONGRESS, JOINT ECONOMIC COMMITTEE. A multi-disciplinary analysis of the problems of underdevelopment, development, and planning for development in Asian countries is found in GUNNAR MYRDAL, *Asian Drama: An Inquiry into the Poverty of Nations,* 3 vol. (1968); the countries covered include Burma, Sri Lanka, Cambodia (Kampuchea), Laos, Indonesia, Malaysia, Thailand, and Pakistan, but most of the work is devoted to India. The following studies in ESCAP's "Mineral Resources Development Series" may be particularly useful in respect to mining and industries: *Mining Developments in Asia and the Far East* (annual); *Mining Developments in Asia and the Far East: A Twenty-Year Review, 1945–1965* (1967); *Lignite Resources of Asia and the Far East: Their Exploration, Exploitation and Utilization* (1956); *Copper, Lead and Zinc Ore Resources of Asia and the Far East* (1960); *Bauxite Ore Resources and Aluminum Industry of Asia and the Far East* (1962); *Tin Ore Resources of Asia and Australia* (1964); *Mineral Raw Material Resources for the Fertilizer Industry in Asia and the Far East* (1967); *Mineral Resources of Lower Mekong Basin and Adjacent Areas of Khmer Republic, Laos, Thailand and Republic of Viet-Nam* (1972); and *Proceedings of the Third Session of the Committee on Natural Resources* (1977). For data on mineral resources located in China see K.P. WANG, "The Mineral Resource Base of Communist China," in U.S. CONGRESS, JOINT ECONOMIC COMMITTEE, *An Economic Profile of Mainland China,* vol. 1 (1967).

The numerous studies ECAFE and ESCAP have made relating to industries include *Asian Industrial Development News* (annual); *Industrial Development in Asia and the Far East* (1965); *Development Prospects of Basic Chemical and Allied Industries in Asia and the Far East* (1963); and *Industrial Developments in Asia and the Far East: Selected Documents Presented to the Asian Conference in Industrialization,* 4 vol. (1966). Helpful works dealing with industries in China include CHOH-MING LI (ed.), *Industrial Development in Communist China* (1964); FREDERICK M. CONE, *Chinese Industrial Growth: Brief Studies of Selected Investment Areas* (1968); YUAN-LI WU and KUNG-CHIA YEH, *Growth, Distribution, and Social Change: Essays on the Economy of the Republic of China* (1978); BARRY M. RICHMAN, *Industrial Society in Communist China* (1969); and YUAN-LI WU, *The Steel Industry in Communist China* (1965). The role of small industries in the development effort is discussed in "Modernization of Small Industries in Asia," *Economic Bulletin for Asia and the Far East,* 11:24–40 (1960); and CARL RISKIN, "Small Industry and the Chinese Model of Development," *China Quarterly,* 46:245–273 (1971). AMNUAY TAPINGKAE (ed.), *Higher Education and Economic Growth in Southeast Asia* (1976), examines the role that higher education plays in the economic growth of the countries of this region. Later overviews are presented in NOBUTOSHI AKAO (ed.), *Japan's Economic Security* (1983); YUJIRO HAYAMI and MASAO KIKUCHI, *Asian Village Economy at the Crossroads: An Economic Approach to Institutional Change* (1982); and K.V. SUNDARAM, *Geography of Underdevelopment: The Spatial Dynamics of Underdevelopment* (1983).

ECAFE and ESCAP publications on the development of power resources include: *Electric Power in Asia and the Far East* (annual); *Proceedings of the Regional Seminar on Energy Resources and Electric Power Development* (1962); and *The Role and Application of Electric Power in the Industrialization of Asia and the Far East* (1965). Projections of future energy requirements are made in the development plans of many countries, but the NATIONAL COUNCIL OF APPLIED ECONOMIC RESEARCH, *Demand for Energy in India, 1960–1975* (1960), is an early example of nonofficial estimates. Material on the power industry in China includes: YUAN-LI WU, *Economic Development and the Use of Energy Resources in Communist China* (1963); JOHN ASHTON, "Development of Electric Energy Resources in Communist China," in U.S. CONGRESS, JOINT ECONOMIC COMMITTEE, *An Economic Profile of Mainland China,* vol. 1 (1967); ROBERT CARRIN, *Power Industry in Communist China* (1969); and VACLAV SMIL, *China's Energy: Achievements, Problems, Prospects* (1976). Possibilities and the potential of nuclear power development are discussed in the *Reports* (1959–60) of the Preliminary Assistance Missions sent to several Asian countries by the International Atomic Energy Agency. A list of civilian power reactors in operation or under construction with all pertinent technical data may be found in the INTERNATIONAL ATOMIC ENERGY AGENCY, *Power and Research*

Reactors in Member States (published twice a year). The vast energy reserves to be found in the Soviet Union are the subject of IAIAN F. ELLIOT, *The Soviet Energy Balance: Natural Gas, Other Fossil Fuels, and Alternative Power Sources* (1974). See also TAISHIRO SHIRAI (ed.), *Contemporary Industrial Relations in Japan* (1983).

Agriculture: Among the several publications of the Food and Agriculture Organization of the United Nations (FAO) are the following: *The State of Food and Agriculture* and *FAO Rice Report* (both are published annually). The ASIAN DEVELOPMENT BANK, *Asian Agricultural Survey,* 2 vol. (1968); and YUJIRO HAYAMI, VERNON W. RUTTAN, and HERMAN M. SOUTHWORTH (eds.), *Agricultural Growth in Japan, Taiwan, Korea, and the Philippines* (1978), are comprehensive surveys covering most of Asia. A succinct account of Asian agriculture may be found in COLIN CLARK, "Agriculture in Asia," *Pacific Community,* 4:283–294 (1970); and the likely ways to improve its contribution to the economy are discussed in "Strategies for Agricultural Growth," *Economic Survey of Asia and the Far East, 1969,* pt. 1A (1970). The agricultural situation in China is described in J.L. BUCK, O.L. DAWSON, and YUAN-LI WU, *Food and Agriculture in Communist China* (1966); and JOLO BUCK, *Three essays on Chinese Farm Economy* (1980). The growth in cereals output and its economic and social impact may be found in LESTER R. BROWN, "The Agricultural Revolution in India," *Foreign Affairs,* 46:688–698 (1968); SAM-CHUNG HSIEH, "New Outlook for Asian Agriculture," *International Development Review,* 10:6–9 (1968); UNITED STATES DEPARTMENT OF AGRICULTURE, *Taiwan's Agricultural Development: Its Relevance for Developing Countries Today* (1968); as well as NORMAN E. BORLAUG, "The Green Revolution: For Bread or Peace?" *Bull. Atom. Scient.* (1971). An informative collection of data is JOHN W. LONGWORTH, *Beef in Japan: Politics, Production, Marketing, and Trade* (1983).

Commerce: (*Transport*): The status and problems of transport in Asian countries and its role in their economic development is exhaustively dealt with in "Transport Development," *Economic Bulletin for Asia and the Far East,* vol. 11, no. 3 (1960). The Asian Highway Project, designed to connect the capitals and seaports of Asian countries, is described by M.S. AHMAD, "The Asian Highway," *ibid.,* 19:45–48 (1968). Despite the role of animals as a major mode of transport in the rural areas of most Asian countries, not much literature is available on the subject; the INDIAN PLANNING COMMISSION, *Role of Bullock Carts and Trucks in Rural Transport: Case Studies* (1963), is most valuable. WILFRED OWEN, *Distance and Development: Transport and Communications in India* (1968), is an excellent treatment of the subject for India; as are VICTOR D. LIPPIT, "Development of Transportation in Communist China," *China Quarterly,* 27:101–119 (1966); and YUAN-LI WU, *The Spatial Economy of Communist China: A Study on Industrial Location and Transportation* (1967). (*Trade*): A historical perspective of Asian trade from its remote beginnings may be found in C.G.F. SIMKIN, *The Traditional Trade of Asia* (1968). J.C. VAN LEUR, *Indonesian Trade and Society: Essays in Asian Social and Economic History* (1955), includes a sociological interpretation of early Asian trade. B.G. GHATE, *Asia's Trade* (1948), is a descriptive account of the situation up to the early 1940s; and ALFRED K. HO, *The Far East in World Trade: Developments and Growth Since 1945* (1967), brings the general survey up to 1960. Among several studies prepared by ECAFE, the following are particularly useful: "Asia's Trade with Western Europe, with Special Reference to the Common Market," *Economic Survey of Asia and the Far East, 1962,* pt. 1 (1963); "Foreign Trade of ECAFE Primary Producing Countries," *Economic Survey of Asia and the Far East, 1959,* pt. 2 (1960); "Trade Between Developing ECAFE Countries and Centrally-Planned Economies," *Economic Bulletin for Asia and the Far East,* 15:16–51 (1964); and "Intra-Regional Trade As Growth Strategy," *Economic Survey of Asia and the Far East, 1969,* pt. 1B (1970). SEIJI NAYA, "The Commodity Pattern and Export Performance of Developing Asian Countries to the Developed Areas," *Economic Development and Cultural Change,* 15:420–437 (1967), is comprehensive and analytical. Material relating to the foreign trade of China includes: PAULINE LEWIN, *The Foreign Trade of Communist China: Its Impact on the Free World* (1964); and ALEXANDER ECKSTEIN, *Communist China's Economic Growth and Foreign Trade: Implications for U.S. Policy* (1966). Later monographs include DENNIS T. YASUTOMO, *Japan and the Asian Development Bank* (1983); and RAE WESTON, *Gold: A World Survey* (1983).

Demographic patterns: GEORG BORGSTROM, *The Hungry Planet: The Modern World at the Edge of Famine,* 2nd rev. ed. (1972); S. CHANDRASEKHAR, *India's Population: Facts, Problem and Policy* (1967), *Hungry People and Empty Lands,* 3rd ed. (1954), *Population and Planned Parenthood in India,* 2nd ed. (1961), *Communist China Today,* 4th rev. ed. (1964), *Asia's Population Problems* (1967, reprinted 1977), and *Infant Mortality, Population Growth and Family Planning in India* (1972); C.D. COWAN (ed.), *The Economic Development of Southeast Asia* (1964); KINGSLEY DAVIS, *The Population of India and Pakistan* (1951); PHILIP M. HAUSER (ed.), *Urbanization in Asia and the Far East* (1957); ALFRED DE SOUZA (ed.), *The Indian City: Poverty, Ecology and Urban Development* (1978); LEA JELLINEK, CHRIS MANNING, and GAVIN JONES, *The Life of the Poor in Indonesian Cities* (1978); PING-TI HO, *Studies on the Population of China, 1368–1953* (1959); JACQUES M. MAY, *The Ecology of Malnutrition in the Far and Near East* (1961); POLITICAL AND ECONOMIC PLANNING (PEP), *World Population and Resources* (1955); JOHN ROBBINS, *Too Many Asians* (1959); EDGAR SNOW, *Red China Today: The Other Side of the River,* rev. ed. (1971); JOSEPH E. SPENCER, *Asia, East by South: A Cultural Geography* (1954); MORRIS B. ULLMAN, *Cities of Mainland China: 1953 and 1958* (1960); United Nations, ECONOMIC AND SOCIAL COUNCIL, *Report on the World Social Situation* (1957–); United Nations, *Department of Economic and Social Affairs, The Future Growth of World Population* (1958); and C.K. YANG, *A Chinese Village in Early Communist Transition* (1959). ESCAP has published a number of country monographs that analyze the demographic trends of individual Asian countries. Transformations in Asian nations are analyzed in BENEDICT ANDERSON, *Imagined Communities: Reflections on the Origin and Spread of Nationalism* (1983).

Contemporary studies of international issues involving Asia include EDWARD INGRAM, *The Beginning of the Great Game in Asia, 1828–1834* (1979), and his *Commitment to Empire: Prophesies of the Great Game in Asia, 1797–1800* (1981); JOHN P. FOX, *Germany and the Far Eastern Crisis, 1931–1938: A Study in Diplomacy and Ideology* (1982); KEITH ST. CARTMAIL, *Exodus Indochina* (1983); LINDA MASON and ROGER BROWN, *Rice, Rivalry, and Politics: Managing Cambodian Relief* (1983); RICHARD H. SOLOMON (ed.), *Asian Security in the 1980s: Problems and Policies for a Time of Transition: Conference on East Asian Security in the 1980s* (1980); RUSSELL D. BUHITE, *Soviet-American Relations in Asia, 1945–1954* (1981); DONALD S. ZAGORIA (ed.), *Soviet Policy in East Asia* (1982); RAJENDRA K. JAIN (ed.), *U.S.–South Asian Relations, 1947–1982,* 3 vol. (1983); and WILBUR SCHRAMM and ERWIN ATWOOD, *Circulation of News in the Third World: A Study of Asia* (1981).

ENAYETUR RAHIM, *Scholars' Guide to Washington, D.C. for South Asian Studies* (1982), is a reference source listing resources of research collections.

Atatürk

Mustafa Kemal, known as Atatürk (Father of Turks), a distinguished Turkish soldier, reformer, and statesman, was the founder of the Republic of Turkey and its first president. His successful struggle for the liberation of Turkey against the powers of the Entente (an alliance of Britain, France, and Russia) after Turkey's defeat in World War I has inspired many embryonic states in Asia and Africa to fight for their independence.

Early life and career. Mustafa was born in 1881 in Salonika, Greece, Ottoman Empire, of a Turkish family of humble origin. His mother was Zübeyde Hanım, his father Ali Riza, a minor government employee. When Mustafa was still in the primary school he lost his father, and his mother took the boy to live in the country with her brother. Returning to Salonika later, Mustafa finished primary school and entered the military secondary school in that town in order to become an officer in the Ottoman army. It was at this school that one of his teachers, who admired the boy for his skill in mathematics and who was also called Mustafa, suggested he should call himself Mustafa Kemal (maturity and perfection). After finishing secondary school, Mustafa Kemal went on to the military high school in Manastir, where, observing with hatred the continuous attacks of the Christian Macedonian anarchists on the Turkish population, he became, like most of his fellow cadets, an ardent nationalist.

Education

In 1899 Mustafa Kemal entered the Military Academy in Istanbul. There he came to take a close interest in politics; he and his fellow students read secret pamphlets attacking the despotic rule of Sultan Abdülhamid II. He was especially influenced by the patriotic and liberal thinking of the poet Namık Kemal Bey. He also read books on the French Revolution and developed an admiration for Napoleon.

In 1902 Mustafa Kemal was graduated from the Military Academy and entered the General Staff College, where his interest in politics continued. After finishing the college with the rank of captain, he was appointed to the cavalry regiment in Damascus. There, together with some of his friends, he founded a secret society called "Fatherland and Freedom," which, however, failed to make much progress. On his return to Salonika, Mustafa Kemal, like many of his fellow officers, joined the secret "Committee of Union and Progress," which spread its revolutionary activities throughout the armed forces and caused the proclamation of the Constitution of 1908.

Mustafa Kemal devoted all his time and energy to his profession in the following years. In 1911, when the Italians attacked Tripoli, an Ottoman province at that time, he hurried there together with some of his officer friends and, forming troops of the natives, launched successful guerrilla raids on the enemy. In the same year Mustafa Kemal was promoted to major. In the Balkan War of 1912 he was charged with the defense of the Gallipoli Peninsula—a task that gave him an excellent opportunity to study the strategic position of this important area. In 1913 he was sent to Sofia as military attaché, and during his stay there he acquired a good knowledge of the Western standards in taste, the arts, and the relations between men and women in polite society. He made good use of this knowledge later when he set about reforming social life in his country. While still in Sofia, Mustafa Kemal was promoted to lieutenant colonel.

Activities during World War I

When World War I broke out, Mustafa Kemal was appointed to the command of the 19th Division at Çanakkale. He defeated the British at Gallipoli twice and gained for himself in the Turkish press the title of "the Saviour of Istanbul." And he was promoted to colonel. In 1916, serving on the eastern front, he stopped the advance of the Russian forces to the south and was promoted to brigadier general.

In 1917 Mustafa Kemal accompanied the crown prince, Vahideddin, on a state visit to Germany. During a tour of the German Western Front he did not hesitate to express openly his view about the vulnerability of the front and Germany's position in the war. On his return to Istanbul Mustafa Kemal fell ill, and for treatment he went to Vienna and Carlsbad (now Karlovy Vary, Czechoslovakia) where he had a further opportunity to observe European civilization.

In 1918 Mustafa Kemal was appointed to command the 7th Army in Palestine; when he took up his duties, however, the fight with the British had all but ended, and the enemy was advancing northward without meeting any resistance. The Arab guerrillas too were launching attacks on the Turkish army. To avoid the capture of the whole 7th Army, Mustafa Kemal withdrew his forces to the north of Aleppo. When, after the Armistice of Mudros (Moúdhros), the German officers and commanders serving in Turkey returned to their country, Mustafa Kemal assumed the command of all the forces of the southeastern front. Disagreeing with the British over the enforcement of the terms of the Armistice, however, he was appointed to a post in the Ministry of War. On his arrival in Istanbul he found the fleet of the Entente anchored in the harbour. The terms of the Armistice were hard enough, but information was now received about a secret agreement reached by the states of the Entente for the partition of the Ottoman territories. Moreover, the minorities in Istanbul and elsewhere had seized the opportunity to organize themselves against the Turks. The Turkish people looked for a means of redress; in some parts of the country they formed organizations called Associations for the Defense of Rights to fight against them.

Activities after World War I. In Istanbul there were two main ideas about Turkey's future: the Sultan and his supporters were thinking of placing the country under English protection, while some well-known Turkish journalists and intellectuals were spreading propaganda for placing Turkey under an American mandate. In both cases the aim was to maintain the Ottoman Empire in its cosmopolitan structure. Mustafa Kemal, however, persisted in the idea of an independent Turkish nation living within its national boundaries and believed that this could be achieved if the nation was prepared for a new struggle. Before deciding on a course of action, he had talks with many Turkish and foreign notables, including the Sultan and his ministers. Then he discussed it with his friends, all commanders who were bitterly disillusioned over the abolition of the Ottoman army by the terms of the Armistice, and saw the solution in starting a war of independence in Anatolia.

An excellent opportunity for this presented itself soon: the powers of the Entente were putting pressure on the Turkish government to take measures against riots likely to break out in the eastern provinces. The Sultan appointed Mustafa Kemal as Inspector of the Third Army in Erzurum, endowing him with power over military and civilian authorities. On May 15, 1919, immediately before Mustafa Kemal's departure for Erzurum, the Greeks occupied Izmir.

After a secret interview with the Sultan, Mustafa Kemal left Istanbul with a large suite of staff officers and set foot in Samsun on May 19. In Amasya, with the approval of local corps commanders, he issued a secret circular dated June 22 in which he described the dangers that the country faced: how the government in Istanbul had yielded weakly to the forces of occupation and how the only hope of salvation lay in the nation's own struggle for its liberation. Such a struggle, he added, had already begun, and to make it the decision of the nation itself a national congress would be convoked in Sivas with the participa-

Mustafa Kemal's secret circular

tion of three delegates from each province. He ordered all unit commanders to strengthen their forces, disregarding the terms of the Armistice about the demobilization of the Turkish army. Finally, he warned both the military and civilian authorities that henceforth they would take their orders from him alone.

Mustafa Kemal's demands were fervently complied with by the military because his demands meant saving the army from extinction. The army took under its control all postal and telegraphic communications in Anatolia and forced into obedience those civil administrators who tried to resist Mustafa Kemal's orders.

In all the towns and cities he called at on his way to Sivas, Mustafa Kemal met the leading citizens and explained to them his views on a national struggle for independence. He arrived in Sivas amid warm demonstrations of support by the people, and after important talks with the notables of the city, he proceeded to Erzurum, ignoring all orders given by the Sultan's government, under pressure from the states of the Entente for his immediate return to Istanbul. In Erzurum a congress was to be convened on July 23 by the Association for the Defense of the Rights of Eastern Anatolia. In the meantime the military and civilian authorities of Erzurum received an order for Mustafa Kemal's arrest and transport to Istanbul. Although this order went unheeded, Mustafa Kemal resigned his commission in the army, deeming it necessary to have more freedom as the leader of the national struggle he had started. Thus he entered the congress as a mere delegate and was elected its president. At his suggestion the congress accepted the National Covenant, which was in the nature of an oath requiring the indivisibility of the fatherland and the successful completion of the national movement. In addition, a Standing Committee of nine members was elected of which Mustafa Kemal was chosen president. On September 4 he opened the National Congress in Sivas, and he was again elected president of the congress. The National Congress adopted all the decisions taken by the Congress of Erzurum and rejected decisively the idea of placing Turkey under American mandate. Resisting a motion for establishing a new state in Anatolia, Mustafa Kemal proposed the joining of all local Associations for the Defense of Rights into one society to be called the Association for the Defense of the Rights of Anatolia and Rumelia. The proposal was accepted, and so the prototype of a political party was formed. The Ottoman cabinet of Ferid Paşa and succeeding Ottoman governments continued to view the national movement as an act of rebellion and Mustafa Kemal's activities as illegitimate.

Participation in nationalist congresses

Role in the founding and reform of modern Turkey. On December 27 Mustafa Kemal transferred the seat of the national struggle to Ankara, thinking it a more convenient location for his purposes. In the meantime, at the general elections of members for the Ottoman Chamber of Deputies in Istanbul, Mustafa Kemal's supporters won an overwhelming majority and succeeded in getting the chamber to proclaim as its own decision the principles of the National Covenant. They also secured the cancellation of the government's former decree about Mustafa Kemal's dismissal from the army. Alarmed at these indications of change in the Ottoman policy, the British occupied Istanbul officially on March 16, 1920, and dissolved the Chamber of Deputies. Mustafa Kemal vehemently protested the British government's action; but, in fact, the occupation of the Ottoman capital and especially the dissolution of the chamber were extremely useful to his aims because they removed the legal obstacle that Istanbul presented to his plan of forming a national government in Anatolia. So, after a new election of deputies, he opened on April 23 in Ankara the first Grand National Assembly of Turkey, and he was elected its president. At Mustafa Kemal's proposal, a constitutional law was passed changing the name of the state to Turkey and stipulating that sovereignty and executive powers would be used on its behalf by the Grand National Assembly. Accordingly, as president of the assembly Mustafa Kemal took upon himself the offices of the prime minister and of the president of the state. Thus ended the Islāmic form of government that had existed in Turkey since the Middle Ages; and, as in the French Revolution, the Turkish people passed suddenly from rule of absolutism and the caliphate to a regime based on national sovereignty. This important change caused serious uprisings in some regions, but they were quickly suppressed by the national forces.

Mustafa Kemal now busied himself with the work of gaining control of such parts of the country as were then under occupation. First, in the east, the Armenians and the Georgians were defeated, and through the mediation of Soviet Russia, a treaty was signed with them that regained for Turkey even the territories it had lost in 1878. After extensive guerrilla warfare, the French in the south evacuated Turkish territories and withdrew to Syria and recognized the legitimacy of the National Government in Ankara. Ignoring Ankara altogether, the British got the Ottoman government to sign the Treaty of Sèvres. The National Government proclaimed that it did not recognize as legitimate a treaty of such terms, whereupon the Greek army extended its area of occupation, advancing within 50 kilometres of Ankara. At this time of great anxiety the National Assembly appointed Mustafa Kemal the commander in chief with extraordinary powers. On August 26, 1922, after an all-out offensive planned and directed personally by the Commander in Chief, the Greek army was defeated and forced within two weeks to leave Anatolia completely. Upon this decisive victory and with the mediation of the states of the Entente, an armistice was signed with the Greeks according to which they evacuated all Turkish territories. The British ceded Çanakkale and Istanbul to the National Government. Vahideddin, the last Ottoman sultan, fled abroad, and upon a motion by Mustafa Kemal the National Assembly terminated the 600 years of Ottoman rule in Turkey. The Treaty of Lausanne, signed on July 24, 1923, established the integrity of Turkey's national frontiers and its complete independence. All privileges granted to the European countries by the Ottomans were cancelled. Thus, Mustafa Kemal realized his dream of founding a completely independent and national Turkish state in place of the Ottoman Empire, that "sick man of Europe" that had been for a long time a subject of strife among the great powers of Europe.

Struggle to consolidate the country

In 1922 Mustafa Kemal married Latife Hanım, the well-educated daughter of a wealthy family in Izmir. The marriage was contracted in the modern manner, not in the tradition of Islām. In order to show the Turkish people that the place of women in society was by the side of their men, he took his wife with him on his trips around the country. His marriage did not last long, however. During his long years of single life he had developed an independent habit of living that he found difficult to give up and that his wife could not tolerate.

Marriage

On one occasion as early as 1917, Mustafa Kemal had remarked that, had he the power and the authority, he would change social life in Turkey at one blow. This opportunity had now presented itself, and he launched on a program of reforms. In place of the Association for the Defense of the Rights of Anatolia and Rumelia, he founded the People's Party (later renamed the Republican People's Party) and became its leader. With the general elections held immediately after the signing of the Treaty of Lausanne, this party, as Turkey's only political party, took complete control of the government. On October 29, 1923, Mustafa Kemal proclaimed the Republic and was elected its first president. In 1924 he abolished the caliphate. In the meantime, a group of his friends who were against his drastic methods of reform and who believed in more gradual progress over a longer period of time founded the Progressive Republican Party. Mustafa Kemal continued his reform program: he closed down all institutions based on the Muslim canon law, monasteries, and religious orders. "Science is the most reliable guide in life," he remarked, and abolishing the traditional system of education, which was mainly religious, he established secular schools of the modern type. The whole Ottoman legal system was modernized, and a new civil and penal code was adopted. His reforms penetrated the daily life of every citizen. The Oriental forms of dress that carried a religious significance were discarded in favour of European dress. Dances, balls, and other forms of entertainment in-

Reforms

volving both men and women were encouraged, and the enlightened classes adopted the European way of life.

Mustafa Kemal's reforms did not go unchallenged. In Eastern Anatolia a man called Şeyh Said stirred up a rebellion to restore the Muslim canon law; in Izmir preparations for a plot to assassinate Mustafa Kemal were reportedly discovered; and there were said also to be some local attempts at rebellion against the use of hats. Mustafa Kemal punished severely all the leaders of these movements, closed down the Progressive Republican Party, and, reverting to the former authoritarian regime, pursued his program of reform. Setting aside all the old laws and traditions that held women inferior to men, he established complete equality between the sexes, including the right of electing and being elected. In 1928 he substituted Roman characters for the Arabic that had been used in Turkey for centuries. He endeavoured to popularize Western classical music and the theatre in Turkey. In 1930 he made a second attempt at introducing a multiparty regime by allowing the creation of the Free Republican Party; but, as this party soon became a centre for antireformist ideas and activities, it met the same fate as the Progressive Republican Party. Mustafa Kemal also launched a large-scale program of research in the fields of Turkish language and history. By this means he wanted to strengthen in society the ties of national feeling in place of the old ties of religion. In 1933 a law was passed to make the use of family names compulsory, and the National Assembly gave Mustafa Kemal the name Atatürk, which soon became so popular as to supersede his previous name and titles.

Atatürk's foreign policy can be summed up by his motto: "Peace at home, and peace in the world." In economy, he followed a policy of national economy, nationalizing all foreign firms and companies. On the question of Turkey's industrialization, he placed his hope on private domestic capital for a while, but discovering its insufficiency, he decided to encourage etatism (state socialism). In neither case, however, did he achieve any important success. If one or two items of foreign policy are excepted, there was a gradual slowing down in the last five years of Atatürk's life, and his final year passed in serious illness. He died on November 10, 1938, in Istanbul, where he had gone to rest.

Atatürk made major reforms in Turkey in the field of politics, law, and culture that only affected, however, bureaucrats and a minority of well-to-do people in the cities. The poorer part of the population, and especially the peasants who still subsisted in an agricultural order of the medieval type, continued to live much the same as before. Nevertheless, the Western view of life had gained enough power among the educated classes to make a return to the old way of life impossible.

Athens

The capital of the republic of Greece and generally considered the nursery of Western civilization, Athens (Greek Athínai) lies five miles (eight kilometres) from the Bay of Phaleron, an inlet of the Aegean (Aigaíon) Sea where Piraeus (Piraiévs), the port of Athens, is situated, in a mountain-girt arid basin divided north-south by a line of hills. Greater Athens has an area of 165 square miles (427 square kilometres). The Kifisós River, only a trickle in summer, flows through the western half; and the Ilisós River, often dry, traverses the eastern half. The surrounding mountains—Párnis, 4,636 feet (1,413 metres); Pentelicus (Pendéli), 3,631 feet; Hymettos (Imittós), 3,365 feet; and Aigáleon, 1,535 feet—add to the impression of barrenness. Yet such considerations are superficial when compared with the fecundity of Athens' bequests to the world, such as its philosophy, its architecture, its literature, and its political ideals.

For treatment of the city in its regional setting, see GREECE; historical and cultural aspects are treated further in the article GRECO-ROMAN CIVILIZATION: *Ancient Greek Civilization.*

This article is divided into the following sections:

Physical and human geography

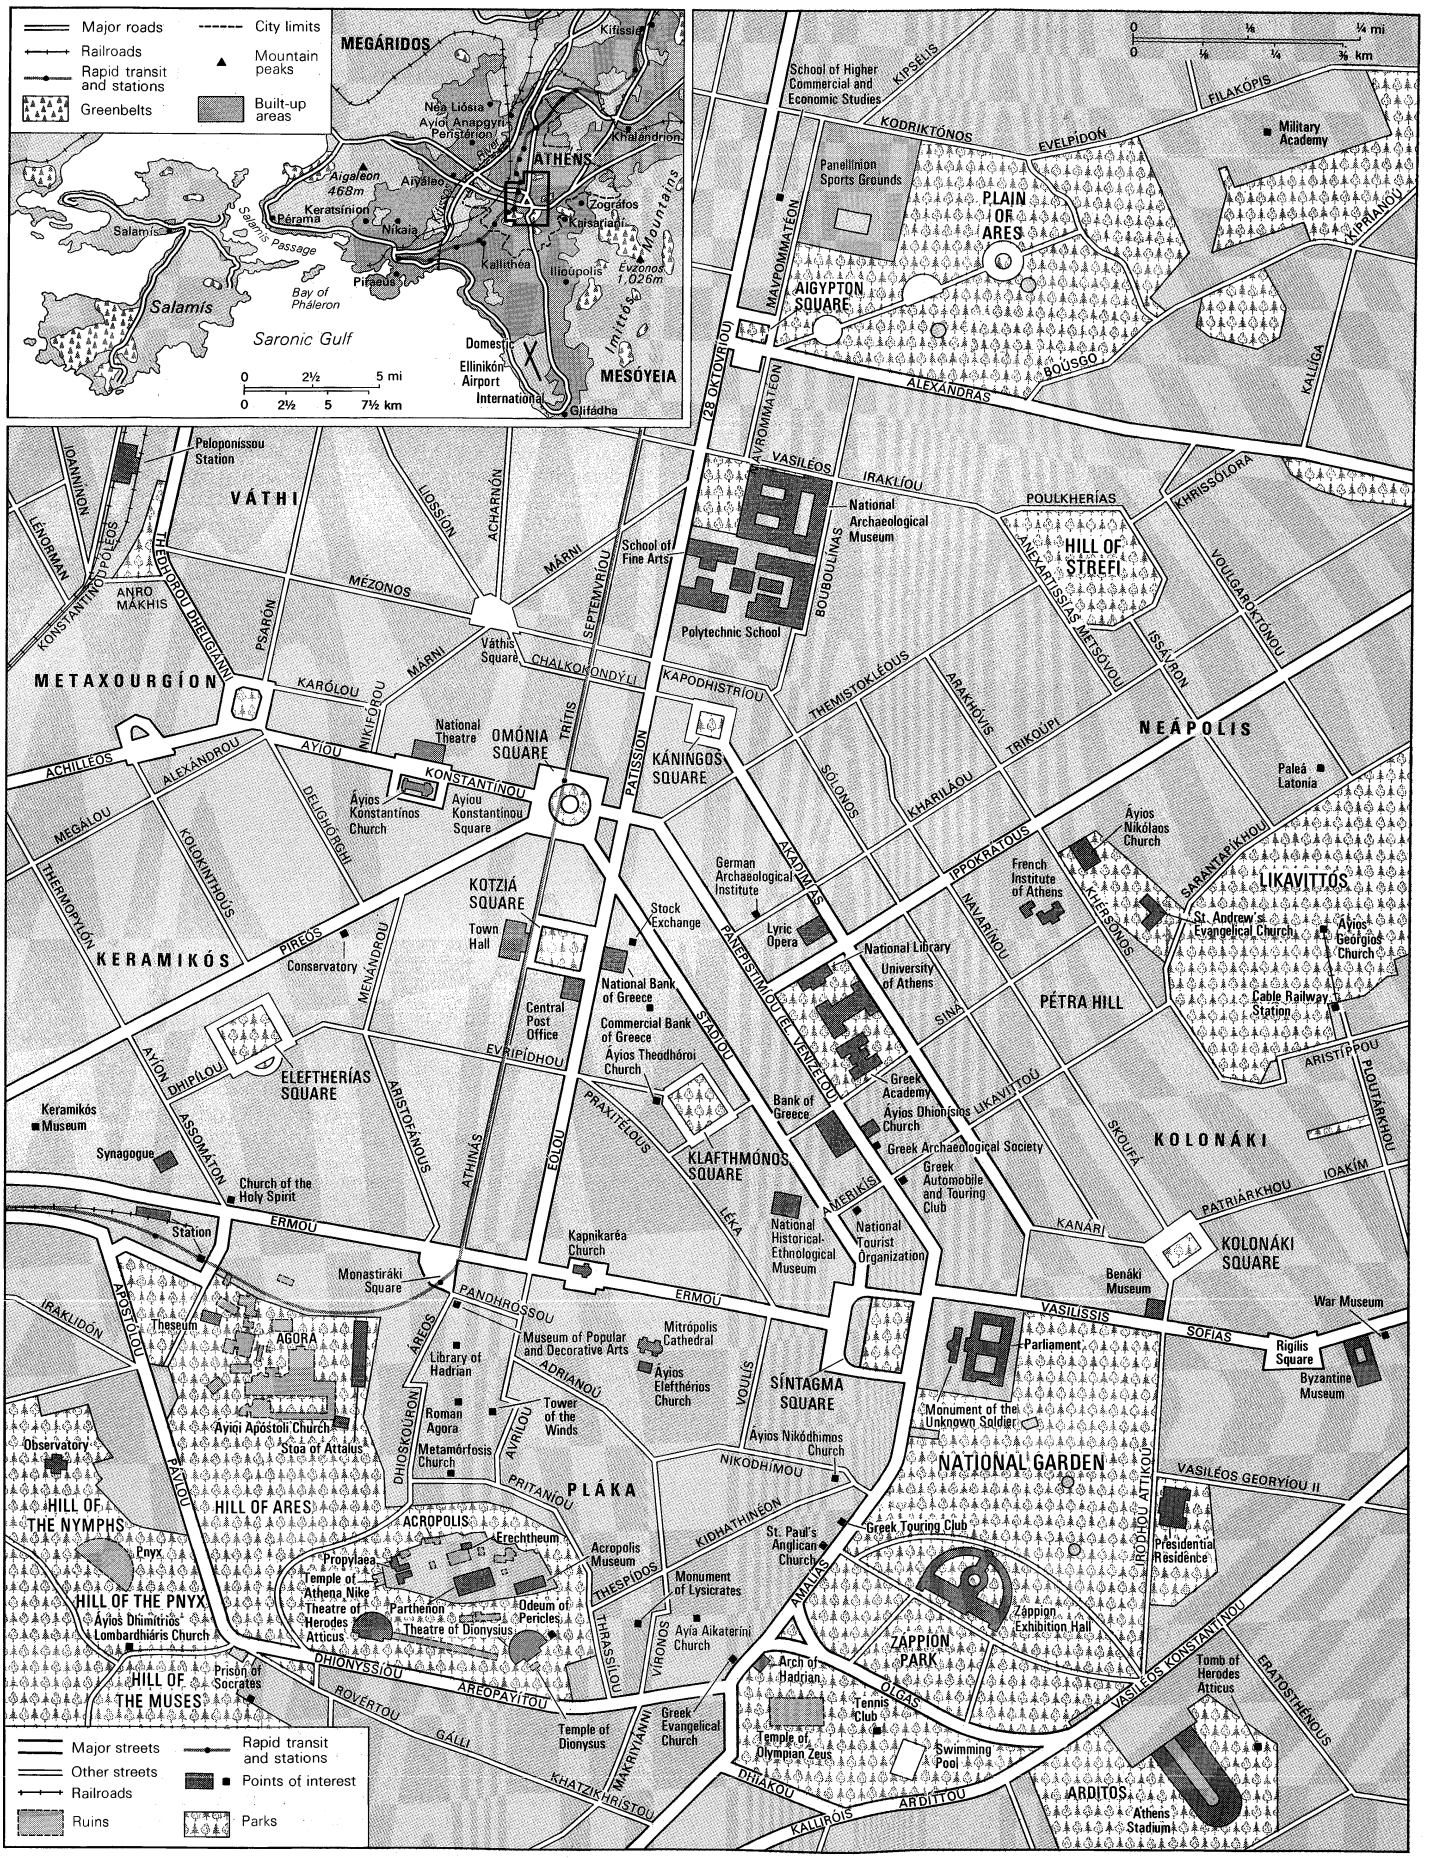
CHARACTER OF THE CITY

Athens, when approached from the Middle East, is the first European city, with tall buildings, newspaper kiosks, modern shops, and modishly dressed citizens. Approached from Europe, it seems, if not exactly the first Oriental city, at any rate not quite European, in its ill-fitting, locally tailored modernity. The European notes a medley of characterless concrete and out-of-style dress, with the smell of spitted meat and spices in narrow, unpaved streets as clamorous as bazaars and a few streets away from the centre.

Nevertheless, it is wrong to say that Athens is a mixture of East and West: it is Greek and, more particularly, Athenian. The Athenians, after all, nurtured Western civilization. Yet, some three centuries after the death of Pericles (429 BC), they entered upon a period of bondage that lasted almost 2,000 years. Athens was freed in 1833, and in the following 135 years it was the scene of 14 revolutions, another brutal foreign occupation, and a civil war of especial savagery. This long history of passion and suffering has had considerable effect on the Athenian character. The core of that character is an implacable will to survive, buttressed by a profound sense of loyalty (especially to the family) and patriotism. The Greek Orthodox Church, which is directed by a synod sitting in Athens, was a main force in keeping alive the Greek language, tradition, and literature when such things were forbidden, and most people still support it.

The 2,000-year bondage

The millennia of oppression, instead of driving the Athe-



Central Athens and (inset) its metropolitan area.

nians into obtuse moroseness, have honed their wit and rendered them tough but supple, while centuries of privation have only preserved their warmth and generosity. The long oral tradition, alive even under the invader, has reflected and stimulated a taste for rich talk. Of course, the poetic impulse to make a good story better leads to considerable exaggeration in daily conversation, suiting a vanity that goes with a sharp-edged sense of personal and family honour and the spoiling of children. The ancient heroes, too, were vain about both themselves and honour, boasting as much about outwitting the enemy as about outfighting him. Cunning, as in the *Odyssey,* is still a virtue there.

THE LANDSCAPE

Climate. The climate of Athens is benign: frost is rare (the minimum temperature is 32° F, or 0° C) and snow seldom lies, while the summers, though hot (maximum temperature is 99° F, or 37° C), are dry, and a fresh northeasterly wind often blows by day. The nights are cool. All of this permits outdoor activity the year around and has had an important effect on both the style of architecture and the life and political institutions of the city.

The city plan. In 1833 there was almost no Athens at all. During the fight for independence, it had been entirely evacuated in 1827, and six years later held perhaps 4,000 people in the straggle of little houses on the north slope below the Acropolis. The newly imported king of the Hellenes, Otho, the 18-year-old son of Ludwig I of Bavaria, was installed in the only two-story stone house, while his German architects hurried ahead with plans for a palace and a new Athens far out in the fields.

Below the well-sited but very plain palace, a large garden square, Síntagma (Constitution) Square, was laid out. Today it is garnished in the tourist season with some of Europe's most luxurious cafe chairs, and at all seasons it is hemmed in by tall new buildings and elderly luxury hotels. Broad avenues were created and are still the city centre's principal thoroughfares (Stadíou and Panepistimíou [Elefthérios Venizélou]), between which an orderly grid of narrow side streets was laid out. The housing that developed was generally the sort of architecture familiar in Victorian London: solid, porched, rather imposing, the later imitations graceless and monotonous. In Athens it is called the Othonian style, but there is little of it left as the centre encroaches on old residential areas.

Growth of the new capital

Once the new capital was established, the city grew at a regular rate of about 7 percent a year, soon reaching 50,000 inhabitants, a figure not much exceeded in the days of Athens' greatest power and glory. By 1907 the municipality had a population of 167,479. Omónia (Harmony) Square had been built at the western end of the two main streets, with other broad avenues radiating from it, but it did not develop as the hoped-for balance to Síntagma.

By then the railway to Piraeus had been built, its station near the antique Agora. Indeed, the city plan projected a logical growth southward along this axis, but a real-estate developer beckoned northward—the National Archaeological Museum is out this way—and the newly rich followed. The palace garden almost touched the Arch of Hadrian and the 15 mammoth columns (some of them seven feet 10 inches in diameter) of the temple of Olympian Zeus, last of the Classical buildings built in Athens, and beyond lay empty fields. The slopes of Mt. Likavittós, outside the town limits, were still pine-clad.

Since then, the garden has become one of the painfully rare public parks in Athens. Likavittós now rears up in the middle of the city (as if Hyde Park or Central Park were a 1,112-foot mountain), its lower slopes built upon, and many of the trees felled for a road leading to a cog railway and restaurant.

Along Panepistimíou Street rose the Academy of Athens, in marble from Mt. Pentelicus, its pediments and colonnades gilded. Its new neighbours were the University of Athens (refounded in 1837), the colonnade adorned with paintings, and the National Library. All were done in Greek Revival style by the court's German architects. A new Royal Palace (now the Presidential Residence) was built during 1891–97, a little southeast of the old (which is now a Parliament house) on Herodes Atticus Street. This leads to the 70,000-seat Panathenaic (Athens) Stadium, reconstructed by an expatriate Greek millionaire in time for the revival of the Olympic Games in 1896.

In 1921 the orderly progress of Athens was overturned and haphazard development began, for ethnic minorities were exchanged between Greece and Turkey, and approximately 1,500,000 Greeks, most of them penniless, came home from Asia Minor. Despite government efforts to resettle them elsewhere, many swarmed into shantytowns around the fringes of Athens and Piraeus, and the area's population soared from 473,000 to 718,000. After that, the city began to spread in two directions, south toward Piraeus and north toward the village of Kifisiá, which first became a smart suburb when Herodes Atticus built his villa there in the 1st century BC.

In the 1940s hideous things happened in Athens. During the German occupation many people died from starvation, and the city began to fall apart from lack of maintenance. When the Germans left, part of the Allied-equipped resistance refused to lay down its arms, and the civil war began. For a while the government held only the Parliament building, neighbouring embassies, and a part of Síntagma Square, while the palace garden was used as a common grave.

Housing. A construction boom began in the 1950s. New apartment houses pushing up everywhere erased old social boundaries (though the Kolonáki district on the southeast slope of Likavittós remained an enclave of respectable fortunes), and villages that had been attached to the city in the previous expansion lost their physical and political identities. A network of major highways was thrown up. The west side of the historic olive grove by the Kifisós River was shorn, and hillside greenery began to disappear under housing, either unauthorized or made legal through political skulduggery. Open space vanished, without provision for parks, playgrounds, or even schools, and Athens spread down to the sea by Glifádha, joining up with Piraeus. Piraeus itself was transformed from one of the world's celebrated honky-tonk ports into a clean, newly built, flower-decorated city.

Enlargement of the city's master plan

The Athens master plan was enlarged several times to keep pace with spread, which by 1964 had already attained 75 square miles, with a built-up area of 17 square miles outside the plan altogether. Land values in the centre quadrupled, then octupled, and rose proportionately elsewhere. Traffic increased almost to the saturation point at rush hours, and the city continued to sprawl beyond its planned limits. As international tourism increased, Ellinikón Airport, south of the city, was expanded and modernized.

The city water supply from an artificial lake at Marathon was insufficient to supply the new building construction, and the Mórnos River 110 miles to the northwest was dammed and tapped. Installation of a modern sewer system was undertaken, together with controls to check the floods that roar into Athens when heavy rains pour off the denuded mountains.

Old Athens

Traditional features. The older Athens has not entirely disappeared in all this hubbub. Older men may have given up smoking hookahs in shadowy cafes but not their 33-bead *kombouloi* ("worry beads"), which were acquired from the Turks.

Old Athens occupies the six streets sidling off Monastiráki Square, by the excavated Agora. In this area are tiny open-fronted shops hung with tinselled folk costumes and all of the monuments of Athens reproduced in copper, plaster, plastic, and paint. There is an alley of antique dealers, a street of smithies, one of hardware merchants, and another of wildly assorted miscellany.

Close to this lively quarter is the Pláka, on the north slope of the Acropolis. Small, one-story houses, dating from about the time of independence, are clustered together up the hillside in peasant simplicity. There are appropriately tiny squares with tavernas, once celebrated for their folk music, dancing, and simple fare. There are vine-covered pergolas and some unpaved streets too narrow for cars. The baths built by the Turks still function morning and

afternoon, but the bouzouki, a local relative of the lute, is giving way to the electric guitar. The taverna signs are multilingual, and the ubiquitous kitchen chair is being replaced by the plastic-ribbed restaurant seat. Progress laps at the Pláka like a vengeful sea, but the Acropolis is just up above, just under the stars.

The Acropolis. Many of Athens' bequests (all, if the theatre of Herodes Atticus may be regarded as an embodiment of the city's literature) to the world are expressed in and around the Acropolis, the natural centre of Athens. Rising some 500 feet above sea level, with springs near the base and a single approach, the Acropolis was an obvious choice of citadel and sanctuary from earliest times. That it could be something more is evidenced in the Parthenon, one of the brightest jewels in mankind's, let alone Athens', treasury. As deceptively simple as Socrates' conversation, this columned, oblong temple is the expression—without a trace of strain or conflict—of a human ideal of clarity and unity. The architectural genius is concentrated in the exterior, for within was a shelter for the goddess Athena—the patroness who lent her name to the city—not a place for mass worship. Its spiritual quality, the sensation of being almost afloat, is enhanced by the lack of a single, straight, vertical line in the peristyle (the surrounding colonnade); each vertical is almost imperceptibly bowed, theoretically meeting some 11,500 feet in the sky. The columns, of diminishing thickness toward the centre of the colonnade, with diminishing space between them, lean toward the centre, too; all these differences are virtually invisible to the beholder. Even the 20 flutings of each column diminish in width as they rise, and the humblest details of craftsmanship are perfect.

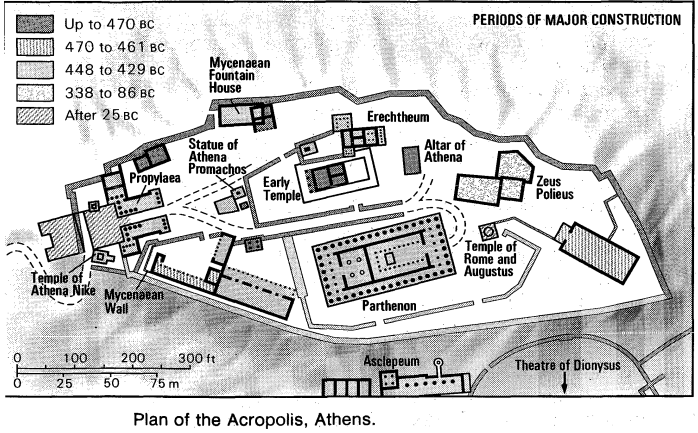
The Parthenon

On the northeast corner of the interior are faint traces of Christian wall paintings dating from the temple's service as the Church of St. Mary, and in the southeast corner of the porch is the stair leading to the minaret that emerged through the roof when the building was a Turkish mosque. The Parthenon was also used as a powder magazine, when, on September 26, 1687, Venetian artillery, attacking the Turks from the Hill of the Muses, scored a direct hit. A member of the party with the field commander, General Königsmark, wrote, "How it dismayed His Excellency to destroy the beautiful temple which had existed three thousand years!" Conversely, Francesco Morosini, the commander in chief, when reporting to the Venetian government, called it "a fortunate shot." Wishing to bring home more than just good news, he also tried to lower Athena's horses in the centre of the west pediment, but his men's dexterity was not as highly developed as their marksmanship and the masterpieces smashed to bits on the rock below.

The Turks regained possession of the Acropolis the following year and later began selling souvenirs to Europeans. The Duc de Choiseul, formerly French ambassador in Constantinople, picked up a piece of the frieze and two metopes. In 1801 the British ambassador, Lord Elgin, arrived with an imperial decree permitting him to pull down Turkish houses on the Acropolis to seek fragments of sculpture. Among the 50 pieces he took home (the shipping charges were £75,000, a huge sum for those days) was most of the remaining Parthenon sculpture, which he later sold to the British Museum for £35,000. The Greeks have forgiven the clumsiness of the Venetian engineers, the accuracy of Venetian cannoneers, and the vandalism of the Turks, but they still nurture rancour against Elgin. He also removed one of the caryatids from the Erechtheum, a temple of Athena called after a shrine dedicated to the legendary king Erechtheus or to Poseidon Erechtheus, but replaced her with a plaster cast. From London he sent a town clock for Athens, duly erected in the Agora and lost in the fire of 1885.

Lord Elgin

Adapted from *Westermann Grosser Atlas zur Weltgeschichte*: Georg Westermann Verlag, Braunschweig



Plan of the Acropolis, Athens.

The Erechtheum (5th century BC), which later became a church under the Byzantines and subsequently the Turkish commander's harem, was originally dedicated to both Athena and Poseidon and was the most venerated of the Acropolis temples.

The Propylaea, the matchless entryway into the Acropolis, was the only opening in the surrounding wall. Just in front of it and to the left is the 27-foot-high pedestal for the thank offering to Agrippa, the victor of the Battle of Actium, who interceded for Athens, which had supported the loser, Mark Antony. To the right was the temple of Athena Nike (Giver of Victory), 27 feet long and 18½ feet wide, which stood untouched until the Turks demolished it in 1686 to use the stones as defenses against the Venetians. In 1836 it was badly restored, and 100 years later its foundations began to slip into previously undiscovered Turkish cisterns, revealing the 6th-century foundations of Peisistratus' earlier shrine to Artemis Epipyrgidea (Artemis on the Tower). The temple was then more accurately reconstructed. The northern wing of the Propylaea, the Pinakotheke, was used by the Frankish dukes, who reconstructed the interior to make a two-story building. In the 12th century, Greek Orthodox bishops lived in the Pinakotheke, and in the 14th century, the dynasty of Athenian dukes from Florence turned the Propylaea into a fortified castle with a Tuscan tower, which Heinrich Schliemann, the German excavator who discovered Troy, paid to have dismantled in 1875.

The Pinakotheke

When the Turks, who had occupied Athens since 1456, departed, they left the monuments in a state of ruin, the ground covered with garden plots, and several hundred small huts. After Greece won its independence, Otho, the first king of the Hellenes, had everything that postdated the classical period swept away, set scholars to work identifying the remains, and encouraged some reconstruction.

According to Pausanias, the Greek traveller and geographer of the 2nd century AD, the colossal 30-foot-high bronze seated statue of Athena Promachos (Athena Who Fights in the Foremost Ranks), by the 5th-century BC Athenian sculptor Phidias, was set up in the open behind the Propylaea, her gleaming helmet and spear visible to mariners off Cape Sunium (Soúnion) 30 miles away. The 6th-century Byzantine emperor Justinian carried the statue off to Constantinople (now Istanbul), just as Phidias' ivory and gold statue of Athena had been taken from the Parthenon. Both of these masterpieces were lost to other looters in the crusaders' sack of Constantinople in 1204. Other statues stood in profusion amid small temples, such as the sculptor Myron's group of Marsyas and Athena, his Perseus, and his heifer; Phidias' Lemnian Athena and his Pericles; and a gigantic bronze effigy of the Trojan horse. There was an altar to Athena Hygeia (the Health Giver), a precinct sacred to the goddess Artemis Brauronia (named after a statue of her, brought from the town of Brauron), the Pandroseum (a building named after Pandrosos, a girl associated with Athena in legend), where the sacred olive tree of Athena grew, and beyond the Parthenon the great altar of Athena.

Other notable buildings. Below the Acropolis sanctuary, on the southwest slope of the hill, Herodes Atticus, a rich Roman, built a 5,000-seat odeum as a memorial to his wife in AD 161. A conventional Roman theatre, except that the semicircular auditorium was hollowed out of the rock, it was roofed in cedar and had a three-story facade of arches. Repaired but roofless, it is now used for the Athens summer festival of music and drama. A 300-yard-long portico stretching toward the Theatre of Diony-

The theatre of Herodes Atticus

sus had been built some 300 years earlier. The Dionysiac theatre itself, scooped out of the south slope early in the 5th century, replaced the Agora stage as the drama centre. It also replaced the Pnyx as the meeting place for the popular assembly. Rebuilt many times, the ruined theatre now visible is largely Roman, the last construction work on the stage probably dating from the early 3rd century AD. The Dionysia, the spring festival, which drew crowds from many parts of Greece and colonies in Asia Minor and Italy, was held in this theatre, which had 13,000 seats in 67 rows. The jury had larger front seats and the ecclesiastical dignitaries small stone thrones, on which their titles can still be read. Three tragic and four comic plays were presented in competition for the prize. Production costs were met by private sponsors who, when their choruses won the prize tripod, displayed it in an elaborate memorial in the Street of Tripods to the east of the theatre. The only one of these monuments still standing is that of Lysicrates, erected 334 BC, a small circular temple 21½ feet high, its six columns an early example of the Corinthian order. The monument was preserved through incorporation into a convent (in which the English poet Lord Byron had a study) and influenced British Georgian and Regency architecture through the engravings of the Edinburgh artist "Athenian" Stuart. Farther east lay the Odeum of Pericles, and to the west are traces (420 BC) of the precinct of Asclepius, the god of healing, which took the form of a hospital portico for patients and temples decorated with votive reliefs.

On the Hill of Ares, the god of war, to the right of the descent from the Propylaea, a legendary jury of gods spared Ares from execution for the murder of the sea god Poseidon's son. Trials for homicide continued to be heard on this hill through the ages, and the Supreme Court of Greece still bears the name.

Other hills in Athens

Across Apostólou Pávlou (Apostle Paul Avenue) are the Hill of the Nymphs, where an Austro-Greek, Baron Sina, built an observatory in 1842; the Hill of the Muses, crowned with the remains of the marble monument to Philopappus, a Syrian who was Roman consul in the 2nd century AD; and the middle hill, the Pnyx (Tightly Crowded Together), the meeting place of the Ecclesia, the assembly of 18,000 citizens who heard the great Athenian orators. (In fact, attendance of more than 5,000 persons was rare at any gathering, but the Pnyx would still have been crowded.)

The Agora. The avenue leads down to the Agora, which the American School of Classical Studies started restoring in 1931, paying $2,500,000 compensation to the several hundred families living there. Financed by, among others, the Rockefeller Foundation, the Marshall Plan, and the Greek government, the work went on until 1960. It includes what has been called "the pitiless replica of a 180-columned portico of the 2nd century BC," which serves as a museum.

The Theseum

At the approaches to the Agora is the best preserved of all Greek temples, the Theseum (5th century BC). Although virtually intact and absolutely genuine, it has all the deadness of a latter-day reproduction. The beauty, the mystery, and the genius that render the Parthenon incandescent eluded the architects and builders of the Theseum.

The Horologium and the Orthodox cathedrals. Another monument is the octagonal, 42-foot-high marble Horologium of Andronicus of Cyrrhus, usually called the Tower of the Winds because each side bears a weather-beaten figure of the wind from that particular compass point. It used to have a sundial, a water clock for telling the hour on cloudy days, and a weather vane. The Turks left it unchanged, believing it to be the tomb of two local prophets, Sakhratis and Aflatun (Socrates and Plato).

In the shadow of the 19th-century, neo-Byzantine Greek Orthodox Cathedral (Mitrópolis) nestles the 12th-century Mitrópolis, Áyios Elefthérios, one of three genuine Byzantine churches still surviving. It is red brick, like the others, and tiny. Its Pentelic marble is ruddied with age, and its outer walls are artfully, if promiscuously, decorated with classical Greek tidbits: panels, votive tablets, and morsels of frieze. Like its sisters, this retired cathedral is charming, unassuming, and comforting.

THE PEOPLE

The population of Greater Athens increased considerably after the war of independence in the early 1830s. The rapid growth was largely due to the great influx of refugees from Asia Minor in the early 1920s and the migration of rural inhabitants from the provinces during World War II and the Communist rebellion (1946–49). By the 1960s Athens had become a bustling cosmopolitan city. Almost all Greeks adhere to the Greek Orthodox faith.

THE ECONOMY

Industry and trade. Since World War I Athens has become the hub of all mercantile business, export and import. With Piraeus, it is the most important manufacturing city in Greece. Athens accounts for half of the jobs in industry and handicrafts, and earnings are much higher than the national average. There are cloth and cotton mills, distilleries, breweries, potteries, flour mills, soap factories, tanneries, chemical works, and carpet factories. Exports include olive oil, tomato products, wine, cement, bauxite, and textile manufactures. Publishing enterprises are important.

The brilliant Attic light, however, is now dimmed by the pall of pollution hovering over the city. To discourage new factories from adding to the problem and to stimulate the economic growth of other regions, an industrial wage tax has been imposed in the Athens area, and tax incentives have been offered to new factories set up in other areas.

Transportation and shipping. Athens accounts for more than half of the nation's cars, trucks, and buses. Furthermore, the number of merchant ships registered in Greece (mostly at Piraeus, the country's largest port) has increased as Greek shipowners, since the late 1960s, have answered the government's call to bring their foreign-registered ships home (though many Greek ships remain under other flags). Scores of shipping offices have opened in refurbished Piraeus, while on weekends shipping magnates sail to the nearby islands of Hydra and Spetse in chrome-fitted luxury yachts, flying Panamanian and Liberian flags.

The metropolitan transit system includes an electrified rail line, buses, and trolleys. The electric railway, which connects Piraeus in the south with the suburb of Kifisiá in the north, runs underground within Athens proper. Larissa, the main railway station, links the city with the rest of the country and the continent. (B.E./Ed.)

History

THE EARLY PERIOD

Factors inducing settlement. The site of Athens has been inhabited since the Neolithic Period (before 3000 BC). Evidence for this has come from pottery finds on and around the Acropolis but particularly from a group of about 20 shallow wells, or pits, on the northwest slope of the Acropolis, just below the Klepsydra spring. These wells contained burnished pots of excellent quality, which show that even at this remote period Athens had a settled population, with high technical and artistic standards. There are similar indications of occupation in the Early and Middle Bronze ages (3000–1500 BC).

Evidence of early inhabitation

The earliest buildings date from the Late Bronze Age, particularly about 1200 BC when the Acropolis was the citadel. Around its top was built a massive wall of cyclopean masonry (a type of construction using huge blocks without mortar). The construction of this wall probably marks the union of the 12 towns of Attica (the department in which Athens lies) under the leadership of Athens, an event traditionally ascribed to Theseus. The palace of the king was in the area of the later Erechtheum, but almost no traces of it have been identified. The town, insofar as it was outside the Acropolis, lay to the south, where wells and slight remains of houses have been found. The principal cemetery lay to the northwest, and several richly furnished chamber tombs and many smaller ones have been discovered in the area that later became the Agora.

Whether through the strength of its walls, the valour of its citizens, or its geographical position away from the main route to the Peloponnesus, Athens seems to have weathered the Late Bronze and Early Iron ages, troubled

times, better than other, more important centres. There is no evidence of complete or widespread destruction, as at Mycenae and Pylos; in fact, the pottery styles show an unbroken development through sub-Mycenaean (later than the Mycenaean but not yet Greek) to Protogeometric (the earliest phase of Geometric) and Geometric Period (1000 BC to about 750 BC). Furthermore, there is positive evidence that from about 1000 BC the city began to expand in a northwesterly direction, into the area that had previously been confined to cemeteries. Wells appear, indicating occupation by the living, and any graves in the area are increasingly confined to restricted plots or placed along the roads outside the town limits. The Agora and some of the public buildings seem, to judge from scattered notices in later writers, to have been located west and northwest of the Acropolis. Though there are few remains of buildings, the wealth and prosperity of the city can be appreciated from late Geometric graves found in the area of the later Dipylon and Erian gates. These graves were adorned with large vases, sometimes more than five feet high, decorated with geometric patterns and with scenes of battles, processions, and funeral ceremonies.

Changes in the 6th century BC

Athens' expansion. The 6th century BC was a period of phenomenal growth, particularly during the tyranny of Peisistratus and his sons (*c.* 560–510 BC). On the Acropolis, the old primitive shrines began to be replaced with large stone temples. About 580 BC a temple to Athena, known as the Hecatompedon (Hundred-Footer), was erected on the site later to be occupied by the Parthenon. The pediments (triangular spaces forming the gable) of this temple were decorated with large-scale sculpture in gaily coloured, porous limestone, representing groups of lions bringing down bulls, and with snaky-tailed monsters in the angles. These sculptures are now displayed in the Acropolis Museum. In 566 BC Peisistratus reorganized the Panathenaic Games in honour of Athena on a four yearly basis. About 530 BC a large peripteral temple (one having a row of columns on all sides) to Athena Polias (Guardian of the City) was erected near the centre of the Acropolis, on the site of the old Bronze Age palace. It had marble pedimental sculpture representing the battle of the gods and giants. Besides these two major temples there were five smaller buildings, treasuries and the like, and a wealth of votive offerings in marble, bronze, and terra-cotta. The Acropolis thus became a full-fledged sanctuary.

This change from citadel to sanctuary is also reflected in the arrangement of the entrance at the west. Instead of a winding path suitable for defense, there was, from about the middle of the 6th century BC, a broad ramp, designed as a ceremonial approach, leading up to the gate. This basic change of attitude toward the Acropolis must mean that the whole lower town was surrounded by a fortification wall and the Acropolis was no longer needed for defense. The ancient historians Herodotus and Thucydides tell of such a wall, but no trace of it has been found, and its course and date are uncertain.

Building of the new Agora

In the lower town, too, the 6th century was a period of growth and change. The old Agora, below the western approach to the Acropolis, was now inadequate, and a new one was therefore laid out in the low ground to the northwest. This was accomplished by demolishing houses and filling in wells and gullies, to create a broad, open square, which was used for gatherings of all sorts: political, judicial, religious, and commercial. Dramatic contests were held there, too, before the construction of a separate theatre. Various public buildings and shrines were erected around the borders of the square, including the Basileios (Royal) Stoa, where the archon Basileus, one of the chief magistrates of the city, had his headquarters; the Old Bouleuterion (or Council House); and a large enclosure (100 square feet) that probably housed the Heliaia, the largest of the popular lawcourts. At the southeast corner of the square a fountain house received water from outside the city through a conduit of terra-cotta pipes.

In 480 BC this flourishing city was captured and destroyed by the Persians. The Acropolis buildings were burned and the houses in the lower town mostly destroyed, except for a few that had been spared to house the Persian leaders.

Athens at its zenith. When the Athenians returned, in 479 BC, they immediately rebuilt their fortification wall larger than before. About 20 years later the famous Long Walls were built, connecting the city with its port, Piraeus, four miles away. They were parallel over most of their course, forming a corridor 550 feet wide. These walls played a vital part in the history of Athens during the Classical period, for they allowed it to carry the supplies brought in by its powerful fleet in safety to the city, even when enemy forces roamed the Attic countryside.

For 30 years after the Persian destruction, the Athenians built only fortifications and some secular buildings in the Agora, notably the Stoa Poikile, or Painted Colonnade, with its famous paintings by Polygnotus and Micon, one of which represented the Battle of Marathon. The Tholos, the round building that served as the headquarters of the executive committee of the council, was also built at this time. Lack of attention to the Acropolis was partly the result of the oath, sworn before the Battle of Plataea in 479 BC, that sanctuaries destroyed by the barbarians would

E. Streichan—Shostal Assoc.

Modern Athens and the Acropolis.

not be rebuilt but left as memorials of their impiety. In 449 BC, however, peace with Persia was at last officially established, and the oath was annulled. Athens, moreover, had ample funds, for the silver mines in the Laurium (Lavrion) Hills of southern Attica were in full production. These mines had always been exploited, but in 483 BC a big strike was made, the proceeds of which were used to build the ships that won the Battle of Salamis in 480 BC. Thereafter, the mines remained productive throughout the 5th and 4th centuries, providing Athens with the sinews of its strength in the great Classical age. Another source of revenue was the tribute that the allies had been paying, as members of the Delian League, to prosecute the war against Persia. Athens had been collecting and administering this money and, even though the war was officially over, continued to collect it in spite of the protests of the allies, who degenerated into subjects of Athens. Pericles deemed it proper, over the protests of his opponents, to use this money on beautifying the city; in this way he could keep the money in circulation and provide jobs for the whole population. Thus began one of the largest and most enduring works programs in history.

Peace with Persia

In a period of 40 years the Acropolis was entirely rebuilt in gleaming white marble quarried from Mt. Pentelicus, 10 miles north of the city. The first great work was the Parthenon, begun in 447 BC and finished, except for some details, in 438 BC. The architects were Ictinus and Callicrates, and Phidias was in charge of the whole artistic program. The building was considerably larger than was usual, having eight columns across the ends and 17 on the long sides, against six by 13 for the average temple. It was richly decorated with sculpture, having a running frieze all around the top of the cella (the walled-in chamber within the colonnade) wall outside, and sculptured metopes and sculptured pediments. Inside the cella stood the cult statue, the great gold and ivory figure of Athena, the work of Phidias. No sooner was the main work on the Parthenon completed than the Propylaea was begun. This was the monumental gateway with five doors at the head of the approach, designed by the architect Mnesicles. Its large outer vestibule was covered by a marble ceiling, supported by marble beams with a free span of 18 feet, about which Pausanias wrote, "The Propylaea has a ceiling of white marble which in the beauty and size of the stones remains supreme even to my time." Work on the Propylaea was nearly finished when it was stopped by the outbreak of the Peloponnesian War in 432 BC, but, as things began to go well for Athens, the little temple of Athena Nike was erected on the bastion in front of the Propylaea, perhaps in 425 BC. Around the time of the Peace of Nicias (421 BC) the Erechtheum was begun. This was a small Ionic temple of highly irregular plan, which housed various early cults and sacred tokens. When the building was about half-finished, work was suddenly interrupted, probably because of the disastrous Athenian expedition to Sicily (415–413 BC), but it was resumed in 409, and the building was completed in 406. The final defeat of Athens two years later put an end to all building, but the Acropolis had been completed, and in later centuries only secondary buildings and monuments were added.

The building of the Erechtheum

In the second half of the 5th century there was also some building activity in the lower town. Even before the Parthenon, work was begun on the temple of Hephaestus (the god of fire), the Theseum, which still stands on a low hill. In the Agora itself, a new Bouleuterion was built, and two colonnades, the Stoa of Zeus and the South Stoa, were constructed. On the south slope of the Acropolis, next to the theatre, Pericles built an odeum, a large enclosed concert hall, its roof supported by a forest of columns. Of the theatre itself there are no identifiable remains, but the arrangements were no doubt quite simple, and it is known that a theatre existed on this spot from the late 6th century BC because of the old temple of Dionysus (the god of wine) nearby, which dates from the same period. A sanctuary of Asclepius was founded on the south slope of the Acropolis in 420 BC.

Athens was slow in recovering from its defeat in the Peloponnesian War, but in 394 BC its admiral, Conon, won a decisive naval victory over Sparta off Cnidus, on the west coast of Asia Minor. As a result he rebuilt the Long Walls, which the Spartans had demolished to the music of flutes 10 years before, believing they were inaugurating the freedom of Greece. The walls of Piraeus were also rebuilt, and those of the city were repeatedly strengthened in the course of the 4th century, notably by the addition of a ditch, or moat, as protection against siege machinery.

Apart from military works, there was little building in 4th-century Athens until the years 338–322 BC, when the orator Lycurgus was in control of the state finances and there was great activity. On the Pnyx, the broad-backed hill west of the Acropolis where the Athenian popular assembly had met since the reforms of Cleisthenes in the 6th century, a large auditorium was constructed. At the same time, two large stoas were started on the terrace above. The Theatre of Dionysus was rebuilt and greatly enlarged, with stone seats to accommodate the crowds. (Lycurgus did another service to the theatre by having definitive copies made of the old plays.) The Panathenaic stadium was also built about then, partly with state funds and partly by private contributions; the land was donated by a certain Deinias, and one Eudemus of Plataea provided 1,000 yoke of draft animals to level the ground. The period was one of lavish private expenditure in other fields as well. The tripods won in choral contests were displayed on elaborate monuments, sometimes even resembling small temples; the best preserved of these is that of Lysicrates (334 BC), a small round building with six Corinthian columns. Tombs also became increasingly elaborate, often portraying the whole family in high relief. In 315 BC a stop was put to all this extravagance by the sumptuary laws of Demetrius of Phalerum.

Building in the late 4th century

Meanwhile, the philosophy schools flourished. Plato (*c.* 428–348/347 BC) established himself in the Academy, a gymnasium that had existed since at least the 6th century BC in the great olive grove about a mile west of the city. Plato himself had a house and garden nearby. Aristotle and his Peripatetics occupied the Lyceum, another gymnasium, just outside the city to the east, and his successor Theophrastus lived nearby. Antisthenes and the Cynics used the Cynosarges gymnasium to the southeast of the city. Zeno held forth in the heart of the city, in the Stoa Poikile, in the Agora, and his followers were therefore known as Stoics. Epicurus and his followers had a house and garden in town.

Apart from its temples and public buildings and its great avenues, however, Athens seems to have made a poor impression. A 3rd-century-BC visitor complained that the city was dry and ill-supplied with water, that it was badly laid out because of its great antiquity, and that most of the houses were mean. The streets were in fact narrow and winding, and the houses, it is true, presented a blank wall to the street except for the entrance door, but then they were built around a central courtyard, off which the various rooms opened. There was often an upper story, and the court had a well. Water brought in by the aqueducts was not considered good because it was hard (containing salts of magnesium or calcium) and caused rheumatism. Waste water was carried off in an elaborate system of underground drains beneath the streets.

Hellenistic and Roman times. Athens in Hellenistic and Roman times depended for its embellishment less on its own resources than on the generosity of foreign princes. One of the Ptolemies (rulers of Egypt) gave a gymnasium, erected near the sanctuary of Theseus, and the Ptolemies were probably also instrumental in the founding of the sanctuary of the Egyptian gods Isis and Sarapis. More important were the donations of the Attalids of Pergamum (a dynasty of Asia Minor); Eumenes II (197–159 BC) gave a large, two-story colonnade on the south slope of the Acropolis near the theatre. His brother Attalus II (159–138 BC), who had studied at Athens under the philosopher Carneades, head of the New Academy, likewise gave a colonnade. This was a large, elaborate, two-story building more than 350 feet long with a row of shops at the rear. It was located on the eastern side of the Agora and has been reconstructed in modern times (1953–56) to serve as the museum of the Agora excavations. The Stoa of Attalus was the first element in a large-scale reconstruction of the

Donations of the Attalids

Agora. It was followed in quick succession by three buildings, the Middle Stoa, the East Building, and the South Stoa, which together formed a separate South Square.

The capture of Athens by the Roman general Sulla in 86 BC was accompanied by great slaughter and much destruction of private houses, but the only public building to be destroyed was the Odeum of Pericles, burned by the defenders lest its timbers be used by the enemy. The odeum was rebuilt a few years later, through the generosity of King Ariobarzanes of Cappadocia.

Under the Roman Empire, Athens enjoyed imperial favour. A spacious market for the sale of oil and other commodities was laid out east of the old Agora with funds originally provided by Julius Caesar and supplemented by the emperor Augustus. In the old Agora itself, a new odeum, or concert hall, was built in the middle of the square by Marcus Agrippa, the emperor's son-in-law and one of his chief lieutenants. A large building, perhaps a lawcourt, was also erected at the northeast corner. At the southeast corner of the Agora a handsome library was erected about AD 100, the gift of one T. Flavius Pantainus and his family. It was decorated with a group of marble sculpture representing Homer flanked by the *Iliad* and the *Odyssey*. On the Acropolis a small round temple was erected to the goddess Roma and the emperor Augustus.

The emperor Hadrian (AD 117–138) completed the great temple of Olympian Zeus, started more than 600 years earlier by the Peisistratids. This temple formed the chief ornament of the new eastern suburb of Athens, and Hadrian gave the area a monumental entrance through a gateway, the inscriptions on which proclaimed, on one side, "This is the Athens of Theseus, the old city," and, on the other, "This is the city of Hadrian, not of Theseus." Hadrian also built a library, a gymnasium, and a pantheon (a sanctuary of all the gods). His aqueduct, which brought water from the mountains to the north, has been reconditioned and still serves the modern city.

Hadrian's devotion to Athens

In the reign of Valerian (AD 253–260), the walls of Athens, which had been neglected since Sulla's capture of the city in 86 BC and had fallen into ruin, were rebuilt, and the circuit was extended to include the new suburb northeast of the Olympieion. This was done because of the threat of a barbarian invasion, but when that invasion came, in AD 267, the walls were of no avail. The Heruli, a Germanic people from northern Europe, easily captured Athens, and though the historian P. Herennius Dexippus rallied 2,000 men on the city outskirts, they could only resort to guerrilla tactics. The lower town was sacked, and all the buildings of the Agora were burned and destroyed. The Acropolis, however, may have held out; at least there is no evidence of extensive damage at this time.

This sack of Athens is comparable only to that by the Persians in 480 BC, but now the reaction was quite different. The Athenians abandoned the outer circuit and established a new and much smaller line north of the Acropolis, leaving even the Agora area outside the walls. This new wall, which, on the evidence of coins, was built in the reign of Probus (276–282), consisted of material taken from ruined buildings in the lower town.

Athens remained confined within this narrow circuit for several generations, but in the 4th and 5th centuries it experienced a revival. The old outer circuit of the walls was restored, and many new buildings were erected. Athens at this time was still the cultural capital of the Greek world and a stronghold of paganism. Its schools of philosophy, which retained their ancient names, however different their outlooks may have been, flourished, attracting students from all parts. These included the emperor Julian the Apostate and two Fathers of the Church, Basil and Gregory of Nazianzus. While the schools existed, Athens remained a place of consequence, but when they were closed by the emperor Justinian in AD 529, Athens sank to the level of a small provincial town. Power and wealth had long since moved to Constantinople, the new centre of the Greek world.

THE BYZANTINE AND TURKISH PERIODS

Christianity started early in Athens, with the visit of the Apostle Paul in AD 51 and the conversion of Dionysius the Areopagite, a former archon and member of the Court of the Areopagus that had heard Paul's defense of his teachings. The little Christian community did not flourish, however, and Athens remained a stronghold of older ways. In the 5th and 6th centuries, however, after the formal establishment of Christianity and the abolition of pagan worship, churches began to be built. These were sometimes ancient temples converted to Christian worship; for example, the Parthenon, the Erechtheum, and the temple of Hephaestus (the Theseum). Newly built churches had a basilica plan and a wooden roof, but these now survive only in foundations. In all, some 22 churches of this period are known.

Effects of Christianity on Athens

The 7th to 10th centuries were dark times for Athens. The city is almost never mentioned in the history of the period, and archaeological remains are few. In the 11th and 12th centuries a measure of prosperity returned, and the taste of Athenians then can be gauged by the number of small stone and brick churches surviving, built on the Byzantine cross-in-square plan, such as the Kapnikaréa, and those of St. Theodore and the Holy Apostles.

Athens fell to the crusaders in 1204, remaining in Latin hands for 250 years. The town's outward appearance changed little, except that the Parthenon, now a Roman Catholic not an Orthodox cathedral, received a bell tower.

When the Turks captured Athens in 1456, the Parthenon became a mosque, and its bell tower was turned into a minaret. Other mosques were built in the lower town, but in general the age of gunpowder was to prove disastrous for Athenian architecture, especially on the Acropolis, which was still virtually intact as late as the mid-17th century.

ATHENS AFTER GREEK INDEPENDENCE

Greek insurgents surprised the city in 1821 and captured the Acropolis in 1822; but in 1826 Athens again fell into the hands of the Turks, who bombarded and took the Acropolis in the following year (the Erechtheum suffered greatly, and the monument of Thrasyllus was destroyed). The Turks remained in possession of the Acropolis until 1833, when Athens was chosen as the capital of the new kingdom of Greece. Its subsequent history is that of the kingdom.

In World War I Athens was the scene of the incidents of 1916–17 that led to the deposition of King Constantine by the Allies. It was occupied by German troops during World War II, but the city was spared aerial bombardment.

Atmosphere

The atmosphere that surrounds the Earth consists of a mixture of gases, primarily nitrogen and oxygen. This gaseous envelope, commonly called the air, also contains numerous less abundant gases, water vapour, and minute solid and liquid particles in suspension. Rocket probes and especially the drag encountered by artificial satellites at altitudes of several thousand kilometres have demonstrated that the terrestrial atmosphere extends to a very great distance.

The composition of the atmosphere encodes a great deal of information bearing on its origin. Furthermore, the nature and variations of the minor components reveal extensive interactions between the atmosphere, terrestrial environment, and biota. The development of the atmosphere and such interactions are discussed in the first major section of this article, with particular attention given to the rise of biologically produced molecular oxygen, O_2, as a major component of air.

The atmosphere is considered in terms of layers, or regions, arranged like spherical shells above the surface of the Earth. The chemical and physical properties of these various regions are treated in considerable detail. Such upper atmospheric phenomena as airglow, auroras, and the Van Allen radiation belts are included in the coverage.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 221 and 241.

This article is divided into the following sections:

Development of the Earth's atmosphere

A complete reconstruction of the origin and development of the atmosphere would include details of its size and composition at all times during the 4,500,000,000 years since the formation of the Earth. This goal could not be achieved without knowledge of the pathways and rates of supply and consumption of all atmospheric constituents at all times. Information regarding these processes, however, is incomplete even for the present atmosphere, and there is almost no direct evidence regarding atmospheric constituents and their rates of supply and consumption in the past.

The contrast with related fields of the Earth's history is notable. Fossils and other structural and chemical details of ancient rocks provide information useful to evolutionary biologists and historical geologists, but ancient atmospheres, "mere vapours," have not left such substantial remnants. These vapours are, however, the stuff of stars and the moving force of storms and erosion. Although historians of the atmosphere must rely heavily on inference, the object of their interest has played so important a role in the Earth's history that evidence related to its development, though indirect, is abundant.

CONCEPTS RELATED TO ATMOSPHERIC DEVELOPMENT

The atmosphere as part of the crust. To the Earth scientist, the crust includes not only the top layer of solid material (soil and rocks to a depth of 6–70 kilometres, separated from the underlying mantle by differences in density and by susceptibility to surficial geologic processes) but also the hydrosphere (oceans, surface waters on land, and groundwater beneath the land surface) and the atmosphere. Interactions among these solid, liquid, and gaseous portions of the crust are so frequent and thorough that considering them separately introduces more complexities than it eliminates. As a result, a description of the history of the atmosphere must concern itself with all volatile components of the crust.

Important volatile components

Materials. Volatile compounds as well as elements important in present and past atmospheres or in interactions between the atmosphere, biosphere, and other portions of the crust include the following:

1. Present major components: molecular nitrogen (N_2) and molecular oxygen (O_2)
2. Noble gases: helium (He), neon (Ne), argon (Ar), krypton (Kr), and xenon (Xe)
3. Abundant variable components: water vapour (H_2O) and carbon dioxide (CO_2)
4. Other components: molecular hydrogen (H_2), methane (CH_4), carbon monoxide (CO), ammonia (NH_3), nitrous oxide (N_2O), nitrogen dioxide (NO_2), hydrogen sulfide (H_2S), dimethyl sulfide [$(CH_3)_2S$], sulfur dioxide (SO_2), and hydrogen chloride (HCl).

Some elements appear in multiple form—for example, carbon as carbon dioxide, methane, or dimethyl sulfide. It is useful to consider the occurrence of the elements before focusing on the more specific aspects of atmospheric chemistry (the forms in which the elements are present). One can speak of the Earth's "inventory of volatiles," recognizing that the components of the inventory may be reorganized from time to time, but that it is always composed primarily of the compounds of hydrogen, carbon, nitrogen, and oxygen, along with the noble gases.

Differentiation of sources

Processes. A process that delivers a gas to the atmosphere is termed a source for the gas. Depending on the question under consideration, it can make sense to speak in terms of either an ultimate source, the process that delivered a component of the volatile inventory to the Earth, or an immediate source, the process that sustains the abundance of a component of the present atmosphere. Any process that removes gas either chemically, as in the consumption of oxygen during the process of combustion, or physically, as in the loss of hydrogen to space at the top of the atmosphere, is called a sink.

Throughout the history of the atmosphere, sources and sinks have often been simultaneously present. While one process consumes a particular component, another produces it, and the concentration of that component in the atmosphere will rise or fall depending on the relative strengths of the sources and sinks. If those strengths are balanced (or nearly so), the composition of the atmosphere will not change (or will change only very slowly, perhaps imperceptibly); however, the molecules of the gas in question are passing through the atmosphere and are not permanently resident. The rate of the resulting turnover of molecules in the atmosphere is expressed in terms of the residence time, the average time spent by a molecule in the atmosphere after it leaves a source and before it encounters a sink.

PROCESSES AFFECTING THE COMPOSITION OF THE EARLY ATMOSPHERE

Formation of the solar system from the primordial gas cloud

Ultimate sources. The material from which the solar system formed is often described as a gas cloud or, at a later stage, solar nebula. The cloud was rich in volatiles (termed primordial gases) and must have been the ultimate source of the atoms in the present atmosphere. What is of primary concern, however, is the sequence of events and processes by which the volatiles present in the initial gas cloud were transferred to the Earth's inventory and the efficiency with which this was accomplished.

The formation of the solar system began when one portion of the gas cloud became dense enough due to compression by some external force—a shock wave from the explosion of a nearby supernova, perhaps—to attract gravitationally the material around it. This material "fell" into the region of higher density, making it even denser and attracting other material from still farther away. As gravitational collapse continued, the centre of the cloud became very dense and hot, because the kinetic energy of the incoming material was released as heat. Thermonuclear reactions began at the core of the central object, the Sun.

Capture and retention of primordial gases. Far from the central point, the material in the gas cloud tended to settle to an extensive equatorial plane around the Sun. As the material in this disk cooled, chunks of rock grew and accreted to form the planets. The planets are much less massive than the Sun, but if they grew large enough and if the gases around them were cool enough, they could accumulate an atmosphere from the volatile components of the gas cloud. A partial inventory of that cosmo-chemical stockpile, the starting point for atmospheric development, is shown in the column for the solar system in Table 1. This direct capture is the first of three source mechanisms that can be described.

A planetary atmosphere accumulated in this way would consist of primordial gases, but the relative abundances of the individual components would differ from those in the gas cloud if the gravitational field of the new planet were strong enough to hold some, but not all, of the gases around it. It is convenient to express the strength of a gravitational field in terms of escape velocity, the speed at which any particle (a molecule or spacecraft) must be traveling in order to overcome the force of gravity. For the Earth this velocity is 11.3 kilometres per second (seven miles per second), and it follows that, once the solid material of the Earth had accumulated, gas molecules passing the planet at lower speeds would have been captured and accumulated to form an atmosphere.

The speed at which a gas molecule moves is proportional to $(T/M)^{1/2}$, where T is absolute temperature and M is molecular mass. As will be shown later, the uppermost layers of the present atmosphere are still very hot and might have been much hotter early in the Earth's history. At temperatures below 2,000 kelvins (K), however, molecules of any compound with a molecular weight greater than about 10 will have an average velocity of less than 11.3 kilometres per second. On this basis, it was long thought that the earliest atmosphere of the Earth must have been a mixture of the primordial gases with molecular weights greater than 10. Hydrogen and helium, with molecular weights of 2 and 4, should have been able to escape. Because hydrogen is the most abundant element in the solar system (see Table 1), it is thought that the most abundant forms of the other volatile elements were their compounds with hydrogen. If so, methane, ammonia, and water vapour, together with the noble gas neon, would have been the most abundant volatiles with molecular weights greater than 10 and, thus, the major constituents of the Earth's primordial atmosphere. The atmospheres of the four giant outer planets (Jupiter, Saturn, Uranus, and Neptune) are rich in such components, as well as in molecular hydrogen and, presumably, helium, which those more massive and colder bodies were apparently able to retain.

Possible major components of the Earth's initial atmosphere

Table 1: Abundances of Elements

	solar system*	Earth*	collection efficiency (percent)
H	27,000,000,000	9,500	0.00003
^{4}He	2,200,000,000	0.00005	0.000000000002
C	12,000,000	360	0.003
N	2,500,000	79	0.003
O	20,000,000	3,400,000	17
^{20}Ne	3,300,000	0.000093	0.000000003
Mg	1,100,000	1,100,000	100
S	520,000	98,000	19
^{36}Ar	88,000	0.00018	0.0000002
^{40}Ar	0.55	0.053	—†
Fe	900,000	1,200,000	133
^{84}Kr	26	0.0000036	0.00001

*Abundances indicate how many atoms of each element (or, in the case of the noble gases, isotopes) would accompany 10^6 silicon (Si) atoms. For example, the abundance of nitrogen (N) in the solar system is 2.5 times greater than that of Si, whereas its abundance in the Earth is less than that of Si by a factor of 0.000079. The Table includes the eight most abundant volatile elements, together with others. †See text.

Outgassing of the solid planet. The release of gases during volcanic eruptions is one example of outgassing; releases at submarine hydrothermal vents are another. Although the gas in modern volcanic emanations commonly derives from rocks that have picked up volatiles at the Earth's surface and then have been buried to depths at which high temperatures remobilized the volatile material, a very different situation must have prevailed at the earliest stages of the Earth's history.

The planet accreted from solid particles that formed as the primordial gas cloud cooled. Long before the volatile components of the cloud began to condense to form massive solid phases (*e.g.*, long before water vapour condensed to form ice), their molecules would have coated the surfaces of the solid particles of rocky material that were forming. As these solid particles continued to grow, a portion of the volatiles coating their surfaces would have been trapped and carried thereafter by the particles. If the solids were not remelted by impact as they collected to form the planet, the volatiles they carried would have been incorporated in the solid planet. In this way, even without collecting an enveloping gaseous atmosphere, a newly formed planet could include—as material occluded in its constituent grains—a substantial inventory of volatiles.

At some point in its early history, the Earth became so hot that much of the iron dispersed among the solid particles melted, became mobile, and collected to form the core. Related events led to the formation of rocky layers that were the precursors of the Earth's present-day mantle and crust. As part of this process of differentiation, volatiles present in the particles would have been released through outgassing. The outgassing must have occurred

Planetary differentiation

on a colossal scale if the accreting particles had retained their volatiles right up to the time of differentiation.

An atmosphere created by retention of these outgassing products would derive ultimately from nebular gases. Its chemical composition, however, would be expected to differ in two principal respects from that of an atmosphere formed by the capture of primordial gases: (1) whereas the captured atmosphere would contain all gases that were moving slowly enough (*i.e.,* that were sufficiently cold and/or of sufficient molecular weight) so that it was possible for the planet to retain them gravitationally, the outgassed atmosphere would contain only those gases "sticky" enough to have been significantly retained in the rocky particles from which the planet formed; and (2) methane and ammonia, two presumed components of a captured atmosphere, would probably not be stable under the conditions involved in outgassing. Thus, the noble gases, which would be poorly held by particles, would be of low abundance relative to gases derived from chemically active elements. Further, the principal forms of carbon and nitrogen in an outgassed atmosphere would be carbon monoxide or carbon dioxide together with molecular nitrogen.

Importation. A compromise between the extremes of direct capture and outgassing proposes that the Earth's inventory of volatiles was delivered to the planet late in its accretionary history—possibly after differentiation was nearly complete—by impact of a "last-minute" crop of solid bodies that were very strongly enriched in volatile materials (these were the last substances to condense as the solar nebula cooled). Such bodies might have had compositions similar to those of comets that still can be observed in the solar system. These last-minute condensates may have coated the planet as a surface veneer that yielded gases only when heated during differentiation, or they may have released their volatiles on impact.

Incorporation of volatile-rich solids

Because such bodies would have been relatively small, they would not have been able to retain primordial gases by means of a substantial gravitational field. Their complement of volatiles, retained by cold trapping in ices and on particle surfaces, would be expected to resemble the "sticky" (*i.e.,* polar and reactive) gases occluded by solid particles at earlier stages of cooling of the gas cloud but possibly lost during earlier higher temperature phases of the Earth's accretion.

Sinks. The dominant pathways by which gases are removed from the present atmosphere are discussed below in the section *Biogeochemical cycles.* Apart from those processes, three other sinks merit attention and are described here.

Photochemical reactions. Sunlight can provide the energy required to drive chemical reactions that consume some gases. Due to a rapid and efficient photochemical consumption of CH_4 and NH_3, a methane–ammonia atmosphere, for example, would have a maximum lifetime of about 1,000,000 years. This finding is of interest because it has been suggested that life originated from mixtures of organic compounds synthesized by nonbiological reactions starting from methane and ammonia. Recognition of the short atmospheric lifetimes of these materials poses grave difficulties for such a theory. Water, too, is not stable against sunlight that has not been filtered by overlying layers containing ozone or molecular oxygen, which very strongly absorb much of the Sun's ultraviolet radiation. Water molecules that rise above these layers are degraded to yield, among other products, hydrogen atoms, $H\cdot$.

Escape. Hydrogen and helium, or products like $H\cdot$, tend to have velocities high enough so that they are not bound by the Earth's gravitational field and are lost to space from the top of the atmosphere. The importance of this process extends beyond the very earliest stages of the Earth's history because continuous sources exist for these light gases. Helium is continually lost as it is produced by the decay of radioactive elements in the crust.

A combination of photochemical reactions and the subsequent escape of products can serve as a source for molecular oxygen (O_2), a major component of the modern atmosphere that, because of its reactivity, cannot possibly have derived from any of the other sources so far discussed. In this process, water vapour is broken up by ultraviolet light and the resulting hydrogen is lost from the top of the atmosphere, so that the products of the photochemical reaction cannot recombine. The residual oxygen-containing products then couple to form O_2.

Source of O_2

Solar-wind stripping. The Sun emits not only visible light but also a continuous flow of particles known as the solar wind. Most of these particles are electrically charged and interact only weakly with the atmosphere, because the Earth's magnetic field tends to steer them around the planet. Prior to the formation of the Earth's iron core and consequent development of the geomagnetic field, however, the solar wind must have struck the top layers of the atmosphere with full force. It is postulated that the solar wind was much more intense at that time than it is today and, further, that the young Sun emitted a powerful flux of extreme ultraviolet radiation. In such circumstances, much gas may have been carried away by a kind of atomic sandblasting that may have had a marked effect on the earliest phases of atmospheric development.

Biogeochemical cycles. Interactions with the crust and, in particular, with living things, the biosphere, can strongly affect the composition of the atmosphere. These interactions, which form the most important sources and sinks for atmospheric constituents, are viewed in terms of biogeochemical cycles, the most prominent and central being that of carbon. The carbon cycle, outlined schematically in Figure 1, includes two major sets of processes: biologic and geologic.

Biologic carbon cycle. The biologic processes of photosynthesis and respiration mediate the exchange of carbon between the atmosphere or hydrosphere and the biosphere,

Photosynthesis and respiration

$$CO_2 + 2H_2A \underset{\text{respiration}}{\overset{\text{photosynthesis}}{\rightleftharpoons}} CH_2O + 2A \text{ (or } A_2) + H_2O.$$

In these reactions, CH_2O crudely represents organic material, the biomass of bacteria, plants, or animals; and A represents the "redox partner" for carbon (reduction + oxidation → redox), the element from which electrons are taken during the biosynthesis of organic material and which accepts electrons during respiratory processes. In the present global environment, oxygen is the most prominent redox partner for carbon (*i.e.,* $A = O$ in the above equation), but sulfur (S) also can serve as a redox partner, and modified cycles based on other partners (*e.g.,* hydrogen) are possible. Imbalances in the biologic carbon cycle can change the composition of the atmosphere. For example, if O is the principal redox partner and if photosynthesis exceeds respiration, the amounts of O_2 will increase. The carbon cycle can in this way serve as a source for O_2. The strength of this source is dependent on the degree of imbalance between photosynthesis and respiration.

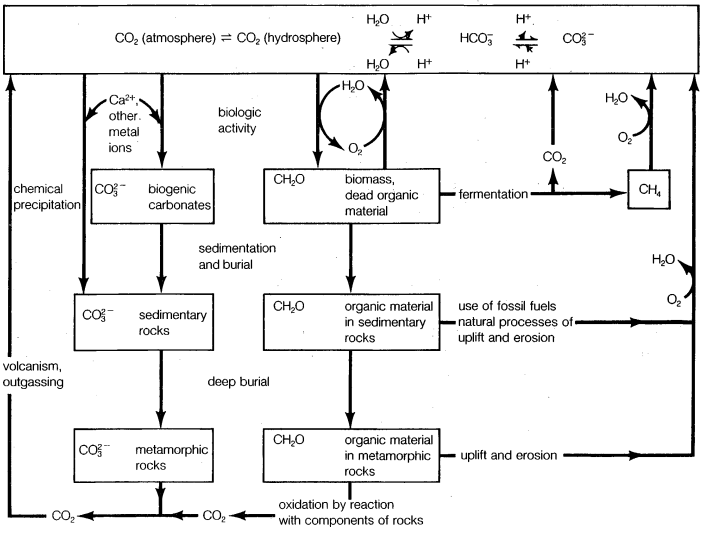

Figure 1: A schematic representation of the biogeochemical cycle of carbon.

The biologic degradation of organic material and the release of products to the atmosphere need not involve an inorganic redox partner such as oxygen or sulfur. Communities of microorganisms found in sediments are capable of carrying out the process of fermentation, in which electrons are shuffled among organic compounds. Many individual steps catalyzed by a variety of organisms are involved, but the overall reaction amounts to

Major source of methane in the atmosphere

$$2CH_2O \rightarrow CO_2 + CH_4.$$

This process is an important source of atmospheric methane.

Geologic carbon cycle. The geologic portions of the carbon cycle can be described most conveniently by following a carbon atom from the moment of its injection into the atmosphere in the form of carbon dioxide released from a volcano. The carbon dioxide—any CO_2 in the atmosphere—will come in contact with water in the environment and is likely to dissolve to form carbonic acid:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3.$$

This weak acid is an important participant in weathering reactions that tend very slowly to dissolve rocks exposed to precipitation and groundwater at the Earth's surface. An exemplary reaction showing the conversion of a solid mineral to soluble products would be

$$CaSiO_3(s) + 2H_2CO_3(aq) \rightarrow Ca^{2+}(aq) + 2HCO_3^-(aq) + H_2SiO_3(aq),$$

where *s* indicates solid and *aq* stands for aqueous solution. Along with the other products of this reaction, the bicarbonate (HCO_3^-) derived from the volcanic CO_2 would eventually be transported to the ocean. At all points in the hydrosphere, the bicarbonate would be in equilibrium with other forms of dissolved CO_2 through chemical reactions that could be depicted as follows:

$$2HCO_3^-(aq) \rightleftharpoons CO_3^{2-}(aq) + H_2O + CO_2(aq).$$

In settings where its concentration was enhanced, carbonate (CO_3^{2-}) produced in this way could unite with the calcium ion Ca^{2+}, which is naturally present in seawater due to weathering reactions, to form solid $CaCO_3$, calcite, the principal mineral in limestone. The dissolved carbon dioxide might return to the atmosphere or remain in the hydrosphere. In either case, it eventually could enter the biologic carbon cycle and be transformed into organic matter. If the $CaCO_3$ and the organic matter sank to the bottom of the ocean, they both would be incorporated in sediments and could eventually become part of the rocky material of the crust. Uplift and erosion, or very deep burial and melting with subsequent volcanic activity, would eventually return the carbon atoms of the $CaCO_3$ and the organic matter to the atmosphere.

Interaction of biologic and geologic cycles. The pace of the biologic carbon cycle is measured in the lifetimes of organisms, while that of the geologic cycle is measured in the lifetimes of sedimentary rocks (which average about 600,000,000 years). Each interacts strongly with the atmosphere, the biologic cycle exchanging CO_2 and redox partners and the geologic cycle supplying CO_2 and removing carbonate minerals and organic matter—the eventual source of fossil fuels (*e.g.*, coal, oil, and natural gas)—in sediments. An understanding of the budgets and pathways of these cycles in the present global environment enables investigators to estimate their effects in the past, when conditions (the extent of evolution of the biota, the composition of the atmosphere, and so on) may have been quite different.

Quantitative significance of the processes of the biogeochemical cycle

The quantitative importance of these processes, now and over geologic time, can be summarized by referring to Table 2. Carbon in the atmosphere as carbon dioxide is almost the smallest reservoir considered in this tabulation, but it is the central point from which processes of the biogeochemical cycle have distributed carbon throughout the Earth's history. Reconstructions of atmospheric development must recognize that the very large quantities of carbon now found in sedimentary carbonates and organic carbon have flowed through the atmosphere and that the organic carbon (which includes all fossil fuels as well as far more abundant, ill-defined organic debris) represents material produced by photosynthesis but not recycled by respiration. The latter process must have been accompanied by the accumulation of the oxidized forms (*e.g.*, molecular oxygen, O_2) of carbon's redox partners.

Table 2: Carbon in the Earth's Crust

form	total amount (Pg* C)
Atmospheric CO_2 (as of 1978)	696
Oceanic CO_2, HCO_3^-, and CO_3^{2-}	34,800
Limestones, other carbonate sediments	64,800,000
Carbonate in metamorphic rocks	2,640,000
Total biomass	594
Organic carbon in ocean water	996
Organic carbon in soils	2,064
Organic carbon in sedimentary rocks	12,000,000
Organic carbon in metamorphic rocks	3,480,000

*One Pg (abbreviation for petagram) equals 10^{15} grams. Entries refer to amounts of carbon.

Table 2 also emphasizes the dissolution of atmospheric gases by the ocean. The carbon dioxide in the atmosphere is in equilibrium with, and far less abundant than, carbon dioxide, bicarbonate ion (HCO_3^-), and carbonate ion (CO_3^{2-}) in the ocean. If all carbon dioxide were somehow suddenly removed from the atmosphere, the ocean would replenish the supply within a few thousand years (the so-called stirring time of the ocean). Likewise, any change in the concentration of CO_2 in the atmosphere is accompanied by a quantitatively far larger change in the amount of CO_2, HCO_3^-, and CO_3^{2-} in the ocean. Similar equilibriums prevail for molecular nitrogen (N_2) and molecular oxygen (O_2). The atmosphere contains about 3,940,000 petagrams (Pg; one petagram equals 10^{15} grams) of nitrogen as N_2, with about 22,000 Pg being dissolved in the ocean. Oxygen is distributed in such a way that 1,200,000 Pg of O_2 are in the atmosphere while 12,390 Pg are in the ocean.

Weathering reactions. No matter what their origins, reactive gases in the atmosphere are likely to interact with other parts of the crust through what are termed weathering reactions. Not just carbonic acid associated with the carbon cycle but any acid becomes involved in acidic dissolution of susceptible rocks. As it does so, its concentration in the atmosphere declines, eventually reaching zero unless some process keeps replenishing the supply.

Even if respiration were suddenly to cease, oxygen produced by photosynthesis, or any oxidant in the atmosphere, would be consumed if oxidizable materials were present. The corrosion of metals is the most familiar example of this process in the modern world, but there are other examples involving natural forms of iron, sulfur, and carbon as well. Much of the iron bound in minerals is in the ferrous form (Fe^{2+}). As this material is exposed by uplift and erosion, it consumes atmospheric oxidants to form ferric iron (Fe^{3+}), the red, fully oxidized form of iron popularly identified as rust. Sulfide minerals (pyrite, or fool's gold, being the most familiar example) also consume oxidants as the sulfur is oxidized to produce sulfate. Finally, natural exposure of sedimentary organic matter, including coal beds or oil seeps, results in the consumption of atmospheric oxidants as the organic carbon is oxidized to produce carbon dioxide.

Oxidation

SEQUENCE OF EVENTS IN THE DEVELOPMENT OF THE ATMOSPHERE

Absence of a captured primordial atmosphere. If the planet grew large (and had, therefore, a substantial gravitational field) before all gases were dispersed from its orbit, it ought to have captured an atmosphere of nebular gases. The size and composition of such an atmosphere would depend on temperature as well as planetary mass. If the solid planet had reached full size and if temperatures were greater than 2,000 K, the minimum molecular weight that could be retained might have been high enough that the very abundant gases with molecular weights between 10 and 20 (methane, ammonia, water, and neon) would have been collected inefficiently, if at all. A thinner primordial atmosphere consisting of nebular gases with higher

molecular weights (*e.g.,* argon and krypton; see Table 1), however, ought still to have been captured.

In spite of this, characteristics of the present atmosphere (see below) show clearly that a primordial atmosphere either never existed or was completely lost. Explanations offered for both of these possibilities are linked to the development of the Sun itself. Astronomical observations of developing stars (*i.e.,* bodies similar to the early Sun) have shown that their early histories are marked by phases during which the gas in their surrounding nebulas is literally blown away by the pressure of light and particles ejected from the stars as they "turn on." (After this initial intense activity, young stars begin life with an energy output significantly below their mid-life maximum.) If the removal of gases occurred in the solar system after involatile solids had condensed but before the inner planets (Mercury, Venus, Earth, and Mars) accreted, it would have been impossible for the Earth to capture a primordial atmosphere. Alternatively, if planetary accretion preceded ejection of gases and the Earth had accumulated a primordial atmosphere, perhaps the early solar radiation, particularly the solar wind, was so intense that it was able to strip all gases from the inner planets, meeting the second condition described above—namely, complete loss.

Secondary atmosphere. The atmosphere that developed after primordial gases had been lost or had failed to accumulate is termed secondary. Although the chemical composition of the atmosphere has changed significantly in the billions of years since its origin, the inventory of volatile elements on which it is based has not.

Evidence for an atmosphere of secondary origin

Origin. The elemental composition of the volatile inventory reveals its secondary origin. Abundances are given in Table 1 for 12 nuclides that can be associated with four groups: (1) chemically active volatiles (H, C, N, O, S), (2) primordial noble gases (^{4}He, ^{20}Ne, ^{36}Ar, ^{84}Kr), (3) elements that form involatile minerals (O, Mg, S, Fe), and (4) a noble gas derived by the radioactive decay of an involatile element (^{40}Ar, derived from potassium). A comparison of entries in Table 1 shows that these groups have been collected by the Earth with sharply varying efficiencies. The column headed "collection efficiency" has been derived by the division of the abundance of each element on Earth by its abundance in the solar system and multiplying by 100. If the collection efficiency is close to 100 percent, the abundances are nearly equal and the transfer of this element from the solar system's initial reservoir to the planet was highly efficient. If the collection efficiency is low, most of the element was lost and is "missing" from the Earth's inventory. It is evident from Table 1 that efficiencies of collection are correlated primarily with chemical characteristics, not mass. This is the pattern expected if volatiles were retained by chemical interactions that yielded involatile phases rather than by gravitational attraction. Collection efficiencies for O, Mg, S, and Fe (which are included here only as representatives of the broad range of elements that were largely bound in involatile solid phases as the solar nebula cooled) are high. Those for the chemically active volatiles that could not form minerals stable at high temperatures (H, C, and N) are much lower. Spectacularly decreased efficiencies of collection are associated with the primordial noble gases.

The evidence points decisively to a process in which the elements to be retained in the terrestrial inventory were separated from those to be lost by a separation of solids from gases. The chemically active volatile elements could be incorporated in solids by formation of nitrides and carbides, by hydration of minerals, and by inclusion in crystal structures (*e.g.,* as ammonium and hydroxide ions) and could form some relatively involatile materials independently (organic compounds with high molecular weights are found in meteorites and were probably abundant in the cooling solar nebula); yet, none of these mechanisms was available to the noble gases. Formation of a group of solids rich in chemically active volatiles but not large enough to retain noble gases, followed by a loss of all materials still in the gas phase and an incorporation of the volatile-rich solids in the Earth, would be consistent with the chemical evidence and with the processes described above as outgassing and importation.

Evidence for outgassing as the primary source of the atmosphere

The special case of ^{40}Ar (Table 1) is particularly indicative of the derivation of the atmosphere through outgassing. Whereas the other noble-gas isotopes noted in Table 1 (^{4}He, ^{20}Ne, ^{36}Ar, ^{84}Kr) are primordial in origin, ^{40}Ar derives primarily from the radioactive decay of the isotope potassium-40. Therefore, even though the solar system abundance of ^{40}Ar is much lower than that of ^{36}Ar, its abundance on Earth is much higher because, uniquely among the noble-gas isotopes listed in Table 1, its source—the rock-forming element potassium (K)—is part of the solid planet. As radioactive potassium in rocks decayed over the Earth's history, the ^{40}Ar produced first became trapped within mineral crystals at sites formerly occupied by K^+, then was released when the crystals were melted in the course of igneous activity, and eventually reached the surface through outgassing. Given the abundance of potassium in the Earth's crust, it would be impossible to attribute the origin of the atmosphere to outgassing if the abundance of ^{40}Ar was far lower than that of ^{36}Ar, as in the solar system.

Early composition. The most critical parameter pertaining to the chemical composition of an atmosphere is its level of oxidation or reduction. At one end of the scale, an atmosphere rich in O_2 (like the present one of the Earth) is termed highly oxidizing, while one containing molecular hydrogen, H_2, is termed reducing. These gases themselves need not be present. Modern volcanic gases are located, for example, toward the oxidized end of the scale. They contain no O_2, but all hydrogen, carbon, and sulfur are present as H_2O, CO_2, and SO_2 (oxidized forms), while nitrogen is present as N_2 (not NH_3). A relationship prevails between the oxidation or reduction of outgassing volatiles and the inorganic material with which they come in contact: any hydrogen, carbon, or sulfur brought into contact with modern crustal rocks at volcanic temperatures will be oxidized by that contact.

The abundance of hydrogen in the solar nebula, the common occurrence of metallic iron in meteorites (representative of primitive solids), and other lines of geochemical evidence all suggest that the Earth's early crust was much less oxidized than its modern counterpart. Although all iron in the modern crust is at least partly oxidized (to Fe^{2+} or Fe^{3+}), metallic iron may have been present in the crust as outgassing began. If the earliest outgassing products were equilibrated with metallic iron, hydrogen would have been released as a mixture of molecular hydrogen and water vapour, carbon as carbon monoxide, and sulfur as hydrogen sulfide. The presence of metallic iron during the last stages of outgassing is, however, unlikely, and, because H_2 is not gravitationally bound, it would have been lost rapidly. At an early point, hydrogen would have been almost completely in the form of water vapour and carbon in the form of carbon dioxide. Nitrogen would have been outgassed along with the carbon and hydrogen. As carbon dioxide was consumed by weathering reactions and water vapour condensed to form the oceans, molecular nitrogen must have become the most abundant gas in the atmosphere. It is certain that molecular oxygen was not among the products of outgassing.

Absence of metallic iron in ancient rocks

Among the oldest rocks are water-laid sediments with an age of 3,800,000,000 years. Neither they nor any other ancient rocks contain metallic iron, though nearly all contain oxidized iron (Fe^{2+}). Carbon is present both as organic material and in a variety of carbonate minerals. The existence of these sediments requires atmospheric pressures and temperatures consistent with the presence of liquid water. The nature of the iron minerals and their abundance suggest that Fe^{2+} was a significant component of ocean water and that concentrations of O_2 had to have been essentially zero because Fe^{2+} reacts very rapidly with O_2.

The presence of organic carbon and carbonate minerals in the sediments dated 3,800,000,000 years old would be consistent with the development of a biologically mediated carbon cycle by that point in time, but the degree of preservation of these materials (which were heated to temperatures near 500° C [932° F] for millions of years at some point in their history) is so poor that the question cannot be settled. Relatively well-preserved sediments with

Rise of a biologically controlled carbon cycle

an age of 3,500,000,000 years are far more abundant. In addition to abundant organic carbon and carbonate minerals, they contain microfossils and sedimentary features demonstrating convincingly that life had arisen on Earth by that time. The distribution of the stable isotopes of carbon (carbon-12 and carbon-13) in sedimentary materials younger than 3,500,000,000 years demonstrates that living organisms were effectively in control of the global carbon cycle from that time onward.

The existence of sedimentary carbonates is direct evidence that carbon dioxide was present in the atmosphere. Its precise abundance is not known, but the best estimates are that it was substantially, perhaps 100 times, higher than the present atmospheric level. A strongly enhanced greenhouse effect (see below *Atmospheric heat budget and energy transfer*), leading to more efficient retention of heat derived from solar radiation, would be expected. For many students of the Earth's history, the fact that the early oceans did not freeze in spite of the dim Sun is evidence that the abundance of atmospheric carbon dioxide was high enough to provide the enhanced greenhouse effect.

Rise of molecular oxygen. Recognition of the nature of the Earth's pre-oxygenic environment is critical to consideration of this problem. If humans could somehow take a spaceflight not to another planet but to the Earth of 3,000,000,000 years ago, they would find that space suits would have been required on their home planet at that time. More dramatically, if those time-traveling astronauts were somehow able to take with them all of the oxygen from the modern atmosphere, they would find that it would disappear soon after release. Not only was oxygen absent in the early atmosphere but potent sinks for O_2 were abundant as well. Oxidizable materials such as ferrous iron, sulfides, and organic compounds littered environments in which they are now absent. These chemicals absorbed O_2 almost immediately after its release. Moreover, as the oxygen-absorbing capacity of such compounds was exhausted, new material that had been eroded from the unoxidized crust took their place. This process continued until the rock cycle (sedimentation, burial, igneous activity, uplift, and erosion) had exposed all oxidizable materials in the crust. No matter what the supply of O_2, the process must have taken time (about half the rock volume of the crust is recycled every 600,000,000 years). It is, therefore, very important to distinguish clearly between the first biologic production of O_2 and its persistent accumulation in the atmosphere. It is conceivable, even likely, that these events were separated by hundreds of millions of years. Evidence bearing on the oxygenation of the Earth's atmosphere is summarized in Figure 2 and discussed in the following sections. The abundance of O_2 at each point is expressed in terms of its approach to the present atmospheric level (PAL). For example, because the pressure of O_2 in the present atmosphere is 0.21 atm (abbreviation for atmosphere, a unit of pressure equal roughly to 14.7 pounds per square inch), a planetary atmosphere containing 10 percent of that amount, 0.021 atm, would be described as having an oxygen level of 0.1 PAL.

Photochemical reactions as a limited source of O_2

Photochemical production. The strength of this source is limited by the requirement that water vapour rise in the atmosphere to altitudes at which solar ultraviolet radiation capable of cleaving water molecules has not yet been absorbed by other atmospheric constituents. The transport of water vapour to high altitudes is severely impeded by a cold layer in the atmosphere. Water vapour freezes in this layer, and the rate of photochemical production of O_2 is thus limited. The severity of this limitation is not precisely known, but it is evident that atmospheric levels of oxygen did not rise until oxygenic photosynthesis was well established. This does not indicate that photochemical production of O_2 was insignificant. Rather, it demonstrates that the strength of the process as a source was exceeded by the strength of the contemporary oxygen sinks (chiefly oxidative weathering reactions at the Earth's surface) and that residence times for O_2 were so short that significant atmospheric concentrations could not accumulate. The best estimate is that pressures of O_2 at sea level and ground level were less than 5×10^{-8} PAL.

Onset of oxygenic photosynthesis. The development of a biologically mediated carbon cycle prior to 3,500,000,000 years ago virtually requires that some form of photosynthesis had arisen by that time, but the possibility remains that sulfur or hydrogen, not oxygen, was serving as the redox partner. It also has been noted that some sediments 3,500,000,000 years in age contain microfossils with shapes resembling those of modern oxygenic photosynthesizers. This is suggestive, though not compelling, evidence that oxygenic photosynthesis had developed by 3,500,000,000 years ago. Shape is an infamously imprecise indicator of biochemical characteristics of microorganisms. More specifically, while it might be possible to recognize a photosynthetic organism from its shape, it is very difficult to determine exactly what redox partners that organism employed.

Geochemical and paleontological features of sedimentary rocks 2,800,000,000 years in age offer stronger evidence

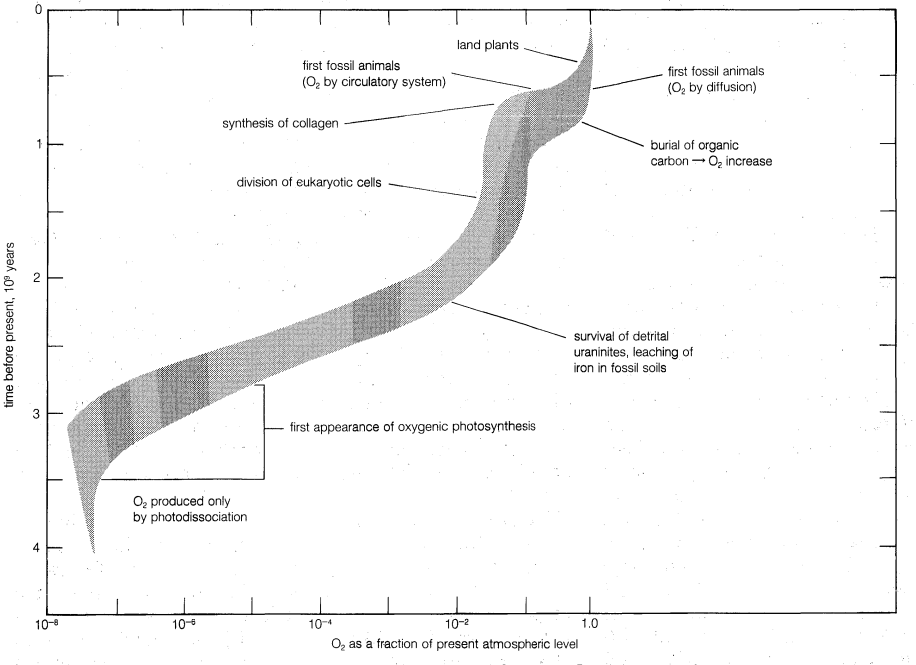

Figure 2: A "best guess" reconstruction of the abundance of O_2 in the Earth's atmosphere as a function of time. The O_2-abundance axis is logarithmic.

that oxygenic photosynthesis had arisen by that time. At 2,800,000,000 years, the abundance of carbon-13 in sedimentary organic carbon decreases sharply from levels maintained between 3,500,000,000 and 2,900,000,000 years ago, then slowly rises, regaining those levels about 2,200,000,000 years ago. This has been interpreted in terms of a transient in the biogeochemical carbon cycle in which biogenic methane (which is strongly depleted in carbon-13) served as an important mobile constituent of the cycle during the interval from 2,800,000,000 to 2,200,000,000 years ago. According to this interpretation, methane was able to play this role only after O_2 became available and facilitated its metabolism. As O_2 sinks decreased in strength and the atmosphere became oxidizing, however, the mobility of methane was reduced and the methane cycle took on its modern form, which seldom leads to strongly decreased abundances of carbon-13 in sedimentary organic matter.

Microfossils resembling modern oxygenic photosynthesizers also appear in sediments of this age, and they are accompanied by sedimentologic features (apparent "fossil gas pockets") that are interpreted as evidence of aerobic metabolism. Thus, evidence dating from about 2,800,000,000 years ago is more abundant and diverse (geochemically, morphologically, and sedimentologically) than that found in rocks 3,500,000,000 years of age. In spite of these points of consistency, this evidence is not decisive.

Evidence from younger sediments (see below) indicates that oxygenic photosynthesis almost certainly developed earlier than 2,200,000,000 years ago. Whatever the precise moment of development, it marked the origin of the first so-called oxygen oasis, a restricted environment in which the abundance of O_2 rose above 5×10^{-8} PAL probably quite significantly. Within such oases, aerobic metabolism could occur. At their margins, the delivery of oxidizable materials from the surrounding global environment overwhelmed the local supply of O_2. Overall, the atmosphere did not become oxidizing, but, as oxygenic photosynthesizers proliferated, the number and size of the oases grew.

Formation of oxygen oases

Transition to an aerobic environment. Pyrite and uraninite are minerals of iron and uranium, respectively, that are not stable in the presence of O_2. Though they can be found in some modern river sediments, neither can survive in them for thousands of years. Yet, many sediments older than about 2,200,000,000 years contain well-rounded grains of these minerals. Their shapes and locations indicate prolonged exposure and tumbling in ancient rivers or as beach deposits, but there is no evidence of chemical attack by oxygen. The precise significance of this observation is best considered together with measurements of the movement of iron in fossil soil profiles.

If soil gases (in equilibrium with the atmosphere) contain O_2, iron exposed during the breakdown of soil minerals will be immobilized by oxidation and will not be leached from near-surface soil horizons. Conversely, if O_2 is absent during soil development, chemical analysis of fossil soils will reveal depletion of iron near the former soil surface. Rates of the dissolution of uraninite and the leaching of iron in soil profiles also depend on the abundance of carbon dioxide (CO_2). Because the patterns of dependence are different, the combination of evidence based on both phenomena allows for the estimation of abundances of both CO_2 and O_2. This line of interpretation leads to the conclusion that about 2,200,000,000 years ago the ratio of the molecular abundance of O_2 to that of CO_2 was about 1.3 (at present it is 635), and that the pressure of O_2 was near 0.01 PAL while that of CO_2 was about nine times higher than at present. Other workers agree that the uraninite and fossil soil data indicate the development of oxidizing conditions at the surface by 2,200,000,000 years ago, but they place the most probable level of O_2 lower by a factor of 10 or more.

The consumption of oxidizing power by the crust is recorded by the inorganic constituents of sedimentary rocks. Iron-bearing sediments, or iron formations, are of particular interest because the collection of substantial quantities of iron in a sedimentary basin requires that iron be mobile in the world ocean. Mobility requires solubility, and, while Fe^{2+} is soluble, Fe^{3+}, the form of iron that results if O_2 comes in contact with Fe^{2+}, is highly insoluble.

Significance of iron-bearing sediments

Three states can be distinguished: (1) The existence of iron formations containing only Fe^{2+} suggests a complete absence of oxygen. (2) The existence of iron formations containing Fe^{2+} and Fe^{3+} indicates that levels of oxygen were low enough—essentially zero in the deep ocean—so that iron was mobile, but it also suggests that O_2 (perhaps at an oxygen oasis) was important in triggering deposition of the iron, though other means of oxidation—photochemical processes, for example—are quite conceivable. (3) The disappearance of iron formations from the sedimentary record suggests persistent oxygenation of the ocean. This sequence of possibilities is represented in the geologic record as follows: (1) The oldest sedimentary rocks are iron formations that contained only Fe^{2+} at the time of their deposition. (2) The first appearance of primary Fe^{3+} (produced during the formation of the rock rather than in later weathering) was in iron formations about 2,700,000,000 years ago. (3) Iron formations disappeared almost completely from the record about 1,700,000,000 years ago (with a few isolated and very small recurrences about 1,000,000,000 years ago). Moreover, the abundance of iron formations increased significantly from 2,700,000,000 to 2,200,000,000 years ago, suggesting that some new factor, possibly oxidative precipitation of Fe^{3+}, was enhancing the rate of deposition. It is for this same time interval that carbon-isotopic evidence indicates the operation of an O_2-dependent methane cycle.

Evidence for the evolution of eukaryotic organisms (those containing a membrane-bound nucleus and other organelles) first appears in the microfossil record of about 1,400,000,000 years ago. Biochemical reactions that occur during the growth and division of such cells require oxygen levels of 0.02 PAL. Attainment of that level by 1,400,000,000 years ago apparently led to oxygenation of the deep sea and the cutoff of deposition of iron formations about 1,700,000,000 years ago.

Attainment of the modern O_2 level. The abundance of carbon-13 in sedimentary organic materials and in carbonates from 900,000,000 to 600,000,000 years ago indicates that unusually large quantities of organic carbon were buried without reoxidation during that interval. The burial of this carbon must have been accompanied by the accumulation of oxidized forms of carbon's redox partners. The quantities released were adequate to raise the level of O_2 to 1.0 PAL or more.

Reconstruction of O_2 levels on the basis of biologic evidence

It has been calculated that oxygen requirements of the earliest animals, which developed about 700,000,000 years ago, would have been met—if the animals had circulatory systems that incorporated oxygen carriers like hemoglobin—by O_2 abundances as low as 0.1 PAL. If circulatory systems had not yet evolved, an O_2 abundance of 1.0 PAL would have been required. Studies of fossils indicate that the animals were very thin (one to six millimetres [0.04–0.24 inch]) in spite of great breadth and length (up to 1,000 millimetres [39 inches]). Such a shape seems optimized for transport of O_2 by diffusion from the surrounding water to the cells in which it was needed, thus pointing to the latter higher value (namely, an O_2 abundance of 1.0 PAL). Other reconstructions of O_2 levels based on biologic evidence suggest that the widespread development of land plants about 400,000,000 years ago must have driven O_2 to levels near 1.0 PAL, and they show O_2 levels rising smoothly from levels near 0.1 PAL at 650,000,000 years ago to 1.0 PAL at 400,000,000 years ago.

Variation in abundance of carbon dioxide. The approximately hundredfold decline of atmospheric CO_2 abundances from 3,500,000,000 years ago to the present has apparently not been monotonous. During that interval, numerous ice ages have come and gone. Significant changes in climate can result from geographic changes, but it is generally concluded that modulation of the efficiency of the Earth's greenhouse effect is also required to produce the extreme variations associated with widespread continental glaciations. In recognition of this, broad climatic variations during the past 750,000,000 years have been described in terms of alternating "icehouse" and "greenhouse" episodes.

Association with extreme climatic changes

Icehouse conditions—apparently associated with the depletion of atmospheric CO_2, the principal greenhouse gas—have prevailed since about 65,000,000 years ago and during two earlier periods, 650,000,000–530,000,000 and 360,000,000–240,000,000 years ago. It is suggested that intervening greenhouse episodes have been associated with higher abundances of CO_2 in the atmosphere. The hypothesis is far from proved. Nonetheless, its details are being explored aggressively amid concerns that the accelerated production of CO_2 due to industrial combustion of fossil fuels may reverse climatic conditions with catastrophic effect. It is feared that such a reversal could result in the melting of the polar ice caps and a consequent flooding of coastal areas (see below *Climate modification*).

(J.M.Ha.)

Structure of the present atmosphere

GENERAL CHARACTERISTICS

The atmosphere extends from the surface of the Earth to heights of thousands of kilometres, where it gradually merges with the solar wind. The composition of the atmosphere as measured by its mean density (the average mass per unit volume) is more or less constant with height to altitudes of about 100 kilometres. This state of approximate uniformity arises as a result of motion and as a consequence of the high frequency with which molecules of a particular species are involved in collisions with their neighbours. A representative oxygen molecule, O_2, for example, encounters a nitrogen molecule, N_2, on average once every 10^{-9} second at the surface. Even at heights of 100 kilometres, where the density of air molecules is much lower, the encounter time is still comparatively brief, about 10^{-3} second. A force imparted to one molecule is rapidly transferred to all.

The atmosphere tends to behave as though it were composed of a single molecular species with an effective molecular mass set by its mean composition. The bulk of the lower atmosphere is composed of N_2 and O_2, with relative abundances of, respectively, 0.78 and 0.21 based on the average number of molecules present in a representative volume of air. The mass of the hypothetical mean molecule of the lower atmosphere is 28.97 atomic units (one atomic unit corresponds to the mass of a hydrogen atom, 1.66×10^{-24} gram). This value is intermediate between that of N_2 (28 atomic units) and that of O_2 (32 atomic units) and reflects the presence in the atmosphere of trace quantities of water (18 atomic units), argon (40 atomic units), carbon dioxide (44 atomic units), and other less abundant compounds as well.

The collisional interaction between individual molecules becomes progressively less efficient at altitudes above 100 kilometres. Molecules begin to experience a force of gravity proportional to their individual molecular masses. Heavy gases are bound more closely to the Earth, whereas lighter gases are free to float higher. The average molecular mass of the atmosphere therefore declines steadily with increasing altitude, as illustrated in Figure 3. Atomic oxygen is more abundant than N_2 above about 160 kilometres. In turn, atomic oxygen gives way to helium above 600 kilometres and hydrogen is the major constituent at altitudes higher than 1,000 kilometres. The region above 100 kilometres is referred to as the heterosphere, a name intended to emphasize the importance of the change in composition as a function of altitude. In the same vein, the region lower than 100 kilometres was given the name homosphere.

Decrease of average molecular mass with increasing altitude

DIVISION BASED ON THERMAL STRUCTURE

A second classification, based on thermal structure, provides a more detailed and, in many respects, more useful scheme for the division of the atmosphere into distinct layers (Figure 4).

The temperature decreases rapidly above the surface of the Earth to an altitude of about 17 kilometres. The air is relatively unstable, a consequence of the decrease of temperature with altitude. Warmer air is comparatively light and has a tendency to rise. Conversely, colder air is dense and tends to sink. The atmosphere is poised to turn over, to convect much like water in a kettle heated from below. This region is known as the troposphere, a term derived from the Greek words *tropos,* "turning," and *sphaira,* "ball." Most of the weather of the planet is confined to the troposphere. The upper boundary of the troposphere is called the tropopause.

Troposphere

The temperature begins to increase slowly with altitude above the tropopause in a region known as the stratosphere, from the Latin word *stratus,* meaning "stretched out" or "layered." Vertical motions are strongly inhibited in the stratosphere. An air parcel that attempts to rise becomes rapidly colder and denser than the air it displaces. Buoyancy forces in this environment act to suppress vertical motion. Motions in the stratosphere are thus largely confined to the horizontal, accounting for the layered structure of high-altitude stratus clouds. The increase of

Stratosphere

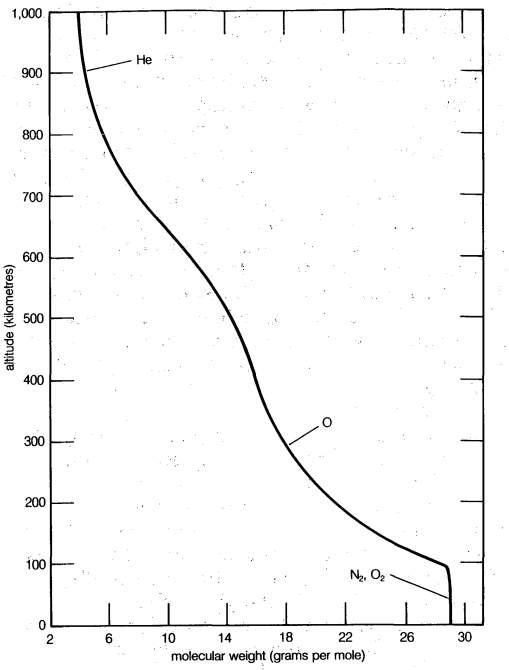

Figure 3: Average molecular mass of the atmosphere in atomic units (one atomic unit corresponds to the mass of a hydrogen atom) illustrating changes in composition with altitude.

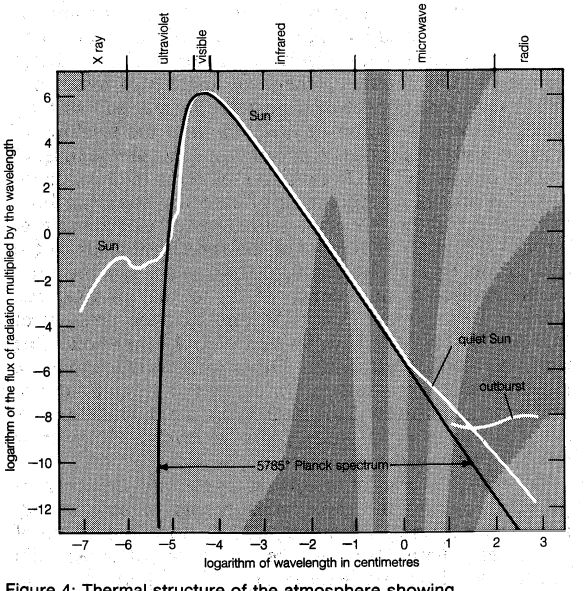

Figure 4: Thermal structure of the atmosphere showing depths of penetration for sunlight of different wavelengths (λ).

temperature with altitude persists to about 50 km, at which point the temperature is about as high as at the surface. This marks the upper boundary of the stratosphere, the stratopause.

The temperature resumes its general decrease with altitude above the stratopause in the mesosphere (*mesos* denoting "middle"). It reaches a minimum near 85 km at the mesopause, which is the coldest region of the atmosphere. The temperature increases again with altitude above the mesopause in the thermosphere, so named because of the importance of thermal conduction in this region. A large portion of the heat deposited in the thermosphere is conducted downward and is radiated out to space from the vicinity of the mesopause.

The thermal structure of the atmosphere reflects in part the influence of energy deposited directly by the absorption of sunlight. It is determined, though, to a much larger extent by a complex suite of processes important to redistributing energy vertically. The Sun is the ultimate source of energy. Approximately 45 percent of the energy incident from the Sun is absorbed by the surface. A comparable amount, about 33 percent, is reflected back to space, either by clouds, 26 percent, or by the surface itself, 7 percent, as shown in Figure 5. The atmosphere absorbs only 22 percent of the incident energy; most of this is captured by dust in the troposphere. The atmosphere is bathed in two more or less distinct radiation fields. The first field, originating in the Sun, has the majority of its energy in the visible and ultraviolet portions of the electromagnetic spectrum. The second, emanating from the surface of the Earth and its lower atmosphere, has most of its energy at longer wavelengths—namely, in the infrared.

The solar spectrum at visible wavelengths is about what would be expected for a blackbody radiating at a temperature of 5,785 K, the temperature of the photosphere from which most of the solar radiation is emitted. (A blackbody is a hypothetical ideal body or surface that absorbs and reemits all radiant energy falling upon it.) Radiation at shorter wavelengths is more intense (see Figure 6). Light at ultraviolet and X-ray wavelengths emanates from the outermost regions of the solar atmosphere, the chromosphere and corona. Temperatures there climb to values above 10^6 K.

Viewed from space, the spectrum of the Earth would be similar to that shown schematically in Figure 7. At longer wavelengths the radiation would be emitted by the atmosphere and surface and derived more or less equally from the dayside and nightside of the planet. At shorter wavelengths the spectrum would be dominated by sunlight reflected by clouds and by the surface on the dayside.

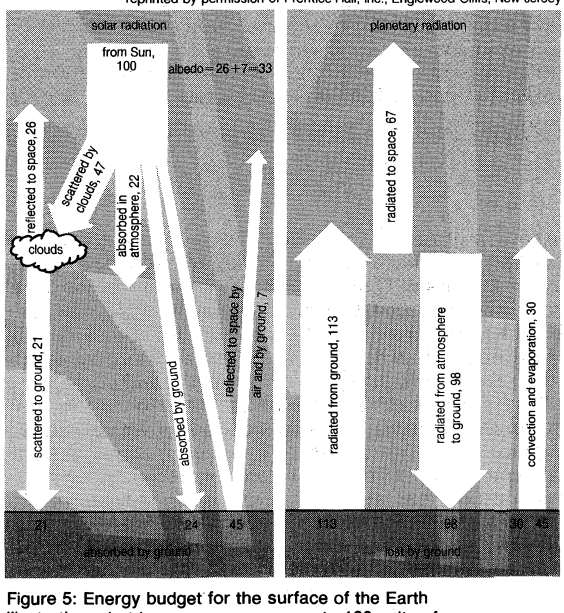

Figure 5: Energy budget for the surface of the Earth illustrating what happens, on average, to 100 units of energy incident from the Sun.

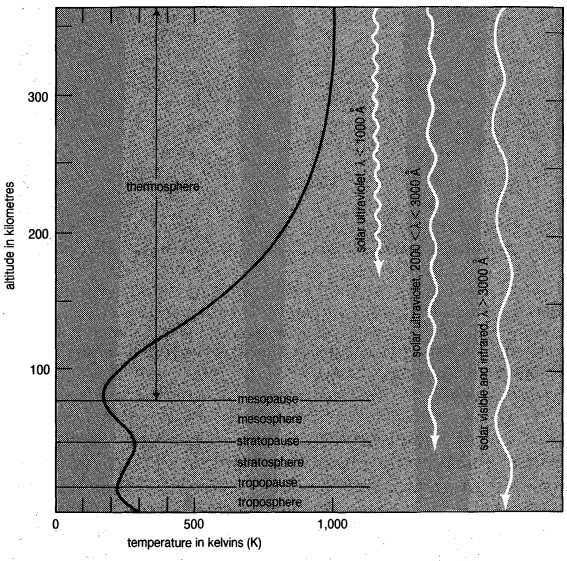

Figure 6: Spectrum of the Sun compared with energy emitted by an ideal blackbody at 5,785 K.

From C.W. Allen, *Quarterly Journal Royal Meteorological Society* (1958)

ATMOSPHERIC HEAT BUDGET AND ENERGY TRANSFER

The overall heat budget of the atmosphere and surface is summarized in Figure 5. The surface, on average, receives 17 percent of its heat directly from the Sun, 15 percent from solar radiation scattered by clouds, and the balance, 68 percent, from absorption of infrared radiation emitted by the atmosphere. The greater part of the energy absorbed by the surface, 79 percent, is returned to the atmosphere in the form of radiation, with spectral properties determined by the local ground temperature. The remainder, 21 percent, is transmitted to the atmosphere by conduction and as a by-product of the exchange of water, H_2O. The surface can cool by evaporation of H_2O, and the associated heat is transmitted to the air as vapour, which recondenses to form clouds and either rain or snow. Phase changes of H_2O play a major role in the energy budget of the lower atmosphere. It is, in fact, the importance of H_2O that sets the Earth apart from all of its neighbours in the solar system.

The atmosphere can be conceived of as a compressible fluid of infinite extent that is heated from below by a moist radiating surface and perturbed locally by energy absorbed from sunlight. Direct absorption of solar radiation is important primarily for the stratosphere and thermosphere. Transfer of energy by infrared radiation is a dominant mode for heat transmission between the different atmospheric layers, with an additional contribution due to motions generated by spatial heterogeneities in heating rates.

Transfer of energy by radiation is effected mainly by trace constituents of the atmosphere, primarily H_2O, CO_2, and O_3. In contrast to the major constituents, N_2 and O_2, these gases are able to absorb the longer wavelengths of the planetary radiation field. They thus assume an importance out of proportion to their abundance. They act to trap heat radiated by the surface, much as the glass panes of a greenhouse do. Like the glass, the atmosphere is transparent to sunlight but is essentially opaque to longer wavelengths. The infrared-active gases return heat to the ground, accounting for about 70 percent of the net input of energy to the surface. If the atmosphere were devoid of water and carbon dioxide, the surface temperature would be about 40 K colder than it is today, and large portions of the planet would be covered by ice.

The so-called greenhouse effect

Since the early 1980s there has been growing concern over the possibility that an increase in the abundance of carbon dioxide caused by combustion of fossil fuels could lead to a general warming of the global climate. Similar effects can arise from increases in the abundances of methane, nitrous oxide, and various chlorofluorocarbons (CFC's) such as CCl_2F_2 and CCl_3F. These species are re-

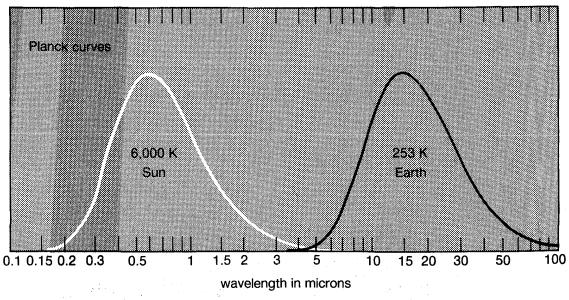

Figure 7: Spectrum of the Earth as viewed from space showing distinction between reflected sunlight and planetary radiation. The Earth is assumed to emit as a blackbody at an average temperature of 253 K.
Royal Meteorological Society

ferred to collectively as the greenhouse gases in recognition of their ability to trap heat. Their importance to climate is explored in greater detail below in *Climate modification.*

The increase of temperature with altitude above the tropopause is due primarily to absorption of solar radiation by ozone, O_3. As noted above, O_3 is a minor constituent of the atmosphere, a product of the interaction of molecular oxygen, O_2, with sunlight. It plays a critical role in the global life-support system, however, absorbing most of the light incident on the Earth in the ultraviolet portion of the spectrum with wavelengths between about 200 and 300 nanometres (one nanometre [nm] equals 10^{-9} metre). The absorption process results in the dissociation of O_3. A portion of the photon energy ($h\nu$) is deposited directly as heat; a larger fraction appears initially as internal excitation of O and O_2. The internal energy is degraded rapidly to heat in the stratosphere by collisions with O_2 and N_2. Finally, the chemical potential energy represented by $O + O_2$ is itself converted to heat as O_3 is reformed by reaction of O with O_2.

ecom-
ination
rocess

The recombination process involves two separate reactions,

$$\begin{aligned} O + O_2 &\rightleftharpoons O_3^* \\ O_3^* + M &\rightarrow O_3 + M, \end{aligned} \qquad (1)$$

where O_3^* denotes an unstable, energetic intermediate form of O_3. The excess energy in O_3^* is removed by collisions with atmospheric molecules M in the second step. The pair of reactions is usually considered as a single reaction,

$$O + O_2 + M \rightarrow O_3 + M. \qquad (2)$$

The rate of recombination, the number of O_3 molecules formed per unit volume per unit time, is proportional to the product of the concentrations of O, O_2, and M. The constant of proportionality, the reaction rate constant, may be determined experimentally in the laboratory.

To an excellent approximation in the stratosphere, it may be assumed that all of the radiative energy absorbed by O_3 is converted locally to heat. The heating rate—and ultimately the course of temperature with altitude—depends on the details of the distribution of O_3 with height.

The inversion of temperature above 80 kilometres, in the thermosphere, is due to energy extracted from sunlight at wavelengths below 200 nanometres. There are several important processes. Between 100 and 200 nanometres, absorption of solar radiation leads to dissociation of O_2,

$$h\nu + O_2 \rightarrow O + O. \qquad (3)$$

At shorter wavelengths, absorption is associated primarily with the ionization of O, O_2, and N_2,

$$\begin{aligned} h\nu + O &\rightarrow O^+ + e \\ h\nu + O_2 &\rightarrow O_2^+ + e \\ h\nu + N_2 &\rightarrow N_2^+ + e. \end{aligned} \qquad (4)$$

(Here, $h\nu$ represents a photon and e is the electron emitted.) Integrated over altitude, dissociation of O_2 is balanced by recombination. Molecular oxygen is reformed, either directly by

$$O + O + M \rightarrow O_2 + M, \qquad (5)$$

or indirectly by reactions such as

$$\begin{aligned} O + O_2 + M &\rightarrow O_3 + M \\ H + O_3 &\rightarrow OH + O_2 \\ O + OH &\rightarrow O_2 + H. \end{aligned} \qquad (6)$$

Sequence (6) is equivalent in effect to reaction (5). It can proceed more rapidly, however, under appropriate conditions in the atmosphere, depending on the efficiency of the step associated with the production of O_3 and the availability of hydrogen, H. The recombination path (5) is said to be catalyzed by the presence of H. As will be seen, catalytic reaction chains play a major role in much of the chemistry of the atmosphere below 80 kilometres.

The path from the absorption of solar energy by reactions (3) and (4) to the ultimate disposal of this energy as heat is less direct for the thermosphere than for the stratosphere. Recombination of O atoms, mainly by reactions (5) and (6), can occur at altitudes quite different from those at which O_2 is dissociated. The lower densities of the thermosphere allow O atoms to diffuse downward, with a compensating upward flow of O_2. Recombination requires relatively high densities and is confined mainly to altitudes below 100 kilometres. Dissociation of O_2, on the other hand, can proceed at any level, limited solely by the supply of O_2 and by the availability of photons with energy sufficient to fragment the bond in O_2. This spatial separation of dissociation and recombination results in a vertical redistribution of energy. Energy absorbed at one level by O_2 is converted to heat at another and is transferred in between in the form of chemical potential energy represented by a downward flow of O. Further, only a fraction of the available chemical potential energy is converted to heat. The balance is released as radiation, contributing to the phenomenon of airglow (see below).

Vertical redistribution of energy

The fate of the energy deposited in (4) is similarly complex. A fraction of the photon energy is imparted initially to the photoelectron (an electron ejected by the action of a single photon). The photoelectron loses energy by collisions, both elastic and inelastic, with atmospheric molecules. It can cause further ionization and contribute to the production of excited states and the associated emission of airglow. Photoelectrons share energy efficiently with ambient electrons. As a consequence, the electron temperature tends to rise above the temperature of the neutral gas. There is a flow of energy from electrons to ions to neutrals. To some extent the thermosphere must be treated as though it were composed of three characteristic thermal reservoirs, each one having its own distinct temperature.

The heating rate depends on a complex suite of atomic and molecular processes and is difficult to evaluate precisely. To further complicate matters, the chemical potential energy represented by the photo-ion can contribute to heating at levels far removed from its original source.

Electrons are removed by dissociative recombination of molecular ions such as the oxygen ion O_2^+ and that of nitric oxide, NO^+:

$$e + O_2^+ \rightarrow O + O \qquad (7)$$

$$e + NO^+ \rightarrow N + O. \qquad (8)$$

A portion of the potential energy is converted to heat in reactions (7) and (8). Some is used to produce excited, radiating states of O and N, and some is stored in excited states and degraded to heat subsequently by collisions. The balance is represented by the atoms N and O and is released only when the atoms recombine at a lower altitude to reform the stable molecules N_2 and O_2.

An atom or molecule of mass m is bound to the Earth by the force of gravity. The work done in moving a vertical distance ΔZ is $mg\ \Delta Z$, where g defines the gravitational acceleration, 9.8 metres per second per second. The work that must be done to escape the gravitational field is mgR, where R is the radius of the Earth—6,400 kilometres. The average kinetic energy of the atom is $(3/2)kT$, where k is the Boltzmann constant, 1.38×10^{-16} erg per degree Kelvin and T is temperature. The atom can escape the gravitational field if kT is much larger than mgR. In practice, escape is impeded by collisions, except at the highest

levels where the density of the atmosphere is low and collisions are comparatively rare.

Scale height

The atmosphere extends to great heights, with density declining by a factor of e (2.72) over an altitude interval given by $(kT)/(mg)$. The quantity $(kT)/(mg)$ is known as the scale height, denoted customarily by H. As noted above, it is proportional to the ratio of thermal kinetic energy to gravitational potential energy and measures the capacity of the atmosphere to support itself thermally in opposition to the confining force of gravity. The scale height is about seven kilometres in the lower atmosphere, rising to values in excess of 50 kilometres in the thermosphere where the mean molecular mass is smaller, reflecting the importance of lighter gases such as oxygen and helium. The scale height provides a useful measure of the vertical extent of the atmosphere: the atmosphere above a height z contains a total mass equivalent to that represented by a hypothetical layer of vertical extent H containing gas with density equal to the density at z.

If the mean distance traveled by an atom or molecule between collisions exceeds H, it can be assumed that the effect of collisions will be relatively unimportant. The average distance between collisions, known as the mean free path and denoted by λ, is given by $\{Qn\}^{-1}$, where Q is the collision cross section, the target area offered by a typical atom or molecule, and n is the number of atoms or molecules (targets) per unit volume. The level at which $\lambda = H$ is defined as the critical level, z_c. Effects of collisions may be ignored for heights greater than z_c. The region above z_c is known as the exosphere. An atom or molecule moving upward through z_c with speed greater than about 11 kilometres per second has kinetic energy in excess of its gravitational potential energy and in the absence of collisions is free to escape from the Earth.

Hydrogen loss

Atoms or molecules of a particular species have a range of speeds determined by their temperature, as described by the Maxwell–Boltzmann distribution law. For temperatures near the critical level, 750–2,000 K, significant numbers of hydrogen atoms have velocities greater than 11 kilometres per second. These atoms readily escape. There is an upward flow of hydrogen at all levels of the atmosphere to supply the flux leaving the Earth. Hydrogen is lost at a rate of about 10^8 atoms per square centimetre per second averaged over the surface of the planet. These escaping hydrogen atoms are derived ultimately from H_2O in the oceans. Integrated over the 4.5×10^9 years of the Earth's history, the escape of hydrogen has removed about two metres depth of H_2O from the surface of the oceans, liberating a quantity of O_2 roughly equivalent to that present in the atmosphere today. The escape of hydrogen is not, however, thought to be the major factor in regulating the level of atmospheric O_2. Burial of organic carbon in sedimentary rocks provides a more immediate source, though the escape of hydrogen may have been important at an earlier stage in the life of the Earth.

Thermal escape, as discussed here, is important mainly for hydrogen. There is, however, also a significant loss of helium. The loss mechanism in this case is believed to involve positively charged helium ions, He^+, formed by photoionization. These ions are thought to be accelerated by electric fields and ejected from the Earth at higher latitudes where magnetic field lines are, on occasion at least, open to space. Helium is a transitory constituent of the atmosphere. It originates in the Earth's crust and is quickly lost to space. Its concentration reflects a dynamic balance between the source from within and loss to the outside.

Composition of the present atmosphere

MAJOR COMPONENTS OF THE LOWER ATMOSPHERE

The atmosphere contains a bewildering array of gases, with relative abundances for important species ranging from 78 percent (N_2) to less than one part in 10^{12} (the hydroxyl radical, OH). The longer lived gases—*e.g.*, N_2 and O_2—are distributed more or less homogeneously around the Earth. The shorter lived species—*e.g.*, carbon monoxide, nitric oxide, and ozone—can vary considerably both in time and space. In many respects, the atmosphere can be considered an extension of the biosphere: almost all of the major constituents, with the exception of the noble gases, are either directly or indirectly under the influence of life.

The lower atmosphere as an extension of the biosphere

There are several natural linkages, as, for example, O_2, CO_2, CH_4, and H_2 (molecular hydrogen). Oxygen is a product of photosynthesis, summarized conveniently by the bulk reaction

$$h\nu + CO_2 + H_2O \rightarrow CH_2O + O_2. \quad (9)$$

The notation is qualitative rather than quantitative. The formula CH_2O denotes any of a variety of organic compounds formed in the primary life-giving photosynthetic event: the stoichiometry is approximately 1:2:1, C:H:O.

Aerobic respiration and decay involve the reverse of reaction (9),

$$CH_2O + O_2 \rightarrow CO_2 + H_2O + \text{energy}. \quad (10)$$

This reaction satisfies the energy needs of the human population and of most of the other higher animals. All life on Earth ultimately depends on the ability of plants to capture solar energy and to store this energy in the form of potential food, CH_2O. It is a two-way street. In the absence of reaction (10), carbon would accumulate in organic form and the fuel for photosynthesis, atmospheric CO_2, would be depleted. Bacteria play a major role in recycling carbon primarily by reactions analogous to (10).

Respiration and decay can proceed even when the supply of O_2 is limited. This can arise, for example, in the sediments of organic-rich swamps and in the stomachs of ruminants. The product of anaerobic decay is methane (CH_4) in this case. Oxidation of carbon may occur photochemically in the atmosphere, initiated by reaction with the OH radical: molecular hydrogen is a product of the oxidation of CH_4 and other hydrocarbons; like CH_4, H_2 is removed from the atmosphere mainly by reaction with OH.

Distribution of carbon, nitrogen, and oxygen compounds. *Carbon compounds.* The bulk of the Earth's volatile carbon resides in sediments, either as organic carbon or as a component of carbonate minerals such as calcite, $CaCO_3$. Carbon is carried to the sediments in detrital material. The fraction lost from the oceans during subsequent burial represents but a small fraction of the total net primary productivity—less than 1 percent.

The life cycle is efficient (see above Figure 1). Carbon atoms are exchanged back and forth between the atmosphere, biosphere, soils, and oceans. Even the sediments provide only a temporary, albeit in human terms long (100,000,000-year), residence for the restive atom. The atom returns to the atmosphere as sediments are uplifted and weathered. The transit time from weathering to eventual return to the sediments is about 100,000 years, most of this spent as a component of the bicarbonate ion, HCO_3^-, in solution in the deep sea.

On time scales of a few hundred years or longer, the abundance of CO_2 in the atmosphere is determined by the dynamics, chemistry, and biology of the oceans. Most of the carbon in the oceans is present in cold, relatively stagnant water at depth. It returns to the atmosphere in association with slow upwelling motion at low latitudes. As surface waters cool and sink at high latitude, they draw carbon from the atmosphere, roughly balancing the source at low latitude. Falling fecal material provides an additional important means for transporting carbon from the surface to the deep.

The dynamics of this complex exchange are just beginning to be understood. It is clear, though, that the level of atmospheric CO_2 is not immutable. Studies of gases trapped in polar ice indicate that CO_2 has fluctuated from about 200 to roughly 280 parts per million (ppm) over the past 100,000 years. Low levels of CO_2 are associated with cold, ice-age conditions at the surface; high values correspond to times when the climate was relatively warm during interglacials. It appears that this behaviour has persisted over at least the past 750,000 years.

It is against this background that assessments must be made of the impact of the recent change in the CO_2 level caused by the burning of fossil fuels. The level of CO_2 has risen since the Industrial Revolution from about 280 ppm in 1850 to approximately 350 ppm today. It is expected to climb to values in excess of 600 ppm by the early part of

the 21st century. This poses a double challenge. Is it possible to predict accurately the effects of an increasing level of CO_2 on climate? If so, can this knowledge be used to influence the course of action over the next few decades? Humankind has developed the ability to change the Earth on a global scale in a single lifetime. Yet, it remains to be seen whether scientific knowledge can develop apace.

Nitrogen compounds. In contrast to carbon, which finds its most stable home in sediments, most of the Earth's nitrogen is in the atmosphere as the relatively inert gas N_2. The N–N bond in N_2 is very strong and is not easily fractured in the atmosphere, except at high altitudes where the molecule is exposed to energetic ultraviolet radiation or at low altitudes where it may be raised to a temperature exceeding 2,000 K near a lightning stroke. The bond can be broken by biologically mediated reactions, however, by photosynthetic blue-green algae or by bacteria functioning in symbiosis with plants of the legume family. Dissociation of N_2 is essential for life: amino groups, represented by NH_2, are indispensable components of living tissue. The N–N bond must be broken before the atom can be incorporated in living organisms. The class of compounds containing odd numbers of N atoms is referred to collectively as fixed nitrogen. When the bond in N_2 is broken, the molecule is said to be fixed.

Fixed nitrogen

Fixed nitrogen occurs in a variety of oxidation states, as shown in Figure 8. Its importance for the biosphere may be attributed in no small measure to this aspect of its chemistry. Oxidation of ammonium, NH_4^+, represented by

$$NH_4^+ + \frac{3}{2}O_2 \rightarrow NO_2^- + H_2O + 2H^+, \quad (11)$$

involves a change in free energy of 51.8 kilocalories at 298 K and one atmosphere. It denotes the first step in the oxidation of nitrogen, primary nitrification, in which nitrogen is transformed from oxidation state −3 to +3. The energy liberated in reaction (11) is utilized by bacteria, *Nitrosomonas* and similar genera, which effect the reaction. A different group of bacteria, *Nitrobacter,* is able to oxidize nitrogen further, from nitrite (NO_2^-) to nitrate (NO_3^-),

$$NO_2^- + \frac{1}{2}O_2 \rightarrow NO_3^-, \quad (12)$$

a process known as secondary nitrification. Reaction (12) involves a release of free energy of 20.1 kilocalories per mole.

Plants can use the ammonium ion, NH_4^+, or NO_2^- or NO_3^- to satisfy their need for fixed nitrogen but generally tend to prefer NH_4^+. Nitrogen in NO_2^- and NO_3^- must be reduced from oxidation state +3 or +5 to −3 before it can be assimilated into living tissue. The reactions—in this case assimilatory reduction—are denoted by

$$NO_2^- + \frac{3}{2}CH_2O + 2H^+ \rightarrow NH_4^+ + \frac{3}{2}CO_2 + \frac{1}{2}H_2O, \quad (13)$$

and

$$NO_3^- + 2CH_2O + 2H^+ \rightarrow NH_4^+ + 2CO_2 + H_2O. \quad (14)$$

The necessary source of energy here is supplied by oxidation of organic matter, represented by CH_2O.

The atmosphere contains 4×10^{15} metric tons of nitrogen in the form of N_2. Approximately 10^8 metric tons are fixed annually by biologic agents, and about the same amount is transformed by various industrial processes associated with the combustion of fossil fuels and the manufacture of chemical fertilizer. In the absence of a source, the atmosphere would lose its reservoir of N_2 in about 2×10^7 years. The gas would be oxidized to NO_3^- and would tend to accumulate in the oceans. This obviously has not happened. There is a return of nitrogen from NO_3^- to N_2 through bacterially mediated denitrification, which is described by the reaction

Denitrification

$$NO_3^- + \frac{5}{4}CH_2O \rightarrow \frac{1}{2}N_2 + \frac{3}{4}H_2O + \frac{5}{4}CO_2 + OH^-. \quad (15)$$

Denitrification proceeds under anaerobic conditions (*i.e.,* in the absence of free oxygen) and provides another example of the splendid efficiency of the global life-support system. Waste for one species is opportunity for another. Reaction (15) is exothermic: it releases energy equivalent to 124 kilocalories per mole. It represents an essential link in the nitrogen cycle, providing a respiratory path for bacteria when O_2 is deficient and serving at the same time to maintain a relatively constant level of atmospheric N_2. The general features of the nitrogen cycle are shown in Figure 9.

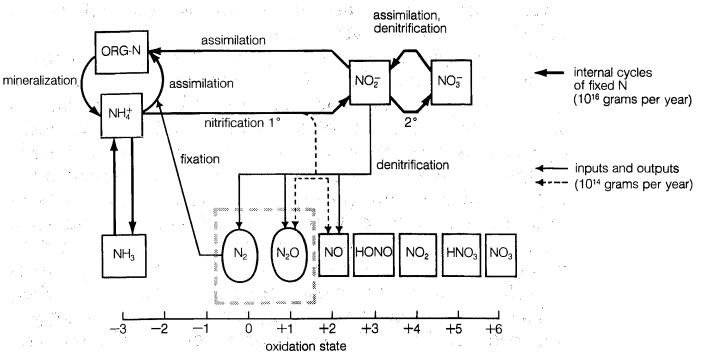

Figure 8: Major paths for oxidation and reduction of nitrogen. The influence of terrestrial life on atmospheric composition is apparent from the biologic transformations of nitrogen shown here.

Nitrous oxide, N_2O, is the second most abundant nitrogen constituent of the atmosphere, as indicated in Table 3. It is formed as a by-product of denitrification, by reduction of NO_3^- and by oxidation of NH_4^+, the first step in nitrification. Additional production of N_2O occurs during fossil fuel combustion. The lifetime of N_2O in the atmosphere is about 150 years; it is removed mainly by photolysis (chemical decomposition by the action of radiant energy) in the stratosphere. Given its relatively short lifetime, as compared with N_2, one might expect N_2O to vary, and indeed there is evidence for a contemporary increase in the concentration of the gas in the atmosphere. This apparent increase is attributed in part to the burning of fossil fuels and in part to the general anthropogenic disturbance of the global nitrogen cycle. The human role in nitrogen fixation is now comparable to that of nature. Other links in the nitrogen cycle might be expected to adjust accordingly. The atmosphere contains various forms of fixed nitrogen besides N_2 and N_2O. As mentioned above, fixed nitrogen is introduced into the air by lightning at a

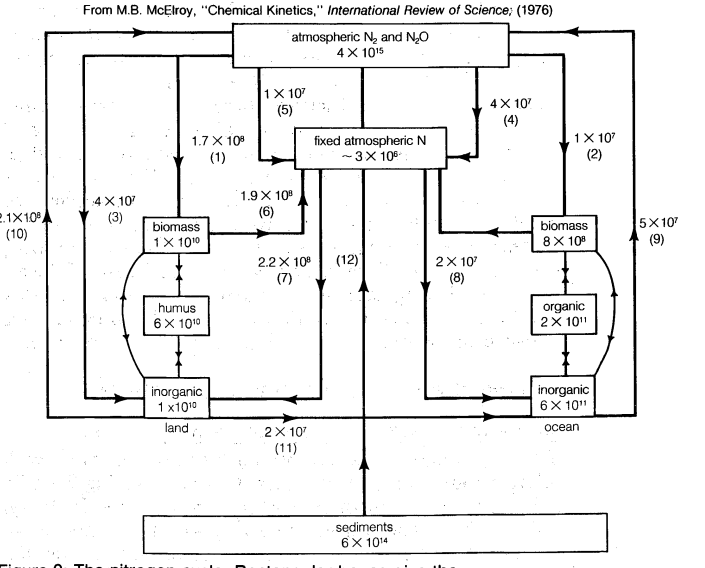

Figure 9: The nitrogen cycle. Rectangular boxes give the major reservoirs, summarizing the approximate contents of nitrogen in units of 10^{15} grams. Exchanges are indicated by lines with arrows. Exchange rates are given in units of 10^6 grams per year.

Table 3: Composition of the Atmosphere

species	relative abundance (parts per billion by volume)	source	comment

*Relatively short lived, with an average lifetime of roughly one month.

rate of about 10^7 tons N yr^{-1} (metric tons of nitrogen per year). It also is released as a product of the combustion of fossil fuels and the burning of biomass. In addition, fixed nitrogen emanates from soil as a result of the microbial oxidation of NH_4^+, and it is formed in the stratosphere by a process involving the reaction of the metastable oxygen atom $O(^1D)$ with N_2O,

$$O(^1D) + N_2O \rightarrow NO + NO. \quad (16)$$

In all cases, the primary source of fixed nitrogen is nitric oxide, NO. About 5×10^7 tons N yr^{-1} of NO are introduced directly into the troposphere, much of this in continental areas, with a particularly large contribution from industrial sources and automobiles and trucks in cities. The stratospheric source is smaller, about 10^6 tons N yr^{-1}.

Reactions in the atmosphere result in a variety of secondary nitrogen species. Important compounds in remote regions include nitrogen dioxide (NO_2), the unstable intermediate nitrogen trioxide (NO_3), dinitrogen pentoxide (N_2O_5), nitrous acid (HNO_2), and nitric acid (HNO_3). Significant, too, is the set of reactive nitrogen compounds, $NO + NO_2 + NO_3 + N_2O_5 + HNO_2 + HNO_3 + NO_2NO_2$, designated NO_x. The subset $NO + NO_2$ plays a particularly important role in the photochemistry of ozone and is identified separately as NO_y.

The compound $CH_3CO.O_2NO_2$, known as peroxyacetyl nitrate, or PAN, is thought to provide an important storage reservoir for NO_x in the unpolluted troposphere. It decomposes thermally in the troposphere, with production of NO_2 and the peroxyacetyl radical, $CH_3CO.O_2$,

$$CH_3CO.O_2NO_2 \rightleftarrows CH_3CO.O_2 + NO_2. \quad (17)$$

Reaction (17) describes an equilibrium, which favours PAN at low temperatures and products at high temperatures. Conditions are such that PAN is relatively stable in the upper troposphere, but it decomposes rapidly in the warm environment near the ground. The compound is believed to form in urban air, a product of the complex set of reactions involved in the oxidation of hydrocarbons. From there, it can be exported via air motions to the upper troposphere, allowing urban air pollution to spread over much wider geographic areas. A typical reaction scheme for the production of PAN is presented in Table 4.

Formation of PAN in urban air

Fixed nitrogen is removed from the atmosphere by solution in rainwater or snow and by deposition on surfaces. The lifetime of NO_x is relatively short—a month or so on average. Investigators have observed considerable temporal and spatial variability in NO_x, with concentrations as high as 100 parts per billion (ppb) in polluted urban environments and as low as 50 parts per trillion (ppt) at remote locations, as, for instance, in the central Pacific. Fixed nitrogen is removed from the atmosphere mainly as HNO_3, contributing to the acidity of precipitation. This matter will be discussed at greater length below in connection with the phenomenon of acid rain.

Table 4: A Scheme for Oxidation of Alkanes Leading to Production of PAN*

$RCH_2 + O_2 \rightarrow RCH_2O_2$	(4.2)
$RCH_2O_2 + NO \rightarrow RCH_2O + NO_2$	(4.3)
$RCH_2O + O_2 \rightarrow RCHO + HO_2$	(4.4)
$OH + RCHO \rightarrow RCO + H_2O$	(4.5)
$RCO + O_2 \rightarrow RCO.O_2$	(4.6)
$RCO.O_2 + NO_2 \rightarrow RCO.O_2.NO_2$	(4.7)

*R denotes a typical methyl radical such as CH_3.

Carbon monoxide. Photochemical processes play a major role not only for NO_x but also for CO. Carbon monoxide is released to the atmosphere as a product of incomplete combustion. It also is formed as an intermediate in the oxidation of hydrocarbons, including methane. Present understanding of the path for decomposition of CH_4 is shown in Figure 10. The hydroxyl radical, OH, is central to this process. Reaction with OH is the first step in the removal of many hydrocarbons, including CH_4. Production of CO by oxidation of CH_4 proceeds at a rate proportional to the concentration of OH, as does the removal of CO, which is effected by the reaction

$$CO + OH \rightarrow CO_2 + H. \quad (18)$$

The radical OH is formed by the reaction of the metastable oxygen atom $O(^1D)$ with H_2O,

$$O(^1D) + H_2O \rightarrow OH + OH, \quad (19)$$

with $O(^1D)$ produced by photolysis of O_3,

$$h\nu + O_3 \rightarrow O(^1D) + O_2. \quad (20)$$

Reactions with CH_4 and CO are the primary paths for removal of OH.

Relationship between increases in carbon monoxide and methane concentrations

This leads to an interesting situation. An increase in carbon monoxide production due to fossil fuel combustion or biomass burning is expected to cause a decrease in OH concentration, with a resulting increase in the lifetime of gases normally removed by reaction with OH. As a consequence, one may expect an increase in CO concentration that is even larger than that due to growth in the magnitude of the source alone, with a related rise in the concentration of CH_4. The increases in the global abundances of CO and CH_4 that have been observed may be attributed, at least in part, to the complexities and nonlinearities of the chemistry affecting the concentration of OH.

Carbon monoxide has a lifetime in the atmosphere of about a month. The concentration in the Northern Hemisphere is larger than in the Southern Hemisphere by about a factor of 2. Surface concentrations at unpolluted sites range from 100 to 200 ppb and vary seasonally, with the highest values in winter when the OH concentration is low. The relative abundance, or mixing ratio, is large near the surface, decreasing aloft in the Northern Hemisphere, with an opposite trend in the south. Mixing ratios of CO in the Southern Hemisphere average about 60 ppb at the surface, climbing to roughly 70 ppb in the upper troposphere. Concentrations in cities reach values as high as one part per million and can pose a problem for public health from time to time.

Suite of sulfur compounds. In addition to the carbon, nitrogen, and oxygen compounds discussed above, the atmosphere contains a suite of sulfur-bearing gases. Like nitrogen, sulfur can occur in a variety of oxidation states. Compounds observed in the atmosphere range from the reduced gases carbonyl sulfide (COS), carbon disulfide (CS_2),

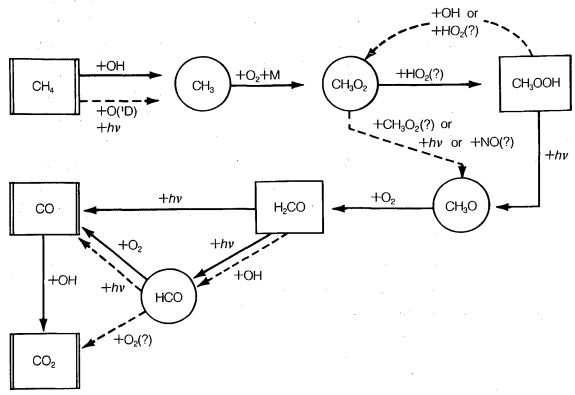

Figure 10: Oxidation path for methane, CH_4.
From M.B. McElroy, "Chemical Kinetics," *International Review of Science*; (1976)

hydrogen sulfide (H_2S), and dimethyl sulfide [$(CH)_2S$], where sulfur is present in the oxidation state +2, to the more oxidized form of sulfur dioxide (SO_2), where sulfur is in the oxidation state +4. The reduced species H_2S and $(CH_3)_2S$ are produced by reactions involving living organisms. Hydrogen sulfide originates mainly from anaerobic environments on land (*e.g.*, swamps and marshes). The ocean is an important source of $(CH_3)_2S$. The origin of COS and CS_2 is less clear; it may include contributions from a variety of sources, both natural and anthropogenic.

Reduced sulfur gases are oxidized at varying rates in the atmosphere and contribute to the global budget of SO_2. The first step in oxidation for most involves reaction with the OH radical. Lifetimes of H_2S and $(CH_3)_2S$ are relatively brief, and the distribution of these species in the atmosphere is correspondingly variable. Carbonyl sulfide is longer lived, and this species is distributed more or less uniformly with latitude, with a mixing ratio of about 500 ppt. The lifetime of carbon disulfide is intermediate; its mixing ratio varies from about 3 to 30 ppt.

Formation of sulfur dioxide

Sulfur dioxide is formed not only by oxidation of reduced gases in the atmosphere but also as a by-product of the combustion of coal and the smelting of ores such as copper. The anthropogenic component is comparable to the natural one on a global scale and is dominant over large areas of the industrially developed Northern Hemisphere. The lifetime of SO_2 is about a week. Sulfur in SO_2 is oxidized rapidly by both homogeneous and heterogeneous reactions and is removed from the atmosphere by precipitation and by dry deposition on surfaces, mainly as sulfuric acid (H_2SO_4) in which sulfur is present with oxidation state +6. The abundance of SO_2 is variable, as would be expected given its relatively short lifetime. On a global basis, the mixing ratio averages about 200 ppt.

Suite of noble gases. Table 3 includes, in addition to the carbon, hydrogen, nitrogen, oxygen, and sulfur species discussed above, a suite of noble gases, with mixing ratios ranging from almost 1 percent in the case of argon to about 1 ppb for xenon. There are two components to the Earth's noble gas inventory. Some of the noble gases are primitive in the sense that the corresponding elements were captured from the solar nebula when the Earth formed some 4,500,000,000 years ago. Others, notably helium-4 and argon-40, are of more recent origin, produced by the radioactive decay of such elements as uranium, thorium, and potassium in the Earth's crust and mantle. Noble gases are released from the interior of the planet at ocean-spreading centres (*i.e.*, the mid-oceanic ridges) when new crust is formed, as well as from volcanoes and hot springs. With the exception of helium, which escapes, the noble gases are inert and accumulate in the atmosphere. Studies of the elemental and isotopic composition of the atmospheric gases, in combination with analogous data for meteorites and other planets, provide valuable clues to the origin and early history of the Earth.

Concentrations of halogenated hydrocarbons. The atmosphere contains a variety of halogenated hydrocarbons as summarized in Table 3. These compounds are for the most part industrial in origin, with the exception of methyl chloride (CH_3Cl) and methyl bromide (CH_3Br), which are produced at least in part by marine organisms. Halogenated hydrocarbons are used as solvents, foam-blowing agents, fire extinguishers, fumigants, refrigerants, and propellants in aerosol spray dispensers. They are among the most ubiquitous products of modern industrial society.

Concentrations of several of the more widely used chlorinated species, CCl_2F_2 (CFC-12, or F-12), CCl_3F (CFC-11, or F-11), $CHClF_2$ (CFC-22), CH_3CCl_3 (methyl chloroform), and $C_2Cl_3F_3$ (CFC-113), have been increasing at compound rates of between 5 and 10 percent over the past several decades. The fully halogenated methanes, CCl_2F_2 and CCl_3F, are exceptionally stable, with lifetimes in the range of 60 to 130 years. They are removed mainly in the stratosphere by photolysis in the ultraviolet. They break down, releasing their constituent chlorine atoms to form reactive radicals, such as Cl and ClO. Chlorine radicals play an important role in the chemistry of stratospheric ozone (see below). There is concern that an increasing burden of stratospheric chlorine could result in a significant global reduction in the column abundance of ozone with an attendant increase in the transmission of ultraviolet solar radiation.

Formation of reactive chlorine radicals

Fluorine is relatively inert in the stratosphere. Atoms of fluorine formed by the decomposition of the halocarbons react with methane to form hydrogen fluoride (HF). In contrast to hydrogen chloride (HCl), which decomposes rapidly by reaction with the OH radical, HF is stable in the stratosphere. The concentration of reactive fluorine radicals is much less than that of chlorine. Consequently, fluorine plays a negligible role in the chemistry of stratospheric ozone.

The abundance of brominated halocarbons is much less than the abundance of the chlorinated species. Hydrogen bromine, however, is less stable than HCl. A relatively large fraction of the bromine in brominated compounds that decompose in the stratosphere ends up in the form of the radicals Br and BrO. It is thought that these species can contribute significantly to removal of ozone. They tend to amplify the effect of chlorine and may become even more significant in the future.

THE ROLE OF PHOTOCHEMISTRY

The preceding section dealt chiefly with gases that enter the atmosphere from below. As explained, the three primary sources for such gases are reactions effected by living organisms excluding man, reactions specifically attributable to human activity, and processes relating to the abiotic metabolism of the Earth. In this section, attention is focused on the role of photochemistry, the synthesis of gases in the atmosphere as a consequence of the interaction with sunlight. Ozone is by far the most important product of the photochemical process.

Ozone as a photochemical product

The bulk of the atmosphere's O_3 is found in the stratosphere at altitudes of about 25 kilometres. It is this reservoir that is primarily responsible for protecting the surface from otherwise harmful rays of ultraviolet sunlight. The abundance of O_3 in the troposphere also is environmentally significant. Direct exposure to high concentrations of O_3 can reduce productivity in plants. It also can have a variety of undesirable effects on public health, causing, for example, respiratory problems.

The processes regulating the abundance of O_3 in the stratosphere and troposphere are quite distinct. In the former case, production of O_3 is initiated by photolysis of O_2; in the latter, the O_2 bond is broken through a complex set of reactions associated with the oxidation of hydrocarbons in the presence of NO_x.

Stratospheric ozone. Studies of O_3 have a long history, dating to about 1930. Early research emphasized the chemistry of a hypothetical pure oxygen system. Four reactions were considered:

$$h\nu + O_2 \rightarrow O + O, \quad (21)$$

$$O + O_2 + M \rightarrow O_3 + M, \quad (22)$$

$$h\nu + O_3 \rightarrow O + O_2, \quad (23)$$

and

$$O + O_3 \rightarrow 2O_2. \quad (24)$$

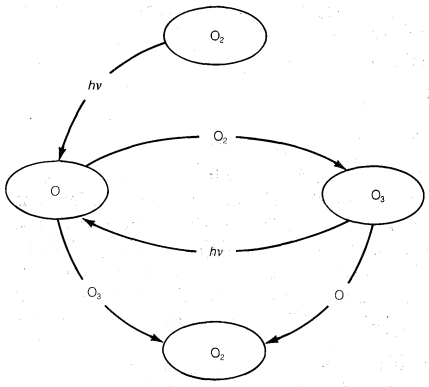

Figure 11: Schematic view of ozone chemistry in a pure oxygen environment.

Reactions (22) and (23) serve to establish the relative abundances of atomic oxygen and ozone. The oxygen atom formed in reaction (21) cycles many times through (22) and (23) before it is eventually removed by (24). It is thus convenient to consider O and O_3 in combination, to think of a family of odd oxygen compounds, $O + O_3$. Reaction (21) is the source of odd oxygen, and reaction (24) is the sink. In equilibrium, source and sink must balance. This simple scheme is illustrated in Figure 11.

Family of odd oxygen compounds

The concentration of O is controlled by reactions (22) and (23) at all levels below about 70 kilometres. Thus,

$$[O] = \frac{J_{23}[O_3]}{k_{22}[O_2][M]}. \tag{25}$$

Balancing (21) and (24), using (25), gives

$$[O_3] = \frac{J_{21}^{1/2} k_{22}^{1/2} f_{O_2} [M]^{3/2}}{k_{24}^{1/2} J_{23}^{1/2}}, \tag{26}$$

where J and k denote rate constants for (21)–(24) with the subscripts identifying the relevant reactions; f_{O_2} is the mixing ratio for O_2, $[O_2] = f_{O_2}[M]$. (Concentration is signified by the bracketing of symbols.)

The essential features of the photochemistry of stratospheric O_3 are summarized by reaction (26). The rate for photolysis of O_2, J_{21}, is vanishingly small at low altitude: photons with sufficient energy to dissociate O_2 are absorbed by O_2 and O_3 above 25 kilometres. Rate constants are more or less invariant with height at high altitude, and the abundance of O_3 decreases accordingly with altitude, as $[M]^{3/2}$ at high elevation. The concentration of O_3 is small at low altitude, limited by the small and declining value of J_{21}. It follows that O_3 must assume a maximum value at some intermediate level. In practice, the maximum is observed at a height of about 25 kilometres. Height variations of J_{21}, J_{23}, [M], [O], and [O_3] are shown schematically in Figure 12.

Much of the complexity of stratospheric chemistry, and indeed much of its recent history, is concerned with working out the paths for removal of odd oxygen besides reaction (24). For example, the pair of reactions

$$NO + O_3 \rightarrow NO_2 + O_2 \tag{27}$$
$$NO_2 + O \rightarrow NO + O_2 \tag{28}$$

have a net effect equivalent to (24). In the presence of nitric oxide, NO, the rate for (24) is faster than would be otherwise the case; in short, reaction (24) is catalyzed by NO. Similarly, (24) can be catalyzed by chlorine, Cl,

$$Cl + O_3 \rightarrow ClO + O_2 \tag{29}$$
$$ClO + O \rightarrow Cl + O_2, \tag{30}$$

by bromine, Br,

$$Br + O_3 \rightarrow BrO + O_2 \tag{31}$$
$$BrO + O \rightarrow Br + O_2, \tag{32}$$

or by the hydroxyl radical, OH,

$$OH + O_3 \rightarrow HO_2 + O_2 \tag{33}$$
$$HO_2 + O \rightarrow OH + O_2. \tag{34}$$

Catalytic paths occur for which there is no direct reaction analogue. The sequence

$$OH + O_3 \rightarrow HO_2 + O_2 \tag{35}$$
$$HO_2 + O_3 \rightarrow OH + O_2 + O_2 \tag{36}$$

is equivalent to

$$O_3 + O_3 \rightarrow 3O_2, \tag{37}$$

as is

$$Cl + O_3 \rightarrow ClO + O_2 \tag{38}$$
$$Br + O_3 \rightarrow BrO + O_2 \tag{39}$$
$$ClO + BrO \rightarrow Cl + Br + O_2. \tag{40}$$

The rate constant for (37) is vanishingly small, and this reaction has a negligible effect on stratospheric ozone. The catalytic paths, (35) + (36) in particular, can be important, however, and provide additional means for the removal of odd oxygen, especially at low altitude where the abundance of atomic oxygen is small.

It is convenient to extend the definition of odd oxygen to include NO_2, ClO, BrO, and HO_2 (hydroperoxyl). The catalog of sinks for odd oxygen expands then to encompass reactions (28), (30), (32), (34), and (40). Note that each of these loss reactions is responsible for the removal of two compounds of odd oxygen. Similarly, (21), the only source reaction, is responsible for two odd oxygen products.

Significance of the odd oxygen concept

The concept of odd oxygen is useful in that it provides a systematic scheme for classifying the several hundred reactions involved in a comprehensive model of stratospheric O_3. Only a few of these reactions are directly implicated in the removal of O_3. The balance is important mainly in regulating the levels of NO_2, ClO, BrO, and HO_2.

It is useful to associate these compounds with specialized families in addition to odd oxygen. The choice of association is to some extent arbitrary. The family of NO_x compounds mentioned earlier provides a natural link for NO_2. In similar fashion, ClO is identified with Cl_x, $Cl + ClO + ClNO_3 + HOCl + HCl$; BrO with Br_x, $Br + BrO + BrNO_3 + HBr$; and HO_2 with HO_x, $OH + HO_2 + H_2O_2$. It is important to note that a particular compound may belong to more than one family.

Reaction of the metastable oxygen atom $O(^1D)$ with nitrous oxide, N_2O,

$$O(^1D) + N_2O \rightarrow NO + NO, \tag{41}$$

is the primary source of stratospheric NO_x. Decomposition of the halocarbons provides the dominant source of Cl_x and Br_x, while reaction

$$O(^1D) + H_2O \rightarrow OH + OH \tag{42}$$

is the most important source of HO_x. Transport to the troposphere is the major means for removal of NO_x, Cl_x, and Br_x from the stratosphere. HO_x is removed in situ by

$$OH + HO_2 \rightarrow H_2O + O_2 \tag{43}$$

and by

$$OH + HNO_3 \rightarrow H_2O + NO_3. \tag{44}$$

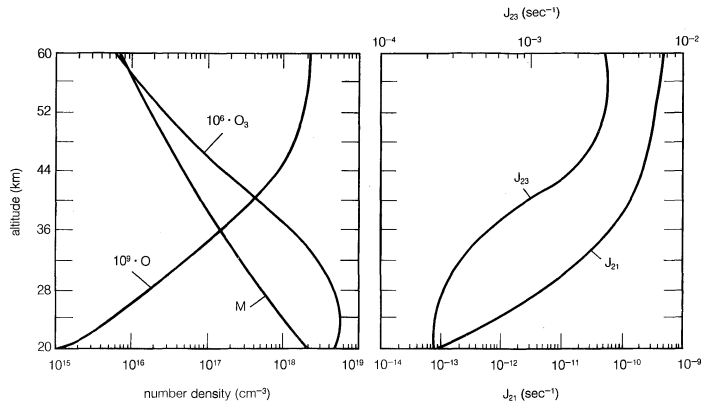

Figure 12: Height profiles for O_3, O, and M illustrating important terms in the equation for O_3, equation (26).

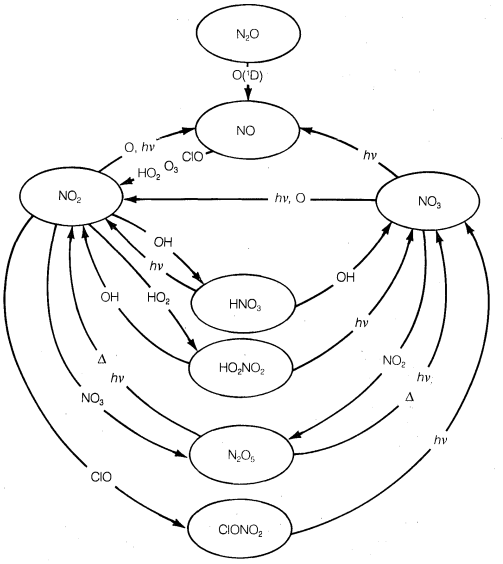

Figure 13: Transformations of nitrogen compounds in the atmosphere.

From *Atmospheric Ozone 1985*, World Meteorological Organization, Report No. 16, (1986), by courtesy of the National Aeronautics and Space Administration

Sources, sinks, and interchange mechanisms are illustrated schematically for NO_x, Cl_x, Br_x, and HO_x in Figures 13–16.

The distribution of O_3 with altitude and latitude is determined not only by chemistry but also by transport. The lifetime of odd oxygen, mainly O_3, is short at high altitude and low latitude where the abundance of atomic oxygen is relatively high. Chemistry is the dominant control in this case. The influence of transport is important at low altitude and high latitude; O_3 tends to accumulate in these regions where it is protected from chemical loss. This accounts for the gross features of the latitudinal distribution displayed in Figure 17. There is a net flow of O_3 from the stratosphere to the troposphere, where it is removed heterogeneously at the surface by gas phase reaction with HO_2.

Tropospheric ozone. Tropospheric O_3 is supplied either by in situ oxidation of hydrocarbons and CO or by downward transport from the stratosphere. The path for production due to oxidation of CO is particularly simple and may be summarized as follows:

$$CO + OH \rightarrow CO_2 + H, \quad (45)$$

$$H + O_2 + M \rightarrow HO_2 + M, \quad (46)$$

$$HO_2 + NO \rightarrow OH + NO_2, \quad (47)$$

$$h\nu + NO_2 \rightarrow NO + O, \quad (48)$$

and

$$O + O_2 + M \rightarrow O_3 + M. \quad (49)$$

Reactions (45)–(49) are equivalent to the bulk reaction

$$CO + 2O_2 \rightarrow CO_2 + O_3. \quad (50)$$

From *Atmospheric Ozone 1985*, World Meteorological Organization, Report No. 16, (1986), by courtesy of the National Aeronautics and Space Administration

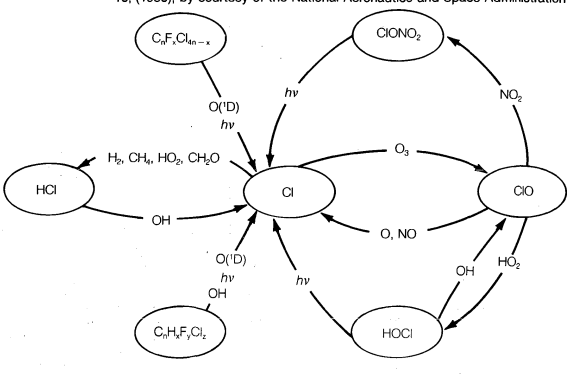

Figure 14: Transformations of chlorine compounds in the atmosphere.

An alternate path for oxidation of CO involves reactions (45) and (46) followed by

$$HO_2 + O_3 \rightarrow OH + 2O_2. \quad (51)$$

The bulk reaction in this case is

$$CO + O_3 \rightarrow CO_2 + O_2. \quad (52)$$

In the first path O_3 is produced, while in the second it is consumed. The choice of oxidation scheme depends on the relative abundance of NO (nitric oxide) and O_3, on the relative importance of reactions (47) and (51). Production of O_3 is favoured if the abundance of NO is high; loss is predominant if NO is low. Similar bifurcation occurs in the oxidation of CH_4 and other more complex hydrocarbons.

The chemistry of tropospheric O_3 is in general less well understood than the chemistry of stratospheric O_3, because the troposphere is intrinsically more complex than the stratosphere. Distributions of NO_x and hydrocarbons are quite inhomogeneous and, as yet, not well defined. Ozone can be produced in one region and consumed in another. In any case, further research is required to understand better the intricacies of tropospheric chemistry.

EFFECTS OF HUMAN ACTIVITY ON ATMOSPHERIC COMPOSITION AND THEIR RAMIFICATIONS

Change has been a fact of life for the Earth for most of its history. Changes in the past have been both fast and slow, regular and episodic, driven by factors internal to the planet and by forces from without. The evolution of an oxygen-mediating enzyme altered the composition of

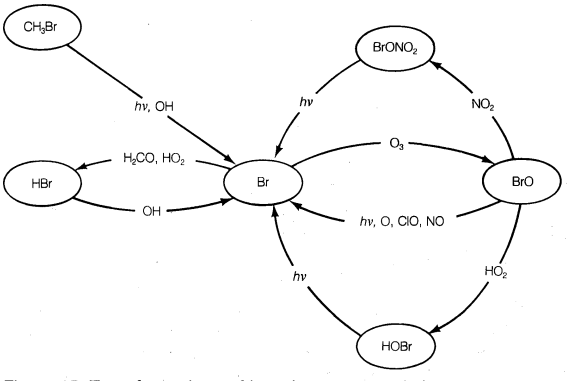

Figure 15: Transformations of bromine compounds in the atmosphere.

the atmosphere irreversibly some 2,000,000,000 years ago, allowing free oxygen to accumulate and thereby changing the nature of the biota for all subsequent time. The impact of a large asteroid (or possibly a comet), it is thought, led to the demise of the dinosaurs and a variety of other species at the end of the Cretaceous Period (from about 136,000,000 to 65,000,000 years ago). Climate has adjusted throughout geologic time to the changing position of the continents driven by the slow motion of giant lithospheric plates, rigid blocks of the Earth's surface rocks (see PLATE TECTONICS). Ice sheets have waxed and waned with regularity in response to the changing orbit and rotation axis of the Earth, and, as noted above, there have been associated changes in the carbon dioxide level of the atmosphere. What sets the present era apart, however, is the unique importance of a single species, man. Since about the mid-19th century, humankind has developed the capacity to harness the powers of nature, to mine the reserves of organic carbon laid down in sediments over millions of years. It has used this abundant source of energy to alter its way of life, with effects, for the most part inadvertent though undoubtedly large, for the global environment. Some of those effects associated with the atmosphere are considered here.

Climate modification. Trace gases, carbon dioxide and water vapour in particular, play an essential role in terrestrial climate. In the absence of these molecules that absorb strongly in the infrared, the surface temperature would be about 40 K colder than it is today. The oceans would be

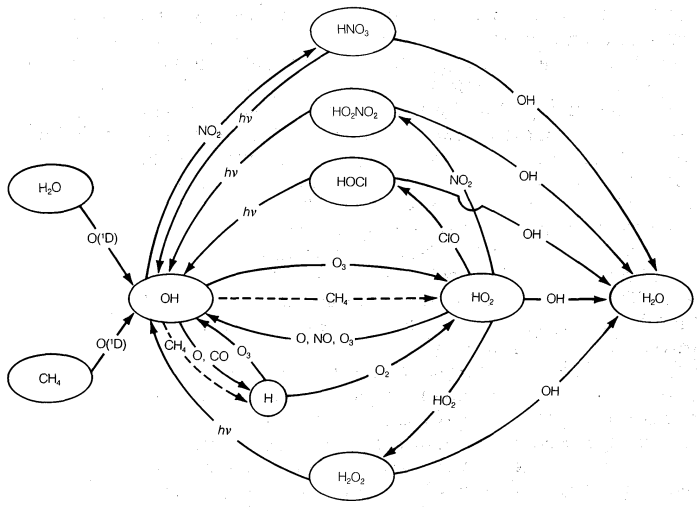

Figure 16: Transformations of hydrogen compounds in the atmosphere.

From *Atmospheric Ozone 1985*, World Meteorological Organization, Report No. 16, (1986), by courtesy of the National Aeronautics and Space Administration

frozen over, and life as we know it would be impossible. There is an important synergism between CO_2 and H_2O. Carbon dioxide itself absorbs only a small fraction of the heat radiated by the Earth's surface. Water vapour is much more significant. The abundance of H_2O, however, is controlled ultimately by temperature. An increase in CO_2 may be expected to cause an increase in temperature, which allows more water vapour to enter the atmosphere and leads to a further increase in temperature.

It has been suggested that the climate of the Earth could be ultimately unstable. Addition of gases capable of trapping heat could accelerate the release of H_2O and raise the temperature to a point where the oceans would evaporate, transforming the atmosphere into a hot steamy vapour. The surface pressure of the atmosphere would then be about 1,000 times higher than it is today, and its dominant constituent would be H_2O. Some believe that such changes may have occurred on Venus, with H_2O subsequently escaping from the top of its atmosphere. In any event, contemporary Venus is a striking example of the importance of the greenhouse effect. Its atmosphere contains a large concentration of CO_2, almost 10^6 times more than that of the Earth. Moreover, the Venusian surface temperature is much hotter than the Earth's—about 780 K—in spite of the fact that Venus absorbs less energy from the Sun because of its ubiquitous cloud cover and associated high albedo.

Increase in CO_2 concentration

The concentration of CO_2 in the Earth's atmosphere has risen steadily over the past 140 or so years, from about 280 parts per million in 1850 to about 350 parts per million. The change is due largely to the combustion of fossil fuels. Since the Industrial Revolution, nearly 1.5×10^{11} metric tons of organic carbon have been mined and consumed in the form of coal, oil, and natural gas. Carbon dioxide is the largest single waste product of modern society. The average person is responsible for the release of almost four tons of CO_2 each year; the amount is even larger in the developed countries. The total global emission in 1985 was close to 5×10^9 metric tons of C.

Approximately half of the carbon emitted since the Industrial Revolution persists in the atmosphere today. The balance is presumed to have made its way into the oceans or to have been incorporated into organic matter on land. Uptake of CO_2 by the oceans is limited by the supply of carbonate ions, CO_3^{2-}, in surface waters. The bulk reaction is

$$CO_2 + CO_3^{2-} + H_2O \rightarrow 2HCO_3^-. \quad (53)$$

Carbon dioxide is a weak acid, and inclusion of CO_2 in the oceans leads to a reduction in pH, transforming carbon from CO_3^{2-} to bicarbonate ions, HCO_3^-, and dissolved neutral carbon. There is a limit, however, to this switching. The total negative charge carried by dissolved carbon compounds is fixed by the alkalinity of the ocean waters:

$$[\text{Alk}] = [HCO_3^-] + 2[CO_3^{2-}]. \quad (54)$$

Alkalinity can be altered only by the addition of salts, which are supplied, for example, by the dissolution of calcite, $CaCO_3$, in sediments. The CO_3^{2-} content of waters at the ocean surface is small, and sustained uptake of CO_2 requires that CO_3^{2-} be supplied continuously to the surface. Over a 100-year period about 10 percent of the water in the oceans is exposed at the surface. If such is the case, only 30 percent of the carbon dioxide released to the atmosphere by burning fossil fuels can be incorporated into the sea.

A continuing rise in carbon dioxide is inevitable. If current estimates for the reserve of fossil fuels—about 4×10^{12} metric tons of carbon—are considered, and if it is assumed that half of this reserve is used up over the next 100 years, the level of CO_2 could exceed 1,000 parts per million. If one assumes more conservatively that the consumption of fossil fuels will double over the next 100 years, CO_2 may be expected to grow to about 600 parts per million—approximately twice the value in 1850.

Impact of other gases on the climate

Carbon dioxide is not the only gas with the ability to affect climate. The trace gases F-11, F-12, methane, and nitrous oxide are even more potent on a molecule-per-molecule basis. It has been estimated that a molecule of F-11 or F-12, for example, can produce warming equivalent to that caused by 10^4 molecules of CO_2. Perturbations to stratospheric ozone and tropospheric ozone also can have a significant impact. In short, a comprehensive theory of climate change must allow for all of these various changes in atmospheric composition.

Most assessments of climatic change are based on simple, one-dimensional energy-balance models. These models, it is hoped, will provide an estimate for the globally averaged change in surface temperature. Studies suggest that the rise in carbon dioxide since 1850 should have resulted in an increase in the contemporary surface temperature of about 0.4° C. The trace gases F-11, F-12, methane, nitrous oxide, ozone, and stratospheric water vapour are estimated to have added to heating by CO_2 an increment equivalent of an additional 0.16° C, for a net change of 0.56° C. A change of this magnitude is generally consistent with observation, as shown in Figure 18.

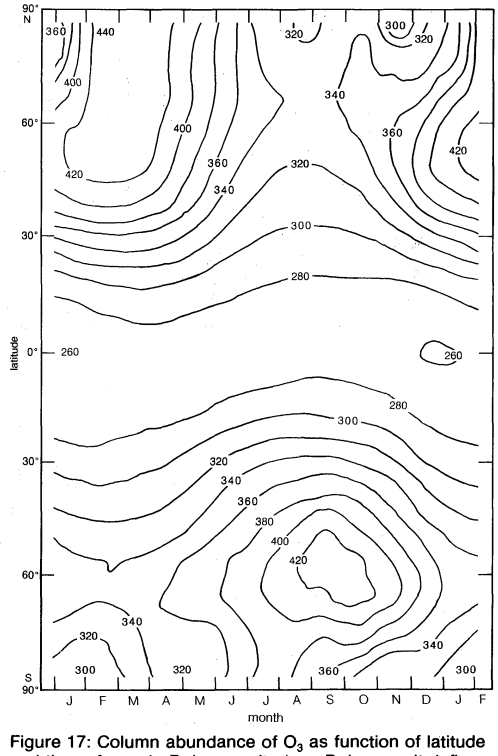

Figure 17: Column abundance of O_3 as function of latitude and time of year in Dobson units (one Dobson unit defines the content of O_3 in a column of one-millimetre length at standard air pressure and temperature).

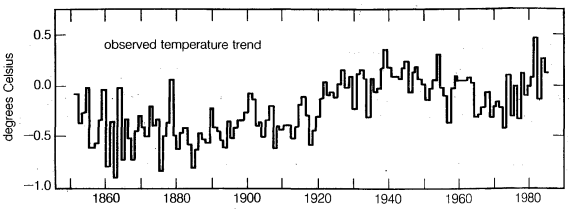

Figure 18: Change in global mean temperature since 1850.
From *Atmospheric Ozone 1985*, World Meteorological Organization, Report No. 16, (1986), by courtesy of the National Aeronautics and Space Administration

The effects of trace gases are expected to grow relative to CO_2 in the years ahead. Results from one particular simulation are given in Figure 19. In this case, CO_2 was predicted to cause an increase in surface temperature of about 0.9° C by the year 2030. With other trace gases included, it was estimated that the temperature increase could be as large as 2.2° C. A change of this magnitude would be unprecedented in recent Earth history.

A prediction of an increase in global mean temperature, whatever its magnitude, has at best limited use for government policymakers. Scientific concern is more with the geographic and temporal distribution of the change. Will it rain more or less, and when? How will the change in climate affect food production? What changes are to be expected in the location of deserts, forests, grasslands, and agricultural zones? Benefits may be expected for some and problems for others. Comprehensive assessment requires a model incorporating all of the important feedbacks between the atmosphere, oceans, and biosphere, with spatial resolution sufficient to distinguish at least the major biomes. Such a model is as yet unavailable, though efforts to develop it are under way. Preliminary studies with three-dimensional models similar to those used for predicting weather suggest that climatic zones can be expected to shift to higher latitudes on a warmer Earth. Further work is required, however, before models of this kind can be used with confidence for quantitative planning.

Depletion of stratospheric ozone. The importance of stratospheric O_3 has been recognized in a general way for almost 50 years. In the absence of O_3, the surface of the Earth would be exposed to lethal ultraviolet radiation with wavelengths as short as 240 nanometres. It was only in 1970, however, that scientists began to focus on the fact that even small changes in O_3 can have a significant impact on humans. Investigators observed that migration of people to lower latitudes—the shift in population from the northeastern part of the United States to the Sun Belt (roughly the southern and southwestern regions of the country), for example—was accompanied by an alarming rise in the incidence of skin cancer. Not all of this increase could be attributed to enhanced sunlight. There appeared to be an underlying factor to the smaller abundance of O_3 at lower latitudes and the associated increase in exposure of fair-skinned people to solar radiation with wavelengths near 300 nanometres. Epidemiological studies suggested that the incidence of skin cancer would rise by about $3x$ percent for every x percent decrease in the column density of O_3. This led to inevitable questions concerning the stability of O_3 as the human influence began to extend upward through the tropopause to the stratosphere.

Shield against shortwave ultraviolet solar radiation

It has long been known that the stratosphere turns over very slowly. Debris from the testing of nuclear bombs in the late 1950s and early 1960s was readily detectable a decade later. Plans were under way in the early 1970s to develop a commercial fleet of supersonic aircraft. These planes were projected to cruise at altitudes of about 20 kilometres. It seemed inevitable that gases from their exhaust would accumulate in the stratosphere, and nitric oxide became a particular concern. It was suggested that nitric oxide from a fleet of 500 supersonic aircraft could lead to a reduction in ozone abundance by as much as 3 percent. This led to a major research program coordinated by the U.S. Department of Transportation, and results from the program played an instrumental role in the decision by the federal government to suspend funds for the development of the large supersonic transport (SST). The British and French, however, continued their work on a smaller version of a supersonic transport, the Concorde, which was eventually introduced for limited service from Europe to North America and the Middle East. Flying at a lower altitude than the SST would have and releasing smaller quantities of nitric oxide, the Concorde has had a negligible effect on stratospheric ozone. It remains as a reminder of a vitriolic debate that served, if nothing else, to draw attention to the stratosphere, to highlight the potential vulnerability of even the most remote regions of the atmospheric environment.

The debate concerning the environmental impact of the SST has had a lasting effect on the development of atmospheric science, spawning a new interdisciplinary program of research linking chemists, physicists, and biologists in a common effort to understand the stratosphere. The program, with international participation, has been remarkably successful and has led to a new view of the interdependence of the atmosphere, hydrosphere, and biosphere.

The concern over the effects of exhaust gases from supersonic aircraft was soon followed by a new issue: the possibility that chlorine atoms released by decomposition of chlorofluorocarbons could have a larger and more persistent effect on stratospheric ozone. CFC's were developed first in the 1930s but found widespread use only in the years following World War II. They were employed with great success by U.S. troops in the Pacific to dispense insecticides from aerosol spray cans. This led to many commercial uses, from propellants and refrigerants to foaming agents and degreasers and a host of other applications. Moreover, the use of CFC's rapidly spread from the United States to Europe and the Far East. All this changed in 1975, when it was recognized that the release of CFC's to the atmosphere could pose a serious problem for stratospheric ozone. Production of F-12 declined from a peak of about 4.5×10^5 metric tons in 1975 to about 3.4×10^5 metric tons in 1982. A similar drop was registered for F-11.

Much of the work undertaken since the mid-1970s has focused on the effects of CFC's on the assumption that the composition of the atmosphere was otherwise constant. It has become clear, however, that the response of ozone depends not simply on the abundance of CFC's but also on the abundances of methane, nitrous oxide, and carbon monoxide. These species, too, are changing. Current mod-

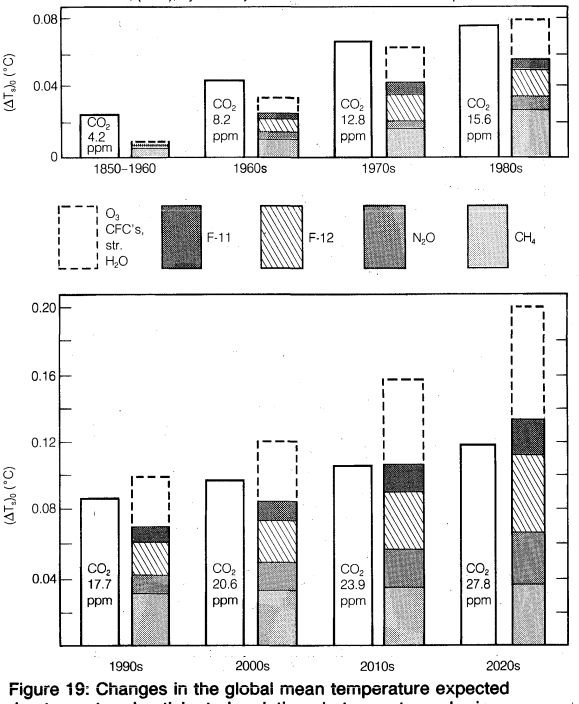

Figure 19: Changes in the global mean temperature expected due to past and anticipated variations in trace atmospheric gases. (Top) Increases in greenhouse forcing per decade from 1850 through the mid-1980s. (Bottom) Decadal increments of greenhouse forcing projected for the period from 1990 to 2030.

els suggest that a continuing release of CFC's at the rate registered in 1980, other gases remaining constant, would lead to a reduction in stratospheric ozone by about 5 percent. Maximum impact is predicted to occur at altitudes above 25 kilometres. An increase in nitrous oxide of 20 percent is expected to cause a reduction in ozone of about 2 percent. An increase in carbon dioxide should lead to a reduction in stratospheric temperatures with a consequent reduction in the anticipated impact of CFC's and nitrous oxide on ozone. The effect of an increasing burden of methane is more complex. Oxidation of methane provides a source of ozone at low altitude, while the reaction of chlorine with methane converts chlorine radicals to hydrogen chloride, resulting in a reduction in the impact of CFC's between 30 and 40 kilometres.

Models suggest that the change in the column density of stratospheric ozone to date should be relatively small. Reductions in ozone at high altitude, near 40 kilometres, ought to be balanced by excess production at low altitudes due in part to the higher level of methane and in part to NO_x released by high-altitude aircraft. Observational evidence is consistent with this view. A statistical analysis concluded that the change in the ozone column from 1970 to 1983 averaged −0.003 percent per decade. It showed, however, that a small though statistically significant drop in ozone—a decline of about 2 percent—occurred at altitudes above 30 kilometres between 1970 and 1980.

Recurrent decrease of ozone concentration over Antarctica

There has been a new development since 1985. That year, Joseph C. Farman and his associates at the British Antarctic Survey reported that the level of ozone over Antarctica had dropped precipitously every October since 1982, with the first such change apparent as early as 1978. A number of theories, or more properly hypotheses, have been advanced to account for this phenomenon. Several implicate effects of anthropogenic chlorine, enhanced by small quantities of bromine. Others suggest that the reduction may be due to a diminished supply of ozone from low latitudes, reflective of a change in stratospheric dynamics. In any case, the phenomenon was quite unexpected and serves as a powerful warning that current scientific understanding of the stratosphere is still rudimentary.

Acid rain and allied problems. The acidity of rain, or of any liquid, depends on the concentration of protons (positively charged hydrogen ions), H^+, in solution. It is measured conventionally by pH, defined by the relation

$$H = -\log_{10} [H^+], \tag{55}$$

where $[H^+]$ denotes the molar abundance of H^+—*i.e.*, the concentration expressed in moles per litre. Pure water is characterized by a pH of 7.0. A liquid is said to be acidic if pH is less than 7.0; otherwise it is considered neutral or alkaline.

Exposed to an atmosphere containing carbon dioxide, water absorbs carbon, releasing protons by

$$CO_2 + H_2O \rightarrow HCO_3^- + H^+. \tag{56}$$

Similar reduction in pH occurs with absorption of nitric acid (HNO_3) or sulfuric acid (H_2SO_4). Reactions in this case may be represented by

$$HNO_3 \rightarrow H^+ + NO_3^- \tag{57}$$

and

$$H_2SO_4 \rightarrow 2H^+ + SO_4^{2-}. \tag{58}$$

Absorption of less oxidized gases such as nitrogen dioxide (NO_2) or sulfur dioxide (SO_2) may be described by

$$4NO_2 + O_2 + 2H_2O \rightarrow 4NO_3^- + 4H^+ \tag{59}$$

and

$$2SO_2 + O_2 + 2H_2O \rightarrow 2SO_4^{2-} + 4H^+. \tag{60}$$

In each case, protons are liberated and pH declines. This result may be viewed as an inevitable consequence of the chemical nature of carbon, nitrogen, and sulfur. These elements are poised to form negative ions in their oxidized states. The resulting negative charge must be balanced, to some extent at least, by production of H^+.

The pH of rain in equilibrium with atmospheric CO_2 would have a value of 5.65. The addition of HNO_3 SO_2 with concentrations typical of the clean environment remote from concentrated sources, about 100 parts per trillion, would lower the pH to approximately 5.3. (This assumes lifetimes for nitric acid and sulfur dioxide of roughly 10 days with precipitation at an average rate of one metre per year.) A concentration of sea salt or alkaline aerosol equivalent to about 50 parts per million, a typical value, would raise the pH to about 6.0. On this basis, it is concluded that the natural range of pH should lie between 5.3 and about 6.0. The data in Table 5 are consistent with this view, except for the measurement in Brazil indicating a value of 4.6. The acid content of rain in the Amazon River basin may reflect the importance of local biologic sources of sulfur, particularly hydrogen sulfide (H_2S). As mentioned above, hydrogen sulfide is oxidized readily in the atmosphere to sulfur dioxide, with a lifetime of no more than a few days.

Table 5: The pH of Rain at a Number of Representative Remote Locations

place	pH
New Zealand	5.5 ± 0.5
Pago Pago	5.3 ± 0.3
Greenland	5.8 ± 0.65
American Samoa	5.3 ± 0.36
Hawaii	5.0 ± 0.4
Amazon	4.6 ± 0.2
El Salvador	5.2 ± 0.4

Rains in the northeastern part of the United States show median values for pH in the range of 4.1 to about 4.5. Values are lowest in a band extending from the Ohio River Valley to upstate regions of New York. Information on the composition of precipitation is particularly illuminating. Table 6 shows data from sites in Minnesota, Georgia, and New York obtained in 1979. Sulfate accounts for about 60 percent of the negative charge in rains at all three sites; nitrate ranges from 20 percent in Georgia to 34 percent in New York. The pH in New York was 4.34, as compared with the high value, 6.31, measured in Minnesota. The difference may be attributed to the presence of alkaline aerosol in rain reaching the site at Minnesota. The addition of calcium carbonate, $CaCO_3$, results in removal of H^+ according to

$$CaCO_3 + H^+ \rightarrow Ca^{2+} + HCO_3^-. \tag{61}$$

Soils in the western part of the United States are generally alkaline, and the aerosol content of the atmosphere tends to reflect this condition. Soils in the eastern United States are more acidic, and the buffering capacity is reduced accordingly.

The low pH and high sulfate content of precipitation in the Northeast is scarcely surprising. Approximately 12,000,000 metric tons of sulfur were vented to the atmosphere from industrial sources east of the Mississippi River in 1978. The sulfur content of rain falling on the same region amounted to only 20 percent of the quantity released. The balance was either exported or deposited by dry processes on various surfaces—vegetation and so forth.

Table 6: Average Ion Concentrations* Observed in Precipitation at Three U.S. Sites (in 1979)

ion	west central Georgia	southwest Minnesota	northwest New York
SO_4^-	38.9	45.8	44.8
NO_3^-	11.6	24.2	25.0
Cl^-	8.2	4.2	4.2

pH	4.75	6.31	4.34

*Microequivalents per litre.

The industrial source grew by a factor of 2.5 between 1950 and 1970, with the rate of growth most rapid during the 1950s. The decline in subsequent growth reflected a shift by utilities from coal to oil and nuclear power and from high-sulfur to low-sulfur coal, a trend that has been reversed somewhat since the early 1980s. The global industrial output of sulfur in 1978 was about 65,000,000 metric tons, which may be compared with estimates of 64,000,000 metric tons per year for production by the unperturbed global biosphere. The biospheric production in the eastern United States is about 100,000 metric tons per year and is surely less than the industrial contribution by at least a factor of 10.

Industrial sources of oxidized nitrogen are similarly dominant. The global industrial output of NO_x (see above) is about 20,000,000 metric tons N per year, distributed more or less equally between North America, Europe, and the rest of the world. The industrial output is thought to exceed production by natural agents in North America by a factor of from 3 to 13. Combustion of fossil fuels accounts for about 40 percent of the NO_x. Biomass burning accounts for another 25 percent, with the remainder from lightning and microbial processes in soils.

The relation between emission of potentially acidic compounds and ultimate delivery of acids to specific geographic regions is by no means straightforward. It depends on the nature of the atmospheric circulation and characteristics of the source—*e.g.,* height of smokestacks. Chemical factors controlling dry deposition are poorly understood, and there are gaps in scientific understanding of the relevant aspects of atmospheric chemistry. Oxidation of nitrogen dioxide to nitric acid is thought to proceed by the reaction

$$OH + NO_2 + M \rightarrow HNO_3 + M. \quad (62)$$

Oxidation of sulfur is initiated similarly by reaction with the hydroxyl radical, OH,

$$OH + SO_2 + M \rightarrow HSO_3 + M, \quad (63)$$

or it may proceed heterogeneously with hydrogen peroxide, H_2O_2, formed from HO_2. Ammonia, NH_3, is important in neutralizing acid aerosols. A complete description of the relevant chemistry must thus include NH_3 and O_3 in addition to oxides of nitrogen and sulfur. Interconnections between various chemical cycles can lead to subtle, unexpected nonlinearities in the composite effects, with important consequences for the geographic pattern of the resulting deposition of acid.

Acids can affect receiving systems in a variety of ways, some good, others bad. Addition of nitrate to ecosystems deficient in nitrogen can lead to enhanced biologic productivity. The benefits, however, may be offset by toxic effects associated with the release of aluminum and magnesium from clay minerals if the pH of soils falls below about 5.5. Leaching of metals from soils and sediments also can have adverse effects on aquatic systems. Fish may be killed by aluminum even under conditions where the pH is considered otherwise benign. Given the current rates of acid deposition, the pH of a number of lakes in the northeastern United States and in southeastern Canada is expected to average 4.2 to 4.8, with occasional depressions to near 3.8 during periods of snowmelt or heavy rain. Most fish species and almost all mollusks perish if the pH falls below 4.8; planktonic communities are simplified in this case, dominated by a few acid-tolerant taxa. Adverse effects of acid precipitation are most obvious for lakes, and it is not surprising that this aspect of the issue has received the most attention in the press. The effects on the terrestrial biosphere are more ambiguous. It appears that elevated levels of ozone in the troposphere may pose a more serious hazard for plant life even at locations removed from major industrial sites. Effects in this case, for a variety of agronomic and forest species, include foliar injury and significant reduction in growth and yield.

Toxic effects of metals leached from soils and sediments

In summary, there are deficiencies in current scientific understanding of acid rain, both in its atmospheric and biospheric dimensions. Uncertainties can be removed or reduced by a suitably directed research program. It is clear that the chemistry of the troposphere, both polluted and clean, should receive attention in this effort.

The ionosphere and phenomena of the upper atmosphere

THE IONOSPHERE

General characteristics. The bulk of the atmosphere consists of electrically neutral atoms and molecules. At high altitudes, however, a significant fraction of the atmosphere is electrically charged. This region is generally called the ionosphere. It extends throughout the mesosphere and thermosphere but is most important and distinct at altitudes above about 80 kilometres. The name was introduced during the 1920s and was formally defined in 1950 by a committee of the Institute of Radio Engineers. Members of the committee identified the region as "the part of the earth's upper atmosphere where ions and electrons are present in quantities sufficient to affect the propagation of radio waves."

Much of the early research on the ionosphere was carried out by radio engineers and was stimulated by the need to define the factors influencing long-range radio communication. Priorities have changed in recent years. Today, the need is to understand the ionosphere as the environment for Earth-orbiting satellites and ballistic missiles. The emphasis is on processes. Scientific knowledge of the ionosphere has grown tremendously, fueled by a steady stream of data from spacecraft-borne instruments and enhanced by measurements of relevant atomic and molecular processes in the laboratory.

Division of the ionosphere into layers

Historically, the ionosphere was thought to be composed of a number of relatively distinct layers. The most important layers were identified by the letters D, E, and F, with the F layer subsequently divided into regions F_1 and F_2. The nomenclature is somewhat peculiar. It appears that Edward V. Appleton of Britain, a pioneer in early radio probing of the ionosphere, was accustomed to using the symbol E to describe the electric field of the wave reflected from the first layer of the ionosphere he studied. Later, Appleton identified a second layer at higher altitude and used the symbol F in this case. Suspecting a layer at lower altitude, he adopted the additional symbol D. In time the letters came to be associated with the layers themselves rather than with the field of the reflected waves. It is now known that Appleton's layers are not particularly distinct. The electron density increases more or less uniformly with altitude from the D region, reaching a maximum in the F_2 region. In spite of the peculiarities of the original rationale for the naming of the layers, the nomenclature employed to describe the different regions of the ionosphere continues in wide use. Though the names persist, the definitions have evolved to reflect present-day understanding of the underlying physics and chemistry.

Ionospheric physics and chemistry. Most of the ionization in the ionosphere is effected by photoionization. Photons of short wavelength (*i.e.,* high energy) are absorbed by atmospheric gases. A portion of the energy is used to eject an electron, converting a neutral atom or molecule to a pair of charged species: an electron, which is negatively charged, and a companion positive ion. Ionization in the F_1 region is produced mainly by ejection of electrons from O_2, O, and N_2. The threshold for ionization of O_2 corresponds to a wavelength of 102.7 nanometres. Thresholds for O and N_2 are at 91.1 and 79.6 nanometres, respectively.

Positive ions can react with neutral gases and change their identity. There is a tendency for these reactions to favour production of more stable ions. Thus, ionized oxygen, O^+, can react with O_2 and N_2, resulting in ionized molecular oxygen, O_2^+, and ionized nitric oxide, NO^+:

$$\begin{aligned} O^+ + O_2 &\rightarrow O + O_2^+ \\ O^+ + N_2 &\rightarrow NO^+ + N. \end{aligned} \quad (64)$$

Similarly, ionized molecular nitrogen, N_2^+, can react with O and O_2, forming NO^+ and O_2^+:

$$\begin{aligned} N_2^+ + O &\rightarrow NO^+ + N \\ N_2^+ + O_2 &\rightarrow N_2 + O_2^+. \end{aligned} \quad (65)$$

The most stable, and consequently most abundant, ions in the E and F_1 regions are O_2^+ and NO^+, the latter more so than the former. At lower altitude, O_2^+ can be converted

to NO^+ by reactions with the minor species N (nitrogen) and NO (nitric oxide),

$$O_2^+ + N \rightarrow O + NO^+$$
$$O_2^+ + NO \rightarrow O_2 + NO^+. \quad (66)$$

In the D region, NO^+ can be converted to H_3O^+, the hydronium ion, and to companion species such as $H_5O_2^+$ and $H_7O_4^+$, formed by the addition of H_2O. Production of hydrated ions is limited by the availability of H_2O. As a consequence, they are confined to altitudes below about 85 kilometres.

The electron density in the D, E, and F_1 regions reflects for the most part a local balance between production and loss. Electrons are removed mainly by dissociative recombination, a process in which electrons attach to positively charged molecular ions and form highly energetic, unstable neutral molecules. These molecules decompose spontaneously, converting internal energy to kinetic energy of fragments. The most important processes in the ionosphere involve recombination of O_2^+ and NO^+. The reactions in this case may be summarized as follows:

$$O_2^+ + e \rightarrow O + O$$
$$NO^+ + e \rightarrow N + O. \quad (67)$$

A portion of the energy released in reaction (67) may appear as internal excitation of either nitrogen, oxygen, or both. The excited atoms can radiate, emitting faint visible light in the green and red regions of the spectrum and thereby contribute to the phenomenon of the airglow.

Airglow

The airglow originates principally from altitudes above 80 kilometres and is responsible for the diffuse background light that makes it possible to distinguish objects at the Earth's surface on dark, moonless nights. Airglow is produced for the most part by reactions involved in the recombination of molecular oxygen. The contribution from reaction (67) is readily detectable, however, and provides a useful technique with which to observe changes in the ionosphere from the ground. Studies of the airglow have a long and checkered history in atmospheric science. Over the years they have contributed significantly to scientific understanding of processes in the upper atmosphere.

As indicated above, dissociative recombination provides an effective path for the removal of molecular ions. There is no comparable means for the removal of atomic ions. Direct recombination of O^+ with an electron requires that the excess energy be radiated as light. Radiative recombination is inefficient, however, compared with dissociative recombination and plays a small role in the removal of ionospheric electrons. There is a complication at high altitudes where atomic oxygen is the major constituent of the neutral atmosphere and where electrons are produced primarily by photoionization of O. The atomic ion O^+ may be converted to NO^+ and O_2^+ through reactions with N_2 and O_2, but the abundances of N_2 and O_2 decline relative to O as a function of increasing altitude. In the absence of competing reactions, the concentration of O^+ and the density of electrons would increase steadily with altitude, paralleling the rise in the relative abundance of O. This occurs to some extent but is limited eventually by vertical transport.

Ions and electrons produced at high altitude are free to diffuse downward, guided by the Earth's magnetic field. The lifetime of O^+ is long at high altitude where the densities of O_2 and N_2 are very small. As ions move downward, the densities of O_2 and N_2 increase. Eventually the time constant for reaction of O^+ with O_2 and N_2 becomes comparable to the time for diffusion: O^+ is converted to either O_2^+ or NO^+ before it can move much farther. The O^+ density exhibits a maximum in this region. Competition between chemistry and transport is responsible for the formation of an electron-density maximum in the F_2 layer. The dominant positive ion is O^+.

The density of O^+ decreases with decreasing altitude below the peak, reflecting a balance between production by photoionization of O and removal by reaction (65). The density of O^+ also decreases above the peak. In this case, the removal of photo-ions is regulated by downward diffusion rather than by chemistry. The distribution of O^+ with altitude above the peak reflects a balance of forces, a pressure gradient that acts to support O^+ in opposition to gravitational and electrostatic forces that combine to pull O^+ down. The electrostatic force is set up to preserve charge neutrality. In its absence, the density of ions, which are much more massive than electrons, would tend to fall off more rapidly with altitude than that of electrons. The abundance of electrons would quickly exceed the density of ions, and the atmosphere would accumulate negative charge. The electric field redresses the imbalance, drawing electrons down and providing additional upward support for positively charged ions. The abundance of O^+ falls with increasing altitude as though O^+ had a mass of 8 atomic units rather than 16 atomic units (the electric field exerts a force equivalent to the gravitational force on a body of mass 8 atomic units, directed upward for ions and downward for electrons). The density of electrons falls off with altitude at precisely the same rate as O^+, preserving the balance of positive and negative charge.

Ionization at any given level depends on three factors: (1) the availability of photons of a wavelength capable of effecting ionization, (2) a supply of atoms and molecules necessary to intercept this radiation, and (3) the efficiency with which the atoms and molecules are able to do so. The efficiency is relatively large for O, O_2, and N_2 from about 10 to 80 nm. This is the portion of the spectrum responsible for the production of electrons and ions in the F_1 region. Photons between 90 and 100 nm are absorbed only by O_2. They therefore penetrate deeper and are responsible for producing about half the ionization in the E layer. The balance is derived from soft X rays (those of longer wavelength), which are absorbed with relatively low efficiency in the F region and so are able to penetrate to altitudes of about 120 kilometres under conditions of high solar elevation. Hard X rays (those of shorter wavelength), notably below about 5 nm, reach even deeper. This portion of the spectrum accounts for the bulk of the ionization in the D region, with an additional contribution from wavelengths longer than 102.6 nm—mainly from photons in the strong solar emission line at Lyman α, 121.6 nm. Lyman α emission is absorbed weakly by the major components of the atmosphere, O, O_2, and N_2. It is absorbed readily by NO and has sufficient energy to ionize this relatively unstable compound. In spite of the low abundance of NO, the high flux of solar radiation at Lyman α is able to provide a significant source of ionization for the D region near 90 kilometres.

Ionospheric variations. The ionosphere is variable in space and time. Some of the changes are chemical in origin and can be readily understood on the basis of the general considerations outlined above. There is a systematic variation, for example, as a function of time of day. In the early morning the Sun is relatively low in the sky. Radiation must penetrate a large column of air before reaching a given level of the atmosphere. Ionization rates are less than at noon, and the profile of ionization is shifted to higher altitudes. The heights of the D, E, and F_1 layers change in response to solar elevation. The layers are lowest and the densities of electrons are highest at noon. Ionization in the D, E, and F_1 regions tends to disappear at night as a result of recombination in the absence of a compensating source.

The diurnal variation of the F_2 layer is less dramatic. Ionization produced at high altitudes during the day maintains a sizable density of electrons at the F_2 peak throughout the day and diffuses downward at night. This accounts for the fact that radio reception (both in the broadcast and shortwave bands) is generally best at night. Ionization at lower altitudes—primarily those corresponding to the D region—tends to interfere with radio transmissions during the day. Interference is minimal at night, since ionization in the D layer effectively disappears with the setting of the Sun.

Impact of solar activity on the density of ionization

The density of ionization varies as a function of solar activity in response to changes in the intensity and spectral properties of solar radiation. The output of solar energy is relatively constant in the visible and near-ultraviolet portions of the spectrum. It varies appreciably, however, at shorter wavelengths, reflecting changes in the temperature of the outermost regions of the solar atmosphere.

The changes are particularly large, in excess of a factor of 10, at X-ray wavelengths. Variations in the D region are correspondingly large, with smaller though still significant changes in the E and F layers. The temperature of the thermosphere varies as a function of solar activity in response to the changing input of energy. Exospheric temperatures range from about 750 K at solar minimum to as high as 2,000 K when activity is particularly intense.

Solar activity varies on a characteristic time scale of about 11 years. It is not entirely periodic, however, as successive cycles can differ significantly. There are indications that activity can be low for periods as long as centuries. For example, the Sun was quiet for more than 200 years from about 1600 to roughly 1850.

As mentioned earlier, ionization above the F_2 peak is removed mainly by downward diffusion. Ionization is constrained, however, to move along the magnetic field. The field is oriented horizontally at the magnetic equator, so vertical diffusion is inhibited at low latitudes. The density of O^+ and electrons at low latitudes is controlled by chemistry to a larger extent than at high latitudes. The F_2 peak is correspondingly higher in altitude and the density of electrons is elevated accordingly.

Ions and electrons formed at high altitudes and low latitudes are transported to higher latitudes by thermospheric winds. As a result, the highest density of electrons at the F_2 peak is observed at intermediate latitudes, displaced by about 10° relative to the magnetic equator.

Transport also can affect the distribution of ionization at lower altitudes. The diurnal pattern of heating in the troposphere and stratosphere excites a spectrum of waves, some of which are free to propagate vertically. The amplitude of the waves grows significantly as the disturbance enters regions of lower density. The passage of the waves is associated with strong alternating horizontal winds. Ionization can be driven up inclined magnetic field lines at one altitude, while winds blowing in an opposite direction at higher altitudes can induce simultaneous downward motion. This can lead to bunching of ionization, causing a local enhancement of the electron density. The mechanism is particularly important in the E region and is responsible for a phenomenon known as sporadic E.

The buildup of ionization is normally limited by dissociative recombination of molecular ions. The ionosphere at D- and E-region altitudes, however, contains a small but variable concentration of atomic ions derived from the ionization of metals ablated from meteorites. The density of metallic ions, notably those of sodium, magnesium, and potassium is sometimes high enough to supply, after concentration, a layer of ionization with density comparable to that of the F layer. This can result in a major temporary disruption of radio communications.

Winds generated in the lower ionosphere by thermal forcing from below have characteristic periods expressed as submultiples of a day. Waves with a period of 24 hours dominate at low latitudes, whereas those with a characteristic period of 12 hours are more important at high latitudes. The waves are basically similar in physical origin to tides excited in the ocean by lunar gravity. The vertical motion to which they owe their origin is generated, however, by the diurnal pattern of heating and cooling rather than by gravity. Additional waves can arise due to irregular forcing associated, for example, with thunderstorms, motion over orographic features, and a range of other small-scale meteorologic disturbances. These small-scale disturbances are referred to as gravity waves to distinguish them from the more regular planetary-scale motions excited by the diurnal cycle of heating and cooling. The regular response to thermal forcing is known as the atmospheric tide.

Gravity waves and atmospheric tides

Tides and gravity waves have similar effects on ionization in the E region. They both are responsible for concentrating ionization in layers. In combination with the large-scale system of winds in the lower thermosphere, they also are effective in driving an irregular current that flows in the E and lower F regions of the ionosphere. The current owes its origin to differences in the facility with which motions of ions and electrons are constrained by the magnetic field. It is associated with an electric field and results in a modulation of the magnetic field that can be readily detected at the surface. The current is particularly intense in the equatorial region where it is known as the electrojet. The region of strong current flow is called the dynamo region.

Protons, H^+, and helium ions, He^+, are important components of the ionosphere above the F_2 peak. They increase in abundance relative to the atomic ion of oxygen, O^+, with increasing altitude. Protons are produced by the photoionization of atomic hydrogen,

$$h\nu + H \rightarrow H^+ + e, \tag{68}$$

and by charge transfer from O^+ to H,

$$O^+ + H \rightarrow O + H^+. \tag{69}$$

Helium ions are formed by the photoionization of helium. The distribution of H^+ and He^+ with altitude reflects the influence of the polarization electric field set up to preserve charge neutrality. When O^+ is the dominant ion, the polarization field acts to lift H^+ and He^+ with a force equivalent, but in opposite direction, to that exerted by the gravitational field on a particle of mass 8 atomic units. Protons behave as though they had an effective gravitational mass of -7 atomic units $(1 - 8)$. The effective mass of He^+ is -4 atomic units $(4 - 8)$.

The abundance of H^+ and He^+ increases with altitude. Eventually H^+ becomes the dominant component of the ionosphere, and the polarization field is then diminished. A field equivalent to the gravitational force acting on a body of mass 0.5 atomic units, directed upward for ions and downward for electrons, is sufficient to maintain equal densities of H^+ and electrons. The effective masses of O^+ and He^+ shift to 15.5 atomic units $(16 - 0.5)$ and 3.5 atomic units $(4 - 0.5)$, respectively, and densities of O^+, He^+, and H^+ decline with further increases in altitude.

The overall structure of the outer ionosphere is influenced strongly by the configuration of the magnetic field. Ionization is removed by diffusion, but diffusion is limited to the directions imposed by the morphology of the field.

Close to the Earth, the magnetic field has a structure similar to that of an ideal dipole. Field lines are oriented more or less vertically at high latitudes, sweep back over the Equator when they are essentially horizontal, and connect to the Earth in a symmetrical pattern at high latitudes in the opposite hemisphere. The field departs from this ideal dipolar configuration, however, at high altitudes. There, the terrestrial field is distorted to a significant extent by the solar wind with its imbedded solar magnetic field. Ultimately the terrestrial field is dominated by the interplanetary field. The solar wind compresses the field of the Earth on the dayside at a distance of about 65,000 kilometres from the planet. The terrestrial field is stretched out on the nightside in a giant tail that reaches past the orbit of the Moon, extending perhaps to distances in excess of 1,000 Earth radii. The boundary between regions dominated by the solar and terrestrial magnetic fields is known as the magnetopause, and the region interior to the magnetopause is called the magnetosphere.

The magnetopause and the magnetosphere

The outermost regions of the magnetosphere are exceedingly complex, especially at high latitudes where the terrestrial field lines are open. Ionization from the solar wind can leak into the magnetosphere in a number of ways. It can enter by turbulent exchange at the dayside magnetopause or more directly at cusps in the magnetopause at high latitudes, where closed loops of the magnetic field on the dayside meet fields connecting to the magnetotail. In addition, it can enter at large distances on the nightside where the magnetic pressure is relatively low and the field lines are able to reconnect readily, providing easy access to the giant plasma sheet in the interior of the magnetotail. For further information about the magnetosphere and related subjects, see EARTH, THE: *The magnetic field of the Earth.*

AURORAS

Auroras are perhaps the most spectacular manifestations of the complex interaction of the solar wind with the outer atmosphere. The energetic electrons and protons responsible for auroras are thought to emanate from the plasma sheet inside the Earth's magnetotail.

Auroras occur in both hemispheres. They are confined for the most part to high latitudes, to oval-shaped regions maintaining a more or less fixed orientation with respect to the Sun. The centre of an auroral oval is displaced a few degrees to the nightside with respect to the geomagnetic pole. The midnight portion of an oval is, on average, at a geomagnetic latitude of 67°; the midday portion is at about 76°. An observer between 67° and 74° magnetic latitudes generally encounters auroras twice a day—once in the evening and once in the morning.

Auroral zone

The portion of the Earth that traverses the midnight portion of an oval is known as the auroral zone. In the Northern Hemisphere, for example, it lies along the curve extending from the northern regions of Scandinavia through Iceland, the southern tip of Greenland, the southern region of Hudson Bay, Alaska, and on to the coast of Siberia. This is the prime region from which to view an aurora. The phenomenon is by no means static, however. The auroral zone shifts poleward at times of low solar activity. It has been known to move as far south as 40° (geographic latitude) in the United States during periods of high solar activity. At low latitudes, an aurora assumes a characteristic red colour. In ancient times this feature was often interpreted as evidence of impending disaster. Auroras assume a variety of forms, depending on the vantage point from which they are observed. The luminosity of an aurora is generally aligned with the magnetic field. Field lines are close to vertical in polar regions, and so an aurora occurring there appears to stand on end, to hang from the sky in great luminous drapes (Figure 20). It is a spectacular sight indeed, especially if viewed from a distance either from the north or south. At lower latitudes, the magnetic field lines are inclined with respect to the vertical. There, an aurora appears as streamers radiating from the zenith. Such is the majesty of auroras that no two displays are totally alike. Light can move rapidly across the sky on some occasions, and at other times, it can appear to stand in place, flickering on and off.

Common cause of auroral displays

The most common type of aurora is associated with the bombardment of the atmosphere by electrons having energies of up to 10,000 electron volts (eV). The energy for these electrons originates ultimately from the Sun. It is propagated through space by the solar wind and is communicated to the magnetosphere, most probably to the plasma sheet, by complex electromagnetic interactions not as yet well understood. The energetic electrons enter the atmosphere along magnetic field lines. They produce a shower of secondary and tertiary electrons, approximately one for every 35 eV of energy in the primary stream.

V.P. Hessler

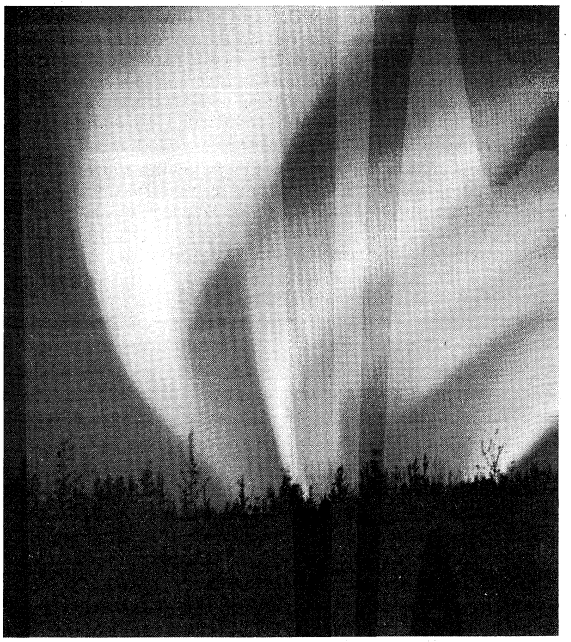

Figure 20: *Aurora borealis.*
Multiple auroral arcs photographed in Alaska.

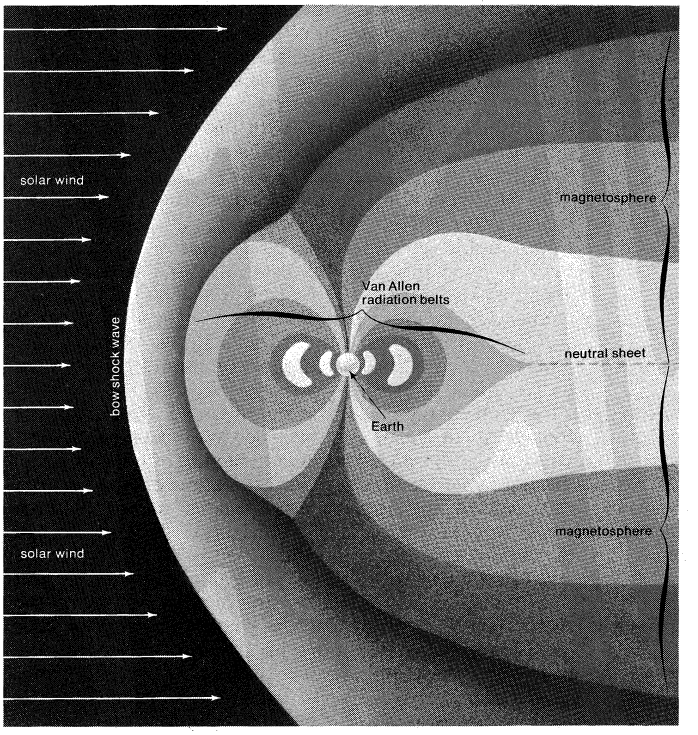

Figure 21: The Van Allen radiation belts contained within the Earth's magnetosphere.

Primaries can propagate to altitudes as low as 100 kilometres. Most of the luminosity is produced, however, by low-energy secondary and tertiary electrons. Prominent emissions are associated with the red line of atomic oxygen at 630 nm, the green line of atomic oxygen at 558 nm, the first negative bands of ionized molecular nitrogen at 391 nm and 428 nm, and a host of emissions from O, O_2, O_2^+ and N_2. Many of these features also are present in the day and night airglow. They are most notable in auroras because of their intensity and the rapidity with which they switch on and off in response to changes in the flux and energy of incoming primaries. An aurora has a characteristic red colour if the energy of primaries is relatively low. In this case, emission is dominated by atomic oxygen and is confined for the most part to altitudes above 200 kilometres. If the energy of the primaries is high, an aurora has a greenish blue colour and extends downward to altitudes as low as 90 kilometres.

Auroral displays also are produced by the bombardment of the atmosphere by energetic protons. Protons with energies of up to 200,000 eV are responsible for auroral activity in a diffuse belt shifted equatorward from the main auroral zone. These protons can be detected from the ground by observation of Doppler-shifted radiation emitted by fast hydrogen atoms formed by charge transfer from atmospheric atoms and molecules. Protons also play a role at higher latitudes, especially at times following major flares on the Sun. It is thought that the protons responsible for auroras at the polar caps are solar in origin. Associated energies may reach as high as 10^6 eV, and particles may penetrate as deep as 80 kilometres. Polar cap auroras can provide a significant transient source of mesospheric and stratospheric nitric oxide. They can be responsible for small but detectable short-term fluctuations in the abundance of stratospheric ozone.

THE VAN ALLEN RADIATION BELTS

Zones of energetic protons and electrons

The magnetosphere includes two doughnut-shaped belts, or zones, centred on the Equator that are occupied by appreciable numbers of energetic protons and electrons trapped in the magnetic field high above the sensible atmosphere (Figure 21). The inner belt extends from roughly 1,000 to 5,000 kilometres above the terrestrial surface and the outer belt from some 15,000 to 25,000 kilometres. The belts were named in honour of James A. Van Allen,

the American physicist who discovered them in 1958. Van Allen's find was a triumph of serendipity: he detected the presence of the trapped particles with a Geiger counter designed to measure the flux of cosmic rays in space. It was the first great discovery of the space age and was achieved by combining data obtained with instruments carried by three of the earliest U.S. scientific satellites—Explorer 1, Explorer 4, and Pioneer 3.

The flux of protons crossing a square centimetre of surface in the inner Van Allen belt can be as large as 20,000 per second, higher than the flux of cosmic radiation in space by a factor of 10^4. Protons in the inner belt have energies in excess of 7×10^8 electron volts, enough to enable them to penetrate several centimetres of lead. Spacecraft that have to fly through the belts thus must be protected; otherwise their electronic components would be subjected to irreparable damage.

Neutron decay as a source of high-energy protons in the inner belt

The high-energy protons in the inner Van Allen belt are thought to originate from the decay of neutrons. These neutrons are produced by the interaction of energetic cosmic rays of galactic origin with the atmosphere. Some of the neutrons are ejected upward, and a fraction of them decay into protons and electrons upon passing through the region occupied by the Van Allen belts. These protons and electrons travel in spiral paths along the flux lines of the Earth's magnetic field. At intermediate latitudes, the converging flux lines cause the particles to reverse their direction, so that they move back and forth between the magnetic poles. Collisions with atoms in the thin atmosphere eventually remove the particles from the belts, but they generally survive for about 10 years. This relatively long lifetime allows particles to accumulate in the radiation belts, providing high fluxes in spite of the small magnitude of the intrinsic source.

The inner belt merges gradually with the outer belt, where a portion of the ionization is derived from the solar wind. Clear evidence of this is provided by the observation of helium ions in addition to protons in the outer belt. It has been established that helium ions account for about 10 percent of the solar wind. (Unlike the outer zone, the inner belt contains no helium ions.) The flux of electrons in the outer belt can vary over time intervals as short as a few days. These changes appear to correlate with periods of strong magnetic disturbance. They are not, however, as yet well understood.

Studies of the outer magnetosphere and related phenomena continue to draw attention. Space physicists find it a challenging task to unravel the mysteries of the ever-changing cosmic laboratory and hope to continue the saga initiated by Van Allen and other pioneers of the space age.

BIBLIOGRAPHY

Development of the Earth's atmosphere: Astrophysical considerations bearing on the earliest stages of atmospheric development are reviewed in JOHN S. LEWIS and RONALD G. PRINN, *Planets and Their Atmospheres: Origin and Evolution* (1984). Aspects of subsequent development are discussed in JAMES C.G. WALKER, *Evolution of the Atmosphere* (1977); and HEINRICH D. HOLLAND, *The Chemical Evolution of the Atmosphere and Oceans* (1984). Numerous chapters in J. WILLIAM SCHOPF (ed.), *Earth's Earliest Biosphere: Its Origin and Evolution* (1983), discuss biologic controls of atmospheric composition and their development over time. The probable rise of oxygen just prior to the development of the earliest animals is discussed in detail by BRUCE RUNNEGAR, "The Cambrian Explosion: Animals or Fossils?," *Journal of the Geological Society of Australia*, 29(4):395–411 (1982). Development of the biogeochemical cycle of carbon and its interactions with the atmosphere are discussed in E.T. SUNDQUIST and W.S. BROECKER (eds.), *The Carbon Cycle and Atmospheric CO_2: Natural Variations Archean to Present* (1985).

(J.M.Ha.)

Structure, composition, and physical properties of the atmosphere: JOHN T. HOUGHTON, *The Physics of Atmospheres*, 2nd ed. (1986), is a readable account of the physical basis for the treatment of atmospheric radiation and a good introduction to atmospheric dynamics. Simpler discussions are given by RICHARD M. GOODY and JAMES C.G. WALKER, *Atmospheres* (1972). A useful account of atmospheric chemistry is given by RICHARD P. WAYNE, *Chemistry of Atmospheres: An Introduction to the Chemistry of the Atmospheres of Earth, the Planets, and Their Satellites* (1985). Atmospheric composition, including an account of the interaction of the atmosphere with the oceans, is discussed by HEINRICH D. HOLLAND, *The Chemistry of the Atmospheres and Oceans* (1978).

Effects of human activities on the atmosphere: An overview of the Earth's endangered, changing atmosphere is given in JOHN GRIBBIN (ed.), *The Breathing Planet* (1986), a collection of essays from *New Scientist;* and "The Changing Atmosphere: Implications for Mankind," *Chemical and Engineering News*, vol. 64, no. 47 (Nov. 24, 1986), a special issue on global warming and the depletion of stratospheric ozone. For a review of current scientific understanding of these problems, see WORLD METEOROLOGICAL ORGANIZATION, *Atmospheric Ozone: An Assessment of Our Understanding of the Processes Controlling Its Present Distribution and Change*, 3 vol. (1985), report no. 16 of the Global Ozone Research and Monitoring Project. See also WILLIAM C. CLARK (ed.), *Carbon Dioxide Review, 1982* (1982); UNITED STATES. CONGRESS. SENATE. COMMITTEE ON ENVIRONMENT AND PUBLIC WORKS. SUBCOMMITTEE ON TOXIC SUBSTANCES AND ENVIRONMENTAL OVERSIGHT, *Global Warming* (1986); and HAROLD W. BERNARD, JR., *The Greenhouse Effect* (1980). A survey of the history of acid deposition from the atmosphere and its sources is provided by EVILLE GORHAM, "Acid Rain: An Overview," ch. 1 in CHANDRAKANT M. BHUMRALKAR (ed.), *Meteorological Aspects of Acid Rain* (1984), pp. 1–18, with an extensive bibliography. More detailed information may be found in JON R. LUOMA, *Troubled Skies, Troubled Waters: The Story of Acid Rain* (1984); and THOMAS PAWLICK, *A Killing Rain: The Global Threat of Acid Precipitation* (1984). Further bibliographic information is available in an annotated bibliography of research, G. HARRY STOPP, JR., *Acid Rain* (1985).

The ionosphere and phenomena of the upper atmosphere: For a general review of the underlying physics of the upper atmosphere, see J.A. RATCLIFFE (ed.), *Physics of the Upper Atmosphere* (1960); and C.O. HINES *et al.* (eds.), *Physics of the Earth's Upper Atmosphere* (1965). A modern account of aeronomy is given in P.M. BANKS and G. KOCKARTS, *Aeronomy*, 2 vol. (1973). A classic treatment of the aurora and airglow is presented in JOSEPH W. CHAMBERLAIN, *Physics of the Aurora and Airglow* (1961). For a specialized account of magnetospheric processes, see WILMOT N. HESS, *The Radiation Belt and Magnetosphere* (1968). A readable summary article is J.G. ROEDERER, "The Particle and Field Environment of the Earth," *Astronautics and Aeronautics*, 7:22–28 (January 1969).

Current research is reported in the following journals: *Advances in Atmospheric Sciences* (quarterly); *Atmospheric Environment* (monthly); *Environmental Science & Technology* (monthly); *Journal of the Atmospheric Sciences* (semimonthly); *Science* (weekly); and *Scientific American* (monthly).

Atoms: Their Structure, Properties, and Component Particles

The atom is the smallest unit into which matter can be divided without the release of electrically charged particles. It also is the smallest unit of matter that has the characteristic properties of a chemical element. As such, the atom is the basic building block of chemistry.

Most of the atom is empty space. The rest consists of a positively charged nucleus of protons and neutrons surrounded by a cloud of negatively charged electrons. The nucleus is small and dense compared to the electrons, which are the lightest charged particles in nature. Electrons are attracted to any positive charge by their electric force; in an atom, electric forces bind the electrons to the nucleus.

It is easier to describe an atom mathematically than conceptually, and so physicists have developed several models to explain its various characteristics. In some respects, the electrons in an atom behave like particles orbiting the nucleus. In others, the electrons behave like waves frozen in position around the nucleus. Such wave patterns, called orbitals, describe the distribution of individual electrons. The behaviour of an atom is strongly influenced by these orbital properties, and its chemical properties are determined by orbital groupings known as shells.

This article opens with a broad overview of the fundamental properties of the atom and its constituent particles and forces. A more mathematical and technical discussion of its structure and nucleus is provided in subsequent sections. Included too is a historical survey of the most influential concepts about the atom that have been formulated through the centuries. For additional information pertaining to nuclear structure and elementary particles, see SUBATOMIC PARTICLES. For coverage of other related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 111, 112, 121, 122, 124, 125, and 128.

This article is divided into the following sections:

Components and properties of atoms

CONSTITUENT PARTICLES AND FORCES

Most matter consists of an agglomeration of molecules, which can be separated relatively easily. Molecules, in turn, are composed of atoms joined by chemical bonds that are more difficult to break. Each individual atom consists of smaller particles—namely, electrons and nuclei. These particles are electrically charged, and the electric forces on the charge are responsible for holding the atom together. Attempts to separate these smaller constituent particles require ever-increasing amounts of energy and result in the creation of new subatomic particles, many of which are charged.

As noted at the outset of this article, an atom consists largely of empty space. The nucleus is the positively charged centre of an atom and contains most of its mass. It is composed of protons, which have a positive charge, and neutrons, which have no charge. These constituent protons and neutrons collectively are called nucleons. Protons, neutrons, and the electrons surrounding them are long-lived particles present in all ordinary, naturally occurring atoms. Other subatomic particles may be found in association with these three types of particles. They can be created only with the addition of enormous amounts of energy, however, and are very short-lived.

Nucleons

All atoms are roughly the same size, whether they have three or 90 electrons. Approximately 50,000,000 atoms of solid matter lined up in a row would measure one centimetre (0.4 inch). A convenient unit of length for measuring atomic sizes is the angstrom (Å), defined as 10^{-10} metre. The radius of an atom measures 1–2 Å.

Compared to the overall size of the atom, the nucleus is even more minute. It is in the same proportion to the atom as a marble is to a football field. In volume, the nucleus takes up only 10^{-14} of the space in the atom—*i.e.*, one part in 100,000,000,000,000. A convenient unit of length for measuring nuclear sizes is the femtometre (fm), which equals 10^{-15} metre. The diameter of a nucleus depends on the number of particles it contains and ranges from about 4 fm for a light nucleus such as carbon to 15 fm for a heavy nucleus such as lead. In spite of the small size of the nucleus, virtually all the mass of the atom is concentrated there. The protons are massive, positively charged particles, whereas the neutrons have no charge and are nearly as massive as the protons. The fact that nuclei can have anywhere from one to about 250 nucleons accounts for their wide variation in mass. The lightest nucleus, that of hydrogen, is 1,836 times more massive than an electron, while heavy nuclei are nearly 500,000 times more massive.

Size of nuclei

Although electrons exhibit complicated behaviour within an atom, they are characterized completely by a few parameters. The intrinsic properties of an electron are its charge, mass, an internal motion called spin, and magnetic moment. All electrons have identical properties. As the lightest charged particles in existence, they are absolutely stable because they cannot decay into smaller units. Their charge and mass, which are important determinants of atomic properties, are listed in Table 1. The spin of the electron provides it with a directional orientation. The electron has a magnetic moment along its spin axis. (Magnetic moment is a property of a particle, which, like a compass needle, causes its axis to align in a magnetic field.) Electrons are subject not only to the electromagnetic force but also to the force of gravity and the so-called weak interaction, the force primarily manifested in the radioactive decay of nuclei.

Electrons

Table 1: Fundamental Atomic Constants

	symbol	value
Avogadro's number	N_A	6.022×10^{23} mol^{-1}
Fundamental charge	e	1.602×10^{-19} C
Faraday	F	9.649×10^{4} C mol^{-1}
Planck's constant	h	6.626×10^{-34} J·s
	$\hbar = h/2\pi$	1.055×10^{-34} J·s
Mass of electron	m_e	9.11×10^{-31} kg
Rest energy of electron	$m_e c^2$	8.2×10^{-14} J $= 5.11 \times 10^{5}$ eV
Mass of proton	m_p	1.673×10^{-27} kg
Rest energy of proton	$m_p c^2$	1.50×10^{-10} J $= 938.3$ MeV
Bohr radius	a_0	5.292×10^{-11} m $= 0.5292$ Å
Speed of light (in vacuum)	c	2.998×10^{8} m s^{-1}

Most properties of atoms—particularly those associated with chemical bonds, physical forces, and the properties of bulk matter—depend solely on the behaviour of the electrons surrounding the nucleus. The chemical properties of an atom depend on the arrangement of its electrons making up the cloud around the nucleus. The atoms of one element differ from those of other elements in the number of their electrons. Also, atoms form molecules by lending and sharing electrons. Some elements, such as alkali metals, have an electron that is loosely bound to the nucleus and thus easily removed in chemical reactions; other elements, such as the noble (or inert) gases, have very tightly bound electrons and little affinity for other electrons. Electrons that have been freed from their atoms can cause lightning, and freed electrons driven through wires make up ordinary electric currents.

The nucleus of an atom is characterized by the number of protons and neutrons in it. Besides a charge and mass, the nucleus also may have a spin and a magnetic moment of its own, depending on the internal arrangement of its protons and neutrons. The forces between nucleons include the three forces affecting electrons as well as the so-called strong force, which is much more powerful than any of the others. Because of the strong force, nuclear binding energies are 1,000,000 times the binding energies of electrons in atoms. The amounts of energy that can be released in a transformation of the nucleus are correspondingly larger than the chemical energies released by a transformation of the electron patterns in atoms. The protons and neutrons in the nucleus are governed by the laws of quantum mechanics (see below), which describe the complex internal structure of the nucleus.

Even the individual protons and neutrons that make up the nucleus have an internal structure of their own. The constituents of nucleons are called quarks. Unlike the particles composing the larger units of matter, the quark cannot be freed from the nucleon and studied in isolation. The strong force acting between quarks is so powerful that they can never be completely separated. Any attempt to probe the substructure of a nucleon releases particles of various types, but the particles produced contain quarks in fixed combinations, never single quarks. Particles containing quarks are collectively called hadrons. Hadrons are classified into two categories: baryons and mesons. Baryons, which are composed of three quarks, include protons and neutrons as their lightest examples. Mesons, which contain two quarks, are largely responsible for nuclear forces. Except for the nucleons, all such particles decay in a small fraction of a second after their creation.

Hadrons and quarks

There is one more broad category of subatomic particles, the leptons. Electrons and neutrinos are leptons. They have no detectable internal components and may be truly fundamental particles of nature. The neutrino is an uncharged particle with little or no mass that is created during the radioactive decay of nuclei.

Leptons

PROPERTIES OF ATOMS

Atomic number. The single most important characteristic of an atom is its atomic number, which is defined as the number of units of positive charge in the nucleus. A neutral atom has an equal number of protons and electrons, so that the positive and negative charges exactly balance. The atomic number determines the chemical properties of an atom, including the kinds of molecules that can be formed and their binding energies. Hence, the atomic number determines an atom's characteristics as an element. (An element is composed of atoms with the same atomic number.) Elements found in nature range from atomic number 1, hydrogen, to atomic number 92, uranium. In addition, artificial elements with atomic numbers beyond 100 have been produced.

Atomic mass number. The total number of nucleons (both protons and neutrons) in an atom is the atomic mass number, or mass number. Atoms with the same atomic number but different atomic masses are called

Differences between isotopes

isotopes. Isotopes have identical chemical properties, yet they can have very different nuclear properties (see below *Isotopes*). The nuclear properties of an atom include possible radioactivity (the propensity to become radioactive in nuclear reactions), magnetic properties, and weight. The element potassium, for example, has two natural isotopes, ^{39}K and ^{40}K. They form exactly the same compounds, but ^{40}K is radioactive and decays into another element. In scientific notation, the isotope of potassium with 19 protons, 20 neutrons, and a total of 39 nucleons can be written either as $_{19}K^{39}$ or as $^{39}_{19}K$.

Because isotopes have the same number of protons, all of the isotopes of a given element occupy the same place in the periodic table of elements. Most elements have stable isotopes. For example, hydrogen has three isotopes, each with one proton. The nucleus of ordinary hydrogen is an isolated proton, but the isotope deuterium has a neutron bound to the proton. Both of these isotopes are stable. The third hydrogen isotope, tritium, has two neutrons and is radioactive. Radioactive isotopes can be made for many elements; the more the number of neutrons deviates from the optimum number for that atomic mass, the shorter the life of the radioactive isotope.

Atomic weight. The term atomic weight, or atomic mass, refers to the mass of a fixed number of atoms of an element. The standard scientific unit for dealing with atoms in macroscopic quantities is the mole (mol), which is defined arbitrarily as the amount of a substance with as many atoms or other units as there are in 12 grams of the carbon isotope ^{12}C. The number of atoms in a mole is called Avogadro's number, the value of which is approximately 6×10^{23}. The atomic mass of an element expressed in daltons, or more commonly atomic mass units (amu's), is the number of grams in one mole of the element. The amu is convenient because atomic masses are nearly equal to atomic mass numbers and therefore are close to integer values.

Historically, the law for chemical combination according to molar weights was the primary evidence for the existence of atoms and molecules. For example, two grams of hydrogen combine with 16 grams of oxygen to form water. This represents two moles of hydrogen of atomic weight 1 combining with one mole of oxygen of atomic weight 16. Elements consisting of a mixture of several isotopes may not have an atomic mass close to an integer, because the mass will be the weighted average of the different isotopes. An example is chlorine, which has two common isotopes, ^{35}Cl and ^{37}Cl, and a weighted average mass of 35.5 amu.

Electric charge. The normal atom is electrically neutral, meaning that it carries a net electric charge of zero. Some atoms, however, have lost or gained electrons in chemical reactions or in collisions with other particles. Atoms with a net charge, either from the gain or loss of electrons, are called ions. If a neutral atom loses an electron, it becomes a positive ion; if it gains an electron, it becomes a negative ion.

Ions

The charge on any particle is a whole multiple of the electron's charge, either positive or negative. The quarks are an exception to this rule. They have charges of $+^2/_3e$ and $-^1/_3e$. However, they exist only in groups, and each group as a whole has an integral multiple of the electron's charge. The amount of charge in this fundamental unit is equal to 1.6×10^{-10} coulomb. This means that in a current of one ampere—roughly what a 100-watt light bulb uses in the ordinary 110-volt household circuit—about 6×10^{18} electrons pass through the wire every second.

Electron shells. The behaviour of electrons in atoms is quite subtle and is governed by the laws of quantum mechanics. According to these laws, electrons occupy various regions of the atom in frozen wave patterns called orbitals. The orbitals are most easily visualized as clouds surrounding the nucleus. The shape and size of the orbital, and the energy of the electron in it, are calculated by differential equations. The orbitals vary in shape from smooth and spherical for the electrons most tightly bound to the nucleus to rather diffuse and lumpy for the least bound electrons. The hydrogen atom has a single electron in a spherical cloud. The electron could go into other orbitals, but it would require additional energy in the atom to do so. The quantum theory provides that the energy of an atom can only change in definite amounts called quanta. The different possible states an atom can be in, each with its own definite energy, are called energy levels. The light emitted from an atom has specific frequencies associated with the energy quanta. Energy at the atomic level is often expressed in electron volts (eV). There are 2.26×10^{25} eV in one kilowatt-hour. To remove an electron from an atom requires several electron volts, depending on the atom. Visible light has a quantum energy of about 2 eV.

Energy levels and quanta

Each electron in a multielectron atom has its own orbital, according to a law of quantum mechanics known as the Pauli principle (also called the Pauli exclusion principle or exclusion principle). Thus, in atoms with many electrons, many different kinds of orbitals are occupied. A group of orbitals with the same or nearly the same energy is called a shell. The pattern of filled and unfilled shells in each element is different; this variety gives the elements their distinctive characteristics.

Chemical behaviour. The chemical behaviour of atoms depends on the shells of the more loosely bound electrons. The Pauli principle is responsible for chemical valence, the principle of chemistry according to which atoms of one element bond to a definite number of atoms in other elements according to simple counting rules. If these shells are completely filled, the electrons are tightly bound and the atom does not readily share or lend its electrons to form chemical bonds. If there is only one electron in the last shell, it is weakly bound and the atom can be easily ionized. Examples of these situations are helium, which has a filled shell and is an inert gas, and lithium, which has one more electron in the next shell and is a highly reactive metal.

Formation of chemical bonds

One kind of chemical bond is the ionic bond, in which a loosely bound electron from one atom transfers to a deeper shell in another atom. The two ions are held together by their electrical forces. Another kind of bond is the covalent bond. In this situation, the electron clouds of one atom are distorted by the presence of another atom. In the new cloud pattern, the outer electrons are more concentrated in the region between the two atoms. Thus, the atoms share their electrons. This allows atoms of the same element to form chemical bonds, which could not happen with ionic bonds. Chemical-bond energies typically measure several electron volts.

Nuclear properties. Like atoms, nuclei have a shell structure with the protons and neutrons in orbitals. Nuclei can exist in states of different energy, but ordinary stable nuclei are always in the most bound state. The scale of these energies is 1,000,000 times as large as atomic or chemical energies.

Nuclear transformations

Nuclei can undergo transformations that affect their binding energies. If a transformation leads to more tightly bound nuclei, the excess energy will be released in some form. If one mole of atoms undergoes a nuclear transformation and releases 1,000,000 electron volts (1 MeV) of energy per nucleus, the total energy will be 10^{11} joules.

Some transformations can take place spontaneously, and such a process is called radioactivity. In one form of radioactivity, a neutron in the nucleus is converted to a proton or vice versa. If an electron is emitted at the same time, the process is known as beta radioactivity and the electron is called a beta ray. In another form of radioactivity, the nucleus disintegrates into one of lower mass number with the excess nucleons being ejected as a small nucleus. The small nucleus is commonly helium-4. This process is called alpha radioactivity, and the emitted helium-4 nuclei are called alpha rays. A third kind of ray observed in radioactivity is the gamma ray. Such rays are quanta of light of very high energy that are emitted when the nucleus makes a transition from one energy state to another of lower energy (see below *Radioactivity*).

Nuclear transformations also take place in nuclear reactions, which are the processes that occur when a nucleus is struck by some external particle. In a fusion reaction, two light nuclei come together and merge into a single heavier nucleus. Another important reaction is fission, the division of a nucleus into two roughly equal parts. Fission can be induced in the heaviest elements by reactions with free

neutrons. Both fusion and fission can release energy by reforming the nuclei so that their atomic masses are closer to the middle range where nuclei have maximum binding energy (see below *Nuclear fission* and *Nuclear fusion*).

Development of atomic theory

The concept of the atom that Western scientists accepted in broad outline from the 1600s until about 1900 originated with Greek philosophers in the 5th century BC. Their speculation about a hard, indivisible fundamental particle of nature was replaced slowly by a scientific theory supported by experiment and mathematical deduction. It was 2,000 years before modern physicists realized that the atom is indeed divisible and that it is not hard, solid, or immutable.

THE ATOMIC PHILOSOPHY OF THE EARLY GREEKS

Leucippus of Miletus (5th century BC) is thought to have originated the atomic philosophy. His famous disciple, Democritus of Abdera, developed and named the building blocks of matter *atomos,* meaning literally "indivisible," about 430 BC. Democritus believed that atoms were uniform, solid, hard, incompressible, and indestructible and that they moved in infinite numbers through empty space until stopped. Differences in atomic shape and size determined the various properties of matter. In Democritus' philosophy, atoms existed not only for matter but also for such qualities as perception and the human soul. For example, sourness was caused by needle-shaped atoms, while the colour white was composed of smooth-surfaced atoms. The atoms of the soul were considered to be particularly fine. Democritus developed his atomic philosophy as a middle ground between two opposing Greek theories about reality and the illusion of change. He argued that matter was subdivided into indivisible and immutable particles that created the appearance of change when they joined and separated from others.

The speculations of Democritus

The philosopher Epicurus of Samos (341–270 BC) used Democritus' ideas to try to quiet the fears of superstitious Greeks. According to Epicurus' materialistic philosophy, the entire universe was composed exclusively of atoms and void, and so even the gods were subject to natural laws.

Most of what is known about the atomic philosophy of the early Greeks comes from Aristotle's attacks on it and from a long poem, *De rerum natura* ("On the Nature of Things"), which the Latin poet and philosopher Titus Lucretius Carus (*c.* 95–55 BC) wrote to popularize its ideas. The Greek atomic theory is significant historically and philosophically, but it has no scientific value. It was not based on observations of nature, measurements, tests, or experiments. Instead, the Greeks used mathematics and reason almost exclusively when they wrote about physics. Like the later theologians of the Middle Ages, they wanted an all-encompassing theory to explain the universe, not merely a detailed experimental view of a tiny portion of it. Science constituted only one aspect of their broad philosophical system. Thus, Plato and Aristotle attacked Democritus' atomic theory on philosophical grounds rather than on scientific ones. Plato valued abstract ideas more than the physical world and rejected the notion that attributes such as goodness and beauty were "mechanical manifestations of material atoms." Where Democritus believed that matter could not move through space without a vacuum and that light was the rapid movement of particles through a void, Aristotle rejected the existence of vacuums because he could not conceive of bodies falling equally fast through a void. Aristotle's conception prevailed in medieval Christian Europe; its science was based on revelation and reason, and the Roman Catholic theologians rejected Democritus as materialistic and atheistic.

THE EMERGENCE OF EXPERIMENTAL SCIENCE

De rerum natura, which was rediscovered in the 15th century, helped fuel the 17th-century debate between orthodox Aristotelian views and the new experimental science. The poem was printed in 1649 and popularized by Pierre Gassendi, a French priest who tried to separate Epicurus' atomism from its materialistic background by arguing that God created atoms.

Soon after Galileo Galilei expressed his belief that vacuums can exist (1638), scientists began studying the properties of air and partial vacuums to test the relative merits of Aristotelian orthodoxy and the atomic theory. The experimental evidence about air was only gradually separated from this philosophical controversy.

The Anglo-Irish chemist Robert Boyle began his systematic study of air in 1658 after he learned that Otto von Guericke, a German physicist and engineer, had invented an improved air pump four years earlier. In 1662 Boyle published the first physical law expressed in the form of an equation that describes the functional dependence of two variable quantities. This formulation became known as Boyle's law. From the beginning, Boyle wanted to analyze the elasticity of air quantitatively, not just qualitatively, and to separate the particular experimental problem about air's "spring" from the surrounding philosophical issues. Pouring mercury into the open end of a closed J-shaped tube, Boyle forced the air in the short side of the tube to contract under the pressure of the mercury on top. By doubling the height of the mercury column, he roughly doubled the pressure and halved the volume of air. By tripling the pressure, he cut the volume of air to a third, and so on.

Boyle's law

This behaviour can be formulated mathematically in the relation $PV = P'V'$, where P and V are the pressure and volume under one set of conditions and P' and V' represent them under different conditions. Boyle's law says that pressure and volume are inversely related for a given quantity of gas. Although it is only approximately true for real gases, Boyle's law is an extremely useful idealization that played an important role in the development of atomic theory.

Soon after his air-pressure experiments, Boyle wrote that all matter is composed of solid particles arranged into molecules to give material its different properties. He explained that all things are "made of one Catholick Matter common to them all, and . . . differ but in the shape, size, motion or rest, and texture of the small parts they consist of."

In France Boyle's law is called Mariotte's law after the physicist Edme Mariotte, who discovered the empirical relationship independently in 1676. Mariotte realized that the law holds true only under constant temperatures; otherwise, the volume of gas expands when heated or contracts when cooled.

Forty years later, Isaac Newton expressed a typical 18th-century view of the atom that was similar to that of Democritus, Boyle, and Gassendi. In the last query in his book *Opticks* (1704), Newton stated:

> All these things being considered, it seems probable to me that God in the Beginning form'd Matter in solid, massy, hard, impenetrable, moveable Particles, of such Sizes and Figures, and with such other Properties, and in such Proportion to Space, as most conduced to the End for which he form'd them; and that these primitive Particles being Solids, are incomparably harder than any porous Bodies compounded of them; even so very hard, as never to wear or break in pieces; no ordinary Power being able to divide what God himself made one in the first Creation.

By the end of the 18th century chemists were just beginning to learn how chemicals combine. In 1794 Joseph-Louis Proust of France published his law of definite proportions (also known as Proust's law). He stated that the components of chemical compounds always combine in the same proportions by weight. For example, Proust found that no matter where he got his samples of the compound copper carbonate, they were composed by weight of five parts copper, four parts oxygen, and one part carbon.

Law of definite proportions

THE BEGINNINGS OF MODERN ATOMIC THEORY

Experimental foundation of atomic chemistry. The British chemist and physicist John Dalton extended Proust's work and converted the atomic philosophy of the Greeks into a scientific theory between 1803 and 1808. His book *New System of Chemical Philosophy* (part I, 1808; part II, 1810) was the first application of atomic

Dalton's application of atomic theory to chemistry

theory to chemistry. It provided a physical picture of how elements combine to form compounds and a phenomenological reason for believing that atoms exist. His work, together with that of Joseph-Louis Gay-Lussac of France and Amedeo Avogadro of Italy, provided the experimental foundation of atomic chemistry.

On the basis of the law of definite proportions, Dalton deduced the law of multiple proportions, which stated that when two elements form more than one compound by combining in more than one proportion by weight, the weight of one element in one of the compounds is in simple, integer ratios to its weights in the other compounds. For example, Dalton knew that oxygen and carbon can combine to form two different compounds and that carbon dioxide (CO_2) contains twice as much oxygen by weight as carbon monoxide (CO). In this case, the ratio of oxygen in one compound to the amount of oxygen in the other is the simple integer ratio 2:1. Although Dalton called his theory "modern" to differentiate it from Democritus' philosophy, he retained the Greek term atom to honour the ancients.

Dalton had begun his atomic studies by wondering why the different gases in the atmosphere do not separate, with the heaviest on the bottom and the lightest on the top. He decided that atoms are not infinite in variety as had been supposed and that they are limited to one of a kind for each element. Proposing that all the atoms of a given element have the same fixed mass, he concluded that elements react in definite proportions to form compounds because their constituent atoms react in definite proportion to produce compounds. He then tried to figure out the masses for well-known compounds. To do so, Dalton made a faulty but understandable assumption that the simplest hypothesis about atomic combinations was true. He maintained that the molecules of an element would always be single atoms. Thus, if two elements form only one compound, he believed that one atom of one element combined with one atom of another element. For example, describing the formation of water, he said that one atom of hydrogen and one of oxygen would combine to form HO instead of H_2O. Dalton's mistaken belief that atoms join together by attractive forces was accepted and formed the basis of most of 19th-century chemistry. As long as scientists worked with masses as ratios, a consistent chemistry could be developed because they did not need to know whether the atoms were separate or joined together as molecules.

Gay-Lussac's law of combining gases

Gay-Lussac soon took the relationship between chemical masses implied by Dalton's atomic theory and expanded it to volumetric relationships of gases. In 1809 he published two observations about gases that have come to be known as Gay-Lussac's law of combining gases. The first part of the law says that, when gases combine chemically, they do so in numerically simple volume ratios. Gay-Lussac illustrated this part of his law with three oxides of nitrogen. The compound NO has equal parts of nitrogen and oxygen by volume. Similarly, in the compound N_2O, the two parts by volume of nitrogen combine with one part of oxygen. He found corresponding volumes of nitrogen and oxygen in NO_2. Thus, Gay-Lussac's law relates volumes of the chemical constituents within a compound, unlike Dalton's law of multiple proportions, which relates only one constituent of a compound with the same constituent in other compounds.

The second part of Gay-Lussac's law states that if gases combine to form gases, the volumes of the products are also in simple numerical ratios to the volume of the original gases. This part of the law was illustrated by the combination of carbon monoxide and oxygen to form carbon dioxide. Gay-Lussac noted that the volume of the carbon dioxide is equal to the volume of carbon monoxide and is twice the volume of oxygen. He did not realize, however, that the reason that only half as much oxygen is needed is because the oxygen molecule splits in two to give a single atom to each molecule of carbon monoxide. In his "Mémoire sur la combinaison des substances gazeuses, les unes avec les autres" (1809; "Memoir on the Combination of Gaseous Substances with Each Other"), Gay-Lussac wrote:

> Thus it appears evident to me that gases always combine in the simplest proportions when they act on one another; and we have seen in reality in all the preceding examples that the ratio of combination is 1 to 1, 1 to 2 or 1 to 3. . . . Gases . . . in whatever proportions they may combine, always give rise to compounds whose elements by volume are multiples of each other. . . . Not only, however, do gases combine in very simple proportions, as we have just seen, but the apparent contraction of volume which they experience on combination has also a simple relation to the volume of the gases, or at least to one of them.

Gay-Lussac's work raised the question of whether atoms differ from molecules and, if so, how many atoms and molecules are in a volume of gas. Amedeo Avogadro, building on Dalton's efforts, solved the puzzle, but his work unfortunately was ignored for 50 years.

Avogadro's hypotheses

In 1811 Avogadro proposed two hypotheses: (1) The atoms of elemental gases may be joined together in molecules rather than existing as separate atoms, as Dalton believed. (2) Equal volumes of gases contain equal numbers of molecules. These hypotheses explained why only half a volume of oxygen was necessary to combine with a volume of carbon monoxide to form carbon dioxide. Each oxygen molecule has two atoms, and each atom of oxygen joins one molecule of carbon monoxide.

Until the early 1860s, however, the allegiance of chemists to another concept espoused by the eminent Swedish chemist Jöns Jacob Berzelius blocked acceptance of Avogadro's ideas. (Berzelius was influential among chemists because he had determined the atomic weights of many elements extremely accurately.) Berzelius contended incorrectly that all atoms of a similar element repel each other because they have the same electric charge. He thought that only atoms with opposite charges could combine to form molecules.

Because early chemists did not know how many atoms were in a molecule, their chemical notation systems were in a state of chaos by the mid-19th century. Berzelius and his followers, for example, used the general formula MO for the chief metallic oxides, while others assigned the formula used today, M_2O. A single formula stood for different substances, depending on the chemist: H_2O_2 was water or hydrogen peroxide; C_2H_4 was marsh gas or ethylene. Proponents of the system used today based their chemical notation on an empirical law formulated in 1819 by the French scientists Pierre-Louis Dulong and Alexis-Thérèse Petit concerning the specific heat of elements. According to the so-called Dulong–Petit law, the specific heat of all elements is the same on a per atom basis. This law, however, was found to have many exceptions and was not fully understood until the development of quantum theory in the 20th century.

To resolve such problems of chemical notation, the Sicilian chemist Stanislao Cannizzaro revived Avogadro's ideas in 1858 and expounded them at the First International Chemical Congress, which met in Karlsruhe, Ger., in 1860. A noted German chemistry professor wrote later that, when he heard Avogadro's theory at the congress, "It was as though scales fell from my eyes, doubt vanished, and was replaced by a feeling of peaceful certainty." Within a few years, Avogadro's hypotheses were widely accepted in the world of chemistry.

Atomic weights and the periodic table. As more and more elements were discovered during the 19th century, scientists began to wonder how the physical properties of the elements were related to their atomic weights. During the 1860s several schemes were suggested. The Russian chemist Dmitry Ivanovich Mendeleyev based his system on the atomic weights of the elements as determined by Avogadro's theory of diatomic molecules. In his paper of 1869 introducing the periodic table, he credited Cannizzaro for using "unshakeable and indubitable" methods to determine atomic weights. "The elements, if arranged according to their atomic weights, show a distinct periodicity of their properties. . . . Elements exhibiting similarities in their chemical behavior have atomic weights which are approximately equal (as in the case of Pt, Ir, Os) or they possess atomic weights which increase in a uniform manner (as in the case of K, Rb, Cs)." Skipping

Mendeleyev's periodic table

hydrogen because it is anomalous, Mendeleyev arranged the 63 elements known to exist at the time into six groups according to valence. Valence, which is the combining power of an element, determines the proportions of the elements in a compound. For example, H_2O combines oxygen with a valence of 2 and hydrogen with a valence of 1. Recognizing that chemical qualities change gradually as atomic weight increases, Mendeleyev predicted a new element wherever there was a gap in atomic weights between adjacent elements. His system was thus a research tool and not merely a system of classification. Mendeleyev's periodic table raised an important question, however, for future atomic theory to answer: Where does the pattern of atomic weights come from?

Kinetic theory of gases. Whereas Avogadro's theory of diatomic molecules was ignored for 50 years, the kinetic theory of gases was rejected for more than a century. The kinetic theory relates the independent motion of molecules to the mechanical and thermal properties of gases—namely, their pressure, volume, temperature, viscosity, and heat conductivity. Three men—Daniel Bernoulli in 1738, John Herapath in 1820, and John James Waterston in 1845—independently developed the theory. The kinetic theory of gases, like the theory of diatomic molecules, was a simple physical idea that chemists ignored in favour of an elaborate explanation of the properties of gases.

The contributions of Bernoulli, Herapath, and Waterston

Bernoulli, a Swiss mathematician and scientist, worked out the first quantitative mathematical treatment of the kinetic theory in 1738, picturing gases as consisting of an enormous number of particles in very fast, chaotic motion (see Figure 1). He derived Boyle's law by assuming that gas pressure is caused by the direct impact of particles on the walls of their container. He understood the difference between heat and temperature, realizing that heat makes gas particles move faster and that temperature merely measures the propensity of heat to flow from one body to another. In spite of its accuracy, Bernoulli's theory remained virtually unknown during the 18th century and early 19th century for several reasons. First, chemistry was more popular than physics among scientists of the day, and Bernoulli's theory involved mathematics. Second, Newton's reputation insured the success of his more comprehensible theory that gas atoms repel one another. Finally, Joseph Black, another noted British scientist, developed the caloric theory of heat, which proposed that heat was an invisible substance permeating matter. At the time, the fact that heat could be transmitted by light seemed a persuasive argument that heat and motion had nothing to do with each other.

Herapath, an amateur ignored by his contemporaries, published his version of the kinetic theory in 1821. He also derived an empirical relation akin to Boyle's law but did not understand correctly the role of heat and temperature in determining the pressure of a gas.

Waterston's efforts met with a similar fate. A civil engineer and amateur physicist, he could not even get his work published by the scientific community, which had become increasingly professional throughout the 19th century. Nevertheless, Waterston made the first statement of the law of equipartition of energy, according to which all kinds of particles have equal amounts of thermal energy. He derived practically all the consequences of the fact that pressure exerted by a gas is related to the number of molecules per cubic centimetre, their mass, and their mean squared velocity. He derived the basic equation of kinetic theory, which reads $P = NMV^2$. Here P is the pressure of a volume of gas, N is the number of molecules per unit volume, M is the mass of the molecule, and V^2 is the average velocity squared of the molecules. Recognizing that the kinetic energy of a molecule is proportional to MV^2 and that the heat energy of a gas is proportional to the temperature, Waterston expressed the law as $PV/T =$ a constant.

During the late 1850s, a decade after Waterston had formulated his law, the scientific community was finally ready to accept a kinetic theory of gases. The studies of heat undertaken by the British physicist James Prescott Joule during the 1840s had shown that heat is a form of energy. This work, together with the law of the conservation of energy that he helped to establish, had persuaded scientists to discard the caloric theory by the mid-1850s. The caloric theory had required that a substance contain a definite amount of caloric (*i.e.*, a hypothetical weightless fluid) to be turned into heat; however, experiments showed that any amount of heat can be generated in a substance by putting enough energy into it. Thus, there was no point to hypothesizing such a special fluid as caloric.

At first, after the collapse of the caloric theory, physicists had nothing with which to replace it. Joule, however, discovered Herapath's kinetic theory and used it to calculate the velocity of hydrogen molecules in 1851. Then Rudolf Clausius developed the kinetic theory mathematically in 1857, and the scientific world took note. Clausius and two other physicists, James Clerk Maxwell and Ludwig Eduard Boltzmann (who developed the kinetic theory of gases in the 1860s), introduced sophisticated mathematics into physics for the first time since Newton. In his 1860 paper "Illustrations of the Dynamical Theory of Gases," Maxwell used probability to produce his famous distribution curve for the velocities of gas molecules. Employing Newtonian laws of mechanics, he also provided a mathematical basis for Avogadro's theory. Maxwell, Clausius, and Boltzmann assumed that gas particles were in constant motion, that they were tiny compared to their space, and that their interactions were very brief. They then related the motion of the particles to pressure, volume, and temperature. Interestingly, none of the three committed himself on the nature of the particles.

From Daniel Bernoulli, *Hydrodynamica* (1738), in *A Source Book of Physics*, trans., W.F. Magie (1935); Harvard University Press

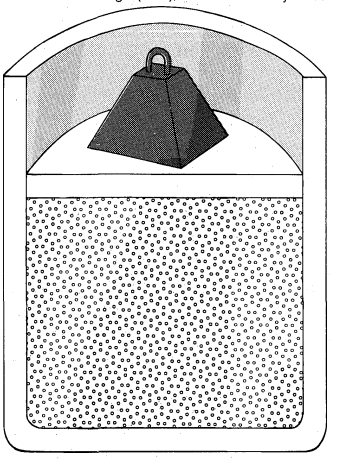

Figure 1: As conceived by Daniel Bernoulli in *Hydrodynamica* (1738), gases consist of numerous particles in rapid, random motion. He assumed that the pressure of a gas is produced by the direct impact of the particles on the walls of the container (see text).

STUDIES OF THE PROPERTIES OF ATOMS

Size of atoms. The first modern estimates of the size of atoms and the numbers of atoms in a given volume were made by the German chemist Joseph Loschmidt in 1865. Loschmidt used the results of kinetic theory and some rough estimates to do his calculation. The size of the atoms and the distance between them in the gaseous state are related both to the contraction of gas upon liquefaction and to the mean free path traveled by molecules in a gas. The mean free path, in turn, can be found from the thermal conductivity and diffusion rates in the gas. Loschmidt calculated the size of the atom and the spacing between atoms by finding a solution common to these relationships. His result for Avogadro's number is remarkably close to the present accepted value of 6.022×10^{23}. The precise definition of Avogadro's number is the number of atoms in 12 grams of the carbon isotope ^{12}C. Loschmidt's result for the diameter of an atom was approximately 10^{-8} centimetres.

Loschmidt's determinations

Much later, in 1908, the French physicist Jean Perrin used Brownian motion to determine Avogadro's number.

Brownian motion, first observed in 1827 by the Scottish botanist Robert Brown, is the continuous movement of tiny particles suspended in water. Their movement is caused by the thermal motion of water molecules bumping into the particles. Perrin's argument for determining Avogadro's number makes an analogy between particles in the liquid and molecules in the atmosphere. The thinning of air at high altitudes depends on the balance between the gravitational force pulling the molecules down and their thermal motion forcing them up. The relationship between the weight of the particles and the height of the atmosphere would be the same for Brownian particles suspended in water. Perrin counted particles of gum mastic at different heights in his water sample and inferred the mass of atoms from the rate of decrease. He then divided the result into the molar weight of atoms to determine Avogadro's number. After Perrin, few scientists could disbelieve the existence of atoms.

Electric properties of atoms. While atomic theory was set back by the failure of scientists to accept simple physical ideas like the diatomic atom and the kinetic theory of gases, it was also delayed by the preoccupation of physicists with mechanics for almost 200 years, from Newton to the 20th century. Nevertheless, several 19th-century investigators, working in the relatively ignored fields of electricity, magnetism, and optics, provided important clues about the interior of the atom. The studies in electrodynamics made by the British physicist Michael Faraday and those of Maxwell indicated for the first time that something existed apart from palpable matter, and data obtained by Gustav Robert Kirchhoff of Germany about elemental spectral lines raised questions that would only be answered in the 20th century by quantum mechanics.

Until Faraday's electrolysis experiments, scientists had had no conception of the nature of the forces binding atoms together in a molecule. Faraday concluded that electrical forces existed inside the molecule after he had produced an electric current and a chemical reaction in a solution with the electrodes of a voltaic cell. No matter what solution or electrode material he used, a fixed quantity of current sent through an electrolyte always caused a specific amount of material to form on an electrode of the electrolytic cell. Faraday concluded that each ion of a given chemical compound has exactly the same charge. Later, he discovered that the ionic charges are integral multiples of a single unit of charge, never fractions.

Faraday's discoveries

On the practical level, Faraday did for charge what Dalton had done for the chemical combination of atomic masses. That is to say, Faraday demonstrated that it takes a definite amount of charge to convert an ion of an element into an atom of the element and that the amount of charge depends on the element used. The unit of charge that releases a gram atomic weight of a simple ion is called the faraday in his honour. For example, one faraday of charge passing through water releases one gram of hydrogen and eight grams of oxygen. In this manner, Faraday gave scientists a rather precise value for the ratios of the masses of atoms to the electric charges of ions. The ratio of the mass of the hydrogen atom to the charge of the electron was found to be 1.035×10^{-8} kilogram per coulomb. Faraday did not know the size of his electrolytic unit of charge in units such as coulombs any more than Dalton knew the magnitude of his unit of atomic weight in grams. Nevertheless, scientists could determine the ratio of these units easily.

More significantly, Faraday's work was the first to imply the electrical nature of matter and the existence of subatomic particles and a fundamental unit of charge. Faraday wrote: "The atoms of matter are in some way endowed or associated with electrical powers, to which they owe their most striking qualities, and amongst them their mutual chemical affinity." Faraday did not, however, conclude that atoms cause electricity.

Light and spectral lines. In 1865 Maxwell unified the laws of electricity and magnetism in his publication "A Dynamical Theory of the Electromagnetic Field." In this paper, he concluded that light is an electromagnetic wave. His theory was confirmed by the German physicist Heinrich Hertz, who produced radio waves with sparks in 1887. With light understood as an electromagnetic wave, Maxwell's theory could be applied to the emission of light from atoms. The theory failed, however, to describe spectral lines and the fact that atoms do not lose all their energy when they radiate light. The problem was not with Maxwell's theory of light itself but rather with its description of the oscillating electron currents generating light. Only quantum mechanics could explain this behaviour (see below *The laws of quantum mechanics*).

By far the richest clues about the structure of the atom came from spectral lines. Mounting a particularly fine prism on a telescope, the German physicist and optician Joseph von Fraunhofer had discovered between 1814 and 1824 hundreds of dark lines in the spectrum of the Sun. He labeled the most prominent of these lines with the letters *A* through *G*. Together, they are now called Fraunhofer lines. A generation later, Kirchhoff heated different elements to incandescence in order to study the different coloured vapours emitted. Observing the vapours through a spectroscope, he discovered that each element has a unique and characteristic pattern of spectral lines. Each element produces the same set of identifying lines, even when it is combined chemically with other elements. In 1859 Kirchhoff and the German chemist Robert Wilhelm Bunsen discovered two new elements—cesium and rubidium—by first observing their spectral lines.

Spectral lines and atomic structure

Johann Jakob Balmer, a Swiss secondary-school teacher with a penchant for numerology, studied hydrogen's spectral lines and found a constant relationship between the wavelengths of the element's four visible lines (see Figure 2). In 1885 he published a generalized mathematical formula for all of the lines of hydrogen. The Swedish physicist Johannes Rydberg extended Balmer's work in 1890 and found a general rule applicable to many elements. Soon more series were discovered elsewhere in the spectrum of hydrogen and in the spectra of other elements as well. Stated in terms of the frequency of the light rather than its wavelength, the formula may be expressed:

$$\nu = R\,(1/n^2 - 1/m^2).$$

Here, n and m are integers and R is a constant. In the Balmer lines, m is equal to 2 and n takes on the values 3, 4, 5, and 6.

Discovery of electrons. During the 1880s and '90s, scientists searched cathode rays for the carrier of the electrical properties in matter. Their work culminated in J.J. Thomson's discovery of the electron in 1897. The existence of the electron showed that the 2,000-year-old conception of the atom as a homogeneous particle was wrong and that in fact the atom has a complex structure.

Cathode-ray studies began in 1854 when Heinrich Geissler, a glassblower and technical assistant to the German physicist Julius Plücker, improved the vacuum tube. Plücker discovered cathode rays in 1858 by sealing two electrodes inside the tube, evacuating the air, and forcing electric current between the electrodes. He found a green glow on the wall of his glass tube and attributed it to rays emanating from the cathode. In 1869, with better vacuums, Plücker's pupil Johann W. Hittorf saw a shadow cast by an object placed in front of the cathode. The shadow proved that the cathode rays originated from the cathode. The British physicist and chemist Sir William Crookes investigated cathode rays in 1879 and found that they were bent by a magnetic field; the direction of deflection

Crookes's study of cathode rays

suggested that they were negatively charged particles. As the luminescence did not depend on what gas had been in the vacuum or what metal the electrodes were made of, he surmised that the rays were a property of the electric current itself. As a result of Crookes's work, cathode rays were widely studied, and the tubes came to be called Crookes tubes.

Although Crookes believed that the particles were electrified charged particles, his work did not settle the issue of whether cathode rays were particles or radiation similar to light. By the late 1880s the controversy over the nature of cathode rays had divided the physics community into two camps. Most French and British physicists, influenced by Crookes, thought that cathode rays were electrically charged particles because they were affected by magnets. Most German physicists, on the other hand, believed that the rays were waves because they traveled in straight lines and were unaffected by gravity. A crucial test of the nature of the cathode rays was how they would be affected by electric fields. Heinrich Hertz, the aforementioned German physicist, reported that the cathode rays were not deflected when they passed between two oppositely charged plates in an 1892 experiment. The English physicist Thomson thought Hertz's vacuum might have been faulty and that residual gas might have reduced the effect of the electric field on the cathode rays.

Thomson repeated Hertz's experiment with a better vacuum in 1897. He directed the cathode rays between two parallel aluminum plates to the end of a tube where they were observed as luminescence on the glass. When the top aluminum plate was negative, the rays moved down; when the upper plate was positive, the rays moved up. The deflection was proportional to the difference in potential between the plates. With both magnetic and electric deflections observed, it was clear that cathode rays were negatively charged particles. Thomson's discovery established the particulate nature of electricity. Accordingly, he called his particles electrons.

Determining the properties of electrons

From the magnitude of the electrical and magnetic deflections, Thomson could calculate the ratio of mass to charge for the electrons. This ratio was known for atoms from electrochemical studies. Measuring and comparing it to the number for an atom, he discovered that the mass of the electron was very small, merely $^1/_{1836}$ that of a hydrogen ion. When scientists realized that an electron was virtually 1,000 times lighter than the smallest atom, they understood how cathode rays could penetrate metal sheets and how electric current could flow through copper wires. In deriving the mass-to-charge ratio, Thomson had calculated the electron's velocity. It was $^1/_{10}$ the speed of light, thus amounting to roughly 30,000 kilometres per second (18,000 miles per second). Thomson emphasized that "we have in the cathode rays matter in a new state, a state in which the subdivision of matter is carried very much further than in the ordinary gaseous state; a state in which all matter, that is, matter derived from different sources such as hydrogen, oxygen, etc., is of one and the same kind; this matter being the substance from which all the chemical elements are built up." Thus, the electron was the first subatomic particle identified, the smallest and the fastest bit of matter known at the time.

Millikan's electron charge experiment

In 1910 and 1911 the American physicist Robert Andrews Millikan greatly improved a method employed by Thomson for measuring the electron charge directly. Millikan produced microscopic oil droplets and observed them falling in the space between two electrically charged plates. Some of the droplets became charged and could be suspended by a delicate adjustment of the electric field. Millikan knew the weight of the droplets from their rate of fall when the electric field was turned off. From the balance of the gravitational and electrical forces, he could determine the charge on the droplets. He could find charges only in integral multiples of a quantity that in contemporary units is 1.602×10^{-19} coulomb. Millikan's electron charge experiment was the first to detect and measure the effect of an individual subatomic particle. Besides confirming the particulate nature of electricity, his experiment also supported previous determinations of Avogadro's number. Avogadro's number times the unit of charge gives Faraday's constant, the amount of charge required to electrolyze one mole of a chemical ion.

Identification of positive ions. In addition to electrons, positively charged particles also emanate from the anode in an energized Crookes tube. The German physicist Wilhelm Wien analyzed these positive rays in 1898 and found that the particles have a mass-to-charge ratio more than 1,000 times larger than that of the electron. Because the ratio of the particles is also comparable to the mass-to-charge-ratio of the residual atoms in the discharge tubes, scientists suspected that the rays were actually ions from the gases in the tube.

In 1913 Thomson refined Wien's apparatus to separate different ions and measure their mass-to-charge ratio on photographic plates. He sorted out the many ions in various charge states produced in a discharge tube. When he conducted his atomic mass experiments with neon gas, he found that a beam of neon atoms subjected to electric and magnetic forces split into two parabolas instead of one on a photographic plate. Chemists had assumed the atomic weight of neon was 20.2, but the traces on Thomson's photographic plate suggested atomic weights of 20.0 and 22.0, with the former parabola much stronger than the latter. He concluded that neon consisted of two stable isotopes: primarily neon-20, with a small percentage of neon-22. Eventually, a third isotope, neon-21, was discovered in very small quantities. It is now known that 1,000 neon atoms will contain 909 of neon-20, 88 of neon-22, and 3 of neon-21. Dalton's assumptions that all atoms of an element have an identical mass and that the atomic weight of an element is its mass were thus disproved. Today, the atomic weight of an element is recognized as the weighted average of the masses of its isotopes.

Development of the mass spectrograph

Francis William Aston, an English physicist, improved Thomson's technique when he developed the mass spectrograph in 1919. This device spread out the beam of positive ions into a "mass spectrum" of lines similar to the way light is separated into a spectrum. Aston analyzed about 50 elements over the next six years and discovered that most have isotopes.

Discovery of radioactivity. Like Thomson's discovery of the electron, the discovery of radioactivity in uranium by the French physicist Henri Becquerel in 1896 forced scientists to radically change their ideas about atomic structure. Radioactivity demonstrated that the atom was neither indivisible nor immutable. Instead of serving merely as an inert matrix for electrons, the atom could change form and emit an enormous amount of energy. Furthermore, radioactivity itself became an important tool for revealing the interior of the atom.

The German physicist Wilhelm Conrad Röntgen had discovered X rays in 1895, and Becquerel thought they might be related to fluorescence and phosphorescence, processes in which substances absorb and emit energy as light. In the course of his investigations, Becquerel stored some photographic plates and uranium salts in a desk drawer. Expecting to find the plates only lightly fogged, he developed them and was surprised to find sharp images of the salts. He then began experiments that showed that uranium salts emit a penetrating radiation independent of external influences. Becquerel also demonstrated that the radiation could discharge electrified bodies. In this case, discharge means the removal of electric charge, and it is now understood that the radiation ionizing molecules of air allows the air to conduct an electric current. Early studies of radioactivity relied on measuring ionization power or on observing the effects of radiation on photographic plates.

In 1898 the French physicists Pierre and Marie Curie discovered the strongly radioactive elements polonium and radium, which occur naturally in uranium minerals. Marie coined the term radioactivity for the spontaneous emission of ionizing, penetrating rays by certain atoms (see below).

Different forms of ionizing radiation

Experiments conducted by the British physicist Ernest Rutherford in 1899 showed that radioactive substances emit more than one kind of ray. It was determined that part of the radiation is 100 times more penetrating than the rest and can pass through aluminum foil $^1/_{50}$ of a

millimetre thick. Rutherford named the less penetrating emanations alpha rays and the more powerful ones beta rays, after the first two letters of the Greek alphabet. Investigators who, in 1899, found that beta rays were deflected by a magnetic field concluded that they are negatively charged particles similar to cathode rays. In 1903 Rutherford found that alpha rays were deflected slightly in the opposite direction, showing that they are massive, positively charged particles. Much later, Rutherford proved that alpha rays are nuclei of helium atoms by collecting the rays in an evacuated tube and detecting the buildup of helium gas over several days. A third kind of radiation was identified by the French chemist Paul Villard in 1900. Designated as the gamma ray, it is not deflected by magnets and is much more penetrating than alpha particles. Gamma rays were later shown to be a form of electromagnetic radiation, like light or X rays, but with much shorter wavelengths. Because of these shorter wavelengths, gamma rays have higher frequencies and are even more penetrating than X rays. In 1902, while studying the radioactivity of thorium, Rutherford and the English chemist Frederick Soddy discovered that radioactivity was associated with changes inside the atom that transformed thorium into a different element. They found that thorium continually generates a chemically different substance that is intensely radioactive. The radioactivity eventually makes the new element disappear. Watching the process, Rutherford and Soddy formulated the exponential decay law, which states that a fixed fraction of the element will decay in each unit of time. For example, half of the thorium product decays in four days, half the remaining sample in the next four days, and so on.

Law of exponential decay

Until the 20th century, physicists had studied such subjects as mechanics, heat, and electromagnetism that they could understand by applying common sense or by extrapolating from everyday experiences. The discovery of the electron and radioactivity, however, showed that classical Newtonian mechanics could not explain phenomena at atomic and subatomic levels. As the primacy of classical mechanics crumbled during the early 20th century, quantum mechanics was developed to replace it. Since then, experiments and theories have led physicists into a world that is often extremely abstract and seemingly contradictory.

MODELS OF ATOMIC STRUCTURE

Thomson's discovery of the negatively charged electron had raised theoretical problems for physicists as early as 1897, because atoms as a whole are electrically neutral. Where was the neutralizing positive charge and what held it in place? Between 1903 and 1907 Thomson tried to solve the mystery by adapting an atomic model that had been first proposed by Lord Kelvin in 1902. According to this theoretical system, often referred to as the "plum pudding" model, the atom is a sphere of uniformly distributed positive charge about one angstrom in diameter. Electrons are embedded in a regular pattern like raisins in a plum pudding to neutralize the positive charge. The advantage of the Thomson atom was that it was inherently stable: if the electrons were displaced, they would attempt to return to their original positions. In another contemporary model, the atom resembled the solar system or the planet Saturn, with rings of electrons surrounding a concentrated positive charge. The Japanese physicist Hantaro Nagaoka, in particular, developed the "Saturnian" system in 1904. The atom, as postulated in this model, was inherently unstable because, by radiating continuously, the electron would gradually lose energy and spiral into the nucleus. No electron could thus remain in any particular orbit indefinitely.

The so-called plum pudding model

Rutherford's nuclear model. Rutherford overturned Thomson's model in 1911 with his well-known gold foil experiment in which he demonstrated that the atom has a tiny, massive nucleus. Five years earlier Rutherford had noticed that alpha particles, beamed through a hole onto a photographic plate, would make a sharp-edged picture, while alpha particles beamed through a sheet of mica only 20 micrometres (or about 0.002 centimetre) thick would make an impression with blurry edges. For some particles, the blurring corresponded to a two-degree deflection. Remembering those results, Rutherford had his postdoctoral fellow, Hans Geiger, and an undergraduate student, Ernest Marsden, refine the experiment. The young physicists beamed alpha particles through gold foil and detected them as flashes of light or scintillations on a screen. The gold foil was only 0.00004 centimetre thick. Most of the alpha particles went straight through the foil, but some were deflected by the foil and hit a spot on a screen placed off to one side. Geiger and Marsden found that about one in 20,000 alpha particles had been deflected 45° or more. Rutherford asked why so many alpha particles passed through the gold foil while a few were deflected so greatly. "It was almost as incredible as if you fired a 15-inch shell at a piece of tissue paper, and it came back to hit you," Rutherford said later. "On consideration, I realized that this scattering backwards must be the result of a single collision, and when I made calculations I saw that it was impossible to get anything of that order of magnitude unless you took a system in which the greater part of the mass of the atom was concentrated in a minute nucleus. It was then that I had the idea of an atom with a minute massive centre carrying a charge."

Many physicists distrusted Rutherford's nuclear model because it was difficult to reconcile with the chemical behaviour of atoms. The model suggested that the charge on the nucleus was the most important characteristic of the atom, determining its structure. On the other hand, Mendeleyev's periodic table of the elements had been organized according to the atomic masses of the elements, implying that the mass was responsible for the structure and chemical behaviour of atoms.

Primacy of the positive charge on the nucleus

Moseley's X-ray studies. Henry Gwyn Jeffreys Moseley, a young English physicist killed in World War I, confirmed that the positive charge on the nucleus revealed more about the fundamental structure of the atom than Mendeleyev's atomic mass. Moseley studied the spectral lines emitted by heavy elements in the X-ray region of the electromagnetic spectrum. He built on the work done by several other British physicists—Charles Glover Barkla, who had studied X rays produced by the impact of electrons on metal plates, and Sir William Bragg and his son Lawrence, who had developed a precise method of using crystals to reflect X rays and measure their wavelength by diffraction. Moseley used a crystal of potassium ferrocyanide as a diffraction grating to examine the spectra of X rays produced by different metals. He arranged his crystal so that he could control and vary the angle between the crystal face and the X-ray beam. The X rays from each element were reflected at a unique set of angles. By measuring the angle, Moseley was able to obtain the wavelength of the X ray hitting the crystal.

Moseley found that the X rays radiated by each element have a characteristic frequency that differs according to a regular pattern. The difference in frequency is not governed by Mendeleyev's change in mass, however, but rather by the change in charge on the nucleus. He called this the atomic number. In his first experiments, conducted in 1913, Moseley used the K series of X rays (X radiation associated with the K energy state of an atom) and studied the elements up to zinc. The following year he extended his work up to gold in the periodic table, using the L series of X rays (X radiation associated with the L atomic-energy state). Moseley was conducting his research at the same time that the Danish theorist Niels Bohr was developing his quantum shell model of the atom (see below). The two conferred and shared data as their work progressed, and Moseley framed his equation in terms of Bohr's theory. Moseley presented formulas for the X-ray frequencies that were closely related to Bohr's formulas for the spectral lines in a hydrogen atom. Moseley showed that the frequency of a line in the X-ray spectrum is proportional to the square of the charge on the nucleus. The constant of proportionality depends on whether the X ray is in the K or L series. This is the same relationship that Bohr used in his formula applied to the Lyman and Balmer series of spectral lines. The regularity of the differences in X-ray frequencies allowed Moseley to order the elements by atomic number from aluminum to gold. He observed

Collaboration with Niels Bohr

that, in some cases, the order by atomic weights was incorrect. For example, cobalt has a larger atomic mass than nickel, but Moseley found that it has atomic number 27, while nickel has 28. When Mendeleyev constructed the periodic table, he based his system on the atomic masses of the elements and had to put cobalt and nickel out of order to make the chemical properties fit better. In a few places where Moseley found more than one integer between elements, he predicted correctly that a new element would be discovered. Because there is just one element for each atomic number, scientists could be confident for the first time of the completeness of the periodic table; no unexpected new elements would be discovered.

Bohr's shell model. In 1913 Bohr proposed his quantized shell model of the atom to explain how electrons can have stable orbits around the nucleus. The motion of the electrons in the Rutherford model was unstable because, according to classical mechanics and electromagnetic theory, any charged particle moving on a curved path emits electromagnetic radiation; thus, the electrons would lose energy and spiral into the nucleus. To remedy the stability problem, Bohr modified the Rutherford model by requiring that the electrons move in orbits of fixed size and energy. The energy of an electron depends on the size of the orbit and is lower for smaller orbits. Radiation can occur only when the electron jumps from one orbit to another. The atom will be completely stable in the state with the smallest orbit, since there is no orbit of lower energy into which the electron can jump.

Electron orbits of fixed size and shape

Bohr's starting point was to realize that classical mechanics by itself could never explain the atom's stability. A stable atom has a certain size so that any equation describing it must contain some fundamental constant or combination of constants with a dimension of length. The classical fundamental constants—namely, the charges and the masses of the electron and the nucleus—cannot be combined to make a length. Bohr noticed, however, that the quantum constant formulated by the German physicist Max Planck (see below) has dimensions which, when combined with the mass and charge of the electron, produce a measure of length. Numerically, the measure is close to the known size of atoms. This encouraged Bohr to use Planck's constant in searching for a theory of the atom.

Planck's constant

Planck had introduced his constant in 1900 in a formula explaining the light radiation emitted from heated bodies. According to classical theory, comparable amounts of light energy should be produced at all frequencies. This is not only contrary to observation but also implies the absurd result that the total energy radiated by a heated body should be infinite. Planck postulated that energy can only be emitted or absorbed in discrete amounts, which he called quanta (the Latin word for "how much"). The energy quantum is related to the frequency of the light by a new fundamental constant, h. When a body is heated, its radiant energy in a particular frequency range is, according to classical theory, proportional to the temperature of the body. With Planck's hypothesis, however, the radiation can occur only in quantum amounts of energy. If the radiant energy is less than the quantum of energy, the amount of light in that frequency range will be reduced. Planck's formula correctly describes radiation from heated bodies. Planck's constant has the dimensions of action, which may be expressed as units of energy multiplied by time, units of momentum multiplied by length, or units of angular momentum. For example, Planck's constant can be written as $h = 6.6 \times 10^{-34}$ joule seconds or 6.6×10^{-34} kilogram-metre/second-metres.

Using Planck's constant, Bohr obtained an accurate formula for the energy levels of the hydrogen atom (see Figure 3). He postulated that the angular momentum of the electron is quantized—*i.e.*, it can have only discrete values. He assumed that otherwise electrons obey the laws of classical mechanics by traveling around the nucleus in circular orbits. Because of the quantization, the electron orbits have fixed sizes and energies. The orbits are labeled by an integer, the quantum number n.

With his model, Bohr explained how electrons could jump from one orbit to another only by emitting or absorbing energy in fixed quanta. For example, if an electron jumps one orbit closer to the nucleus, it must emit energy equal to the difference of the energies of the two orbits. Conversely, when the electron jumps to a larger orbit, it must absorb a quantum of light equal in energy to the difference in orbits.

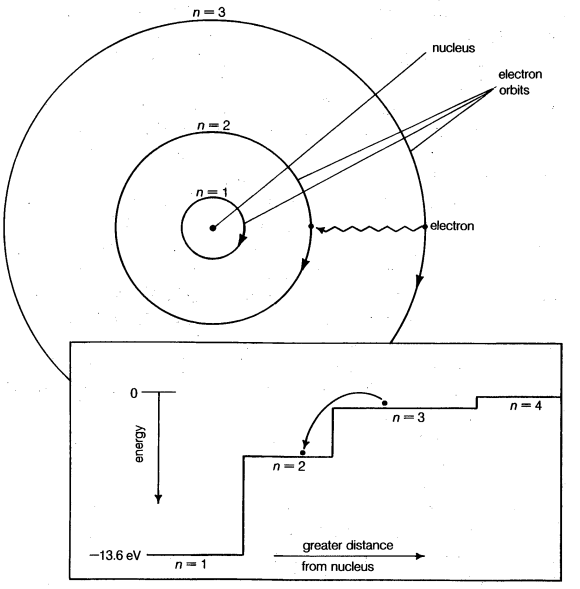

Figure 3: *The Bohr atom.*
The electron travels in circular orbits around the nucleus. The orbits have quantized sizes and energies. Energy is emitted from the atom when the electron jumps from one orbit to another closer to the nucleus. Shown here is the first Balmer transition, in which an electron jumps from orbit $n = 3$ to orbit $n = 2$, producing a photon of red light with an energy of 1.89 eV and a wavelength of 656×10^{-9} m.

The inherent stability of atoms

Bohr's model accounts for the stability of atoms because the electron cannot lose more energy than it has in the smallest orbit, the one with $n = 1$. The model also explains the Balmer formula for the spectral lines of hydrogen. The frequency of the light is related to its energy by Einstein's formula $E = hv$. The light energy is calculated from the difference in energies between the two orbits. The Balmer formula can be expressed as the difference of two terms, each term giving the energy of an orbit. Bohr's model not only explains the form of the Balmer formula but also accurately gives the value of the constant of proportionality R.

The usefulness of Bohr's theory extends beyond the hydrogen atom. Bohr himself noted that the formula also applies to the singly ionized helium atom, which, like hydrogen, has a single electron. The nucleus of the helium atom has twice the charge of the hydrogen nucleus, however. In Bohr's formula the charge of the electron is raised to the fourth power. Two of those powers stem from the charge on the nucleus; the other two come from the charge on the electron itself. Bohr modified his formula for the hydrogen atom to fit the helium atom by doubling the charge on the nucleus. Moseley applied Bohr's formula with an arbitrary atomic charge Z to explain the K- and L-series X-ray spectra of heavier atoms. The German physicists James Franck and Gustav Hertz confirmed the existence of quantum states in atoms in experiments reported in 1914. They made atoms absorb energy by bombarding them with electrons. The atoms would only absorb discrete amounts of energy from the electron beam. When the energy of an electron was below the threshold for producing an excited state, the atom would not absorb any energy.

Limitations of Bohr's model

Bohr's theory had major drawbacks, however. Except for the spectra of X rays in the K and L series, it could not explain properties of atoms having more than one electron. The binding energy of the helium atom, which has two electrons, was not understood until the development of quantum mechanics. Several features of the spectrum were inexplicable even in the hydrogen atom. High-resolution spectroscopy shows that the individual spectral lines

of hydrogen are divided into several closely spaced, fine lines. In a magnetic field the lines split even further. The German physicist Arnold Sommerfeld modified Bohr's theory by quantizing the shapes and orientations of orbits to introduce additional energy levels corresponding to the fine spectral lines. The quantization of the orientation of the angular-momentum vector was confirmed in an experiment in 1922 by other German physicists, Otto Stern and Walter Gerlach. They passed a beam of silver atoms through a nonhomogeneous magnetic field, one that is stronger on one side than on the other. The field deflected the atoms according to the orientation of their magnetic moments. (The magnetic moment of an object such as an atom or a compass needle is the measure of its interaction with a magnetic field. The moment points in some direction and is associated in classical physics with orbital currents and the angular momentum of charges.) In their experiment, Stern and Gerlach found only two deflections, not the continuous distribution of deflections that would have been seen if the magnetic moment had been oriented in any direction. Thus, it was determined that the magnetic moment and the angular momentum of an atom can have only two orientations. The discrete orientations of the orbits explain some of the magnetic field effects—namely, the so-called normal Zeeman effect, which is the splitting of a spectral line into three sublines. These sublines correspond to quantum jumps in which the angular momentum along the magnetic field is increased by one unit. decreased by one unit, or left unchanged.

Normal Zeeman effect

An additional quantum number was needed to complete the description of electrons in an atom. In 1925 Samuel A. Goudsmit and George E. Uhlenbeck, two graduate students in physics at the University of Leiden, in The Netherlands, added a quantum number to account for the fact that some spectral lines are divided into more sublines than can be explained with the original quantum numbers. Goudsmit and Uhlenbeck postulated that an electron has an internal spinning motion and that the corresponding angular momentum is one-half of the orbital angular momentum quantum. An electron has a magnetic moment, and its energy depends on whether the spin is aligned with or against the magnetic field. Independently, the Austrian-born physicist Wolfgang Pauli also suggested adding a two-valued quantum number for electrons, but for different reasons. He needed this additional quantum number to formulate his exclusion principle, which serves as the atomic basis of the periodic table and the chemical behaviour of the elements. According to the exclusion principle, one electron at most can occupy an orbital, taking into account all the quantum numbers. Pauli was led to this principle by the observation that an alkali in a magnetic field has a number of orbitals in the shell equal to the number of electrons that must be added to make the next noble gas. These numbers are twice the number of orbits available if the angular momentum and its orientation are considered alone.

In spite of these modifications, Bohr's model seemed to be a dead end by the early 1920s. It did not explain most fine spectral lines or the anomalous Zeeman effect, which is a complicated type of spectral line splitting that sometimes involves up to 15 sublines. (Its name notwithstanding, the anomalous Zeeman effect is more common than the aforementioned normal Zeeman effect.) Efforts to generalize the model to multielectron atoms had proved futile, and physicists despaired of ever explaining them.

The laws of quantum mechanics. Within a few short years scientists developed a consistent theory of the atom that explained its fundamental structure and its interactions. Crucial to the development of the theory was new evidence indicating that light and matter have both wave and particle characteristics at the atomic and subatomic levels. Theoreticians had objected to the fact that Bohr had used an ad hoc hybrid of classical Newtonian dynamics for the orbits and some quantum postulates for limiting the motion. The new theory ignored the fact that electrons are particles and treated them as waves. By 1926, physicists had developed the laws of quantum mechanics, also called wave mechanics, to explain atomic and subatomic phenomena.

The duality between the wave and particle nature of light was highlighted by the American physicist Arthur H. Compton in an X-ray scattering experiment conducted in 1922. Compton showed that X rays scatter from electrons exactly like particles. The X rays have discrete amounts of momentum, which is a property of particles. When X rays are scattered, their momentum is partially transferred to the electrons. The recoil electron takes some energy from an X ray, and as a result the X ray frequency is shifted. Both the discrete amount of momentum and the frequency shift of the light scattering are completely at variance with classical electromagnetic theory.

Louis-Victor de Broglie, a French physicist, had proposed in his 1923 doctoral thesis that all matter and radiations have both particle- and wavelike characteristics. Until the emergence of the quantum theory, physicists had assumed that matter was distinct from energy and followed different laws: energy radiations were waves and matter was particulate. Planck's theory was the first to propose that radiation has characteristics of both waves and particles. Believing in the symmetry of nature, Broglie ended the wave-particle dichotomy by applying Einstein's mass-energy formula. Using the old-fashioned word corpuscles for particles, Broglie wrote, "For both matter and radiations, light in particular, it is necessary to introduce the corpuscle concept and the wave concept at the same time. In other words, the existence of corpuscles accompanied by waves has to be assumed in all cases." Broglie's conception was an inspired one, but it had no experimental or theoretical foundation. The Austrian physicist Erwin Schrödinger had to supply the theory.

Broglie's wave-particle concept

Schrödinger's wave equation. In 1926 Schrödinger produced the mathematical wave equation that established quantum mechanics in widely applicable form. To understand how a wave equation is used, it is helpful to think of an analogy with the vibrations of a bell, violin string, or drumhead. These vibrations are governed by a wave equation, since the motion can propagate as a wave from one side of the object to the other. Certain vibrations in these objects are simple modes that are easily excited and have definite frequencies. For example, the motion of the lowest vibrational mode in a drumhead is in phase all over the drumhead with a pattern that is uniform around it; the highest amplitude of the vibratory motion is in the middle of the drumhead. In more complicated, higher frequency modes, the motion on different parts of the vibrating drumhead are out of phase, with inward motion on one part at the same time that there is outward motion on another.

Schrödinger postulated that the electrons in an atom should be treated like the waves on the drumhead. The different energy levels of atoms are identified with the simple vibrational modes of the wave equation. The equation is solved to find these modes, and then the energy of an electron is obtained from the frequency of the mode and Einstein's formula. Schrödinger's wave equation gives the same energies as Bohr's original formula but with a much more precise description of an electron in an atom. The lowest energy level of the hydrogen atom, called the ground state, is analogous to the motion in the lowest vibrational mode of the drumhead. In the atom the electron wave is uniform in all directions from the nucleus, is peaked at the centre of the atom, and has the same phase everywhere. Higher energy levels in the atom have waves that are peaked at greater distances from the nucleus. Like the vibrations in the drumhead, the waves have peaks and nodes that may form a complex shape. The different shapes of the wave pattern explain the quantum numbers of the energy levels, including the quantum numbers for angular momentum and its orientation.

The year before Schrödinger produced his wave theory, the German physicist Werner Heisenberg published a mathematically equivalent system using matrix algebra to describe energy levels and their transitions. Today, physicists use Schrödinger's system because it can be visualized more easily.

In 1929 the Norwegian physicist Egil Hylleraas applied the Schrödinger equation to the helium atom with two electrons. He obtained only an approximate solution, but

his energy calculation was quite accurate. With Hylleraas' explanation of the two-electron atom, physicists realized that the Schrödinger equation could be a powerful mathematical tool for describing nature on the atomic level, even if exact solutions could not be obtained.

The existence of antiparticles. The English physicist P.A.M. Dirac introduced a new equation for the electron in 1928. The Schrödinger equation does not satisfy the principles of relativity, and so it can be used to describe only those phenomena in which the particles move much more slowly than the velocity of light. In order to satisfy the conditions of relativity, Dirac was forced to postulate not one but four distinct wave functions for the electron. Two of these correspond to the two spin orientations. The remaining components allowed additional states of the electron that had not yet been observed. Dirac interpreted them as antiparticles with a charge opposite to that of electrons. The discovery of the positron in 1932 by the American physicist Carl David Anderson proved the existence of antiparticles and was a triumph for Dirac's theory.

The discovery of the positron

After his discovery, subatomic particles could no longer be considered immutable. Given enough energy, electrons and positrons can be created from a few particles in a vacuum tube. They also can annihilate each other and disappear into some other form of energy. The history of subatomic physics from this point has been much the story of finding new kinds of particles that can be created in vacuums.

ADVANCES IN NUCLEAR AND SUBATOMIC PHYSICS

The 1920s witnessed further advances in nuclear physics with Rutherford's discovery of induced radioactivity. Bombardment of light nuclei by alpha particles produced new radioactive nuclei. In 1928 the Russian-born American physicist George Gamow explained the lifetimes in alpha radioactivity using the Schrödinger equation.

Discovery of neutrons. The constitution of the nucleus was poorly understood at the time because the only known particles were the electron and the proton. It had been established that nuclei are typically about twice as heavy as can be accounted for by protons alone and thus have to contain more than just such particles. A consistent theory was impossible until the English physicist James Chadwick discovered the neutron in 1932. He found that alpha particles reacted with beryllium nuclei, ejecting neutral particles with nearly the same mass as protons. Almost all nuclear phenomena can be understood in terms of a nucleus composed of neutrons and protons. Surprisingly, the neutrons and protons in the nucleus behave to a large extent as though they were in independent wave functions, just like the electrons in an atom. Each neutron or proton is described by a wave pattern with peaks and nodes and angular momentum quantum numbers. The theory of the nucleus based on these independent wave functions is called the shell model. It was introduced in 1948 by Maria Goeppert Mayer of the United States and J. Hans D. Jensen of West Germany, and it developed in succeeding decades into a comprehensive theory of the nucleus.

Shell model of the nucleus

The interactions of neutrons with nuclei had been studied during the mid-1930s by the Italian-born American physicist Enrico Fermi and others. Nuclei readily capture neutrons, which, unlike protons or alpha particles, are not repelled from the nucleus by a positive charge. When a neutron is captured, the new nucleus has one higher unit of atomic mass. If a nearby isotope of that atomic mass is more stable, the new nucleus will be radioactive, convert the neutron to a proton, and assume the more stable form.

Nuclear fission was discovered by the German chemists Otto Hahn and Fritz Strassmann in 1938. In fission, a uranium nucleus captures a neutron and gains enough energy to trigger the inherent instability of the nucleus, which splits into two lighter nuclei of roughly equal size. The fission process releases more neutrons, which can be used to produce further fissions (see below *Nuclear fission*). The first nuclear reactor, a device designed to permit controlled fission chain reactions, was constructed at the University of Chicago under Fermi's direction, and the first self-sustaining chain reaction was achieved in this reactor in 1942. In 1945 American scientists produced the first atomic bomb, which used uncontrolled fission reactions in either uranium or the artificial element plutonium.

Quantum field theory. Dirac not only proposed the relativistic equation for the electron but also initiated the relativistic treatment of interactions between particles known as quantum field theory. An important aspect of quantum field theory is that interactions can extend only over a given distance if there is a particle to carry the force. The electromagnetic force, which operates over a long distance, is carried by a particle called the photon, the light quantum. In 1934 the Japanese physicist Yukawa Hideki proposed that there should be a particle that carries the nuclear force as well. Because the force is short-range, the particle should be massive. Massive particles were indeed found in cosmic rays, but these did not have the correct interaction properties. They were later dubbed muons. Evidence for Yukawa's particle, known as the pion, was found in cosmic-ray tracks in 1947 by the British physicist Cecil Frank Powell. The existence of the pion was confirmed when the particle was created in a particle accelerator in 1948.

Pions

Since then, the number of subatomic particles discovered has grown enormously. Most of them have been created and studied by means of accelerators that produce high-energy collisions between particles. The new particles, formed by the collision process, live only a short time before decaying into more stable particles. Particularly noteworthy among the many particles discovered since 1960 are those responsible for the interaction in beta radioactivity. In quantum field theory, beta radioactivity is a manifestation of an interaction called the weak force. The particles that transmit this force are known as W and Z particles. These messenger particles, or bosons, were discovered in 1983 during experiments at the European Organization for Nuclear Research (CERN).

Hadrons and quarks. Many of the newly discovered particles did not at first seem to have any specific role in subatomic physics. Particles of a class known as hadrons, which includes protons and neutrons, interact strongly with one another. They show patterns analogous to the patterns of energy levels in atoms. Just as the existence of energy levels in hydrogen is explained by the presence of the electron, the different hadrons are considered to be energy levels of a more fundamental particle inside them. The specific patterns of the hadrons have been explained by postulating a new fundamental constituent, the quark. Three quarks are thought to combine to form a proton, a neutron, or any of the massive hadrons known as baryons. A quark combines with an antiquark to form mesons such as the pion.

Quarks have never been observed, and physicists do not expect to find one. Presumably the forces between quarks are so strong that they cannot be separated from other quarks in a hadron. There are several indirect confirmations of the existence of quarks. In experiments conducted with high-energy electron accelerators in the 1960s, electrons that had been deflected by large angles in scattering from hadrons were observed. As in Rutherford's experiment, the large-angle deflection implies that there are very small objects inside the hadron surrounded by large electric fields. The small objects are presumed to be quarks. Physicists developed a quantum field theory known as quantum chromodynamics (QCD) during the mid-1970s to accommodate quarks and their peculiar properties. This theory explains qualitatively the confinement of quarks to hadrons. Physicists believe that the theory should explain all aspects of hadrons, but mathematical complications unfortunately prevent rigorous calculations.

Quantum chromodynamics

Atomic structure and interactions

ELECTRONS

As noted above, the electron was the first subatomic particle discovered. Its interactions determine atomic structure, the chemical behaviour of atoms in molecules, and the properties of larger aggregations of atoms such as bulk solids. There are four kinds of forces in nature, and the electron is subject to three of them—gravity, electromagnetism, and weak interaction. Only the electromagnetic

force is significant in determining the properties of atoms and their chemistry. Within the framework of the equations used to describe the motion of the electron, the only two numerical properties that need to be specified are the electron's mass and its charge. These are given in Table I along with other basic atomic constants.

There are four levels of complexity in the equations used to describe the properties of electrons. At the simplest level, classical equations such as Newton's equation are applied. The motion of the electron beam in a television tube is adequately described by classical physics.

The equations of classical physics, however, become invalid when one attempts to describe the motion within distances smaller than the de Broglie wavelength of the electron (see MECHANICS: *Quantum mechanics*). Atomic properties fall into this small-distance regime, and quantum equations must be used. The simplest quantum equation is the above-mentioned Schrödinger equation, which is valid when the velocity of the electron is small compared to the speed of light. The electron is described by a function that obeys a wave equation. The function may be visualized as a cloud; where the function is large, the cloud is dense and the electron's presence is strongly felt.

Atomic and chemical structure is well described by the Schrödinger wave functions when two additional nonclassical properties of the electron are included. The first property is spin, which is like an internal rotational motion of the electron. The magnitude of an electron's spin is fixed, but its orientation in space can vary. Spin appears in the Schrödinger equation as an attribute of the electron. There are, in fact, two separate wave functions associated with the probability that spin will be pointed in a particular direction or in the opposite direction. Other spin orientations are obtained by suitably combining the two functions to make intermediate directions. The other nonclassical property involved is the Pauli exclusion principle, which states in its general form that the wave function of identical particles must reverse sign when the coordinates of the particles are interchanged. As a consequence of the Pauli principle, two electrons cannot have the same wave function. This principle is extremely important in determining the structure of atoms, molecules, and bulk matter.

The third level of complexity in the description of the electron is Dirac's equation (see above), which is a quantum equation postulated to satisfy the requirements of Einstein's relativity. Any particle governed by the Dirac equation is called a fermion; the electron is the most familiar example. The mathematics of the Dirac equation require that its particles have two spin orientations and obey the generalized Pauli principle. Thus, all the properties needed for determining atomic structure are built automatically into the theory. Furthermore, the Dirac equation predicts that for each kind of fermion there is an oppositely charged antiparticle with the same mass. The electron's antiparticle is the positron. The electron can be made to disappear by combining with a positron. When the two particles annihilate each other, their rest energy is converted to gamma rays or some other form of energy. Electrons can also be created from other forms of energy, but always in association with positrons. According to the Dirac equation, charged fermions such as the electron have a magnetic moment pointing along the direction of spin. The magnetic moment of electrons is very close to the value predicted by the Dirac equation. The magnetism of permanent magnets arises from the combined effect of individual electrons having spins aligned in the same direction.

The electron as a fermion

The most sophisticated level of complexity in describing electrons is the theory of quantum electrodynamics. Using the Dirac and other equations, this theory builds a wave function not only for observable electrons but also for particles and quanta that may be created from a vacuum. The predictions of quantum electrodynamics deviate only slightly from the Dirac equation. For example, the magnetic moment of electrons is predicted to deviate by 0.1 percent from the Dirac value due to vacuum modifications. These deviations have been measured accurately and agree perfectly with quantum electrodynamics as far as experiments can determine.

Quantum electrodynamics

ELECTRONIC STRUCTURE OF ATOMS

Schrödinger's theory of atoms. The theory of the electronic structure of atoms is based for the most part on the Schrödinger equation, which in actuality is not a single equation. Each different physical system is described by its own equation, a partial differential equation that has as many variables as there are coordinates of interest in the application. For example, the Schrödinger equation for the hydrogen atom has three coordinates—the x, y, and z coordinates of the separation between the electron and the hydrogen nucleus. Similarly, there are six variables in the Schrödinger equation of the helium atom, since the positions of two electrons are required.

The Schrödinger equation has many solutions, each of which describes a possible state of the atom. Each state is specified by a function that depends on the coordinates of the particle(s) and by its associated energy. The function, called the wave function, is the mathematical representation of what is descriptively called the cloud. The wave function describes, among other things, the probability of an electron being at any given coordinate position. Electrons are more likely to be found in regions of the atom where the wave function is large. More precisely, the probability is proportional to the square of the wave function. At positions where the wave function goes through zero, the probability of finding electrons vanishes.

Normally, an atom is found in its ground state, *i.e.*, the state with the least energy or the most bound state. States with higher energy are called excited states. Atomic spectra are the light quanta emitted when an atom makes a transition from an excited state to one of lower energy.

The Schrödinger equation can only be solved exactly in special circumstances. Schrödinger himself found the solution for the hydrogen atom. It is important for physicists and chemists to understand the properties of the hydrogen atom obtained from the Schrödinger equation because these same properties appear in the behaviour of electrons in more complex atoms.

For atoms with more than one electron, no exact solutions of the Schrödinger equation are known. Nevertheless, it is possible to obtain very accurate numerical solutions using approximation methods. An approximation scheme introduced by the English physicist Douglas R. Hartree is the basis for most calculations and for the prevailing physical understanding of the wave mechanics of atoms. In this method it is assumed that the electrons move independently. The electrons are allowed to interact only through the average electric field made by combining the charge of the nucleus with the charge distribution of the other electrons. A Schrödinger equation for individual electrons moving in an average electric field must then be solved. Each electron has its own wave function, which is called an orbital.

The Hartree method

A technical difficulty with this method is that the electric field is not known ahead of time because it depends on the charge distribution of the electrons. In turn, the charge distribution can be determined only from the wave functions, which require prior knowledge of the field. The difficulty is overcome by solving the Schrödinger equation in successive approximations. First, one makes a guess for the field, finds the wave functions, and then uses the derived charge distribution to make a better approximation for the field. This iterative process is continued until the final charge and electric field distribution agree with the input to the Schrödinger equation. The Hartree method (sometimes called the Hartree–Fok method to give credit to V. Fok, a Soviet physicist who generalized Hartree's scheme) is widely used to describe electrons in atoms, molecules, and solids.

The hydrogen atom. Bohr's model of the hydrogen atom is rudimentary but nevertheless remarkably accurate in its predicted energy levels. The derivation of the energy formula is as follows. Bohr begins with the classical equation relating the velocity of a charged particle in a circular orbit, v, to the radius of the orbit r and the electric force constants. The equation, obtained by balancing the centrifugal force and the electric force, is

$$mv^2/r = e^2/4\pi\varepsilon_0 r^2.$$

Next, Bohr postulates that angular momentum is quantized in integer multiples of the reduced Planck's constant, $\hbar$. The angular momentum is then given by the formula

$$m_e v r = n\hbar,$$

where m_e is the mass of the electron, and n is an integer, which can have values 1, 2, 3, and so on. The two equations are combined to solve for the unknown quantities v and r. The resulting orbits have discrete radii, depending on n. The energies of the electrons in these orbits are given by Bohr's formula,

$$E_n = \frac{m_e e^4}{(4\pi\varepsilon_0)^2\, 2\hbar^2}\,\frac{1}{n^2}.$$

When the Schrödinger equation is solved for the hydrogen atom, one finds that the possible energies of the electron are the same as those in Bohr's model (see Figure 4). The wave functions associated with these energies are, however, quite different from the circular orbits hypothesized by Bohr. The lowest orbital is a spherically symmetric function. It falls off with distance from the nucleus r according to

$$\exp(-r/a_0).$$

Here, a_0 is a length constant, which happens to coincide with the radius of the smallest Bohr orbit. Known as the Bohr radius, it is given by the formula

$$a_0 = \frac{4\pi\varepsilon_0\hbar^2}{m_e e^2}.$$

The numerical value of a_0 is 0.53 angstrom; the meaning and values of the other quantities in this equation are given in Table 1. Since the wave function depends only on distance and not on angle, the electron cloud surrounding the nucleus has a spherical shape. Its radius is roughly one angstrom. The electron probability is highest at the nucleus and in its immediate vicinity. The probability falls off smoothly with distance from the nucleus, vanishing completely only at infinite distance. The wave function falls to inconsequentially small values at moderate distances, however. For example, the probability for the particle to be farther than $10a_0$ from the nucleus is only 1 in 30,000.

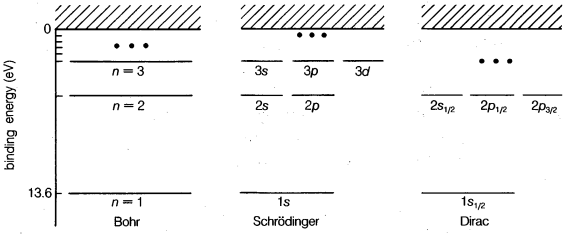

Figure 4: Energy levels of the hydrogen atom, according to Bohr's model and quantum mechanics using the Schrödinger equation and the Dirac equation.

Higher states of the hydrogen atom have more complex patterns in the wave function. All of the bound states of the hydrogen atom may be described by wave functions having the form

$$(\text{polynomial in } x, y, \text{ and } z)\exp(-r/n\,a_0),$$

where n is a positive integer called the principal quantum number. The energy of the state is given by Bohr's formula with the same integer value of n. Several different states may have the same energy, in which case they are said to be degenerate. Shells are sets of degenerate states. The number of distinct orbitals in a shell is its degeneracy or its multiplicity. For example, there are four orbitals with $n = 2$ at the energy E_2 in the Bohr formula, forming a shell. One of the orbitals in this shell, like the ground state, has a spherically symmetric wave function. Spherically symmetric orbitals are called s states; the nomenclature for orbitals of different symmetry is provided in Table 2. The excited s state differs from the ground state in that it is smaller at the centre, and it goes through zero at some intermediate distance from the nucleus. The excited s state has another peak beyond this point, and the overall probability extends farther out than in the ground state. The other $n = 2$ orbitals form a threefold shell that is designated the p shell. The polynomials in their wave functions are simply the monomials x, y, or z. The orbital having the monomial x has a vanishing probability on the plane with $x = 0$, which is therefore a nodal plane. Similarly, the other p states have nodal planes oriented in other directions but all going through the centre. The probability distributions of the electron for these orbitals are sketched in Figure 5. One could imagine a state with a nodal plane in some other direction as well. Such a state, however, could be made by adding the wave functions of the three original p orbitals, with some constant multiplying factors. According to the rules of quantum mechanics, this state would not be distinct from the original ones that produced it. The atom would have some probability of being in one of the three original states, depending on the multiplying factors.

Degenerate states

Table 2: Spectroscopic Designation of Orbitals

angular momentum quantum number l	degeneracy	designation
0	1	s
1	3	p
2	5	d
3	7	f

States are distinguished from each other by numerical labels called quantum numbers. The principal quantum number n has already been mentioned. Three additional quantum numbers are associated with the electron wave functions of the hydrogen atom. Two of these depend on the polynomial function of x, y, and z in the wave function. Conventionally, these two quantum numbers are labeled l, representing orbital angular momentum, and m, representing the orientation of the angular momentum with respect to some axis. The states of different l are often designated by letters, as given in Table 2. There are several general rules for determining the values of l and m allowed in a wave function. The orbital angular momentum takes on integer values starting from $l = 0$. Spherically symmetric wave functions have $l = 0$. Positive values of l apply to states whose wave function varies with angle. The more lobes there are in the angular pattern of the wave function, the higher is the value of l. The m quantum number, also called the magnetic quantum number, is restricted to a range of integers depending on l. The m quantum number ranges from $-l$ and increases in integer steps to $+l$. Distinct states exist for all values of m in this range. Thus, wave functions with a given orbital angular momentum l always have a degeneracy equal to $2l + 1$. The quantum number l and the associated degeneracy $2l + 1$ of the m states is a general feature of

Quantum numbers

wave functions obtained in physical systems with a force directed toward a centre. For example, the ground state of the hydrogen atom is spherically symmetric with $l = 0$ and only one distinct orientation. The p-wave states in the $n = 2$ shell have orbital angular momentum $l = 1$. By the rules of the orientational degeneracy, there are three distinct p states, labeled $m = -1$, 0, and $+1$. In higher shells one finds $l = 2$ states, which have two angular nodal surfaces and a degeneracy of 5.

The relationship between the principal quantum number n and the orbital angular momentum l has not been discussed up to this point. For each value of n, states of the hydrogen atom exist with l ranging from 0 to $n - 1$. The fact that all l states for a given n are degenerate is a special circumstance of the Schrödinger equation for the hydrogen atom. Each of the l's has a multiplet of m states, described in the previous paragraph.

The Schrödinger equation and Bohr's formula are quite accurate, but small deviations in energy can be observed in the hydrogen spectrum, and the actual multiplicity of states is twice that predicted by the Schrödinger equation. These flaws can be corrected by introducing the electron spin, with either the Schrödinger equation or the more precise Dirac equation. The electron spin behaves exactly like an angular momentum, but with a value ½. There are two m states, with values $-½$ and $+½$, which provide the needed doubling in the multiplicity of states. The interaction of the spin changes the energies of the states, so they are no longer independent of l. The coupling of the spin to the orbital angular momentum is treated by defining a new angular momentum quantum number j. For a given l, j can have the value $l + ½$ or $l - ½$, depending on whether the orientations of the spin and orbital angular momentum are parallel or antiparallel. However, in an $l = 0$ state such as the ground state, only $j = ½$ is allowed. This method of combining spin and orbital angular momentum is known as spin-orbit coupling. In the Dirac equation the $n = 2$ states are shifted in energy by the spin-orbit coupling, with the $j = ½$ states slightly lower than the $j = 3/2$ state. The predicted splitting agrees very well with the observed fine structure in the spectrum.

Spin-orbit coupling

Further refinements to the theory of the hydrogen atom have been made with quantum field theory. The theory predicts a very small energy difference between the two multiplets with $j = ½$. This tiny splitting has been observed, and its magnitude agrees with theory.

One final ingredient completes the description of the hydrogen atom—the interaction of its electron with the magnetic moment of its nucleus. The proton nucleus of ordinary hydrogen has a spin of ½ and a magnetic moment. The energies of the atom depend on the relative orientation of the electron and the proton's spin. This can be characterized by a new quantum number, the total spin F. It can have a value 0 or 1, depending on whether the two spins are parallel or antiparallel. The energy difference between these two states is very small, so that transitions are in the microwave region of the electromagnetic spectrum. The frequency of the radiation is 1.4×10^9 hertz, which is a well-known feature of the radiation from interstellar hydrogen gas observed in radio astronomy.

Multielectron atoms. The properties of multielectron atoms are governed to a large extent by simple principles that determine the electron wave function. Electrons are placed in orbitals similar to the wave functions of hydrogen, starting with the lowest energy $n = 1$ orbital. The Pauli principle requires that each electron go into a different orbital. (It should be remembered that the two spin orientations in a wave function count as different orbitals.) With this procedure, each element acquires a unique structure of electron orbitals that gives it its characteristic atomic and chemical properties. A simple example is the helium atom. Helium has two electrons, both of which go into the $n = 1$ orbitals according to the spin degeneracy rule. All $n = 1$ electrons are tightly bound, and so the helium atom is not readily ionized; neither does it form chemical bonds by sharing its electrons with other atoms. The next element, lithium, has three electrons; only two can go in the $n = 1$ orbitals, so the third must be placed in an $n = 2$ orbital. This shell is much higher in energy; thus, the last electron is loosely bound. The ionization energy, which is the energy required to remove an electron from an atom, shows clearly the effects of the electron shells. Figure 6, displaying the ionization energies of the elements, shows that helium is the highest of any element. There is a big jump from helium to lithium, which needs only 5 eV of energy to ionize.

Ionization energy

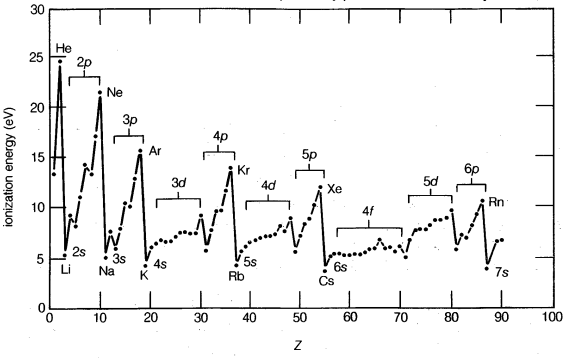

Figure 6: *Ionization energies of the elements.* The shell of the least bound electron is designated by the principal quantum number n, followed by the letter for the angular momentum.

The shell behaviour of complex atoms is derived from the approximate solution of the Schrödinger equation, since exact solutions to the multielectron equation do not exist. The Hartree method (see above), treating each electron with its own wave function, gives an adequate approximation for most purposes. In Hartree's theoretical scheme, the Pauli principle is imposed by requiring all wave functions of the electrons to be distinct. An important part of the Hartree theory is the behaviour of the self-consistent force field governing the electrons. At small distances from the nucleus, the Hartree field is virtually the same as the field of the nucleus. The contribution from the electrons is small because they are spread out in all directions. At large distances the nucleus appears to be surrounded by a cloud of electrons screening its positive charge with their negative charges. The last electron, if it is far away, "sees" a field resembling that of a single positive charge. The electron wave functions in this potential are qualitatively very similar to the hydrogen wave functions, retaining strong shell effects. The range of the wave functions and their energies, however, depend on both the atomic number and the presence of electrons in other shells. The $n = 1$ electrons are closest to the nucleus and are exposed to nearly its full electric field. The highest shell electrons are farthest away on average and feel a field similar to that of a hydrogen atom.

The size of atoms does not vary much from element to element, growing only slightly from light to heavy elements. This is due to a compensation between two opposing tendencies. The outer electrons of heavy atoms are in higher shells, the probability distributions of which are farther from the nucleus. On the other hand, the size of each shell is dependent on nuclear charge; the higher charge in heavier nuclei pulls a given shell in closer.

Atomic spectroscopy and lasers. The energy levels of atoms are studied by measuring the wavelengths of light emitted by the atoms in excited states. Atoms become excited when they absorb energy. In a gas, excited atoms are produced with heat or electric currents. The light emitted is analyzed in a spectrograph, which disperses the light in different directions according to its wavelength or frequency. Transitions from higher to lower energy levels appear as bright lines in the spectrum (Figure 7). This technique is known as emission spectroscopy. If white light is passed through a gas of the element being studied, light will be absorbed for those frequencies that allow a transition of the atom from the ground state to an excited state. The absorption creates a dark line in the spectrum of the white light. This is called absorption spectroscopy. The characteristics of the lines can be measured with great accuracy using spectrographs together with other optical

Emission and absorption spectroscopy

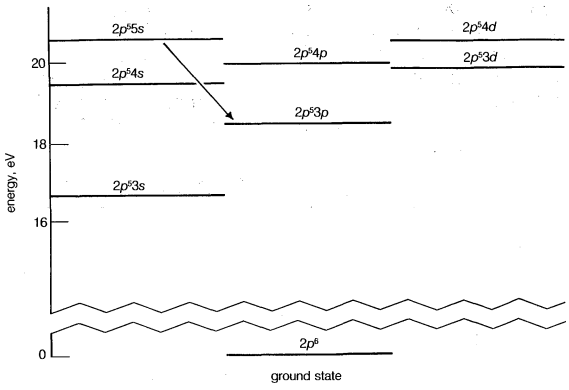

Figure 7: *Energy levels of the neon atom.*

instruments called interferometers. Until lasers were developed, however, it was impossible to achieve the resolution desired because the frequency of the light emitted is affected by the motion of the atoms and collisions between them. The frequency shift from atomic motion, known as the Doppler effect, limits the resolution to about 1 part in 10,000. However, with intense light at a fixed frequency available from lasers, one can preferentially excite atoms moving at some particular velocity. Modern instrumentation makes it possible to observe structure in the lines to 1 part in 10,000,000. This accuracy allows the effects of nuclear spin, size, and shape to be measured directly with atomic lines.

The principle of the laser is based on the transitions between energy levels in an atom, or molecule. Normally, more atoms are in lower states than in upper states. Energy would be absorbed from a beam of radiation because most of the transitions would go from a lower level to an upper one. If the number of atoms in the upper and lower states is equal, there will be the same number of transitions in both directions. Therefore, the intensity of the atom's light beam would not change going through the medium. Conditions for the laser are obtained if more atoms are in the upper state than in the lower state; this is called a population inversion. As a result, a laser has more transitions going downward than upward, and a beam going through the medium is amplified. Passing the amplified beam back and forth between mirrors produces the very high intensity laser light.

Characteristic X rays. The inner shells of an atom are responsible for the characteristic X rays of an element. These are X rays of definite wavelengths emitted when atoms are bombarded with energetic electrons or other forms of radiation. The radiation knocks an inner electron out of its orbital, leaving a vacancy. An electron from a higher shell then jumps into the empty orbital, emitting a photon in the process. Because of the strong binding of inner shells in heavy atoms, such photons are produced with energies ranging from 100 to 100,000 eV in the X-ray region of the electromagnetic spectrum. The approximate energies of these transitions are given by the Bohr formula with a modified value of the nuclear charge. More accurate values for the energies can be calculated on the basis of the Hartree theory.

The ionization energy of atoms depends on the energy of the electron orbitals in the highest occupied shells. The variation of these energies with atomic number displays a periodic behaviour, as seen in Figure 6. Particularly noticeable is the increase in ionization energy as the *p* shells of the atom are filled. This is precisely what one expects to find: as the charge of the nucleus increases, the binding energy of the orbitals in a given shell increases. When a shell is filled, the next electron must go into a higher, less bound shell, producing a break in the ionization-energy plot. The fact that the behaviour is periodic shows that the inner cores of atoms act on the outer electrons in much the same way for different atomic numbers. The nuclear charge is screened by the inner electrons so that the outer electrons are effectively governed by the field from a lower atomic number.

The electron affinity of atoms exhibits a similar periodicity. Electron affinity is the binding energy of the extra electron when an atom forms a negative ion. Such atoms as helium that have all their electrons in tightly bound filled shells do not attract additional electrons strongly enough to bind them. On the other hand, such atoms as fluorine that have a single vacancy in a tightly bound shell readily attract and capture an extra electron into that orbital. The systematics of the electron affinities are shown in Figure 8. Obviously, the behaviour of the loosely bound electrons and shell effects are crucial to an understanding of the chemical properties of elements. The basic period of eight in the periodic table is associated with the filling of the *s* and *p* orbitals of a given *n* shell (see Figure 9). For each spin orientation, there are one *s* orbital and three *p* orbitals, for a total degeneracy of eight. In the hydrogen atom, the *s* and *p* shells are degenerate, and in complex atoms they remain close in energy. Higher angular momentum shells, however, have considerably less binding than their *s* and *p* partners in the same *n* shell. As a result, they are filled out of sequence in the periodic table. For example, the 3*d* shell is filled after the 4*s* shell.

Electron affinity

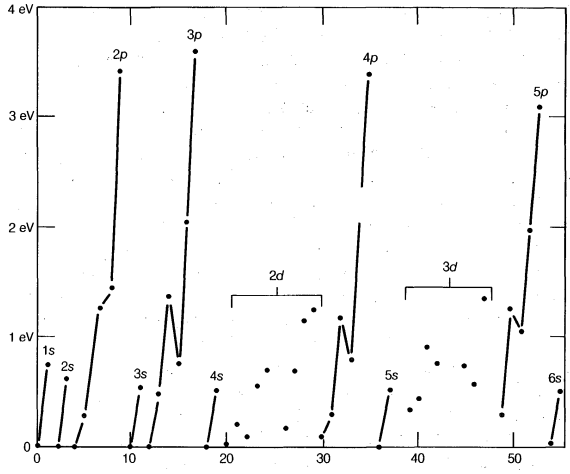

Figure 8: *Electron affinities of the elements.*
The shell of the most bound vacancy is indicated by its spectroscopic designation.

The diminished binding of the higher 1 shells can be understood simply with a classical picture of the electron's motion. The higher angular momentum shells correspond to orbits that are more nearly circular, whereas the *s*- and *p*-wave functions correspond to elliptical orbits in which the electron approaches the centre of the atom more closely. Because the centre has the strong attraction from the unscreened nucleus, these low 1 orbitals will have a greater binding. For a given energy, elongated orbits extend farther out than the circular orbits. This greater

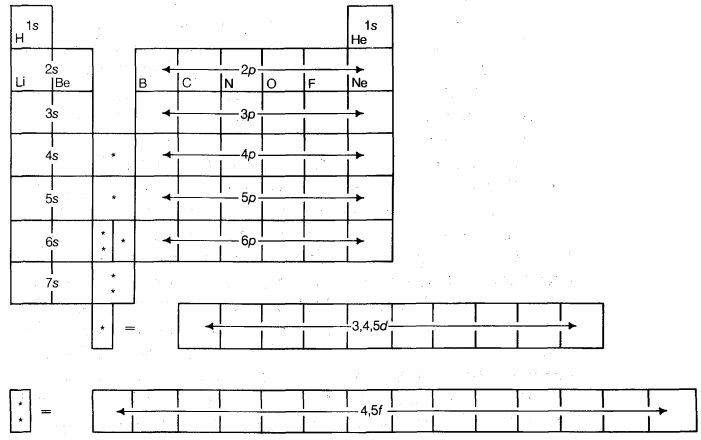

Figure 9: Periodic table of the elements showing the valence shells.

extension corresponds to the fact that in s and p orbits the electron probability is significant to larger distances. Most of chemistry has to do with these outer electrons. The $l = 3$ shell (f shell) is well shielded by other electrons, and the elements that differ only in the number of f-shell electrons have very similar chemical properties.

Exotic atoms. Atoms can be formed with other charged particles serving as the negatively charged electrons or the positively charged nucleus. Mu mesons, pi mesons, or antiprotons can be substituted for electrons, while a positron can replace the nucleus. These exotic atoms exhibit energy levels and transitions just like ordinary atoms. The transitions between high n orbits follow the Bohr formula, with an appropriate change in the mass m in that formula. The energy levels with low n are affected by the finite size of the particles and by other forces that may act besides the electric force. Physicists use these atoms to investigate the forces and the sizes of the particles involved.

Interatomic forces and chemical bonds. The forces between atoms are complex and varied. In close proximity, all atoms repel each other. At intermediate distances, the forces of chemical binding are prominent. Finally, at large distances, all atoms are attracted to each other by a much weaker force. These forces are all explained by the quantum theory of electrons in atoms. In the presence of other atoms, the electrons become rearranged. If the new arrangement has less energy, it is the preferred state of the atoms, and there is an attractive force to reach this state. Conversely, if the rearrangement increases the energy, the resulting force between the atoms is repulsive. The rearrangement of electrons may take place in different ways, and different names are given for the resulting chemical bonds (see below).

Repulsion between atoms

The universal repulsion between atoms at short distances is responsible for atoms taking up a definite amount of space and for the incompressibility of solid materials. This repulsion has two causes. First, as the atoms are pushed into each other, the shielding provided by the electrons around each nucleus is less effective and the electric force between the two nuclei repels them. A second repulsive influence arises from the Pauli principle. Not only is it forbidden to have two electrons with the same wave function but the wave functions must be different enough to construct an antisymmetric total wave function. When two atoms are close together, the electrons in the overlapping region spend part of their time in their original orbitals and part of their time in orbitals of higher energy in order to satisfy the Pauli principle.

In chemical bonds the rearrangement of electrons leaves atoms in a state of lower energy, stabilizing them at fixed distances from each other in definite geometric configurations. The amount of energy associated with chemical bonds ranges from 1 to 10 eV. A number of different kinds of bonds are recognized in chemistry. If the rearrangement causes a net shift of the electron's probability from one atom to the other, the bond is called heteropolar. An extreme example of this would be an ionic bond, in which an electron has moved from an orbital in one atom to that in the other. This electron transfer gives one atom a net positive charge and the other a net negative charge. The two resulting ions are then held together by the electric force of attraction between unlike charges. An example of ionic bonding occurs in alkali halide crystals such as sodium chloride (common table salt). The alkali metals are easily ionized, and the halogens have a strong affinity for additional electrons, as seen in Figures 6 and 8. The original concept of chemical binding was based on the attraction of opposite charges.

Strong chemical bonding of the homopolar, or covalent, type also occurs. In this case there is no net transfer of electrons from one atom to another. The rearrangement of the electron distribution is more subtle. In a covalent bond between two atoms, the electron density shifts from the outer surfaces of the atoms to the region between the two atomic centres. In general this does not happen, because the Pauli principle affects the wave functions by spreading the electrons apart. The Pauli principle, however, may be satisfied for a pair of electrons by giving them opposite spin orientations, in which case the spatial wave functions are combined to bring the two electrons closer together. A covalent bond can be formed between two atoms if there is an unpaired electron on each atom. In the bonded state the electrons will have their spins oppositely aligned. An atom can form a number of covalent bonds equal to the number of its unpaired electrons, which in turn depends on the shell degeneracy. For example, the nitrogen atom has five electrons distributed over four orbitals in the $n = 2$ s and p shells. Two electrons must occupy the same orbital as a pair, but the remaining three electrons can go unpaired in separate orbitals, giving nitrogen a valence of 3.

The geometry of chemical bonding, with definite angles between the bonds in triatomic and more complicated molecules, depends on the geometry of orbitals with lobes extending at various angles. If atoms bonded with pure p orbitals, the bonds would extend out at 90° angles from each other like the wave functions depicted in Figure 5. Actual chemical bonds, however, are made primarily by combining s and p orbitals together in the wave functions. This so-called hybridization produces wave functions with different geometries. In the carbon atom, for example, the hybridization yields four bonds directed toward the corners of a tetrahedron.

Hybridization

The ionic and covalent bonds are two extremes in a range of bonding behaviour. The bonding wave functions do not need to be localized on two neighbouring atoms. In so-called delocalized bonding the electron wave functions extend over several atoms.

All of these properties can be predicted quite well using the Hartree theory. The positions of the atomic centres are first roughly estimated. The Schrödinger equation is then solved for each electron, with the requirement that the total forces from all the atoms be consistent with the total charge density from the electrons and nuclei. After the wave functions of all the electrons are found, the energy of the molecule can be calculated. This is repeated for other positions of the atomic centres until the minimum energy is found. The resulting arrangement of atomic centres and electron wave functions provides the configuration of the stable molecule. Depending on the behaviour of the Hartree wave functions, one can find various kinds of chemical bonds. The Hartree theory is quite reliable in predicting the geometry of molecules and the character of the bonds, but it is less successful in predicting accurate bond energies.

Some forces between atoms at larger distances are too weak to form chemical bonds. These forces have two origins. One long-range force is associated with the electric fields that extend outside of any molecule with heteropolar electron distributions. An example is the water molecule, which has a net shift of electron charges from the hydrogen atoms to those of oxygen. The electric field attracts both positively and negatively charged ions, depending on the orientation of the water molecule. This explains why liquid water is such a good solvent for polar and ionicly bonded molecules. Another long-range force, called the van der Waals force, is a weak attraction between all atoms. It provides the cohesive force in nonpolar liquids such as liquid air or gasoline. These liquids have a low boiling point because the bond energies of the van der Waals force are very low (only a few tenths of an electron volt). The force arises from a subtle effect in quantum mechanics—namely, the existence of fluctuating electric fields outside an atom even though the electron wave function surrounds the nucleus and neutralizes its charge. The fluctuating fields are associated with the possible positions of the electron if it is frozen at some particular spot in its orbital.

Van der Waals force

Observing atoms. Individual atoms are far too small to be seen in any light microscope. The inherent limitation on such a microscope is the wavelength of light, which determines the minimum size of an image. In comparison, the distance between atoms in a solid is less than 1,000th of the wavelength of light. Therefore, the minimum size of any image would contain too many atoms for the eye to differentiate. There are, however, several direct methods for observing individual atoms and their arrangement in molecules and solids. In a transmission

Direct observation methods

electron microscope, electrons are transmitted through the material to be studied. Images are formed because the electrons are absorbed differently by different atoms. With this technique, one can just barely see the individual atoms of the heaviest elements when they are separated by several atomic lengths (see Figure 10). Another technique involves the use of a field-ion microscope. In this case, a wire with a very fine tip is placed in a near-vacuum and given a positive electric charge. Individual atoms on the surface of the tip ionize residual gas molecules. The ions are then accelerated by the charge in straight lines away from the tip. They form spots on photographic plates at different positions corresponding to the location of atoms on the tip (see Figure 11). A third imaging technique is called scanning tunneling electron microscopy. Here, a wire with an extremely fine point is positioned within 10^{-9} metres of the surface to be studied. Electrons jump from the surface to the wire through individual atoms on the surface. The probe wire is moved back and forth over the surface in a raster pattern, and variations in the electron current indicate the positions of the atoms.

Diffraction techniques

The positions of atoms in solids and molecules are commonly determined by wave diffraction. Diffraction refers to the highly directional patterns formed by waves when they travel through regularly ordered mediums. Diffraction techniques use a crystal or a large number of atoms in a regular arrangement. The pattern of the waves reflected from the crystal depends on the relative positions of the atoms in the crystal. The information contained in the wave pattern is far from complete, however, so there may be ambiguities in reconstructing the atomic arrangement. The most common technique of this kind is X-ray diffraction. X rays are similar to visible light, but they have much shorter wavelengths. Radiation of this type that can be used for diffraction has a wavelength of 10^{-10} metre or smaller, which is even smaller than atoms. As the X-ray waves are most affected by the electrons in atoms, this technique locates atoms primarily by their electron cloud. Another diffraction technique uses neutrons from a nuclear reactor. Neutrons, like all particles, have wave properties and can be diffracted from a crystal. Neutrons of a particular wavelength are beamed on a crystal, and diffraction sends them off in various directions. The geometric arrangement of the atoms being studied is inferred from the diffraction pattern. Neutron waves interact most strongly with atomic nuclei, and so this technique complements X-ray diffraction by mapping the nuclear centres of atoms.

Bulk matter. The behaviour of bulk matter depends on the relative magnitude of the binding forces between atoms or molecules and the thermal energy of motion. The thermal energy of motion at room temperature is about 0.025 eV. If the binding energy is less than about 10 times the thermal energy, the substance will be in a gaseous state under normal conditions. This typically applies to small molecules such as air molecules that interact only by the weak van der Waals force. With larger ratios of binding energies to thermal energies, the substance condenses into a liquid or a solid. Solids are classified into several types, depending on the kind of bonding between their atoms. Four main types of ordered solids are ionic crystals, molecular crystals, covalent crystals, and metals. Ionic crystals are held together entirely by the electrostatic forces between ions. Common table salt is an example. A molecular crystal is composed of distinct molecules held together by weaker forces such as the van der Waals force. In covalent crystals the chemical bonds extend from atom to atom over the entire crystal. Diamond, a form of carbon, is an example of a covalently bonded solid; as in simple organic compounds, each carbon atom has four bonds pointed to the corners of a tetrahedron. In metals the concept of chemical valence breaks down. The atoms are closely packed together, and the number of neighbours for a given atom is determined more by the geometry of touching spheres than by the number of valence electrons.

Classification of solids on the basis of bonding

The Hartree theory provides a common framework for describing the varying properties of these different kinds of solids. The electron orbitals are allowed to spread out over the entire solid. Effectively, one deals with an infinite number of electrons and orbitals, which can be handled with mathematical techniques developed by the Swiss-born U.S. physicist Felix Bloch and others. The orbitals display shell-like features even in a very large system. There are groups of orbitals with energies close together. Known as bands, they are separated by gaps in energy. The characteristics of any such solid depend very much on the extent to which the orbitals are filled in the highest band. This filling level is called the Fermi energy. If

Band structure of solids

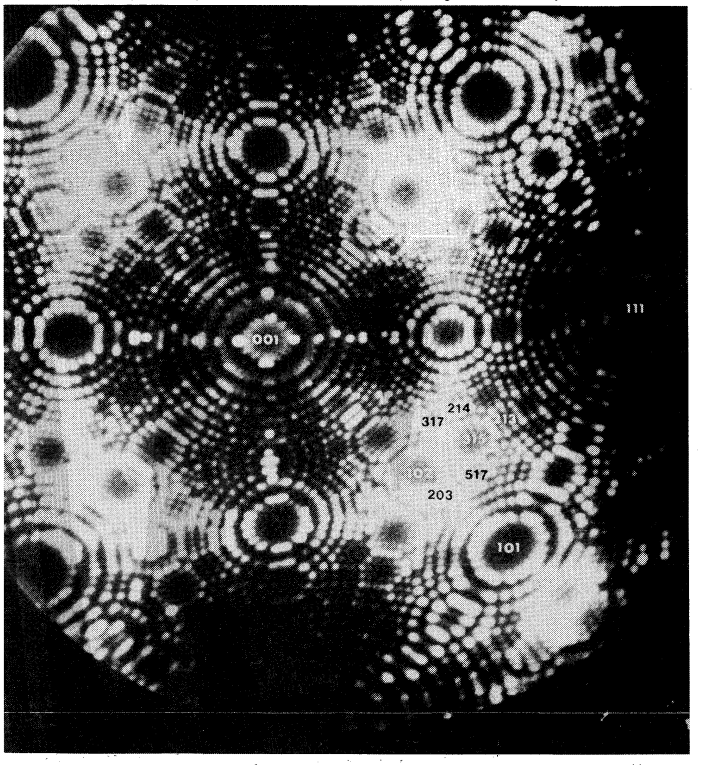

Figure 11: Field-ion micrograph of atoms on the surface of a platinum needle.

the orbitals are completely filled up to the band gap, the states of the electrons are essentially fixed and the material will be an insulator. On the other hand, if the band is only partially filled, electrons can jump from one state to another with only an infinitesimal change in energy. In this case, the electrons can move about, and the material is a conductor. The sharp distinction between insulators and conductors becomes blurred in materials called semiconductors, which have small energy gaps. In silicon, for instance, the energy gap is only 1.4 eV, and it is possible to make silicon conduct by exciting electrons to the higher band. In some materials there is no energy gap between the occupied and empty orbitals, but the number of orbitals at the Fermi energy is so small that conductivity is poor. Graphite, another form of carbon, has a band structure of this type.

THE NUCLEUS

Nucleons. The protons and neutrons that make up the atomic nucleus are the lightest members of the baryon family of subatomic particles. The proton has a mass of 1.673×10^{-27} kilogram, which is 1,836 times larger than the mass of the electron. The neutron has approximately the same mass as the proton—1.675×10^{-27} kilogram. Subatomic masses are commonly expressed in units of rest energy, which is related to mass by Einstein's formula $E = mc^2$. The proton's rest energy is 938.3 MeV and that of the neutron is 939.6 MeV. All baryons except the proton are unstable and can decay into lighter baryons. The neutron, having more rest energy than the proton, can decay into a proton with the emission of an electron and an anti-neutrino. Its lifetime outside the nucleus is 10 minutes. In the nucleus the binding energy is larger than the difference in rest energies between the neutron and the proton. The binding forces stabilize the nucleus against the decay of its neutrons.

Properties of protons and neutrons

Other properties of nucleons are their charge, spin, and magnetic moment. The charge on a proton is equal and opposite to the electron's charge. The neutron is uncharged. Like electrons and other elementary fermions, nucleons have a spin quantum number of $1/2$ and are described by a wave function that is doubled in multiplicity by two spin orientations. Nucleons and electrons also have a magnetic moment associated with their spin. However, the numerical value of a nucleon's magnetic moment, unlike an electron's, is quite different from that predicted by the Dirac equation; in fact, the proton's moment is 2.8 times the value predicted. Furthermore, the neutron has a somewhat smaller moment opposite to that of the proton, though according to the Dirac equation it should have none at all.

While electrons are point particles, nucleons have a finite extension. The distribution of the positive charge in a proton can be measured in electron scattering experiments. The charge is distributed in a smooth cloud extending to a distance of about 1×10^{-15} metre, or 1 femtometre, from the centre. The neutron is neutral overall, but electron scattering measurements show that it also has an internal structure with a slight positive charge in the core surrounded by a shell of negative charge.

Internuclear forces. The most important characteristic that distinguishes nucleons from electrons and other leptons has to do with the forces acting on them. Nucleons are subject to the three forces of nature affecting leptons: gravitation, electromagnetism, and the weak force. However, nucleons also exert a very powerful force on each other—namely, the nuclear, or strong, force. This force has an extremely short range so that its effects are not felt outside an atom. Indeed, even within an atom, the strong force is insignificant just a few fermis (one fermi = 10^{-15} metre) from the surface of the nucleus. By contrast, the effects of the electromagnetic and gravitational forces can be felt at all distances.

Strong force

The character of the strong force is rather complicated and only partially understood. At very small distances between nucleons, less than one femtometre, the force is repulsive and tends to keep the nucleons apart. At intermediate distances, about one to two femtometres, the force is strongly attractive and can bind the nucleons by energy amounting to many millions of electron volts. Beyond a few femtometres, the strong force becomes inconsequential in comparison to the electromagnetic force. A graph of the behaviour of the strong force is shown in Figure 12.

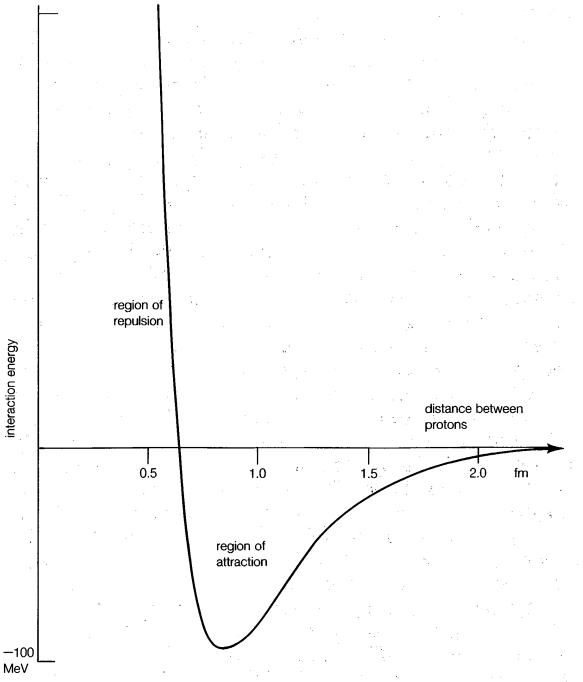

Figure 12: *Proton force.*
The interaction energy of two protons is shown as a function of the distance between them. At small separations, the energy is positive and the force is repulsive. At intermediate distances, the nuclear interaction is negative and the force is attractive. At distances larger than shown on the graph, the nuclear force becomes negligible and the repulsive electric force between the two charges is all that is left. The interaction depicted is for protons with antiparallel spins.

The effects of the strong force are seen in the interactions of free nucleons and the binding energy of nuclei. Nucleon interactions can be studied by bombarding hydrogen with a beam of protons or neutrons. The beam particles passing within a certain distance of a proton from the hydrogen target will be deflected by the strong force. The strength of the interaction between beam and target nucleons is characterized by a quantity called the cross section, which has units of area. It is the apparent area of the target particle that intercepts the beam particle and results in an interaction or a deflection. The cross section of high-energy nucleons scattering or otherwise interacting with each other is about four square femtometres. If the particles are thought of as spheres that interact when they come into contact, the radius of the individual nucleon sphere would be about 0.7 femtometre. At low energies the cross sections become larger, partly because there is more time for the forces to act with slower moving particles. Quantum wave effects also become more important at low energy; they allow the influence of the force to be felt at larger distances and help increase the cross section.

The cross section

Most of the existing detailed knowledge about nuclear forces comes from matching observed cross sections, including their dependence on energy and scattering angle, with quantum mechanical calculations based on models of the strong force. Yukawa's meson exchange picture (see above) explains the major features of the strong force beyond one femtometre. In quantum field theory, two particles may exert a force on each other at a distance only by exchanging a third particle. The particles exchanged in the strong force are mesons. The pion, the lightest of the mesons, is responsible for the longest range portion of the strong force. When the pion is exchanged, it can transfer a charge from one nucleon to another. In this process, called an exchange interaction, a proton is converted to a neutron and a neutron becomes a proton. At shorter distances, heavier mesons become important, and several pions may be exchanged at the same time. The main

Exchange of mesons

attraction between nucleons in bound nuclei is caused by the exchange of multiple pions and higher mesons. The exchange of mesons also can change the internal structure of the nucleon, transforming it into some other baryon. Even when there is not enough energy to produce the excited baryon, its effects are felt in the strong force.

The strong force also depends on the spin orientation of the nucleons. This dependence adds to the complexity of the force. For example, the force between protons and neutrons is most attractive when the spins are pointing in the same direction. On the other hand, the Pauli principle does not allow two protons with parallel spins to be located close to each other, and the interaction with the opposite spin alignment is weaker. Part of the spin dependence is known as the tensor force. This force reorients the spin and exerts a torque on the nucleons. The tensor force helps explain a property of the deuteron, which is a neutron and proton bound together. Under the influence of ordinary forces, the wave function would be spherically symmetric. Due to the tensor force, however, the deuteron is elongated in shape. The elongation is measured as its quadrupole moment. Another significant part of the spin-dependent force is the spin-orbit force. This force acts when the nucleons are moving around each other and have orbital angular momentum. It tends to align the orbital angular momentum with the spin orientation.

Tensor and spin-orbit forces

An important consequence of the strong force is the binding of nuclei. The simplest example is the deuteron, with a binding energy of 2.2 MeV. The binding energy is the sum of an interaction energy and a kinetic energy of the particles. By itself, the interaction energy is much more than 2 MeV, but a large kinetic energy nearly cancels it. In heavier nuclei the interaction energy is higher because there are more neighbouring nucleons; consequently, the binding is greater. Protons also are attracted to each other by the strong force, but their interaction is not sufficient to bind them together. Thus, there is no isotope of helium consisting only of two protons.

Shape and size of nuclei. Most nuclei are spherical, and their size is determined by the number of nucleons present. The density of nucleons is roughly constant in the interior of a nucleus, and so the volume of the sphere is proportional to the atomic mass number. In this respect, the nucleus resembles a liquid drop, the volume of which is proportional to the amount of matter it contains. The density of nucleons in the interior of a nucleus is about 3×10^{17} kilograms per cubic metre; each nucleon takes up about six cubic femtometres of volume. The radii of nuclei found in nature range from two to eight femtometres.

The constant interior density of nuclei, called the saturation property, is quite different from the distribution of electrons in atoms. The density of electrons varies considerably with their distance from the centre of the atom; electrons are highly concentrated in the inner shells and more dispersed in the outer ones. The saturation of nuclear matter, on the other hand, arises from a delicate balance between the attractive and repulsive components of the nuclear force. Aspects of the interaction contributing to the saturation are: (1) the short-range repulsion that prevents the nucleons from occupying the same volume; (2) the charged pion exchange that is less effective at high density; (3) the tensor force; and (4) the interactions that make internal excitations of the nucleons.

Saturation property

The most precise information on nuclear sizes comes from electron-scattering measurements. Because of their quantum-wave properties, electrons scattering from nuclei exhibit diffraction, which is preferential scattering at specific angles. Detailed pictures of the size and shape of the nucleus can be inferred from these diffraction patterns. Figure 13 shows an example of inferred charge density on a slice through the centre of a nucleus of lead-208. The charge is roughly uniform inside a sphere and has a diffuse edge on the surface. The density falls from its inside value to zero over a distance of roughly two femtometres. One does not see the individual particles in the nucleus because their wave functions are diffuse clouds. There are, however, perceptible variations in density in the interior. These oscillations show that the wave functions of the nucleons inside a nucleus have a shell behaviour just like

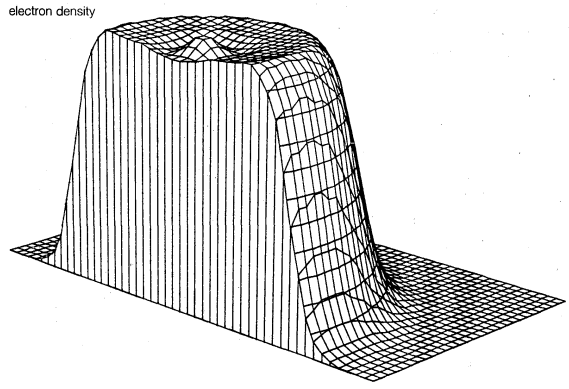

Figure 13: Profile of the charge distribution within the nucleus of lead-208 inferred from electron-scattering experiments.

the electrons in atoms. The peaks occur at positions where the proton wave functions are maximal, and the valleys occur where the wave functions pass through zero.

Mass and binding energy. The mass of a nucleus is typically about 1 percent less than the total mass of the nucleons composing it. This mass deficiency is related to the binding energy of nuclei by Einstein's formula $E = mc^2$. The binding energy determines which nuclei are stable and how much energy is released in a nuclear reaction. The picture of the nucleus as a charged liquid drop describes the overall trends of the binding energies. Each particle in the interior of a classical liquid is bound by the same amount. Very roughly, nuclear binding energies behave accordingly, with a typical binding energy of 8 MeV per nucleon. In detail, the trend of nuclear binding energies may be seen in Figure 14, which graphs the binding energy per nucleon as a function of the atomic mass number. The graph shows the near constancy of the binding energy from nuclei as light as helium-4 up to very heavy nuclei. By contrast, the binding energy of atoms varies greatly with atomic number because their inner shells are so tightly bound.

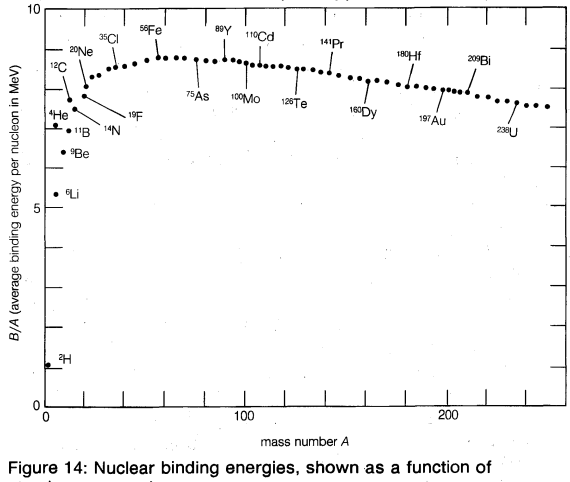

Figure 14: Nuclear binding energies, shown as a function of atomic mass number.

Particles at the surface of a liquid have fewer neighbours to interact with, so there is surface tension and a deficiency of energy from the surface. In the same way, lighter nuclei have a relatively large surface-to-volume ratio and are not as strongly bound. This may be seen in Figure 14 in the behaviour of the curve for smaller atomic mass numbers.

Repulsion between the charges of protons reduces the binding energy of a nucleus. The negative contribution from this repulsion is called the Coulomb energy. The effect is largest for the highest atomic numbers, which are the most highly charged nuclei. The surface energy favouring large nuclei and the Coulomb energy favouring low atomic numbers oppose each other; consequently, the optimum mass number for a nucleus is in the middle

Coulomb energy

region, around mass 60 and the iron nucleus. Nuclear energy can be released by any process that transforms nuclei to others closer to the middle masses. Thus, nuclear energy can be released by fusing light nuclei or by splitting heavy nuclei in the fission process. Energy production in stars results primarily from the fusion of hydrogen to make helium. Hotter stars can fuse heavier elements, but all nuclear energy is exhausted when iron is attained as a fusion product. Terrestrial elements are believed to have been formed by this process of stellar nucleosynthesis. Elements heavier than iron may have been formed by very transient processes in supernova explosions. (For a more detailed discussion of stellar nucleosynthesis, see STARS AND STAR CLUSTERS.)

Nuclear binding energy also depends on the relative numbers of neutrons and protons in a nucleus. In light nuclei the most binding is obtained with an equal number of neutrons and protons, which optimizes the neutron-proton attraction. In heavier nuclei the Coulomb repulsion between protons gives more binding to nuclei with an excess of neutrons. The most stable heavy nuclei have 50 percent more neutrons than protons.

Nuclear spin and magnetic moment. Nuclei, like atoms or other particles, may have an internal angular momentum called spin. Because of the characteristics of the forces involved, the spin of a nucleus is zero if the nucleus has an even number of neutrons and protons. Nuclei with an odd number of nucleons always have a half-integer spin. In many cases the magnitude of the spin can be determined from the nuclear shell model (see below). A nucleus with a spin also has a magnetic moment aligned along the spin axis. The magnetic moment of a nucleus is very weak compared to that of an electron, but it can still produce an observable effect in atomic properties. The magnetic field from a nucleus disturbs the degeneracy of atomic levels and causes the atomic spectral lines to split. This splitting is called hyperfine structure, as distinguished from the fine-structure splitting caused by the magnetic moment of electrons.

Magnetic resonance

An important application of nuclear magnetism is a method of analysis called magnetic resonance. In this technique, a material is placed in a strong magnetic field that tends to align the nuclear spins. Partially aligned spins will precess about the magnetic field direction, the way a gyroscope precesses when it is subjected to an outside torque. With the application of an extra time-varying magnetic field, the nuclei can be induced to precess in phase with each other. The resulting precessional motion of the spins causes the magnetization of the material to vary at a definite frequency, which is detected as a radio-frequency signal from the material. Magnetic resonance has several practical applications. Based on the fact that the precession rate is proportional to the field, it can be used to measure magnetic fields precisely. Notable is its use in a medical diagnostic procedure known as magnetic resonance imaging (MRI; see RADIATION: *Imaging techniques*). The nucleus most commonly employed in magnetic resonance is the proton in the hydrogen atom. Because the hydrogen nucleus has the largest magnetic moment for its spin, it provides the strongest resonance signals. Other nuclei used include those of phosphorus and fluorine.

Energy levels. Nuclei have energy levels just as atoms do. A typical excitation energy of a nuclear level is 1 MeV, which is 1,000,000 times larger than atomic energy levels. As in atomic transitions, a quantum of light may be emitted when the nucleus changes states. These quanta are the gamma rays that are often by-products of radioactivity.

Each energy level is characterized by its own values of spin, magnetic moment, and quadrupole moment. In addition, the quantum numbers of isotopic spin and parity are useful for describing nuclear levels. The isotopic spin quantum number characterizes the symmetry of the wave function when neutrons are interchanged with protons. Levels can exist in different nuclei with wave functions that are identical except for the interchange of neutrons and protons. Except for the Coulomb energy, these sets of wave functions have the same energies; the sets are called isospin multiplets (Figure 15). The parity quantum number can take on only two values, even or odd, depending on whether the wave function reverses sign when the coordinates of the particles are reversed. The parity and spin quantum numbers are useful in understanding the rates of transitions between energy levels; selection rules govern changes in spin and parity for the favoured transitions.

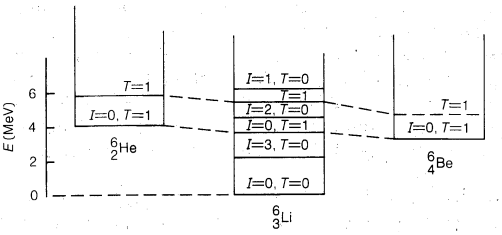

Figure 15: The energy levels of three nuclei with $A = 6$, relative to the ground state of ^{6}Li after subtraction of the calculated electrostatic energy. The isospin $T = 1$ levels exist in all three nuclei.

To excite nuclei out of their ground states, energy must be provided from some external source. A common way to do this is with nuclear reactions. A nucleus is bombarded with energetic particles of one sort or another. The particles interact, giving up part of their energy to induce an excited state of the nucleus. Under special circumstances it is possible to excite a nucleus with the gamma ray produced by another nucleus. In a nuclear process known as the Mössbauer effect, the nucleus of some isotope absorbs a gamma ray that has been emitted by another nucleus of the same isotope. Because the transitions take place between the same two levels, the gamma ray has exactly the right energy to be absorbed. The effect is difficult to produce because part of the transition energy normally goes to nuclear recoil during emission and absorption and is unavailable to the gamma ray.

Mössbauer effect

Among the many energy levels to which a nucleus can be excited, a few correspond to simple modes of motion for the nucleons. Deformed nuclei (see below) can be given energy in the form of rotational motion. Nuclei also can vibrate, and corresponding vibrational states may be found among the energy levels. Giant dipole resonance is an example of a nuclear vibration exhibited by all nuclei. In this mode of motion neutrons and protons in the nucleus oscillate back and forth, with the neutrons moving against the protons, as shown in Figure 16. Because there is a large oscillating electric field associated with this motion, gamma rays are absorbed and emitted readily. Another kind of vibration is called the quadrupole vibration. In this mode the nucleus oscillates in shape, changing between

From G.F. Bertsch and R.A. Broglia, "Giant Resonances in Hot Nuclei," *Physics Today* (August 1986)

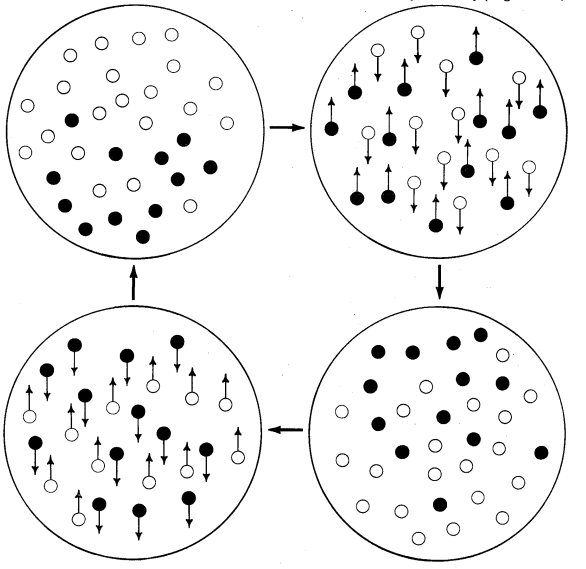

Figure 16: *Nuclear vibratory motion in the giant dipole resonance.*
Protons and neutrons, indicated by circles and solid dots, move in opposite directions.

prolate and oblate spheroids. This mode is easily excited by the inelastic scattering of particles from the nucleus. Its properties are deduced from the diffraction pattern observed in the scattering. In yet another kind of vibration, called the breathing mode, the nucleus expands and contracts. The frequency of the breathing mode depends on the compressibility of the nuclear medium and is used to establish its value.

Nuclear shell model. A comprehensive explanation of many nuclear properties is provided by a theory known as the shell model. It is based on the Hartree approximation to the Schrödinger equation. As noted earlier, this approximation assumes that all the particles have independent wave functions governed by a common force field. Of course, the forces in the nucleus are different from those in the atom as a whole. In the nuclear Hartree theory the forces are too strong to include directly, varying violently from repulsive to attractive. Instead, true interaction is replaced by smoother forces that are adjusted to reproduce the saturation property of nuclei.

The resulting force field pulls the nucleons in when they come to the surface, but it cancels out when nucleons are in the interior. The nucleons behave as though they were in a potential well with a flat bottom. The nuclear shells are the sets of wave functions that go with this flat-bottomed potential well. Some of the properties of these shells are similar to those of atomic shells, but there are also important differences. Provided the well is spherically symmetric, the shells have an angular momentum quantum number, as do the atomic shells. The lowest shell is the *s* shell, which can hold a neutron and proton of each spin orientation. Thus, the two protons and two neutrons of helium-4 fill the *s* shell and give this light nucleus its unusual stability. The energy levels of higher shells are shown in Figure 17. Differences from the atomic levels in hydrogen are readily apparent. First, there is no degeneracy between the *s* and *p* shells, so that the atomic periodicity of 8 does not occur in nuclear physics. Second, the spin-orbit force makes shells that have nucleon spin parallel to orbital angular momentum lower in energy than the shell with antiparallel spin. For example, in the *p* shell, there are two sub-shells, the $p_{3/2}$ and the $p_{1/2}$. The $p_{3/2}$, with orbital angular momentum 1 parallel to spin angular momentum 1/2, is lower in energy than the $p_{1/2}$, which has an antiparallel spin and orbital angular momentum. Combining orbital and spin angular momentum in this way is called *j-j* coupling. The number of protons or neutrons that can go in a *j* shell is its multiplicity equal to $2j + 1$. From this filling rule and the shell ordering in Figure 17, one can determine the shell structure of a nucleus for any given proton and neutron number.

Properties of nuclear shells

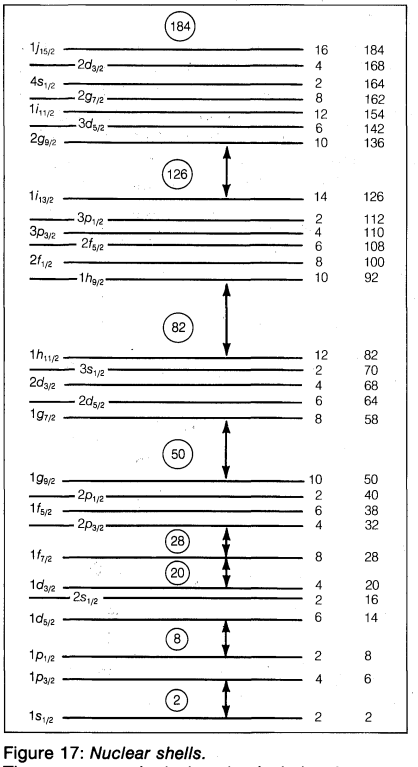

Figure 17: *Nuclear shells.*
The spectroscopic designation includes the quantum number *j*, which is a half integer. The degeneracy of the shells and the cumulative number of particles contained are listed on the right. Especially stable nuclei are found at the magic numbers, shown in circles.

An important consequence of the *j-j* coupling is the energy gap between shells that occurs at proton or neutron numbers 28, 50, 82, and 126. These so-called magic numbers are the nuclear equivalent of the atomic numbers of the noble (or inert) gases 2, 10, 18, 36, 54, 86. Nuclei with magic numbers of protons and neutrons are unusually stable and have especially large gaps between their ground and excited states.

Magic numbers

The ground state of nuclei with an odd number of neutrons or protons has a spin that is often given by a simple rule—namely, that the angular momentum of all the nucleons except the last are aligned to cancel. The last nucleon has the angular momentum of its shell, which gives the spin of the nucleus. For example, the nucleus of lithium-7 consists of three protons and four neutrons. According to the rule, the spin of lithium-7 is determined by the shell of the third proton. This is the $p_{3/2}$ shell, and indeed the spin of the nucleus is 3/2. Another property that can be inferred from the shell model is the parity of the nucleus. It can be determined from the shell model simply by combining the parities of the individual shell wave functions for nucleons.

Nuclear excited states are described in the shell model either by changing the orbitals that nucleons occupy in a shell or by moving nucleons from a lower shell to a higher one. Wave functions constructed in this way accurately describe the excited-state properties of light nuclei and nuclei near magic numbers. Outside of these limited regions of nuclei, the shell model allows an enormous number of states. The numerical complexity of dealing with so many states, however, prevents precise calculations from being carried out. A simplified treatment of the wave function explaining many properties of nuclear vibrations is based on a generalization of the Hartree method to allow the potential field to vary in time. The nucleons move in the time-varying field, and the frequency of motion can be calculated by requiring the field generated by the nucleons to be consistent with the field in which they move.

Deformed nuclei. Not all nuclei are spherical in shape. In certain regions of the periodic table, many nuclei are spheroidal. Typically, these nuclei have a prolate distortion, meaning that they have an elongated shape like a lemon. For example, the nuclei near mass number 160 are prolate spheroids, with the longer axis about 30 percent larger than the other two axes. The existence of these deformations was first detected in atomic spectra: the quadrupole moment distorts the electric field around the nucleus, producing characteristic features in the hyperfine structure of the atomic spectrum. The energy levels of these nuclei also exhibit characteristic features. A body capable of rotation and governed by the laws of quantum mechanics has energy levels with spacings that increase uniformly with higher angular momentum. Deformed nuclei exhibit this type of spectrum (see Figure 18).

Elongation of nuclei

Deformations can be explained by the Hartree theory of the nuclear wave function. The orbitals describing the individual nucleons are rarely spherically symmetric; many are, in fact, quite elongated. When a shell is filled, the various asymmetries in the different orbitals balance out so that the entire shell has a spherical mass distribution. If a shell is only partly filled, the overall shape deviates more or less from spherical symmetry, depending on which particular orbitals are occupied. In the case of an atom, the repulsion of the electrons tends to make the overall shape spherical: when one electron is in an orbital elongated in a certain direction, the energy is minimized if the other electrons are in orbitals elongated in other directions. The

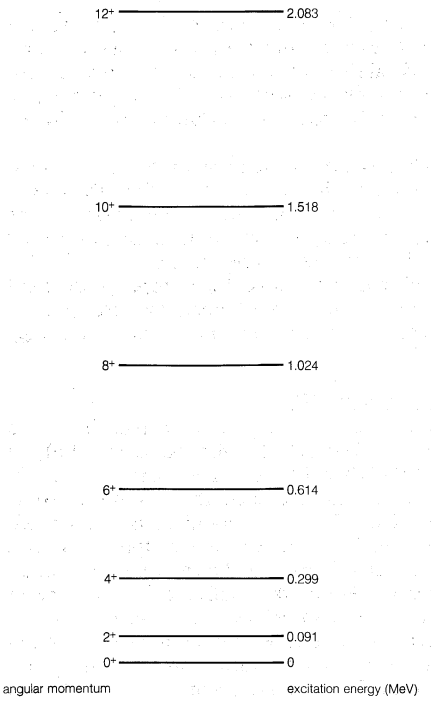

Figure 18: Energy-level spectrum of the deformed nucleus erbium-164.

overall density ends up being close to spherical, even when the individual orbitals are not. In a nucleus there is a net attraction between nucleons so that, if a proton's orbital is elongated in some particular direction, the neutron would tend to be in a similarly directed orbital. Many nucleons can act together and deform the entire nucleus. When the Hartree equations are solved for nuclei with partially filled shells, the resulting potential well is elongated and the nucleons occupy states elongated in the same direction.

Nuclear reactions. Nuclear reactions mediated by the strong force can occur when a nucleus is bombarded by some hadronic projectile, such as a proton, a pion, or another nucleus. For a reaction to occur, the projectile must come within a few femtometres of the nucleus, preventing positively charged particles from producing reactions at low energy. Since the nucleus is positively charged, a similarly charged projectile will not be able to come within range unless it has enough energy to overcome the force of the electric repulsion. For example, alpha particles will not come close enough to interact with an iron nucleus unless their energy exceeds about 10 MeV. For less highly charged nuclei, the numbers are smaller; a proton of 1 MeV can interact with a lithium nucleus. The first artificial nuclear reactions were induced by using a voltage source of 1,000,000 volts to accelerate protons to an energy of 1 MeV and bombard a lithium target. At high bombarding energies the electrostatic force is less important, and the cross section for producing a reaction is approximately equal to the area of a circle with the radius of the nucleus.

Neutrons can induce reactions at very low energies, even thermal energies, because they are not repelled by the positive charge of the nucleus. The cross section for reactions with thermal neutrons can be extremely large because the wave function of the neutron is spread out at low energy. Radioactive nuclei are commonly produced by bombarding nuclei with neutrons in nuclear reactors.

Hadronic reactions

Reactions induced by hadronic projectiles may be divided into two main categories: direct reactions and more complex reactions. In direct reactions the projectile retains most of its energy and momentum. A small amount of energy is transferred to the target, producing transitions to particular excited states. These direct reactions occur when the projectile passes near the target nucleus without penetrating it. The angular distribution of scattered projectile particles shows diffraction behaviour depending on the properties of the energy level excited. An example of a direct reaction is the following:

$$p + {}^{40}\mathrm{Ca} \longrightarrow d + {}^{39}\mathrm{Ca}.$$

Here, a proton, p, passes by the calcium-40 nucleus, picking up a neutron to form a deuteron, d. The deuteron comes off in approximately the same direction as the motion of the incident proton but with diffractional variations in intensity at different angles. From the diffraction pattern, the orbital angular momentum of the neutron in the target may be inferred. Measurements such as these were important in establishing the validity of the shell model.

If the projectile goes into the target nucleus, it is likely to be absorbed completely, sharing its energy with the other nucleons in the nucleus. The resulting highly excited nucleus, called a compound nucleus, can decay in many different ways. The main constraints in determining the possible reactions are that the total number of neutrons and protons, the total charge, and the total energy must remain the same. These are the conservation laws for baryon number, charge, and energy. In principle, it is possible to change a neutron into a proton or vice versa in a hadronic reaction, but the probability is so small that this cannot be observed in the laboratory.

An example of a reaction following this more complex path is

$$a + {}^{14}\mathrm{N} \longrightarrow {}^{17}\mathrm{O} + p$$

This reaction was observed by Rutherford, who used alpha particles from a radioactive source. This provided enough energy to allow the alpha particle, a, to touch and fuse with the nitrogen-14 nucleus. There is a high probability that the resulting compound nucleus will decay by emitting a proton, but it can decay by other modes as well. The following example is a reaction that takes place when a hydrogen-containing medium is bombarded with low-energy neutrons, n:

$$n + {}^{1}\mathrm{H} \longrightarrow {}^{2}\mathrm{H} + \gamma$$

In this case, the energy released is equal to the binding energy of hydrogen-2, which is given off in the gamma ray, γ.

Many different kinds of reactions are possible in collisions induced by accelerated particles. Accelerators can give the projectiles enough energy to disrupt the nucleus completely and create new particles in the process. For example, a cyclotron can boost carbon nuclei to an energy of 500 MeV, enough to dissociate all the nucleons in a target nucleus of oxygen. In practice, such a reaction would involve many different processes, and the end result would be the fusion and dissociation of the nuclei into fragments of various sizes (see Figure 19). The annihilation of a pion in a nucleus is another example of a hadronic reaction. In this process, the rest energy of the pion would be released, dissociating the nucleus and giving kinetic energy to nucleons or other fragments.

Lepton-induced reactions

Nuclear reactions also can be induced by leptons such as electrons and neutrinos. The probability for an electron-induced reaction is smaller than for a hadronic reaction because of the difference in forces. The main process is inelastic scattering, in which the nucleus is excited to a higher energy level. If the inelastic scattering transfers a large amount of energy to the nucleus (*e.g.*, 20 MeV or larger), the nucleus becomes disrupted and ejects particles.

The weak interaction also causes reactions, but these are very difficult to observe. One part of the weak interaction changes a neutron into a proton or vice versa and brings about a corresponding conversion between an electron and a neutrino. The direction of the change is such as to conserve the total charge. An example of a neutrino-induced reaction is the reaction by which neutrinos were detected from a supernova in 1987. In this case, the neutrinos—or more precisely antineutrinos, $\bar{\nu}$—from the cosmic object interacted with protons of hydrogen atoms in a large tank of water. Positrons, e^+, were created according to the reaction

$$\bar{\nu} + p \longrightarrow n + e^{+}$$

* * *

The positrons were detected by the light they emitted as they traveled through the water. (G.F.B./S.McG.)

Isotopes

Every chemical element has one or more isotopes. All the isotopes of an element exhibit nearly identical chemical behaviour but have different masses. The differences in mass can be explained in terms of atomic structure.

As explained earlier, an atom is first identified and labeled according to the number of protons in its nucleus. This atomic number is ordinarily given the symbol Z. The great importance of the atomic number derives from the observation that all atoms with the same atomic number have nearly, if not precisely, identical chemical properties. A large collection of atoms with the same atomic number constitutes a sample of an element. A bar of pure uranium, for instance, would consist entirely of atoms with atomic number 92. The periodic table of the elements (see above) assigns one place to every atomic number, and each of these places is labeled with the common name of the element, as, for example, calcium, radon, or uranium.

Not all the atoms of an element need have the same number of neutrons in their nuclei. In fact, it is precisely the variation in the number of neutrons in the nuclei of atoms that gives rise to isotopes. Hydrogen is a case in point. It has the atomic number 1. Three nuclei with one proton are known that contain 0, 1, and 2 neutrons, respectively. The three share the place in the periodic table assigned to atomic number 1 and hence are called isotopes (from the Greek *isos,* meaning "same," and *topos,* signifying "place") of hydrogen.

Many important properties of an isotope depend on its mass. The total number of neutrons and protons (symbol A), or mass number, of the nucleus gives approximately the mass measured on the so-called atomic-mass-unit (amu) scale. The numerical difference between the actual measured mass of an isotope and A is called the mass defect (symbol Δ; see Table 3).

The specification of Z, A, and the chemical symbol (a one- or two-letter abbreviation of the element's name, say Sy) in the form ${}^{A}_{Z}\mathrm{Sy}$ identifies an isotope adequately for most purposes. Thus in the standard notation, ${}^{1}_{1}\mathrm{H}$ refers to the simplest isotope of hydrogen and ${}^{235}_{92}\mathrm{U}$ to an isotope of uranium widely used for nuclear power generation and nuclear weapons fabrication. (Authors who do not wish to use symbols sometimes write out the element name and mass number—hydrogen-1 and uranium-235 in the examples above.)

The term nuclide is used to describe particular isotopes, notably in cases where the nuclear rather than the chemical properties of an atom are to be emphasized. The lexicon of isotopes includes three other frequently used terms: isotones for isotopes of different elements with the same number of neutrons; isobars for isotopes of different elements with the same mass number; and isomers for isotopes identical in all respects except for the total energy content of the nuclei.

Isotones, isobars, and isomers

THE DISCOVERY OF ISOTOPES

Evidence for the existence of isotopes emerged from two independent lines of research, the first being the study of radioactivity. By 1910 it had become clear that certain processes associated with radioactivity, discovered some years before by Henri Becquerel, could transform one element into another. In particular, ores of the radioactive elements uranium and thorium had been found to contain small quantities of several radioactive substances never before observed. These substances were thought to be elements and accordingly received special names. Uranium ores, for example, yielded "ionium," and thorium ores gave "mesothorium." Painstaking work completed soon afterward revealed, however, that ionium, once mixed with ordinary thorium, could no longer be retrieved by chemical means alone. Similarly, mesothorium was shown to be chemically indistinguishable from radium. As chemists used the criterion of chemical indistinguishability as part of the definition of an element, they were forced to conclude that ionium and mesothorium were not new elements after all, but rather new forms of old ones. Generalizing from these and other data, Frederick Soddy in 1910 observed that "elements of different atomic weights may possess identical (chemical) properties" and so belong in the same place in the periodic table. With considerable prescience, he extended the scope of his conclusion to include not only radioactive species but stable elements as well. A few years later, Soddy published a comparison of the atomic weights of the stable element lead as measured in ores rich in uranium and thorium, respectively. He expected a difference because uranium and thorium

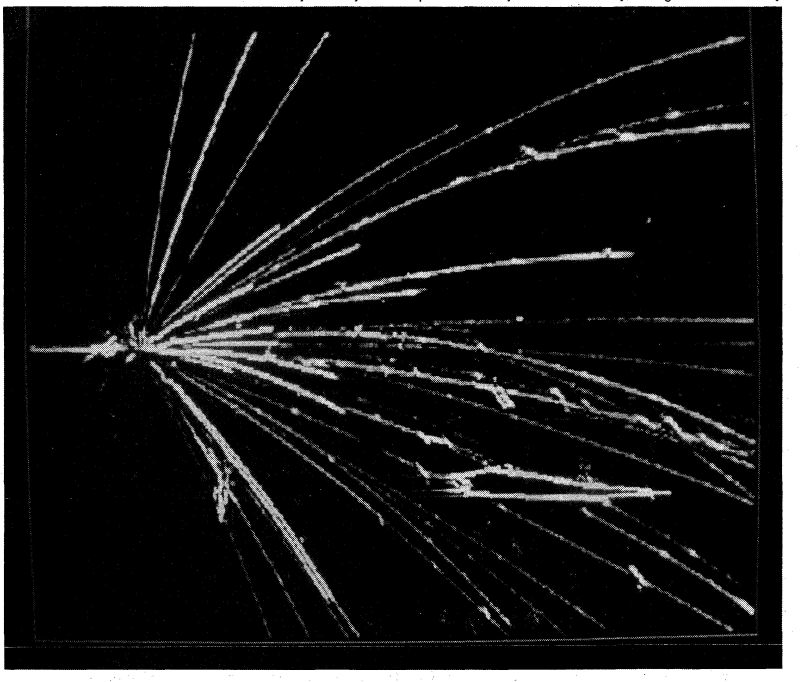

Figure 19: Particle tracks from the collision of an accelerated nucleus of a niobium atom with another niobium nucleus. The single line on the left is the track of the incoming projectile nucleus, and the other tracks are fragments from the collision.

decay into different isotopes of lead. The lead from the uranium-rich ore had an average atomic weight of 206.08 compared to 207.69 for the lead from the thorium-rich ore, thus verifying Soddy's conclusion.

The unambiguous confirmation of isotopes in stable elements not associated directly with either uranium or thorium followed a few years later with the development of the mass spectrograph by Francis William Aston. His work grew out of the study of positive rays (sometimes called canal rays), first discovered in 1886 by Eugen Goldstein and soon thereafter recognized as beams of positive ions. As a student in the laboratory of J.J. Thomson, Aston had learned that the gaseous element neon produced two positive rays. The ions in the heavier ray had masses about two units, or 10 percent, greater than the ions in the lighter ray. To prove that the lighter neon had a mass very close to 20 and that the heavier ray was indeed neon and not a spurious signal of some kind, Aston had to construct an instrument that was considerably more precise than any other of the time. By 1919 he had done so and convincingly argued for the existence of neon-20 and neon-22. Information from his and other laboratories accumulated rapidly in the ensuing years, and by 1935 the principal isotopes and their relative proportions were known for all but a handful of elements.

NUCLEAR STABILITY

Isotopes are said to be stable if, when left alone, they show no perceptible tendency to change spontaneously. Under the proper conditions, however, say in a nuclear reactor or particle accelerator or in the interior of a star, even stable isotopes may be transformed, one into another. The ease or difficulty with which these nuclear transformations occur varies considerably and reflects differing degrees of stability in the isotopes. Accordingly, it is important and useful to measure stability in more quantitative terms.

A uniform scale of nuclear stability, one that applies to stable and unstable isotopes alike, is based on a comparison of measured isotope masses with the masses of their constituent electrons, protons, and neutrons. For this purpose, electrons and protons are paired together as hydrogen atoms. The actual masses of all the stable isotopes differ appreciably from the sums of their individual particle masses. For example, the isotope $^{12}_{6}C$, which has a particularly stable nucleus, has an atomic mass defined to be exactly 12 amu. The total separate masses of 6 electrons and 6 protons, treated as 6 hydrogen atoms and 6 neutrons, add up to 12.09894 amu. The difference, Δm, between the actual mass of the assembled isotope and the masses of the particles gives a measure of the stability of the isotope: the larger and more negative the value of Δm, the greater the stability of the isotope. The difference in mass is often expressed as energy by using Einstein's equation in the form $E = \Delta mc^2$. Here, c is the speed of light. The quantity of energy calculated in this way is called the nuclear binding energy (E_B).

Calculating nuclear binding energies of nuclides

A single mathematical equation accurately reproduces the nuclear binding energies of more than 1,000 nuclides. It can be written in the form

$$E_B(\text{MeV}) = c_1 A[1 - k\{(N-Z)/A\}^2] - c_2 A^{2/3}[1 - k\{(N-Z)/A\}^2] - c_3 Z^2 A^{-1/3} + c_4 Z^2 A^{-1} + \delta.$$

The terms $c_1 = 15.677$, $c_2 = 18.56$, $c_3 = 0.717$, $c_4 = 1.211$, and $k = 1.79$, while δ may take any of several values (see below). The numerical values of these terms do not come from theory but from a selection process that ensures the best possible agreement with experimental data. On the other hand, theory helps justify, at least qualitatively, the mathematical form of each term. Modeled on an analogy to a liquid drop (see above), the first term represents the favourable contribution to the binding of the nucleus made by short-range, attractive nuclear forces between neutrons and protons. The second term corrects the first by allowing for the expectation that nucleons at the surface of the nucleus, unlike those in the interior, do not experience forces of nuclear attraction equally from all sides. Both the first and second terms have a second empirical component of the form $k[(N-Z)/A]^2$, which is referred to as the symmetry energy. It vanishes (neither helps nor hinders binding) when N is equal to Z (when the nucleus is "symmetric"), but then works increasingly to destabilize the nucleus as N and Z grow apart. The third term symbolizes the coulombic, or electrostatic, energy of repulsion of the protons; its derivation assumes a uniform distribution of charge within the nucleus. The fourth term makes a small correction to the third. This correction is necessitated by the observation that the nuclear charge distribution becomes somewhat more spread out near the surface of the nucleus. The last term, the so-called pairing energy, takes on any one of three values depending on whether N and Z are both even ($\delta = 11/A^{1/2}$), their sum is odd ($\delta = 0$), or both are odd ($\delta = -11/A^{1/2}$). More detailed treatments sometimes give other values for δ as well.

Symmetry energy

The largest observed deviations from the equation occur at certain favoured, or magic, numbers of neutrons or protons (2, 8, 20, 28, 50, 82, and 126). Magic nuclei are more stable than the binding energy equation would predict. The isotope of helium with 2 neutrons and 2 protons is said to be doubly magic. Various models of nuclear shell structure help to explain its stability.

Division of the binding energy E_B by A, the mass number, yields the binding energy per nucleon. This important quantity reaches a maximum value for nuclei in the vicinity of $^{56}_{26}Fe$. When two deuterium atoms fuse to form helium, the binding energy per nucleon increases and energy is released. Similarly, when the nucleus of an atom of ^{235}U fissions into two smaller nuclei, the binding energy per nucleon again increases with a concomitant release of energy.

RADIOACTIVE ISOTOPES

Only a small fraction of the isotopes are known to be stable indefinitely. All the others disintegrate spontaneously with the release of energy by processes broadly designated as radioactive decay. Each "parent" radioactive isotope eventually decays into one or at most a few stable isotope "daughters" specific to that parent. The radioactive parent tritium (^3H, or hydrogen-3), for example, always turns into the daughter helium-3 (^3He) by emitting an electron.

Radioactive decay

Under ordinary conditions, the disintegration of each radioactive isotope proceeds at a well-defined and characteristic rate. Thus, without replenishment, any radioactive isotope will ultimately vanish. Some isotopes, however, decay so slowly that they persist on Earth today even after the passage of more than 4,500,000,000 years since the last significant injection of freshly synthesized atoms from some nearby star. Examples of such long-lived radioisotopes include potassium-40, rubidium-87, neodymium-144, uranium-235, uranium-238, and thorium-232.

In this context, the widespread occurrence of radioisotopes that decay more rapidly, such as radon-222 and carbon-14, may at first seem puzzling. The explanation of the apparent paradox is that nuclides in this category are continually replenished by specialized nuclear processes: by the slow decay of uranium in the Earth in the case of radon and by the interactions of cosmic rays with the atmosphere in the case of carbon-14. Nuclear testing and the release of material from nuclear reactors also introduce radioactive isotopes into the environment.

ELEMENTAL AND ISOTOPIC ABUNDANCES

The composition of any object can be given as a set of elemental and isotopic abundances. One may speak, for example, of the composition of the ocean, the solar system, or indeed the Galaxy in terms of their respective elemental and isotopic abundances. Formally, the phrase elemental abundances usually connotes the amounts of the elements in an object expressed relative to one particular element (or isotope of it) selected as the standard for comparison. Isotopic abundances refer to the relative proportions of the stable isotopes of each element. They are most often quoted as atom percentages, as in Table 3.

Since the late 1930s, geochemists, astrophysicists, and nuclear physicists have joined together to try to explain the observed pattern of elemental and isotopic abundances. A more or less consistent picture has emerged. Hydrogen and

much helium are thought to have formed at the time of the "big bang"—the primordial explosion from which the universe is believed to have originated. The rest of the elements come, directly or indirectly, from stars. Cosmic rays (see below) produce a sizable proportion of the elements with mass numbers between 5 and 10; these elements are relatively rare. A substantial body of evidence shows that stars synthesize the heavier elements by nuclear processes collectively termed nucleosynthesis. In the first instance, then, nucleosynthesis determines the pattern of elemental abundances everywhere. The pattern is not immutable, for once matter escapes from stars it may undergo various processes of physical and chemical separation. A newly formed small planet, for example, may not exert enough gravitational attraction to capture the light gases hydrogen and helium. On the other hand, the processes that change elemental abundances normally alter isotopic abundances to a much lesser degree. Thus, virtually all terrestrial and meteoritic iron analyzed to date consists of 5.8 percent ^{54}Fe, 91.8 percent ^{56}Fe, 2.15 percent ^{57}Fe, and 0.29 percent ^{58}Fe. Table 3 lists the isotopic abundances of the stable elements and of a few radioactive elements as well. The relative constancy of the isotopic abundances makes it possible to tabulate meaningful average atomic weights for the elements. The availability of atomic weights is very important to chemists.

While there is general agreement on how the elements formed, the interpretation of elemental and isotopic abundances in specific bodies continues to occupy the attention of scientists. They obtain their raw data from several sources. Most knowledge concerning abundances comes from the study of the Earth, meteorites, and the Sun.

Solar system abundances of isotopes

Currently accepted estimates of solar-system (as opposed to terrestrial) abundances are pieced together mainly from two sources: (1) Chemical analyses of Type I carbonaceous chondrites, a special kind of meteorite, provide information about all but the most volatile elements—*i.e.*, those that existed as gases that the parent body of the meteorite could not trap in representative amounts. (2) Spectroscopic analysis of light from the Sun furnishes information about the volatile elements deficient in meteorites.

To the extent that the Sun resembles other stars, the elemental and isotopic abundances of the solar system have universal significance. Figure 20 shows the solar-system pattern. It has several notable features. First, the lighter isotopes, those of hydrogen and helium, constitute more than 98 percent of the mass; heavier isotopes make up scarcely 2 percent. Second, apart from the exceptions discussed below, as A or Z increases through the periodic table of the elements, abundances generally decrease. For example, the solar system as a whole contains about 1,000,000 times more carbon, nitrogen, and oxygen than the much heavier elements platinum and gold, though the proportions of the latter may vary widely from object to object. The decrease in abundance with increasing mass reflects in part the successive nature of nucleosynthesis. In nucleosynthesis, a nuclide of lower mass often serves as the seed or target for the production of a nuclide of

Table 3: Abundances of the Isotopes

higher mass. As the conversion of the lower mass target to the higher mass product is usually far from complete, abundances tend to decrease as mass increases. A third feature of interest is that stable isotopes with even numbers of protons and neutrons occur more often than do isotopes with odd ones (the so-called odd-even effect). Out of the almost 300 stable nuclides known, only five have odd numbers of both protons and neutrons; more than half have even values of Z and A-Z. Fourth, among the isotopes with even Z and A-Z certain species stand out by virtue of their considerable nuclear stability and comparatively high abundances. Nuclides that have equal and even numbers of neutrons and protons, the "alpha-particle" nuclides, fall into this category, which includes carbon-12, magnesium-24, and argon-36. Finally, peaks in the abundance distribution occur near the special values of Z and A-Z defined above as magic numbers. The high abundances manifest the extra nuclear stability that the magic numbers confer. Elements with enhanced abundances include nickel ($Z = 28$), tin ($Z = 50$), and lead ($Z = 82$).

The odd-even effect

The study of cosmic rays and of the light emitted by stars yields information about elemental and isotopic abundances outside the solar system. Cosmic rays are ions with high energy that are given off by stars. The Sun produces cosmic rays, too, but of much lower average energy than those reaching the solar system from outside. The abundance pattern in cosmic rays resembles that of the solar system in many ways. This fact suggests that solar and overall galactic abundances may be similar. Two explanations have been advanced to account for why solar and cosmic-ray abundances do not agree in all respects. The first is that cosmic rays undergo nuclear reactions as they pass through interstellar matter—*i.e.*, collisions that transform their nuclei. The second is that material from unusual stars with exotic compositions may be more prominent in either the solar system or in cosmic rays.

The determination of elemental and isotopic abundances in stars of the Milky Way system and of more distant galaxies poses formidable experimental difficulties. Research in the field is active and reveals trends in composition among stars that are consistent with nucleosynthetic theory. The "metallicity"—or proportion of heavy elements—in stars, for instance, seems to increase with stellar age. In addition, many stars with compositions far different from that of the solar system are known. Their existence has led some investigators to doubt whether the concept of cosmic, as opposed to solar-system, abundances is meaningful. For the present it is perhaps enough to quote the American astrophysicist James W. Truran: "The local pattern of abundances is generally representative. The gross abundance features throughout our galaxy, in other galaxies, and even apparently in quasars are generally similar to those of solar system matter, testifying to the fact that the underlying stellar systems share the same nucleosynthetic processes."

VARIATIONS IN ISOTOPIC ABUNDANCES

Although isotopic abundances are fairly constant throughout the solar system, variations do occur. Variations in stable isotopic abundances are usually less than 1 percent, but they can be larger. Whatever their size, they provide geologists and astronomers with valuable clues to the histories of the objects under study. Several different processes can cause abundances to vary, among them radioactive decay and mass fractionation.

Radioactive decay. This process transmutes an isotope of one element into an isotope of another; *e.g.*, potassium-40 (^{40}K) to argon-40 (^{40}Ar) or uranium-235 (^{235}U) to lead-207 (^{207}Pb). As a consequence, the isotopic composition of the daughter element produced by the radioactive decay—argon or lead in the cases cited—may vary significantly from sample to sample. The variations become especially pronounced when the material under study forms with only a small amount of the daughter element present initially. The isotopic composition of argon in the earth's atmosphere is a case in point.

Transmutation of isotopes

Compared to stellar or solar-system abundances, atmospheric argon contains a much higher proportion of ^{40}Ar and much less ^{36}Ar and ^{38}Ar. The excess ^{40}Ar in the atmosphere evidently leaked out of crustal rocks and other potassium-bearing materials where it was produced by the decay of ^{40}K. Because the Earth trapped a relatively small amount of cosmically normal argon during its accretion, the ^{40}Ar generated since then by radioactive decay dominates the isotopic pattern in the atmosphere.

Mass fractionation. Physical and/or chemical processes affect differently the isotopes of an element. When the effect is systematic, increasing or decreasing steadily as mass number increases, the new pattern of isotopic abundances is said to be mass fractionated with respect to some standard pattern. For small fractionations—a few percent or less—the normal isotopic ratio M_h/M_l changes by an amount proportional to $\Delta m = M_h - M_l$, where M_l is the mass of the lighter isotope. For oxygen subjected to mass fractionation the percentage change of the ratio ^{18}O/^{16}O should be twice that in the ratio ^{17}O/^{16}O. Sometimes a set of samples will form from a single reservoir but with each one having experienced a different degree of mass fractionation. A graph of one isotopic ratio M_h/M_l against a second, $M_{h'}/M_l$ will then yield a straight line of slope $(M_h - M_l)/(M_{h'} - M_l)$. Such plots find important use in deciding whether groups of objects originated from a common source and how those groups evolved. When the oxygen isotope abundances of samples from the Earth and the Moon are considered in this way, the results suggest that both the planet and its satellite are members of a family of objects distinct from the families to which most meteorites belong.

Other causes of isotopic abundance variations. In addition to the known processes described, unknown causes also contribute to observed variations in isotopic abundances. To explain the variations scientists have speculated that certain stars, novas or supernovas, may have injected unusual packets of mass that somehow avoided thorough mixing with normal matter. Another proposal is that some samples underwent intense irradiation by high-energy particles.

PHYSICAL PROPERTIES ASSOCIATED WITH ISOTOPES

Broadly speaking, differences in the properties of isotopes can be attributed to either of two causes: differences in mass or differences in nuclear structure. Scientists usually refer to the former as isotope effects and to the latter by a variety of more specialized names. The isotopes of helium afford examples of both kinds. Mass effects are considered first.

Isotope effects

Helium has two stable isotopes, ^{3}He and ^{4}He, and exists in the gaseous state under normal conditions. At a given temperature and pressure, any volume of ^{4}He will weigh one-third more than the same volume of ^{3}He. More generally, for the same spatial distribution of atoms, the substance with the heavier isotope is expected to be denser. When deuterium, $^2_1$H, is substituted for hydrogen, $^1_1$H, to form heavy water, $^2_1H_2O$, its density is about 10 percent greater than that of normal H_2O.

A second difference related directly to mass concerns atomic velocities. Lighter species travel at higher average speeds. Atoms of ^{3}He, on the average, move 15 percent faster than those of gaseous ^{4}He at the same temperature. Many other properties that depend on atomic motion such as the thermal conductivity and viscosity of gases manifest predictable isotope effects.

Contrasts in the behaviour of the helium isotopes extend to the liquid and solid states. The contrasts are attributable to the effects of both mass and nuclear structure. Figure 21 shows which states or phases of helium are stable—

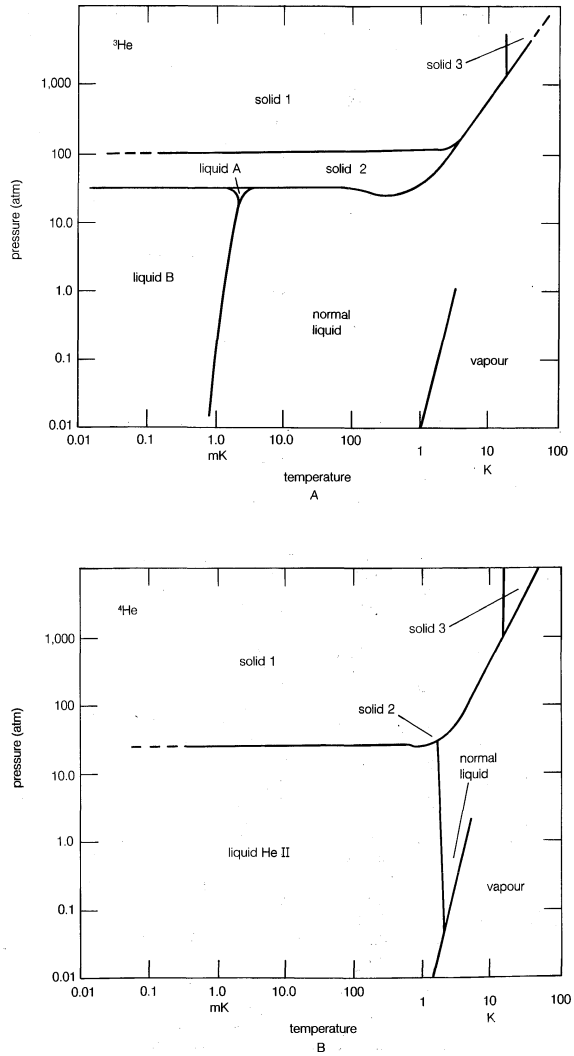

Figure 21: The phase diagrams of (A) helium-3 and (B) helium-4 show which states of these isotopes are stable (see text).

i.e., which actually occur at various temperatures and pressures. The lines on the diagrams delimit the ranges of stability of each phase. Although there are many similarities between the two diagrams, close examination reveals that they do not match up either quantitatively (in the positions of the lines) or qualitatively (in the types and numbers of phases at the lowest temperatures). It will be noted that ^{3}He forms three distinguishable liquid phases of which two are superfluids, while ^{4}He may exist only as two distinct liquids of which one is a superfluid. Unlike all other isotopes of the elements in the periodic table, neither ^{3}He nor ^{4}He solidifies under low pressures at a temperature near 0 Kelvin (K) (−273° C, or −459° F).

Effects of nuclear structure

Several other differences between isotopes depend on nuclear structure rather than on nuclear mass. First, radioactivity results from the interplay, distinctive for each nucleus, of nuclear and electrostatic forces between neutrons, protons, and electrons. Helium-6, for example, is radioactive, whereas helium-4 is stable. Second, nuclei may have differing quantities of angular momentum and may (or may not) act as tiny magnets, depending on the number and arrangement of their neutrons and protons. The magnetic properties of a nucleus play a crucial role in determining how the corresponding atom interacts with light. Finally, the spatial distribution of the protons in the nucleus affects in measurable ways the behaviour of the surrounding electrons. The addition of one neutron to an isotope allows the protons to spread out or to occupy a larger region of space. Electrons that have an appreciable probability of penetrating the nucleus are sensitive to this change. The addition of a neutron may also cause the nucleus to assume a nonspherical shape. A nonspherical distribution of charge in the nucleus affects the way in which the electrons behave, in particular the energies that they may emit or absorb in the form of light.

EFFECT OF ISOTOPES ON ATOMIC AND MOLECULAR SPECTRA

The study of how atoms and molecules interact with electromagnetic radiation, of which visible light is one form, goes by the name of spectroscopy. Spectroscopy has contributed much to the understanding of isotopes, and vice versa. To the extent that the characteristic spectrum of an atom or a molecule (*i.e.,* the light emitted or absorbed by it) is regarded as a physical property, the special relation between spectroscopy and isotopy warrants individual treatment here.

Atoms typically absorb or emit light exclusively at certain frequencies. Quantum mechanics explains this observation in a general way by associating with each atom (or molecule) well-defined states of energy. The atom may pass from one state to another only when energy is supplied (or removed) in the amount separating one state from another.

Precise measurements of the light emitted by isotopes of an element show small but significant differences termed shifts by spectroscopists. On the whole, these shifts are quite small. They originate in both mass and nuclear structure effects. The effects due to mass are largest for light isotopes. As nuclear mass increases, they decrease by an amount roughly proportional to $1/A^2$ and become insignificant in the heavier elements.

The effects due to nuclear structure relate primarily to the angular momentum, the magnetic moment, and the so-called electric quadrupole moment of the nucleus. The latter measures deviations from sphericity in the charge distribution. The magnetic moment and its attendant effects form the foundation of magnetic resonance spectroscopy, a field that has become very important in many branches of science.

When atoms join together in molecules, they can enter into characteristic vibrations and rotations. Just as an atom has a set of energy states associated primarily with the possible configurations of its electrons, so molecules have sets of energy states associated with their vibrations and rotations, as well as a set of electronic states. Light of the correct energy will induce changes from one vibrational (and/or rotational) state to another. Two ways in which isotopy relates to molecular vibrations, in particular, can be illustrated with the simplest of all molecules—diatomic molecules—which consist of only two atoms. Vibrational spectroscopy shows that isotopically heavier diatomic molecules have higher bond energies. (Bond energy is the amount of energy needed to separate the two atoms.) Quantum mechanical theory makes it possible to calculate from vibrational spectra just how much stronger the bond to the heavier isotope is. The differences between the chemical bond energies of isotopes help to explain why the isotopes do not behave identically in chemical reactions (see below). The second relation concerns the spacing between vibrational energy levels: the vibrational energy levels of an isotopically heavier molecule lie closer together. Consequently, it takes less energy to excite ^{18}O–^{18}O from one vibrational level to the next than it does ^{16}O–^{16}O. Spectroscopists made good use of this fact when they inferred from the spectra of isotopically mixed diatoms the existence of previously unknown isotopes. Oxygen-18 was discovered in this way.

Analysis of vibrational spectra

This second point, the distinguishability of the vibrational spectra of isotopically different molecules, is of great importance in the study of polyatomic molecules (molecules that contain three or more atoms). One key issue for chemists is the nature of the vibrations in polyatomic molecules: How do the nuclei of the atoms oscillate in relation to each other? The answer to this question bears strongly on what transient shapes the molecule may assume, how it will react with other molecules, and the rate at which it will do so. It is usually impossible to obtain this information from a study of the vibrational spectra of molecules made from atoms at natural abundance levels. Fortunately, the systematic substitution of heavier isotopes at known points in polyatomic molecules gives rise to new sets of vibrational spectra that clarify the nature of the atomic motions.

There is a second, fundamental reason for investigating the vibrational spectra of isotopically substituted, or "labeled," molecules. In interpreting spectra, spectroscopists rely on the mathematical results of quantum theory. Often, a close analysis of vibrational spectra of labeled molecules offers the best means for testing the soundness of the prevailing theoretical understanding of molecules.

CHEMICAL EFFECTS OF ISOTOPIC SUBSTITUTION

As isotopic abundances remain almost constant during most chemical processes, chemists do not normally distinguish the behaviour of one isotope from that of another. Indeed, in the limit of high temperatures, isotopes distribute themselves at random without preference for any particular chemical form. Nonetheless, under certain circumstances, nonrandom isotopic effects can become appreciable. Specifically, the lower the temperature and the lighter the isotope, the more noticeable the effects are likely to be. The reason is that the heavier isotopes tend to displace the lighter ones in those molecules where both heavy and light isotopes form the strongest chemical bond.

The exchange reaction $H_2 + D_2 \rightarrow 2HD$ provides an example of random behaviour at high temperature and isotope-specific behaviour at lower ones. If two volumes of gas consisting, respectively, of H_2 and D_2 only, are mixed, the hydrogen–hydrogen and deuterium–deuterium bonds will gradually break and new molecules will form until the vessel contains an appreciable quantity of H–D as well as of H_2 and D_2. At high temperatures the amount of HD observed at equilibrium approaches that predicted on the basis of probability (entropy) considerations alone—*i.e.,* a random distribution. How much would that be? A mathematical analysis shows that the concentrations of H_2, D_2, and HD should be equal to f_{H^2}, f_{D^2}, and $2f_Hf_D$, respectively, to a very good approximation. Here f represents the fraction of each kind of atom.

Experiment shows that as temperature increases, the concentrations of H_2, D_2 and HD approach the values expected. Although gratifying, the corroboration provides little information of chemical interest because the same results apply equally to the nitrogen isotopes ^{14}N and ^{15}N, to the chlorine isotopes ^{35}Cl and ^{37}Cl, and to many other pairs that differ greatly from hydrogen in their chemical behaviour. The variations from the random statistical distribution that occur at lower temperatures are more

interesting to a chemist because of what they reveal about the particular element.

At low temperatures the formation of D_2 (and H_2) is favoured at the expense of HD. A detailed theoretical treatment traces the cause of this favouritism to the comparative strength of the deuterium–deuterium bond. The result can be generalized: At equilibrium, the heavier isotope tends to concentrate wherever it forms the strongest chemical bond. For example, in the exchange reaction,

$$R-H+R'-D \rightarrow R-D+R'-H,$$

the hydrogen and deuterium switch partners. One may think of the hydrogen and deuterium as competing for the more attractive partner, supposed here to be R rather than R′. In accordance with the generalization above, the deuterium will tend to monopolize R with which, by hypothesis, it forms a stronger bond than it does with R′. Deuterium has a slight edge in the competition for R in spite of the fact that the hydrogen must also form a stronger bond with R than with R′.

Chemical equilibrium constants

Special quantities called chemical equilibrium constants express in quantitative terms the extent to which a chemical reaction favours products (the substances written to the right of the arrow) or reactants (the substances written to the left of the arrow). For reactions of the type cited, which chemists call exchange reactions, equilibrium constants are typically within a few percent of the values expected for a random distribution. The largest variations are observed for the low-Z elements, such as hydrogen; the variations are quite small for elements with higher atomic numbers, seldom exceeding 1 percent.

As implied above, the equilibrium constants for exchange reactions change slightly with temperature. This fact was put to use by the American chemist Harold C. Urey when he devised a method for inferring the temperature at which carbonates formed in the sea. He noted that, given a choice between water (H_2O) and carbonate (CO_3^{2-}, a principal constituent of seashells), the isotope ^{18}O shows a slight preference for the carbonate. The preference increases as temperature decreases. By measuring the $^{18}O/^{16}O$ ratio in a sample of carbonate and comparing it with the ratio in local seawater, it is possible to calculate a temperature at which the carbonate and the water equilibrated.

While isotopic substitutions usually change chemical equilibrium constants by small amounts, they can increase the rates of chemical reactions by a factor of 10 or more in the most extreme cases.

EFFECT OF ISOTOPIC SUBSTITUTION ON REACTION RATES

Chemical reactions take place when chemical bonds between atoms break or form. In the laboratory, chemical reactions proceed at well-defined rates. By introducing a heavy isotope into a reacting molecule, one may change the rate at which the molecule reacts. Two factors determine the size of the change.

The first factor is where the isotopic substitution is made in the reacting molecule. The largest effects, primary isotope effects, occur when one introduces a new isotope in the reaction "centre"—*i.e.*, the place in the molecule where chemical bonds are broken and/or formed during the reaction. If, on the other hand, the isotope is placed some distance from the reaction centre, it produces a much smaller, secondary isotope effect.

The second factor determining the size of the change in reaction rate is the relative, or percentage, difference in the masses of the original and substituted isotopes. The 300 percent difference in mass between ^3H (tritium) and ^1H can lead to more than 15-fold changes in reaction rates.

Both primary and secondary isotope effects decrease rapidly with increasing atomic number because the percentage difference in mass between isotopes tends to decrease. The substitution of deuterium for hydrogen, for example, may slow a reaction down by a factor of six. In contrast, the substitution of ^{18}O for ^{16}O would typically change a reaction rate by only a few percent. There is a much larger relative mass difference between hydrogen and deuterium than there is between ^{18}O and ^{16}O.

Primary isotope effects are often interpreted in terms of what is known as transition state theory. The theory postulates that to react, molecules must first reorganize themselves into a special, energy-rich configuration called a transition state. Other things being equal, the more energy required to form the transition state, the slower the reaction will be. A reaction in which a hydrogen atom shifts from one large molecule, symbolized as R–H, to another, symbolized as R′–H, furnishes an example:

The transition state theory

$$R-H+R' \rightarrow R\cdots H\cdots R' \rightarrow R+H-R'.$$

The middle structure with the dotted lines represents a transition state. The energy needed to form the transition state and hence the rate of reaction depends on the strength of the R–H bond among other factors. As deuterium would form a stronger bond to R than hydrogen, it follows that the substitution of deuterium for hydrogen would slow the reaction down. The amount by which the reaction slows down would depend heavily on just how much stronger the R–D bond is than the R–H bond.

ISOTOPE SEPARATION AND ENRICHMENT

Most elements are found as mixtures of several isotopes. For certain applications in industry, medicine, and science, samples enriched in one particular isotope are needed. Many methods have therefore been developed to separate the isotopes of an element from one another. Each method is based on some difference—sometimes a very slight one—between the physical or chemical properties of the isotopes of an element.

Mass spectrometry. Although the instrumentation normally serves analytical purposes, when suitably modified a mass spectrometer can also be used on a larger scale to prepare a purified sample of virtually any isotope. Uranium-235 for the first atomic bomb was separated with specially built mass spectrometers. Because of its high operational costs, this method is ordinarily restricted to the production of a few milligrams to a few grams of various stable isotopes for scientific investigation.

Distillation. The same factors that lead to the enrichment of alcohol in the vapour above a solution of water and alcohol permit the enrichment of isotopes. At temperatures below 220° C, for example, light water ($^1_1H_2O$) vaporizes to a slightly greater extent than heavy water ($^2_1H_2O$, or D_2O). The distillation of normal water, which contains both molecules, produces a vapour slightly enriched in $^1_1H_2O$. The residual liquid retains a correspondingly enhanced concentration of heavy water. It is usually, though not always, true that the molecule with the lighter isotope will be more volatile.

Chemical exchange reactions. Slight differences between the preferences of isotopes for one chemical form over another can serve as the basis for separation. The preparation of nitrogen enriched in ^{15}N by ion-exchange techniques illustrates this principle. Ammonia in water $NH_3(aq)$ will bind to a so-called ion-exchange resin (R–H). When poured over a vertical column of resin, a solution of ammonia reacts to form a well-defined horizontal band at the top of the column. The addition of a solution of lye (sodium hydroxide) will force the band of ammonia to move down the column. As the resin holds $^{15}NH_3$ slightly more tenaciously than $^{14}NH_3$, the $^{14}NH_3$ tends to concentrate at the leading, or bottom, edge of the band and the $^{15}NH_3$ at the trailing, or topmost, edge. Solutions depleted or enriched in ^{15}N are collected as they wash off the column.

Gaseous diffusion. Gases can diffuse through the small pores present in many materials. The diffusion proceeds in a random manner as gas molecules bounce unpredictably off the walls of the porous medium. The average time a molecule of gas takes to traverse such a barrier depends on its velocity and certain other factors. According to kinetic theory, at a given temperature a lighter molecule will have a larger average velocity than a heavier one. This result provides the basis for a separation method widely used to produce uranium enriched in the readily fissionable isotope ^{235}U, which is needed for nuclear reactors and nuclear weapons. (Natural uranium contains only about 0.7 percent ^{235}U, with the remainder of the isotopic mixture consisting almost entirely of ^{238}U.) In the separation process, natural uranium in the form of uranium hexafluoride

Uranium isotope separation and enrichment

(UF_6) gas is diffused from one compartment of a chamber to another through a porous barrier. Since the molecules of $^{235}UF_6$ travel at a higher velocity than those of $^{238}UF_6$, they pass into the second compartment more rapidly than the latter. Because the percentage of ^{235}U increases only slightly after traversal of the barrier, the process must be repeated hundreds of thousands of times to obtain the desired concentration of the isotope.

Gas centrifugation. When a mixture of gaseous molecules spins at high speed in a specially designed closed container, the heaviest species will concentrate near the outer walls and the lightest near the axis. The American physicist Jesse W. Beams used a gas centrifuge to separate isotopes, specifically the isotopes of chlorine, for the first time in 1936. Much subsequent work focused on the separation of $^{235}UF_6$ from $^{238}UF_6$ for which the gas centrifuge promised considerable savings in energy costs. Today, something less than 5 percent of the world's enriched uranium is produced by this method.

Photochemical enrichment methods. As discussed above, the frequencies of light absorbed by isotopes differ slightly. Once an atom has absorbed radiation and reached an excited state, its chemical properties may become quite different from what they were in the initial, or ground, state. Certain chemical and physical processes may proceed from an excited state that would not occur at all in the ground state. This observation is the nub of a method for isotope separation conceived some time ago but made practical only recently by the development of the laser. A laser produces light with such a narrow range of frequencies that it can excite one isotope without exciting neighbouring isotopes. Ordinary light sources produce much broader ranges of frequencies and therefore cannot excite isotopes selectively.

Several schemes of enrichment based on the use of lasers have been proposed because they promise to be relatively inexpensive compared to gas diffusion. Government-sponsored research in the United States has concentrated on a method that begins with metallic uranium. Upon heating in an oven, uranium vaporizes and escapes as a beam of particles through a small hole. Lasers tuned to the correct frequencies cause the ^{235}U atoms (but not the ^{238}U atoms) in the beam to be converted to a form (ions) in which they can be collected on a charged plate. (G.F.H.)

Radioactivity

As was noted above, an unstable nucleus will decompose spontaneously, or decay, into a more stable configuration but will do so only in a few specific ways by emitting certain particles or certain forms of electromagnetic energy. Radioactive decay is a property of several naturally occurring elements as well as of artificially produced isotopes of the elements. The rate at which a radioactive element decays is expressed in terms of its half-life; *i.e.,* the time required for one-half of any given quantity of the isotope to decay. Half-lives range from more than 1,000,000,000 years for some nuclei to less than 10^{-9} second (see below *Rates of radioactive transitions*). The product of a radioactive decay process—called the daughter of the parent isotope—may itself be unstable, in which case it, too, will decay. The process continues until a stable nuclide has been formed.

THE NATURE OF RADIOACTIVE EMISSIONS

The emissions of the most common forms of spontaneous radioactive decay are the alpha (α) particle, the beta (β) particle, the gamma (γ) ray, and the neutrino. The alpha particle is actually the nucleus of a helium-4 atom, with two positive charges ^4_2He. Such charged atoms are called ions. The neutral helium atom has two electrons outside its nucleus balancing these two charges. Beta particles may be negatively charged (beta minus, symbol e^-), also called a negatron, or positively charged (beta plus, symbol e^+), also called a positron. (The beta minus [β^-] particle is actually an electron created in the nucleus during beta decay without any relationship to the orbital electron cloud of the atom.) The positron is regarded as the antiparticle of the negatron because the two particles, when brought together, will mutually annihilate each other. Gamma rays are electromagnetic radiations like radio waves, light, and X rays. Beta radioactivity also produces the neutrino and antineutrino, particles that have no charge and no rest mass, symbolized by ν and $\bar{\nu}$, respectively.

Positive and negative beta particles

In the less common forms of radioactivity, fission fragments, neutrons, or protons may be emitted. Fission fragments are themselves complex nuclei with usually between one-third and two-thirds the charge Z and mass A of the parent nucleus. Neutrons and protons are, of course, the basic building blocks of complex nuclei, having approximately unit mass on the atomic scale and having zero charge or unit positive charge, respectively. The neutron cannot long exist in the free state. It is rapidly captured by nuclei in matter; otherwise, in free space it will undergo beta-minus decay to a proton, a negatron, and an antineutrino with a half-life of 12.8 minutes. The proton is the nucleus of ordinary hydrogen and is stable.

TYPES OF RADIOACTIVITY

The early work on natural radioactivity associated with uranium and thorium ores identified two distinct types of radioactivity: alpha and beta decay.

Alpha decay. In alpha decay, an energetic helium ion (alpha particle) is ejected, leaving a daughter nucleus of atomic number two less than the parent and of atomic mass number four less than the parent. An example is the decay (symbolized by an arrow) of the abundant isotope of uranium, ^{238}U, to a thorium daughter plus an alpha particle:

$$^{238}_{92}U \longrightarrow {}^{234}_{90}Th + {}^{4}_{2}He \qquad \begin{matrix} Q_a = 4.268 \text{ MeV} \\ t_{1/2} = 4.51 \times 10^9 \text{ years} \end{matrix}$$

Given for this and subsequent reactions are the energy released (Q) in millions of electron volts (MeV) and the half-life ($t_{1/2}$). It should be noted that in every reaction the charges, or number of protons, shown in subscript are in balance on both sides of the arrow, as are the atomic masses, shown in superscript.

Beta-minus decay. In beta-minus decay, or negatron emission, an energetic negative electron is emitted, producing a daughter nucleus of one higher atomic number and the same mass number. An example is the decay of the uranium daughter product thorium-234 into protactinium-234:

$$^{234}_{90}Th \longrightarrow {}^{234}_{91}Pa + e^- + \bar{\nu} \qquad \begin{matrix} Q_{\beta^+} = 0.263 \text{ MeV} \\ t_{1/2} = 24.1 \text{ days} \end{matrix}$$

In the above reaction for beta decay, $\bar{\nu}$ represents the antineutrino. (In the accepted relativistic theory a particle has a total mass m, given by Einstein's equation $E = mc^2$, in which c is the speed of light, and E is the total energy. Most particles have a characteristic rest mass, m_0, their mass when they are not moving. Neutrinos and antineutrinos have zero rest mass; hence, they must always have the speed of light.)

Gamma decay. A third type of radiation, gamma radiation, usually accompanies alpha or beta decay. Gamma rays are photons and are without rest mass or charge. Alpha or beta decay may simply proceed directly to the ground (lowest energy) state of the daughter nucleus without gamma emission, but the decay may also proceed wholly or partly to higher energy states (excited states) of the daughter. In the latter case, gamma emission may occur as the excited states transform to lower energy states of the same nucleus. (Alternatively to gamma emission, an excited nucleus may transform to a lower energy state by ejecting an electron from the cloud surrounding the nucleus. This orbital electron ejection is known as internal conversion and gives rise to an energetic electron and often an X ray as the atomic cloud fills in the empty orbital of the ejected electron. The ratio of internal conversion to the alternative gamma emission is called the internal-conversion coefficient.)

Gamma rays–photon emission

Isomeric transitions. There is a wide range of rates of half-lives for the gamma-emission process. Usually dipole transitions (see below *Gamma transition*), in which the

gamma ray carries off one $\hbar$ unit of angular momentum, are fast, less than nanoseconds (one nanosecond equals 10^{-9} second). The law of conservation of angular momentum requires that the sum of angular momenta of the radiation and daughter nucleus is equal to the angular momentum (spin) of the parent. If the spins of initial and final states differ by more than one, dipole radiation is forbidden, and gamma emission must proceed more slowly by a higher multipole (quadrupole, octupole, etc.) gamma transition. If the gamma-emission half-life exceeds about one nanosecond, the excited nucleus is said to be in a metastable, or isomeric, state (the names for a long-lived excited state), and it is customary to classify the decay as another type of radioactivity, an isomeric transition. An example of isomerism is found in the protactinium-234 nucleus of the uranium-238 decay chain:

somerism

$$^{234m}_{91}\text{Pa} \longrightarrow {}^{234}_{91}\text{Pa} + \gamma \qquad Q_\gamma = 0.0698 \text{ MeV}, \quad t_{1/2} = 1.17 \text{ min}$$

The letter *m* following the mass number stands for metastable and indicates a nuclear isomer.

Beta-plus decay. During the 1930s new types of radioactivity were found among the artificial products of nuclear reactions: beta-plus decay, or positron emission, and electron capture. In beta-plus decay an energetic positive electron is created and emitted, along with a neutrino, and the nucleus transforms to a daughter, lower by one in atomic number and the same in mass number. For instance, carbon-11 ($Z = 6$) decays to boron-11 ($Z = 5$), plus one positron and one neutrino:

$$^{11}_{6}\text{C} \longrightarrow {}^{11}_{5}\text{B} + e^+ + \nu \qquad Q_{\beta^+} = 0.97 \text{ MeV}, \quad t_{1/2} = 20.4 \text{ min}$$

Electron capture. Electron capture (EC) is a process in which decay follows the capture by the nucleus of an orbital electron. It is similar to positron decay in that the nucleus transforms to a daughter of one lower atomic number. It differs in that an orbital electron from the cloud is captured and annihilated by the nucleus with subsequent emission of an atomic X ray as the orbital vacancy is filled by an electron from the cloud about the nucleus. An example is the nucleus of beryllium-7 capturing one of its inner electrons to give lithium-7:

$$^{7}_{4}\text{Be} + e^- \longrightarrow {}^{7}_{3}\text{Li} + \nu \qquad Q_{\text{EC}} = 0.8616 \text{ MeV}, \quad t_{1/2} = 53 \text{ days}$$

The main features of radioactive decay of a nuclear species are often displayed in a decay scheme. Figure 22 shows the decay scheme of beryllium-7. Indicated are the half-life of the parent and that of the excited daughter state, as well as its energy 0.4774 MeV. The spins and parities of all three states are provided on the upper left-hand side of the level. The multipolarity of the gamma ray (magnetic dipole, M1, plus 0.005 percent electric quadrupole, E2) is indicated above the vertical arrow symbolizing the gamma transition. The slanted arrows symbolize the electron-capture decay with labels giving the percentage of decay directly to ground state (89.7 percent) and the percentage of EC decay going via the excited state (10.3 percent). The boldface numbers following the percentages are so-called log *ft* values, to be encountered below in connection with beta-decay rates. The overall energy release, Q_{EC}, is indicated below. The Q_{EC} is necessarily a calculated value because there is no general practical means of measuring the neutrino energies accompanying EC decay. With a few electron-capturing nuclides, it has been possible to measure directly the decay energy by measurement of a rare process called inner bremsstrahlung (braking radiation). In this process the energy release is shared between the neutrino and a gamma ray. The measured distribution of gamma-ray energies indicates the total energy release. Usually there is so much ordinary gamma radiation with radioactive decay that the inner bremsstrahlung is unobservable.

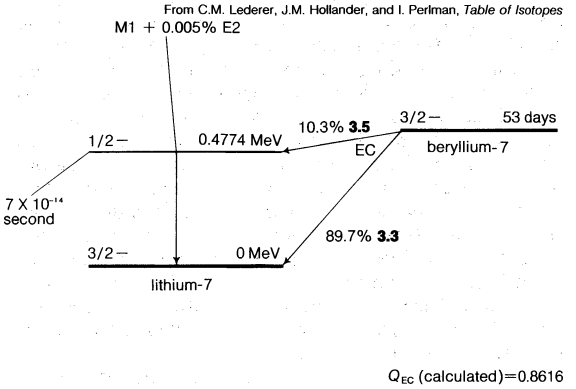

Figure 22: Radioactive decay of beryllium-7 to lithium-7 by electron capture (EC; see text).

Inner bremsstrahlung

Spontaneous fission. Yet another type of radioactivity is spontaneous fission. In this process the nucleus splits into two fragment nuclei of roughly half the mass of the parent. This process is only barely detectable in competition with the more prevalent alpha decay for uranium, but for some of the heaviest artificial nuclei, such as fermium-256, spontaneous fission becomes the predominant mode of radioactive decay. Kinetic-energy releases from 150 to 200 MeV may occur as the fragments are accelerated apart by the large electrical repulsion between their nuclear charges. The reaction is as follows:

$$^{256}_{100}\text{Fm} \longrightarrow {}^{140}_{54}\text{Xe} + {}^{112}_{46}\text{Pd} + 4n + \text{other fission products} \qquad Q = 150\text{–}200 \text{ MeV}, \quad t_{1/2} = 2.7 \text{ hours}$$

Only one of several product sets is shown. A few neutrons are always emitted in fission of this isotope, a feature essential to chain reactions. Spontaneous fission is not to be confused with induced fission, the process involved in nuclear reactors. It is a property of uranium-235, plutonium-239, and other isotopes to undergo fission after absorption of a slow neutron. Other than the requirement of a neutron capture to initiate it, induced fission is quite similar to spontaneous fission regarding total energy release, numbers of secondary neutrons, and so on (see below *Nuclear fission*).

Proton radioactivity. Proton radioactivity, discovered in 1970, is exhibited by an excited isomeric state of cobalt-53, ^{53m}Co, 1.5 percent of which emits protons:

$$^{53m}_{27}\text{Co} \xrightarrow{1.5\%} {}^{52}_{26}\text{Fe} + p \qquad Q_p = 1.57 \text{ MeV}$$
$$^{53m}_{27}\text{Co} \xrightarrow{98.5\%} {}^{53}_{26}\text{Fe} + e^+ + \nu \qquad t_{1/2} = 0.243 \text{ sec}$$

In addition to the above types of radioactivity, there is a special class of rare beta-decay processes that gives rise to heavy-particle emission. In these processes the beta decay partly goes to a high excited state of the daughter nucleus, and this state rapidly emits a heavy particle.

Special beta-decay processes. One such process is beta-delayed neutron emission, which is exemplified by the following reaction:

$$^{17}_{7}\text{N} \longrightarrow {}^{17*}_{8}\text{O} + e^- + \bar{\nu} \qquad Q_{\beta^-} = 8.68 \text{ MeV}$$
$$\longrightarrow {}^{16}_{8}\text{O} + n \qquad E_{max\ n} = 1.81 \text{ MeV}$$
$$t_{1/2} = 4.16 \text{ sec}$$

(Note: the asterisk denotes the short-lived intermediate excited states of oxygen-17, and $E_{max\ n}$ denotes the maximum energy observed for emitted neutrons.) There is a small production of delayed neutron emitters following nuclear fission, and these radioactivities are especially important in providing a reasonable response time to allow control of nuclear fission reactors by mechanically moved control rods.

Beta-delayed alpha emission

Among the positron emitters in the light-element region, a number beta decay partly to excited states that are unstable with respect to emission of an alpha particle. Thus, these species exhibit alpha radiation with the half-life of the beta emission. Both the positron decay from boron-8

and negatron decay from lithium-8 are beta-delayed alpha emission, because ground as well as excited states of beryllium-8 are unstable with respect to breakup into two alpha particles. Another example, sodium-20 (^{20}Na) to give successively neon-20 (^{20}Ne; the asterisk again indicating the short-lived intermediate state) and finally oxygen-16 is listed below:

$$^{20}_{11}\mathrm{Na} \longrightarrow {}^{20}_{10}\mathrm{Ne}^{*} + e^{+} + \nu \qquad Q_{\beta^+} = 13.0 \text{ MeV}$$
$$\hookrightarrow {}^{16}_{8}\mathrm{O} + \alpha \qquad E_{max\,\alpha} = 4.44 \text{ MeV}$$
$$t_{1/2} = 0.39 \text{ sec}$$

Beta-delayed proton emissions

In a few cases, positron decay leads to an excited nuclear state not able to bind a proton. In these cases, proton radiation appears with the half-life of the beta transition. The combination of high positron-decay energy and low proton-binding energy in the daughter ground state is required. In the example given below, tellurium-111 (^{111}Te) yields antimony-111 (^{111}Sb) and then tin-110 (^{110}Sn) successively:

$$^{111}_{52}\mathrm{Te} \longrightarrow {}^{111}_{51}\mathrm{Sb}^{*} + e^{+} + \nu \qquad Q_{\beta^+} \text{ uncertain}$$
$$\hookrightarrow {}^{110}_{50}\mathrm{Sn} + p \qquad E_{max\,p} = 3.7 \text{ MeV}$$
$$t_{1/2} = 19.5 \text{ sec}$$

Heavy-ion radioactivity. In 1980 A. Sandulescu, D.N. Poenaru, and W. Greiner described calculations indicating the possibility of a new type of decay of heavy nuclei intermediate between alpha decay and spontaneous fission. The first observation of heavy-ion radioactivity was that of a 30-MeV, carbon-14 emission from radium-223 by H.J. Rose and G.A. Jones in 1984. The ratio of carbon-14 decay to alpha decay is about 5×10^{-10}. Observations also have been made of carbon-14 from radium-222, radium-224, and radium-226, as well as neon-24 from thorium-230, protactinium-231, and uranium-232. Such heavy-ion radioactivity, like alpha decay and spontaneous fission, involves quantum-mechanical tunneling through the potential-energy barrier. Shell effects play a major role in this phenomenon, and in all cases observed to date the heavy partner of carbon-14 or neon-24 is close to doubly magic lead-208 (see below *Nuclear models*).

OCCURRENCE OF RADIOACTIVITY

Some species of radioactivity occur naturally on Earth. A few species have half-lives comparable to the age of the elements (about 6×10^9 years), so that they have not decayed away after their formation in stars. Notable among these are uranium-238, uranium-235, and thorium-232. Also, there is potassium-40, the chief source of irradiation of the body through its presence in potassium of tissue. Of lesser significance are the beta emitters vanadium-50, rubidium-87, indium-115, tellurium-123, lanthanum-138, lutetium-176, and rhenium-187, and the alpha emitters cerium-142, neodymium-144, samarium-147, gadolinium-152, dysprosium-156, hafnium-174, platinum-190, and lead-204. Besides these approximately 10^9-year species, there are the shorter-lived daughter activities fed by one or another of the above species; *e.g.*, by various nuclei of the elements between lead ($Z = 82$) and thorium ($Z = 90$).

Cosmic ray bombardment

Another category of natural radioactivity includes species produced in the upper atmosphere by cosmic ray bombardment. Notable are 5,720-year carbon-14 and 12.3-year tritium (hydrogen-3), 53-day beryllium-7, and 2,700,000-year beryllium-10. Meteorites are found to contain additional small amounts of radioactivity, the result of cosmic ray bombardments during their history outside the Earth's atmospheric shield. Activities as short-lived as 35-day argon-37 have been measured in fresh falls of meteorites. Nuclear explosions since 1945 have injected additional radioactivities into the environment, consisting of both nuclear fission products and secondary products formed by the action of neutrons from nuclear weapons on surrounding matter.

The fission products encompass most of the known beta emitters in the mass region 75–160. They are formed in varying yields, rising to maxima of about 7 percent per fission in the mass region 92–102 (light peak of the fission yield versus atomic mass curve) and 134–144 (heavy peak). Two kinds of delayed hazards caused by radioactivity are recognized. First, the general radiation level is raised by fallout settling to Earth. Protection can be provided by concrete or earth shielding until the activity has decayed to a sufficiently low level. Second, ingestion or inhalation of even low levels of certain radioactive species can pose a special hazard, depending on the half-life, nature of radiations, and chemical behaviour within the body. For a detailed discussion on the biologic effects of radiation, see RADIATION.

Nuclear reactors also produce fission products but under conditions in which the activities may be contained. Containment and waste-disposal practices should keep the activities confined and eliminate the possibility of leaching into groundwaters for times that are long compared to the half-lives. A great advantage of thermonuclear fusion power over fission power, if it can be practically realized, is not only that its fuel reserves, heavy hydrogen and lithium, are vastly greater than uranium, but also that the generation of radioactive fission product wastes can be largely avoided. In this connection, it may be noted that a major source of heat in the interior of both the Earth and the Moon is provided by radioactive decay. Theories about the formation and evolution of the Earth, Moon, and other planets must take into account these large heat production sources.

Heat from radioactive decay

Desired radioactivities other than natural activities and fission products may be produced either by irradiation of certain selected target materials by reactor neutrons or by charged particle beams or gamma ray beams of accelerators.

ENERGETICS AND KINETICS OF RADIOACTIVITY

Energy release in radioactive transitions. Consideration of the energy release of various radioactive transitions leads to the fundamental question of nuclear binding energies and stabilities. A much-used method of displaying nuclear-stability relationships is an isotope chart, those positions on the same horizontal row corresponding to a given proton number (Z) and those on the same vertical column to a given neutron number (N). Such a map is shown in Figure 23. The irregular bold line surrounds the region of presently known nuclei. The area encompassed by this is often referred to as the valley of stability because the chart may be considered a map of a binding energy surface, the lowest areas of which are the most stable.

From *Proceedings of the International Conference on Properties of Nuclei Far from the Region of Beta-Stability*, Leysin, 1970, (CERN 70-30)

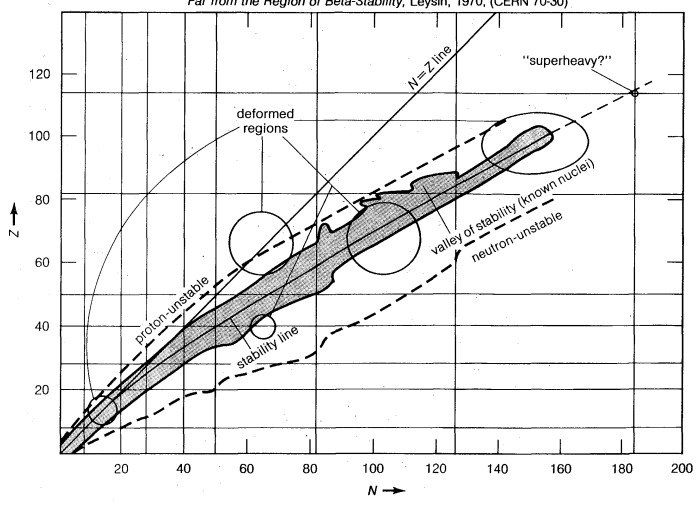

Figure 23: *Map of the nuclei.*
The coordinates are number of neutrons N and number of protons Z. The bold line encloses the region of known nuclei. The dashed lines are estimated limits for barely binding nucleons. The stability line gives the locus of nuclei most stable with respect to beta decay. Nuclei within the circular regions are cigar-shaped; otherwise the nuclei are spherical. The grid line intersections of the graph indicate the closed shell "magic numbers" of extra stability. A possible region of undiscovered longer-lived nuclei is indicated as "superheavy?"

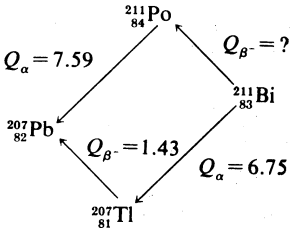
The most tightly bound nuclei of all are the abundant iron and nickel isotopes. Near the region of the valley containing the heaviest nuclei (largest mass number A; *i.e.*, largest number of nucleons, $N+Z$), the processes of alpha decay and spontaneous fission are most prevalent; both these processes relieve the energetically unfavourable concentration of positive charge in the heavy nuclei.

Along the region that borders on the valley of stability on the upper left-hand side are the positron-emitting and electron-capturing radioactive nuclei, with the energy release and decay rates increasing the farther away the nucleus is from the stability line. Along the lower right-hand border region, beta-minus decay is the predominant process, with energy release and decay rates increasing the farther the nucleus is from the stability line.

The grid lines of the graph are at the nucleon numbers corresponding to extra stability, the "magic numbers" (see below *Nuclear models*). The circles labeled "deformed regions" enclose regions in which nuclei should exhibit cigar shapes; elsewhere the nuclei are spherical. Outside the dashed lines nuclei would be unbound with respect to neutron or proton loss and would be exceedingly short-lived (less than 10^{-19} second).

Closed energy cycles

Calculation and measurement of energy. By the method of closed energy cycles, it is possible to use measured radioactive-energy-release (Q) values for alpha and beta decay to calculate the energy release for unmeasured transitions. An illustration is provided by the cycle of four nuclei below:



In this cycle, energies from two of the alpha decays and one beta decay are measurable. The unmeasured beta-decay energy for bismuth-211, $Q_{\beta^-}(\mathrm{Bi})$, is readily calculated because conservation of energy requires the sum of Q values around the cycle to be zero. Thus, $Q_{\beta^-}(\mathrm{Bi}) + 7.59 - 1.43 - 6.75 = 0$. Solving this equation gives $Q_{\beta^-}(\mathrm{Bi}) = 0.59$ MeV. This calculation by closed energy cycles can be extended from stable lead-207 back up the chain of alpha and beta decays to its natural precursor uranium-235 and beyond. In this manner the nuclear binding energies of a series of nuclei can be linked together. Because alpha decay decreases the mass number A by 4, and beta decay does not change A, closed α–β-cycle calculations based on lead-207 can link up only those nuclei with mass numbers of the general type $A = 4n + 3$, in which n is an integer. Another, the $4n$ series, has as its natural precursor thorium-232 and its stable end product lead-208. Another, the $4n + 2$ series, has uranium-238 as its natural precursor and lead-206 as its end product.

In early research on natural radioactivity, the classification of isotopes into the series cited above was of great significance because they were identified and studied as families. Newly discovered radioactivities were given symbols relating them to the family and order of occurrence therein. Thus, thorium-234 was known as UX_1, the isomers of protactinium-234 as UX_2 and UZ, uranium-234 as U_{II}, and so forth. These original symbols and names are occasionally encountered in more recent literature but are mainly of historical interest. The remaining $4n + 1$ series is not naturally occurring but comprises well-known artificial activities decaying down to stable thallium-205.

To extend the knowledge of nuclear binding energies, it is clearly necessary to make measurements to supplement the radioactive-decay energy cycles. In part, this extension can be made by measurement of Q values of artificial nuclear reactions. For example, the neutron-binding energies of the lead isotopes needed to link the energies of the four radioactive families together can be measured by determining the threshold gamma-ray energy to remove a neutron (photonuclear reaction); or the energies of incoming deuteron and outgoing proton in the reaction can be measured to provide this information.

Further extensions of nuclear-binding-energy measurements rely on precision mass spectroscopy (see ANALYSIS AND MEASUREMENT, PHYSICAL AND CHEMICAL). By ionizing, accelerating, and magnetically deflecting various nuclides, their masses can be measured with great precision. A precise measurement of the masses of atoms involved in radioactive decay is equivalent to direct measurement of the energy release in the decay process. The atomic mass of naturally occurring but radioactive potassium-40 is measured to be 39.964008 amu. Potassium-40 decays predominantly by β-emission to calcium-40, having a measured mass 39.962589. Through Einstein's equation, energy is equal to mass (m) times velocity of light (c) squared, or $E = mc^2$, the energy release (Q) and the mass difference, Δm, are related, the conversion factor being one amu, equal to 931.478 MeV. Thus, the excess mass of potassium-40 over calcium-40 appears as the total energy release Q_β in the radioactive decay $Q_{\beta^-} = (39.964008 - 39.962589) \times 931.478$ MeV $= 1.31$ MeV. The other neighbouring isobar (same mass number, different atomic number) to argon-40 is also of lower mass, 39.962384, than potassium-40. This mass difference converted to energy units gives an energy release of 1.5 MeV, this being the energy release for EC decay to argon-40. The maximum energy release for positron emission is always less than that for electron capture by twice the rest mass energy of an electron ($2m_0c^2 = 1.022$ MeV); thus, the maximum positron energy for this reaction is $1.5 - 1.02$, or 0.48 MeV.

Energy–mass conversions

To connect alpha-decay energies and nuclear mass differences requires a precise knowledge of the alpha-particle (helium-4) atomic mass. The mass of the parent minus the sum of the masses of the decay products gives the energy release. Thus, for alpha decay of plutonium-239 to uranium-235 and helium-4 the calculation goes as follows:

$M(^{239}\mathrm{Pu})$	239.05216
$-M(^{235}\mathrm{U})$	−235.04393
$-M(^{4}\mathrm{He})$	− 4.00260
	0.00563×931.478

$$Q_\alpha = 5.24 \text{ MeV}$$

By combining radioactive-decay-energy information with nuclear-reaction Q values and precision mass spectroscopy, extensive tables of nuclear masses have been prepared. From them the Q values of unmeasured reactions or decay may be calculated.

Alternative to the full mass, the atomic masses may be expressed as mass defect, symbolized by the Greek letter delta, Δ (the difference between the exact mass M and the integer A, the mass number), either in energy units or atomic mass units.

Absolute nuclear binding energy. The absolute nuclear binding energy is the hypothetical energy release if a given nuclide were synthesized from Z separate hydrogen atoms and N (equal to $A - Z$) separate neutrons. An example is the calculation giving the absolute binding energy of the stablest of all nuclei, iron-56:

$26 \times M(^1\mathrm{H})$	$26 \times 1.007825 =$	26.20345
$30 \times M(n)$	$30 \times 1.008665 =$	30.25995
$M(^{56}\mathrm{Fe})$	−	55.93493
	binding energy =	$0.52847 \times 931.478 =$ 492.58 MeV

average binding energy per nucleon of ^{56}Fe $= 492.58/56 = 8.796$ MeV

A general survey of the average binding energy per nucleon (for nuclei of all elements grouped according to ascending mass) shows a maximum at iron-56 falling off gradually on both sides to about 7 MeV at helium-4 and to about 7.4 MeV for the most massive nuclei known. Most of

the naturally occurring nuclei are thus not stable in an absolute nuclear sense. Nuclei heavier than iron would gain energy by degrading into nuclear products closer to iron, but it is only for the elements of greatest mass that the rates of degradation processes such as alpha decay and spontaneous fission attain observable rates. In a similar manner, nuclear energy is to be gained by fusion of most elements lighter than iron. The coulombic repulsion between nuclei, however, keeps the rates of fusion reactions unobservably low unless the nuclei are subjected to temperatures of greater than 10^7 K. Only in the hot cores of the Sun and other stars or in thermonuclear bombs or controlled fusion plasmas are these temperatures attained and nuclear-fusion energy released.

NUCLEAR MODELS

The liquid-drop model. The average behaviour of the nuclear binding energy can be understood with the model of a charged liquid drop. In this model, the aggregate of nucleons has the same properties of a liquid drop, such as surface tension, cohesion, and deformation. There is a dominant attractive-binding-energy term proportional to the number of nucleons A. From this must be subtracted a surface-energy term proportional to surface area and a coulombic repulsion energy proportional to the square of the number of protons and inversely proportional to the nuclear radius. Furthermore, there is a symmetry-energy term of quantum-mechanical origin favouring equal numbers of protons and neutrons. Finally, there is a pairing term that gives slight extra binding to nuclei with even numbers of neutrons or protons.

The pairing-energy term accounts for the great rarity of odd–odd nuclei (the terms odd–odd, even–even, even–odd, and odd–even refer to the evenness or oddness of proton number, Z, and neutron number, N, respectively) that are stable against beta decay. The sole examples are deuterium, lithium-6, boron-10, and nitrogen-14. A few other odd–odd nuclei, such as potassium-40, occur in nature, but they are unstable with respect to beta decay. Furthermore, the pairing-energy term makes for the larger number of stable isotopes of even-Z elements, compared to odd-Z, and for the lack of stable isotopes altogether in element 43, technetium, and element 61, promethium.

Mirror nuclei

The beta-decay energies of so-called mirror nuclei afford one means of estimating nuclear sizes. For example, the neon and fluorine nuclei, $^{19}_{10}Ne_9$ and $^{19}_{9}F_{10}$, are mirror nuclei because the proton and neutron numbers of one of them equal the respective neutron and proton numbers of the other. Thus, all binding-energy terms are the same in each except for the coulombic term, which is inversely proportional to the nuclear radius. Such calculations along with more direct determinations by high-energy electron scattering and energy measurements of X rays from mumesic atoms (hydrogen atoms in which the electrons are replaced by negative mu mesons) establish the nuclear charge as roughly uniformly distributed in a sphere of radius $1.2\ A^{1/3} \times 10^{-13}$ centimetre. That the radius is proportional to the cube root of the mass number has the great significance that the average density of all nuclei is nearly constant.

Careful examination of nuclear-binding energies reveals periodic deviations from the smooth average behaviour of the charged-liquid-drop model. An extra binding energy arises in the neighbourhood of certain numbers of neutrons or protons, the so-called magic numbers (2, 8, 20, 28, 50, 82, and 126). Nuclei such as $^{4}_{2}He_2$, $^{16}_{8}O_8$, $^{40}_{20}Ca_{20}$, $^{48}_{20}Ca_{28}$, and $^{208}_{82}Pb_{126}$ are especially stable species, doubly magic, in view of their having both proton and neutron numbers magic. These doubly magic nuclei are situated at the intersections of grid lines on Figure 23 above.

The shell model. In the preceding section, the overall trends of nuclear binding energies were described in terms of a charged-liquid-drop model. Yet there were noted periodic binding-energy irregularities at the magic numbers. The periodic occurrence of magic numbers of extra stability is strongly analogous to the extra electronic stabilities occurring at the atomic numbers of the noble-gas atoms (see above). The explanations of these stabilities are quite analogous in atomic and nuclear cases as arising from filling of particles into quantized orbitals of motion. The completion of filling of a shell of orbitals is accompanied by an extra stability. The nuclear model accounting for the magic numbers is, as previously noted, the shell model. In its simplest form, this model can account for the occurrence of spin zero for all even–even nuclear ground states; the nucleons fill pairwise into orbitals with angular momenta canceling. The shell model also readily accounts for the observed nuclear spins of the odd-mass nuclei adjacent to doubly magic nuclei, such as $^{208}_{82}Pb$. Here, the spins of 1/2 for neighbouring $^{207}_{81}Tl$ and $^{207}_{82}Pb$ are accounted for by having all nucleons fill pairwise into the lowest energy orbits and putting the odd nucleon into the last available orbital before reaching the doubly magic configuration (the Pauli exclusion principle dictates that no more than two nucleons may occupy a given orbital, and their spins must be oppositely directed); calculations show the last available orbitals below lead-208 to have angular momentum 1/2. Likewise, the spins of 9/2 for $^{209}_{82}Pb$ and $^{209}_{83}Bi$ are understandable because spin-9/2 orbitals are the next available orbitals beyond doubly magic lead-208. Even the associated magnetization, as expressed by the magnetic dipole moment, is rather well explained by the simple spherical-shell model.

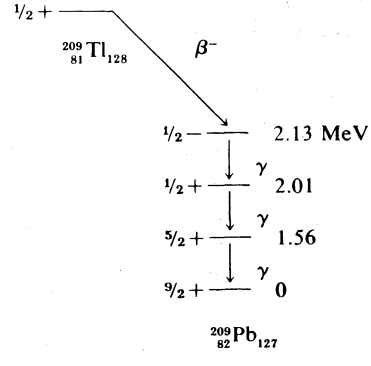
Doubly magic nuclei

The orbitals of the spherical-shell model are labeled in a notation close to that for electronic orbitals in atoms. The orbital configuration of calcium-40 has protons and neutrons filling the following orbitals: $1s_{1/2}$, $1p_{3/2}$, $1p_{1/2}$, $1d_{5/2}$, and $1d_{3/2}$. The letter denotes the orbital angular momentum in usual spectroscopic notation, in which the letters s, p, d, f, g, h, i, etc., represent integer values of l running from zero for s (not to be confused with spins) through six for i. The fractional subscript gives the total angular momentum j with values of $l + 1/2$ and $l - 1/2$ allowed, as the intrinsic spin of a nucleon is 1/2. The first integer is a radial quantum number taking successive values 1, 2, 3, etc., for successively higher energy values of an orbital of given l and j. Each orbital can accommodate a maximum of $2j + 1$ nucleons. Table 4 lists the orbitals comprising each shell, the exact order of various orbitals within a shell differing somewhat for neutrons and protons. The parity associated with an orbital is even (+) if l is even (s, d, g, i) and odd (−) if l is odd (p, f, h).

Table 4: Spherical-Shell-Model Orbitals

shell closure number	
2	$1s_{1/2}$
8	$1p_{3/2}$, $1p_{1/2}$
20	$1d_{5/2}$, $2s_{1/2}$, $1d_{3/2}$
28	$1f_{7/2}$
50	$2p_{3/2}$, $1f_{5/2}$, $2p_{1/2}$, $1g_{9/2}$
82	$1g_{7/2}$, $2d_{5/2}$, $1h_{11/2}$, $2d_{3/2}$, $3s_{1/2}$
126	$2f_{7/2}$, $1h_{9/2}$, $1i_{13/2}$, $3p_{3/2}$, $2f_{5/2}$, $3p_{1/2}$
184 (?)	$2g_{9/2}$, $1i_{11/2}$, $1j_{15/2}$, $3d_{5/2}$, $2g_{7/2}$, $4s_{1/2}$, $3d_{3/2}$

An example of a spherical-shell-model interpretation is provided by the beta-decay scheme of 2.2-minute thallium-209 shown below, in which spin and parity are given for each state. The ground and lowest excited states of lead-209 are to be associated with occupation by the 127th neutron of the lowest available orbitals above the closed shell of 126. From the last line of Table 4, it is to be noted



that there are available $g_{9/2}$, $d_{5/2}$, and $s_{1/2}$ orbitals with which to explain the ground and first two excited states. Low-lying states associated with the $i_{11/2}$ and $j_{15/2}$ orbitals are known from nuclear-reaction studies, but they are not populated in the beta decay.

The 2.13-MeV state that receives the primary beta decay is not so simply interpreted as the other states. It is to be associated with the promotion of a neutron from the $3p_{1/2}$ orbital below the 126 shell closure. The density (number per MeV) of states increases rapidly above this excitation, and the interpretations become more complex and less certain.

By suitable refinements, the spherical-shell model can be extended further from the doubly magic region. Primarily, it is necessary to drop the approximation that nucleons move independently in orbitals and to invoke a residual force, mainly short-range and attractive, between the nucleons. The spherical-shell model augmented by residual interactions can explain and correlate around the magic regions a large amount of data on binding energies, spins, magnetic moments, and the spectra of excited states.

The unified model. For nuclei more removed from the doubly magic regions, the spherical-shell model encounters difficulty in explaining the large observed electric quadrupole moments indicating cigar-shaped nuclei. For these nuclei a hybrid of liquid-drop and shell models, the unified model, has been proposed. (See the circular regions of Figure 23 for occurrence of cigar-shaped nuclei.)

Deformed regions

Nucleons can interact with one another in a collective fashion to deform the nuclear shape to a cigar shape. Such large spheroidal distortions are usual for nuclei far from magic, notably with $150 \lesssim A \lesssim 190$, and $224 \lesssim A$ (the symbol $<$ denotes less than, and $\sim$ means that the number is approximate). In these deformed regions the unified model prescribes that orbitals be computed in a cigar-shaped potential and that the relatively low-energy rotational excitations of the tumbling motion of the cigar shape be taken into account. The unified model has been highly successful in correlating and predicting nuclear properties in deformed regions. An example of a nuclear rotational band (a series of adjacent states) is provided by the decay of the isomer hafnium-180*m*, in Figure 24, through a cascade of gamma rays down the ground rotational band (see below *Gamma transition* for explanation of *M*2, *E*1, *E*2, and *E*3).

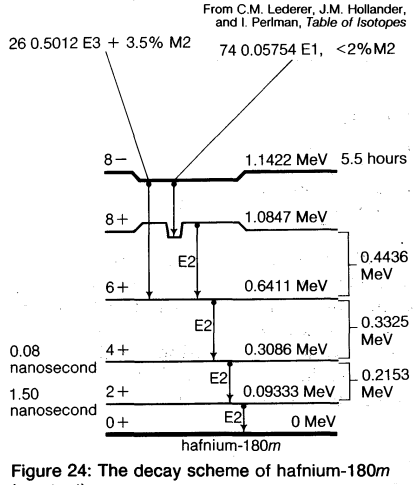


Figure 24: The decay scheme of hafnium-180*m* (see text).

RATES OF RADIOACTIVE TRANSITIONS

Equations governing radioactive decay

There is a vast range of the rates of radioactive decay, from undetectably slow to unmeasurably short. Before considering the factors governing particular decay rates in detail, it seems appropriate to review the mathematical equations governing radioactive decay and the general methods of rate measurement in different ranges of half-life.

Exponential-decay law. Radioactive decay occurs as a statistical exponential rate process. That is to say, the number of atoms likely to decay in a given infinitesimal time interval (dN/dt) is proportional to the number (N) of atoms present. The proportionality constant, symbolized by the Greek letter lambda, λ, is called the decay constant. Mathematically, this statement is expressed by the first-order differential equation,

Decay constant

$$-\frac{dN}{dt} = \lambda N. \tag{1}$$

This equation is readily integrated to give

$$N(t) = N_0 e^{-\lambda t}, \tag{2}$$

in which N_0 is the number of atoms present when time equals zero. From the above two equations it may be seen that a disintegration rate, as well as the number of parent nuclei, falls exponentially with time. An equivalent expression in terms of half-life $t_{1/2}$ is

$$N(t) = N_0(1/2)^r; \; r = t/t_{1/2}.$$

It can readily be shown that the decay constant λ and half-life ($t_{1/2}$) are related as follows: $\lambda = \log_e 2/t_{1/2} = 0.693/t_{1/2}$. The reciprocal of the decay constant λ is the mean life, symbolized by the Greek letter tau, τ.

For a radioactive nucleus such as potassium-40 that decays by more than one process (89 percent $\beta-$, 11 percent electron capture), the total decay constant is the sum of partial decay constants for each decay mode. (The partial half-life for a particular mode is the reciprocal of the partial decay constant times 0.693.) It is helpful to consider a radioactive chain in which the parent (generation 1) of decay constant λ_1 decays into a radioactive daughter (generation 2) of decay constant λ_2. The case in which none of the daughter isotope (2) is originally present yields an initial growth of daughter nuclei followed by its decay. The equation giving the number (N_2) of daughter nuclei existing at time t in terms of the number $N_1(0)$ of parent nuclei present when time equals zero is

$$N_2(t) = \lambda_1 N_1(0) \frac{e^{-\lambda_1 t} - e^{-\lambda_2 t}}{\lambda_2 - \lambda_1}, \tag{3}$$

in which e represents the logarithmic constant 2.71828.

Radioactive decay chain

The general equation for a chain of n generations with only the parent initially present (when time equals zero) is as follows:

$$N_n(t) = N_1(0)(C_1 e^{-\lambda_1 t} + C_2 e^{-\lambda_2 t} + \ldots . C_n e^{-\lambda_n t})\lambda_1\lambda_2 \ldots \lambda_{n-1}, \tag{4}$$

in which e represents the logarithmic constant 2.71828.

$$C_1 = 1/(\lambda_2 - \lambda_1)(\lambda_3 - \lambda_1) \ldots (\lambda_n - \lambda_1),$$

$$C_2 = 1/(\lambda_1 - \lambda_2)(\lambda_3 - \lambda_2) \ldots (\lambda_n - \lambda_2),$$

$$C_n = 1/(\lambda_1 - \lambda_n)(\lambda_2 - \lambda_n) \ldots (\lambda_{n-1} - \lambda_n).$$

These equations can readily be modified to the case of production of isotopes in the steady neutron flux of a reactor or in a star. In such cases, the chain of transformations might be mixed with some steps occurring by neutron capture and some by radioactive decay. The neutron-capture probability for a nucleus is expressed in terms of an effective cross-sectional area. If one imagines the nuclei replaced by spheres of the same cross-sectional area, the rate of reaction in a neutron flux would be given by the rate at which neutrons strike the spheres. The cross section is usually symbolized by the Greek letter sigma, σ, with the units of barns (10^{-24} cm^2) or millibarns (10^{-3} b) or microbarns (10^{-6} b). Neutron flux is often symbolized by the letters nv (neutron density, n, or number per cubic centimetre, times average speed, v) and given in neutrons per square centimetre per second.

The modification of the transformation equations merely involves substituting the product $nv\sigma_i$ in place of λ_i for any step involving neutron capture rather than radioactive decay. Reactor fluxes nv even higher than 10^{15} neutrons per square centimetre per second are available in several research reactors, but usual fluxes are somewhat lower by a factor of 1,000 or so. Tables of neutron-capture cross sections of the naturally occurring nuclei and some radioactive nuclei can be used for calculation of isotope production rates in reactors.

Measurement of half-life. The measurement of half-lives of radioactivity in the range of seconds to a few years commonly involves measuring the intensity of radiation at successive times over a time range comparable to the half-life. The logarithm of the decay rate is plotted against time, and a straight line is fitted to the points. The time interval for this straight-line decay curve to fall by a factor of 2 is read from the graph as the half-life, by virtue of equations (1) and (2). If there is more than one activity present in the sample, the decay curve will not be a straight line over its entire length, but it should be resolvable graphically (or by more sophisticated statistical analysis) into sums and differences of straight-line exponential terms. The general equations (4) for chain decays show a time dependence given by sums and differences of exponential terms, though special modified equations are required in the unlikely case that two or more decay constants are identically equal.

Decay curve for two or more activities

For half-lives longer than several years it is often not feasible to measure accurately the decrease in counting rate over a reasonable length of time. In such cases, a measurement of specific activity may be resorted to; *i.e.*, a carefully weighed amount of the radioactive isotope is taken for counting measurements to determine the disintegration rate, D. Then by equation (1) the decay constant λ_i may be calculated. Alternately, it may be possible to produce the activity of interest in such a way that the number of nuclei, N, is known, and again with a measurement of D equation (1) may be used. The number of nuclei, N, might be known from counting the decay of a parent activity or from knowledge of the production rate by a nuclear reaction in a reactor or accelerator beam.

Half-lives from 100 microseconds to one nanosecond are measured electronically in coincidence experiments. The radiation yielding the species of interest is detected to provide a start pulse for an electronic clock, and the radiation by which the species decays is detected in another device to provide a stop pulse. The distribution of these time intervals is plotted semi-logarithmically, as discussed for the decay-rate treatment, and the half-life is determined from the slope of the straight line.

Half-lives in the range of 100 microseconds to one second must often be determined by special techniques. For example, the activities produced may be deposited on rapidly rotating drums or moving tapes, with detectors positioned along the travel path. The activity may be produced so as to travel through a vacuum at a known velocity and the disintegration rate measured as a function of distance; however, this method usually applies to shorter half-lives in or beyond the range of the electronic circuit.

Species with half-lives shorter than the electronic measurement limit are not considered as separate radioactivities, and the various techniques of determining their half-lives will hence not be cited here.

Decay-rate considerations for various types of radioactivity are given here in the same order as listed above in *Types of radioactivity*.

Alpha decay. Alpha decay, the emission of helium ions, exhibits sharp line spectra when spectroscopic measurements of the alpha-particle energies are made. For even–even alpha emitters the most intense alpha group or line is always that leading to the ground state of the daughter. Weaker lines of lower energy go to excited states, and there are frequently numerous lines observable.

The main decay group of even–even alpha emitters exhibits a highly regular dependence on the atomic number, Z, and the energy release, Q_a. (Total alpha energy release, Q_α, is equal to alpha-particle energy, E_α, plus daughter recoil energy needed for conservation of momentum; $E_{\text{recoil}} = (m_a/[m_a + M_d])E_\alpha$, with m_a equal to the mass of the alpha particle and M_d the mass of the daughter product.) As early as 1911 the German physicist Johannes Wilhelm Geiger, together with the British physicist John Mitchell Nuttall, noted the regularities of rates for even–even nuclei and proposed a remarkably successful equation for the decay constant, $\log \lambda = a + b \log r$, in which r is the range in air, b is a constant, and a is given different values for the different radioactive series. The decay constants of odd alpha emitters (odd A or odd Z or both) are not quite so regular and may be much smaller. The values of the constant b that were used by Geiger and Nuttall implied a roughly 90th-power dependence of λ on Q_a. There is a tremendous range of known half-lives from the 2×10^{15} years of $^{144}_{60}$Nd (neodymium) with its 1.83-MeV alpha-particle energy (E_a) to the 0.3 microsecond of $^{212}_{84}$Po (polonium) with $E_a = 8.78$ MeV.

Geiger–Nuttall law

The theoretical basis for the Geiger–Nuttall empirical rate law remained unknown until the formulation of wave mechanics. A dramatic early success of wave mechanics was the quantitative theory of alpha-decay rates. One curious feature of wave mechanics is that particles may have a nonvanishing probability of being in regions of negative kinetic energy. In classical mechanics a ball that is tossed to roll up a hill will slow down until its gravitational potential energy equals its total energy, and then it will roll back toward its starting point. In quantum mechanics the ball has a certain probability of tunneling through the hill and popping out on the other side. For objects large enough to be visible to the eye, the probability of tunneling through energetically forbidden regions is unobservably small. For submicroscopic objects such as alpha particles, nucleons, or electrons, however, quantum mechanical tunneling can be an important process—as in alpha decay.

The logarithm of tunneling probability on a single collision with an energy barrier of height B and thickness D is a negative number proportional to thickness D, to the square root of the product of B and particle mass m. The size of the proportionality constant will depend on the shape of the barrier and will depend inversely on Planck's constant h.

In the case of alpha decay, the electrostatic repulsive potential between alpha particle and nucleus generates an energetically forbidden region, or potential barrier, from the nuclear radius out to several times this distance. The maximum height (B) of this alpha barrier is given approximately by the expression $B = 2Ze^2/R$, in which Z is the charge of the daughter nucleus, e is the elementary charge in electrostatic units, and R is the nuclear radius. Numerically, B is roughly equal to $2Z/A^{1/3}$, with A the mass number and B in energy units of MeV. Thus, although the height of the potential barrier for $^{212}_{84}$Po decay is nearly 28 MeV, the total energy released is $Q_a = 8.95$ MeV. The thickness of the barrier (*i.e.*, distance of the alpha particle from the centre of the nucleus at the moment of recoil) is about twice the nuclear radius of 8.8×10^{-13} centimetre. The tunneling calculation for the transition probability (P) through the barrier gives approximately

Tunneling of alpha particles

$$P = \exp\left[\left(-\frac{\sqrt{2MB}\,R}{\hbar}\right)\left(\frac{\pi B^{1/2}}{Q^{1/2}} - 4\right)\right], \qquad (5)$$

in which M is the mass of the alpha particle and $\hbar$ is Planck's constant h divided by 2π. By making simple assumptions about the frequency of the alpha particle striking the barrier, the penetration formula (5) can be used to calculate an effective nuclear radius for alpha decay. This method was one of the early ways of estimating nuclear sizes. In more sophisticated modern techniques the radius value is taken from other experiments, and alpha-decay data and penetrabilities are used to calculate the frequency factor.

The form of equation (5) suggests the correlation of decay rates by an empirical expression relating the half-life ($t_{1/2}$) of decay in seconds to the release energy (Q_a) in MeV:

$$\log t_{1/2} = \frac{a}{\sqrt{Q_a}} + b. \qquad (6)$$

Values of the constants a and b that give best fits to experimental rates of even–even nuclei with neutron number greater than 126 are given in Table 5. The nuclei with 126 or fewer neutrons decay more slowly than the heavier nuclei, and constants a and b must be readjusted to fit their decay rates.

The alpha-decay rates to excited states of even–even nuclei and to ground and excited states of nuclei with odd numbers of neutrons, protons, or both may exhibit retardations from equation (6) rates ranging to factors of thousands or more. The factor by which the rate is slower

than the rate formula (6) is the hindrance factor. The existence of uranium-235 in nature rests on the fact that alpha decay to the ground and low excited states exhibits hindrance factors of over 1,000. Thus the uranium-235 half-life is lengthened to 7×10^8 years, a time barely long enough compared to the age of the elements in the solar system for uranium-235 to exist in nature today.

Alpha hindrance factors

The alpha hindrance factors are fairly well understood in terms of the orbital motion of the individual protons and neutrons that make up the emitted alpha particle. The alpha-emitting nuclei heavier than radium are considered to be cigar-shaped, and alpha hindrance factor data have been used to infer the most probable zones of emission on the nuclear surface—whether polar, equatorial, or intermediate latitudes.

Table 5: Semi-empirical Constants*

	a	*b*
98 californium (Cf)	152.86	−52.9506
96 curium (Cm)	152.44	−53.6825
94 plutonium (Pu)	146.23	−52.0899
92 uranium (U)	147.49	−53.6565
90 thorium (Th)	144.19	−53.2644

84 polonium (Po)	129.35	−49.9229

*From correlation of ground-state decay rates of even–even nuclei with $N > 126$. See equation (6) in text.

Beta decay. The processes separately introduced at the beginning of this section as beta-minus decay, beta-plus decay, and orbital electron capture can be appropriately treated together. They all are processes whereby neutrons and protons may transform to one another by weak interaction. In striking contrast to alpha decay, the electrons (minus or plus charged) emitted in beta-minus and beta-plus decay do not exhibit sharp, discrete energy spectra but have distributions of electron energies ranging from zero up to the maximum energy release, Q_β. Furthermore, measurements of heat released by beta emitters (most radiation stopped in surrounding material is converted into heat energy) show a substantial fraction of the energy, Q_β, is missing. These observations, along with other considerations involving the spins or angular momenta of nuclei and electrons, led Wolfgang Pauli to postulate the simultaneous emission of the neutrino (1931). The neutrino, as a light and uncharged particle with nearly no interaction with matter, was supposed to carry off the missing heat energy. Today, neutrino theory is well accepted with the elaboration that there are six kinds of neutrinos, the electron neutrino, mu neutrino, and tau neutrino and corresponding antineutrinos of each. The electron neutrinos are involved in nuclear beta-decay transformations, the mu neutrinos are encountered in decay of muons (mu mesons) to electrons, and the tau neutrinos are produced when a massive lepton called a tau breaks down.

Although in general the more energetic the beta decay the shorter is its half-life, the rate relationships do not show the clear regularities of the alpha-decay dependence on energy and atomic number.

Fermi theory

The first quantitative rate theory of beta decay was given by Enrico Fermi in 1934, and the essentials of this theory form the basis of modern theory. As an example, in the simplest beta-decay process, a free neutron decays into a proton, a negative electron, and an antineutrino: $n \rightarrow p + e^- + \bar{\nu}$. The weak interaction responsible for this process, in which there is a change of species (n to p) by a nucleon with creation of electron and antineutrino, is characterized in Fermi theory by a universal constant, g. The sharing of energy between electron and antineutrino is governed by statistical probability laws giving a probability factor for each particle proportional to the square of its linear momentum (defined by mass times velocity for speeds much less than the speed of light and by a more complicated, relativistic relation for faster speeds). The overall probability law from Fermi theory gives the probability per unit time per unit electron energy interval, $P(W)$, as follows:

$$P(W) = \frac{64\pi^4 m_0^5 c^4 g^2}{h^7} W(W^2 - 1)^{1/2} (W_0 - W)^2 , \quad (7)$$

in which W is the electron energy in relativistic units ($W = 1 + E/m_0c^2$) and W_0 is the maximum ($W_0 = 1 + Q_\beta/m_0c^2$), m_0 the rest mass of the electron, c the speed of light, and h Planck's constant. This rate law expresses the neutron beta-decay spectrum in good agreement with experiment, the spectrum falling to zero at lowest energies by the factor W and falling to zero at the maximum energy by virtue of the factor $(W_0 - W)^2$.

In Fermi's original formulation, the spins of an emitted beta and neutrino are opposing and so cancel to zero. Later work showed that neutron beta decay partly proceeds with the $\frac{1}{2}\hbar$ spins of beta and neutrino adding to one unit of $\hbar$. The former process is known as Fermi decay (F) and the latter Gamow–Teller (GT) decay, after George Gamow and Edward Teller, the physicists who first proposed it. The interaction constants are determined to be in the ratio $g_{GT}^2/g_F^2 = 1.4$. Thus, g^2 in equation (7) should be replaced by $(g_F^2 + g_{GT}^2)$.

Parity violation in beta decay

The scientific world was shaken in 1957 by the measurement in beta decay of maximum violation of the law of conservation of parity. The meaning of this nonconservation in the case of neutron beta decay considered above is that the preferred direction of electron emission is opposite to the direction of the neutron spin of $\frac{1}{2}\hbar$. By means of a magnetic field and low temperature it is possible to cause neutrons in cobalt-60 and other nuclei, or free neutrons, to have their spins set preferentially in the up direction perpendicular to the plane of the coil generating the magnetic field. The fact that beta decay prefers the down direction for spin means that the reflection of the experiment as seen in a mirror parallel to the coil represents an unphysical situation: conservation of parity, obeyed by most physical processes, demands that experiments with positions reversed by mirror reflection should also occur. Further consequences of parity violation in beta decay are that spins of emitted neutrinos and electrons are directed along the direction of flight, totally so for neutrinos and partially so by the ratio of electron speed to the speed of light for electrons.

The overall half-life for beta decay of the free neutron, measured as 12 minutes, may be related to the interaction constants g^2 (equal to $g_F^2 + g_{GT}^2$) by integrating (summing) probability expression (7) over all possible electron energies from zero to the maximum. The result for the decay constant is

$$\lambda = \frac{64\pi^4 m_0^5 c^4 g^2}{h^7} \left\{ (W_0^2 - 1)^{1/2} \left(\frac{W_0^4}{30} - \frac{3W_0^2}{20} - \frac{2}{15} \right) + \right.$$
$$\left. + \frac{W_0}{4} \ln[W_0 + (W_0^2 - 1)^{1/2}] \right\} , \quad (8)$$

in which W_0 is the maximum beta-particle energy in relativistic units ($W_0 = 1 + Q_\beta/m_0c^2$), with m_0 the rest mass of the electron, c the speed of light, and h Planck's constant. The best g value from decay rates is approximately 10^{-49} erg per cubic centimetre. As may be noted from equation (8), there is a limiting fifth-power energy dependence for highest decay energies.

In the case of a decaying neutron not free but bound within a nucleus, the above formulas must be modified. First, as the nuclear charge Z increases, the relative probability of low-energy electron emission increases by virtue of the coulombic attraction. For positron emission, which is energetically impossible for free protons but can occur for bound protons in proton-rich nuclei, the nuclear coulomb charge suppresses lower energy positrons from the shape given by equation (7). This equation can be corrected by a factor $F(Z, W)$ depending on the daughter atomic number Z and electron energy W. The factor can be calculated quantum mechanically. The coulomb charge also affects the overall rate expression (8) such that it can no longer be expressed as an algebraic function, but tables are available for analysis of beta decay rates. The rates are analyzed in terms of a function $f(Z, Q_\beta)$ calculated by integration of equation (7) with correction factor $F(Z, W)$.

Approximate expressions for the f functions usable for decay energies Q between 0.1 MeV and 10 MeV, in which Q is measured in MeV, and Z is the atomic number of the daughter nucleus, are as follows (the symbol $\approx$ means approximately equal to):

$$f_{\beta^-} \approx 6.0Q^{4-0.005(Z-1)} \cdot 10^{Z/50},$$

$$f_{\beta^+} \approx 6.2Q^4/10^{0.007Z} \cdot 10^{0.009Z(\log 1/3Q)^2}.$$

For electron capture, a much weaker dependence on energy is found:

$$f_{EC} \approx (Z+1)^{3.5}Q/4 \times 10^5.$$

The basic beta decay rate expression obeyed by the class of so-called superallowed transitions, including decay of the neutron and several light nuclei is

$$\lambda_\beta = \frac{64\pi^4 m_0^5 c^4 g^2}{h^7} f_\beta. \qquad (9)$$

Like the ground-to-ground alpha transitions of even–even nuclei, the superallowed beta transitions obey the basic rate law, but most beta transitions go much more slowly. The extra retardation is explained in terms of mismatched orbitals of neutrons and protons involved in the transition. For the superallowed transitions the orbitals in initial and final states are almost the same. Most of them occur between mirror nuclei, with one more or less neutron than protons; *i.e.,* beta-minus decay of hydrogen-3, electron capture of beryllium-7 and positron emission of carbon-11, oxygen-15, neon-19, . . . titanium-43.

The nuclear retardation of beta decay rates below those of the superallowed class may be expressed in a fundamental way by multiplying the right side of equation (9) by the square of a nuclear matrix element (a quantity of quantum mechanics), which may range from unity down to zero depending on the degree of mismatch of initial and final nuclear states of internal motion. A more usual way of expressing the nuclear factor of the beta rate is the log ft value, in which f refers to the function $f(Z,Q_\beta)$. Because the half-life is inversely proportional to the decay constant λ, the product $f_\beta t_{1/2}$ will be a measure of (inversely proportional to) the square of the nuclear matrix element. For the log ft value, the beta half-life is taken in seconds, and the ordinary logarithm to the base 10 is used. The superallowed transitions have log ft values in the range of 3 to 3.5. Beta log ft values are known up to as large as ~23 in the case of indium-115. There is some correlation of log ft values with spin changes between parent and daughter nucleons, the indium-115 decay involving a spin change of four, whereas the superallowed transitions all have spin changes of zero or one.

Beta log ft values

Gamma transition. The nuclear gamma transitions belong to the large class of electromagnetic transitions encompassing radio-frequency emission by antennas or rotating molecules, infrared emission by vibrating molecules or hot filaments, visible light, ultraviolet light, and X-ray emission by electronic jumps in atoms or molecules. The usual relations apply for connecting frequency ν, wavelength λ, and photon quantum energy E with speed of light c and Planck's constant h; namely, $\lambda = c/\nu$ and $E = h\nu$. It is sometimes necessary to consider the momentum (p) of the photon given by $p = E/c$.

Classically, radiation accompanies any acceleration of electric charge. Quantum mechanically there is a probability of photon emission from higher to lower energy nuclear states, in which the internal state of motion involves acceleration of charge in the transition. Therefore, purely neutron orbital acceleration would carry no radiative contribution.

A great simplification in nuclear gamma transition rate theory is brought about by the circumstance that the nuclear diameters are always much smaller than the shortest wavelengths of gamma radiation in radioactivity—*i.e.,* the nucleus is too small to be a good antenna for the radiation. The simplification is that nuclear gamma transitions can be classified according to multipolarity, or amount of spin angular momentum carried off by the radiation. One unit of angular momentum in the radiation is associated with dipole transitions (a dipole consists of two separated equal charges, plus and minus). If there is a change of nuclear parity, the transition is designated electric dipole (E1) and is analogous to the radiation of a linear half-wave dipole radio antenna. If there is no parity change, the transition is magnetic dipole (M1) and is analogous to the radiation of a full-wave loop antenna. With two units of angular momentum change, the transition is electric quadrupole (E2), analogous to a full-wave linear antenna of two dipoles out-of-phase, and magnetic quadrupole (M2), analogous to coaxial loop antennas driven out-of-phase. Higher multipolarity radiation also frequently occurs with radioactivity.

Transition rates are usually compared to the single-proton theoretical rate, or Weisskopf formula, named after the American physicist Victor Frederick Weisskopf, who developed it. Table 6 gives the theoretical reference rate formulas in their dependence on nuclear mass number A and gamma-ray energy $E\gamma$ (in MeV).

Weisskopf formula

Table 6: Gamma Transition Rates*

transition type	partial half-life t_γ (seconds)	illustrative t_γ values for $A = 125$, $E = 0.1$ MeV (seconds)
E1	$5.7 \times 10^{-15} E^{-3} A^{-2/3}$	2×10^{-13}
E2	$6.7 \times 10^{-9} E^{-5} A^{-4/3}$	1×10^{-6}
E3	$1.2 \times 10^{-2} E^{-7} A^{-2}$	8
E4	$3.4 \times 10^{4} E^{-9} A^{-8/3}$	9×10^{7}
E5	$1.3 \times 10^{11} E^{-11} A^{-10/3}$	1×10^{15}
M1	$2.2 \times 10^{-14} E^{-3}$	2×10^{-11}
M2	$2.6 \times 10^{-8} E^{-5} A^{-2/3}$	1×10^{-4}
M3	$4.9 \times 10^{-2} E^{-7} A^{-4/3}$	8×10^{2}
M4	$1.3 \times 10^{5} E^{-9} A^{-2}$	8×10^{9}
M5	$5.0 \times 10^{11} E^{-11} A^{-8/3}$	1×10^{17}

*The energies E are expressed in MeV. The nuclear radius has been taken as 1.3 fermis. It is to be noted that t_γ is the partial half-life for γ emission only; the occurrence of internal conversion will always shorten the measured half-life.

It is seen for the illustrative case of gamma energy 0.1 MeV and mass number 125 that there occurs an additional factor of 10^7 retardation with each higher multipole order. For a given multipole, magnetic radiation should be a factor of 100 or so slower than electric. These rate factors ensure that nuclear gamma transitions are nearly purely one multipole, the lowest permitted by the nuclear spin change. There are many exceptions, however; mixed M1–E2 transitions are common, because E2 transitions are often much faster than the Weisskopf formula gives and M1 transitions are generally slower. All E1 transitions encountered in radioactivity are much slower than the Weisskopf formula. The other higher multipolarities show some scatter in rates, ranging from agreement to considerable retardation. In most cases the retardations are well understood in terms of nuclear model calculations.

Though not literally a gamma transition, electric monopole (E0) transitions may appropriately be mentioned here. These may occur when there is no angular momentum change between initial and final nuclear states and no parity change. For spin-zero to spin-zero transitions, single gamma emission is strictly forbidden. The electric monopole transition occurs largely by the ejection of electrons from the orbital cloud in heavier elements and by positron–electron pair creation in the lighter elements.

Electric monopole transitions

APPLICATIONS OF RADIOACTIVITY

In medicine. Radioisotopes have found extensive use in diagnosis and therapy, and this has given rise to a rapidly growing field called nuclear medicine. These radioactive isotopes have proven particularly effective as tracers in certain diagnostic procedures. As radioisotopes are identical chemically with stable isotopes of the same element, they can take the place of the latter in physiological processes. Moreover, because of their radioactivity, they can be readily traced even in minute quantities with such detection devices as gamma-ray spectrometers and proportional counters. Though many radioisotopes are used as tracers, iodine-131, phosphorus-32, and technetium-99m are among the most important. Physicians employ iodine-131 to determine cardiac output, plasma volume, and fat metabolism and particularly to measure the activity of the thyroid gland where this isotope accumulates. Phosphorus-

Use as tracers in diagnostic procedures

32 is useful in the identification of malignant tumours because cancerous cells tend to accumulate phosphates more than normal cells do. Technetium-99*m*, used with radiographic scanning devices, is valuable for studying the anatomic structure of organs.

Such radioisotopes as cobalt-60 and cesium-137 are widely used to treat cancer. They can be administered selectively to malignant tumours and so minimize damage to adjacent healthy tissue.

In industry. Foremost among industrial applications is power generation based on the release of the fission energy of uranium (see below *Nuclear fission* and also the article ENERGY CONVERSION: *Nuclear reactors*). Other applications include the use of radioisotopes to measure (and control) the thickness or density of metal and plastic sheets, to stimulate the cross-linking of polymers, to induce mutations in plants in order to develop hardier species, and to preserve certain kinds of foods by killing microorganisms that cause spoilage. In tracer applications radioactive isotopes are employed, for example, to measure the effectiveness of motor oils on the wearability of alloys for piston rings and cylinder walls in automobile engines. For additional information about industrial uses, see RADIATION: *Applications in science and industry.*

Radiometric dating

In science. Research in the Earth sciences has benefited greatly from the use of radiometric-dating techniques, which are based on the principle that a particular radioisotope (radioactive parent) in geologic material decays at a constant known rate to daughter isotopes. Using such techniques, investigators have been able to determine the ages of various rocks and rock formations and thereby quantify the geologic time scale (see GEOCHRONOLOGY: *Radiometric dating*). A special application of this type of radioactivity age method, carbon-14 dating, has proved especially useful to physical anthropologists and archaeologists. It has helped them to better determine the chronological sequence of past events by enabling them to date more accurately fossils and artifacts from 500 to 50,000 years old.

Radioisotopic tracers are employed in environmental studies, as, for instance, those of water pollution in rivers and lakes and of air pollution by smokestack effluents. They also have been used to measure deep-water currents in oceans and snow-water content in watersheds. Researchers in the biologic sciences, too, have made use of radioactive tracers to study complex processes. For example, thousands of plant metabolic studies have been conducted on amino acids and compounds of sulfur, phosphorus, and nitrogen. (J.O.R./E.P.S.)

Energy from atoms

NUCLEAR FISSION

Spontaneous and induced fission

Nuclear fission is the breakup of the nucleus of an atom into two lighter nuclei. Occurring primarily in heavy nuclei, this process may take place spontaneously in some cases or may be induced by the excitation of the nucleus with a variety of particles (*e.g.*, neutrons, protons, deuterons, or alpha particles) or with electromagnetic radiation in the form of gamma rays. In the fission process, a large quantity of energy is released, radioactive products are formed, and several neutrons are emitted. These neutrons can induce fission in a nearby nucleus of fissionable material and release more neutrons that can repeat the sequence, causing a chain reaction in which a large number of nuclei undergo fission and an enormous amount of energy is released. If controlled in a nuclear reactor, such a chain reaction can provide power for society's benefit. If uncontrolled, as in the case of the so-called atomic bomb, it can lead to an explosion of awesome destructive force.

The discovery of nuclear fission has opened a new era—the "Atomic Age." The potential of nuclear fission for good or evil and the risk/benefit ratio of its applications have not only provided the basis of many sociological, political, economic, and scientific advances but grave concerns as well. Even from a purely scientific perspective, the process of nuclear fission has given rise to many puzzles and complexities, and a complete theoretical explanation is still not at hand.

History of fission research and technology. The term fission was first used by the German physicists Lise Meitner and Otto Frisch in 1939 to describe the disintegration of a heavy nucleus into two lighter nuclei of approximately equal size. The conclusion that such an unusual nuclear reaction can in fact occur was the culmination of a truly dramatic episode in the history of science, and it set in motion an extremely intense and productive period of investigation.

The story of the discovery of nuclear fission actually began with the discovery of the neutron in 1932 by James Chadwick in England (see above). Shortly thereafter, Enrico Fermi and his associates in Italy undertook an extensive investigation of the nuclear reactions produced by the bombardment of various elements with this uncharged particle. In particular, these workers observed (1934) that at least four different radioactive species resulted from the bombardment of uranium with slow neutrons. These newly discovered species emitted beta particles and were thought to be isotopes of unstable "transuranium elements" of atomic numbers 93, 94, and perhaps higher. There was, of course, intense interest in examining the properties of these elements, and many radiochemists participated in the studies. The results of these investigations, however, were extremely perplexing, and confusion persisted until 1939 when Otto Hahn and Fritz Strassmann in Germany, following a clue provided by Irène Joliot-Curie and Pavle Savić in France (1938), proved definitely that the so-called transuranic elements were in fact radioisotopes of barium, lanthanum, and other elements in the middle of the periodic table.

Discovery of fission by Hahn and Strassmann

That lighter elements could be formed by bombarding heavy nuclei with neutrons had been suggested earlier (notably by the German chemist Walter Noddack in 1934), but the idea was not given serious consideration because it entailed such a broad departure from the accepted views of nuclear physics and was unsupported by clear chemical evidence. Armed with the unequivocal results of Hahn and Strassmann, however, Meitner and Frisch invoked the recently formulated liquid-drop model of the nucleus (see above) to give a qualitative theoretical interpretation of the fission process and called attention to the large energy release that should accompany it. There was almost immediate confirmation of this reaction in dozens of laboratories throughout the world, and within a year more than 100 papers describing most of the important features of the process were published. These experiments confirmed the formation of extremely energetic heavy particles and extended the chemical identification of the products.

The chemical evidence that was so vital in leading Hahn and Strassmann to the discovery of nuclear fission was obtained by the application of carrier and tracer techniques. Since invisible amounts of the radioactive species were formed, their chemical identity had to be deduced from the manner in which they followed known carrier elements, present in macroscopic quantity, through various chemical operations. Known radioactive species were also added as tracers and their behaviour was compared with that of the unknown species to aid in the identification of the latter. Over the years, these radiochemical techniques have been used to isolate and identify some 34 elements from zinc (atomic number 30) to gadolinium (atomic number 64) that are formed as fission products. The wide range of radioactivities produced in fission makes this reaction a rich source of tracers for chemical, biologic, and industrial use (see above).

Although the early experiments involved the fission of ordinary uranium with slow neutrons, it was rapidly established that the rare isotope uranium-235 was responsible for this phenomenon. The more abundant isotope uranium-238 could be made to undergo fission only by fast neutrons with energy exceeding 1 MeV. The nuclei of other heavy elements, such as thorium and protactinium, also were shown to be fissionable with fast neutrons; and other particles, such as fast protons, deuterons, and alphas, along with gamma rays, proved to be effective in inducing the reaction.

In 1939, Frédéric Joliot-Curie, Hans von Halban, and Lew Kowarski found that several neutrons were emitted

in the fission of uranium-235, and this discovery led to the possibility of a self-sustaining chain reaction. Fermi and his coworkers recognized the enormous potential of such a reaction if it could be controlled. On Dec. 2, 1942, they succeeded in doing so, operating the world's first nuclear reactor. Known as a "pile," this device consisted of an array of uranium and graphite blocks and was built on the campus of the University of Chicago.

First controlled chain reaction

The secret Manhattan Project, established not long after the United States entered World War II, developed the atomic bomb. Once the war had ended, efforts were made to develop new reactor types for large-scale power generation, giving birth to the nuclear power industry.

Fundamentals of the fission process. *Structure and stability of nuclear matter.* The fission process may be best understood through a consideration of the structure and stability of nuclear matter. Nuclei consist of nucleons (neutrons and protons), the total number of which is equal to the mass number of the nucleus. The actual mass of a nucleus is always less than the sum of the masses of the free neutrons and protons that constitute it, the difference being the mass equivalent of the energy of formation of the nucleus from its constituents. The conversion of mass to energy follows Einstein's equation, $E = mc^2$, where E is the energy equivalent of a mass, m, and c is the velocity of light. This difference is known as the mass defect and is a measure of the total binding energy (and, hence, the stability) of the nucleus. This binding energy is released during the formation of a nucleus from its constituent nucleons and would have to be supplied to the nucleus to decompose it into its individual nucleon components.

Binding energy and stability of the nucleus

A curve illustrating the average binding energy per nucleon as a function of the nuclear mass number is shown in Figure 25. The largest binding energy (highest stability) occurs near mass number 56—the mass region of the element iron. Figure 25 indicates that any nucleus heavier than mass number 56 would become a more stable system by breaking into lighter nuclei of higher binding energy with the difference in binding energy being released in the process. (It should be noted that nuclei lighter than mass number 56 can gain in stability by fusing to produce a heavier nucleus of greater mass defect—again, with the release of the energy equivalent of the mass difference. It is the fusion of the lightest nuclei that provides the energy released by the Sun and constitutes the basis of the hydrogen, or fusion, bomb. Efforts to harness fusion reaction for power production are being actively pursued. [See below *Nuclear fusion.*])

On the basis of energy considerations alone, Figure 25 would indicate that all matter should seek its most stable configuration, becoming nuclei of mass number near 56. However, this does not happen, because barriers to such a spontaneous conversion are provided by other factors. A good qualitative understanding of the nucleus is achieved by treating it as analogous to a uniformly charged liquid drop. The strong attractive nuclear force between pairs of nucleons is of short range and acts only between the closest neighbours. Since nucleons near the surface of the drop have fewer close neighbours than those in the interior, a surface tension is developed, and the nuclear drop assumes a spherical shape in order to minimize this surface energy. (The smallest surface area enclosing a given volume is provided by a sphere.) The protons in the nucleus exert a long-range, repulsive (Coulomb) force on each other due to their positive charge. As the number of nucleons in a nucleus increases beyond about 40, the number of protons must be diluted with an excess of neutrons to maintain relative stability.

If the nucleus is excited by some stimulus and begins to oscillate (*i.e.*, deform from its spherical shape), the surface forces will increase and tend to restore it to a sphere, where the surface tension is at a minimum. On the other hand, the Coulomb repulsion decreases as the drop deforms and the protons are positioned farther apart. These opposing tendencies set up a barrier in the potential energy of the system, as indicated in Figure 26.

Fission barrier

The curve in Figure 26 rises initially with elongation, since the strong, short-range nuclear force that gives rise to the surface tension increases. The Coulomb repulsion between protons decreases faster with elongation than the surface tension increases, and the two are in balance at point *B*, which represents the height of the barrier to fission. (This point is called the "saddle point" because, in a three-dimensional view of the potential energy surface, the shape of the pass over the barrier resembles a saddle.) Beyond point *B*, the Coulomb repulsion between the protons drives the nucleus into further elongation until at some point, *S* (the scission point), the nucleus breaks in two. Qualitatively, at least, the fission process is thus seen to be a consequence of the Coulomb repulsion between protons. Further discussion of the potential energy in fission is provided below.

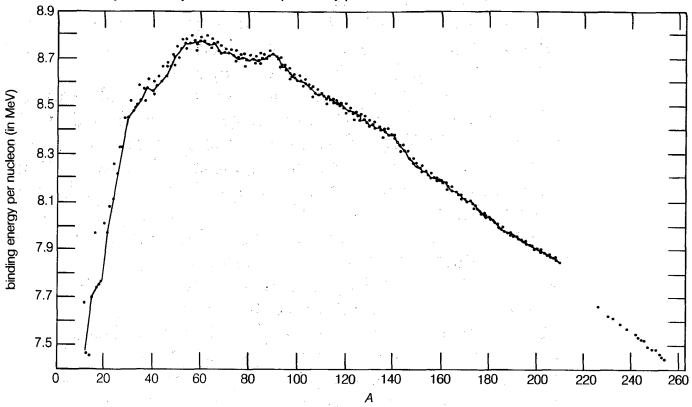

Figure 25: The average binding energy per nucleon as a function of the mass number, *A* (see text). The line connects the odd-*A* points.

Induced fission. The height and shape of the fission barrier are dependent on the particular nucleus being considered. Fission can be induced by exciting the nucleus to an energy equal to or greater than that of the barrier. This can be done by gamma-ray excitation (photofission) or through excitation of the nucleus by the capture of a neutron, proton, or other particle (particle-induced fission). The binding energy of a particular nucleon to a nucleus will depend on—in addition to the factors considered above—the odd–even character of the nucleus. Thus, if a neutron is added to a nucleus having an odd number of neutrons, an even number of neutrons will result, and the binding energy will be greater than for the addition of a neutron that makes the total number of neutrons odd. This "pairing energy" accounts in part for the difference in behaviour of nuclides in which fission can be induced with slow (low-energy) neutrons and those that require fast (higher-energy) neutrons. Although the heavy elements are unstable with respect to fission, the reaction takes place to an appreciable extent only if sufficient energy of acti-

Photofission and particle-induced fission

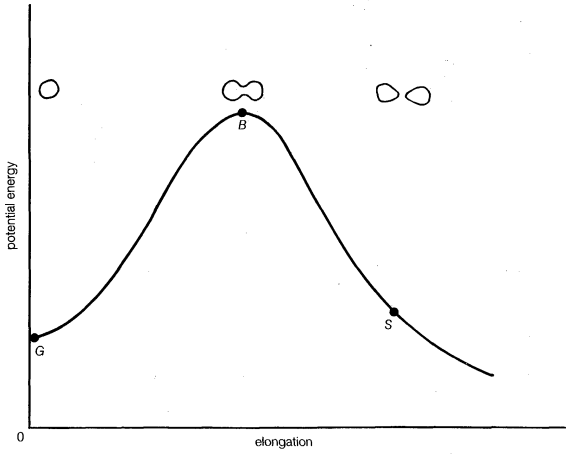

Figure 26: *The potential energy as a function of elongation of a fissioning nucleus.*
G is the ground state of the nucleus; *B* is the top of the barrier to fission (called the saddle point); and *S* is the scission point. The nuclear shape at these points is shown at the top.

vation is available to surmount the fission barrier. Most nuclei that are fissionable with slow neutrons contain an odd number of neutrons (*e.g.*, uranium-233, uranium-235, or plutonium-239), whereas most of those requiring fast neutrons (*e.g.*, thorium-232 or uranium-238) have an even number. The addition of a neutron in the former case liberates sufficient binding energy to induce fission. In the latter case, the binding energy is less and may be insufficient to surmount the barrier and induce fission. Additional energy must then be supplied in the form of the kinetic energy of the incident neutron. (In the case of thorium-232 or uranium-238, a neutron having about 1 MeV of kinetic energy is required.)

Spontaneous fission. The laws of quantum mechanics deal with the probability of a system such as a nucleus or atom being in any of its possible states or configurations at any given time. A fissionable system (uranium-238, for example) in its ground state (*i.e.*, at its lowest excitation energy and with an elongation small enough that it is confined inside the fission barrier) has a small but finite probability of being in the energetically favoured configuration of two fission fragments. In effect, when this occurs, the system has penetrated the barrier by the process of quantum mechanical tunneling. This process is called spontaneous fission because it does not involve any outside influences. In the case of uranium-238, the process has a very low probability, requiring more than 10^{15} years for half of the material to be transformed (its so-called half-life) by this reaction. On the other hand, the probability for spontaneous fission increases dramatically for the heaviest nuclides known and becomes the dominant mode of decay for some—those having half-lives of only fractions of a second. In fact, spontaneous fission becomes the limiting factor that may prevent the formation of still heavier (super-heavy) nuclei.

The stages of fission. A pictorial representation of the sequence of events in the fission of a heavy nucleus is given in Figure 27. In this figure, neutrons are shown in black and protons in white. The approximate time elapse between stages of the process is indicated at the bottom of the Figure.

The phenomenology of fission. When a heavy nucleus undergoes fission, a variety of fragment pairs may be formed, depending on the distribution of neutrons and protons between the fragments. This leads to probability distribution of both mass and nuclear charge for the fragments. The probability of formation of a particular fragment is called its fission yield and is expressed as the percentage of fissions leading to it.

'ission ragments

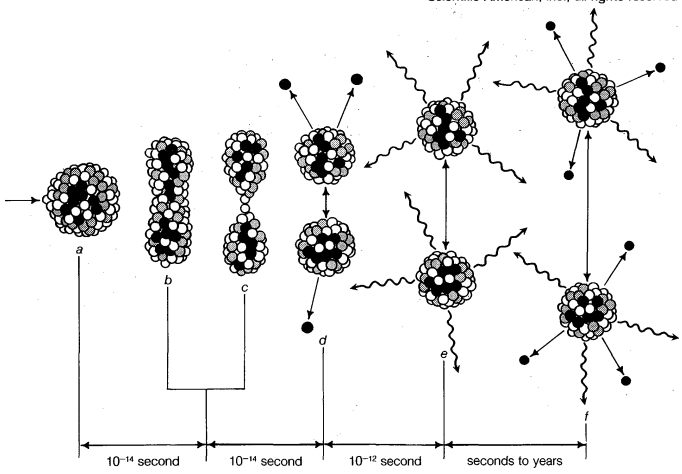

Figure 27: *Sequence of events in the fission of a uranium nucleus by a neutron.*
In *a*, the neutron strikes the nucleus and is absorbed, causing the nucleus to undergo deformation, *b*. In about 10^{-14} second, one of the deformations, *c*, is so drastic that the nucleus cannot recover and fissions, *d*, releasing two or three neutrons. In about 10^{-12} second, the fission fragments lose their kinetic energy and come to rest, emitting a number of gamma rays. At this stage, *e*, they are called fission products. In the final stage, *f*, the fission products lose their excess energy by radioactive decay, emitting beta particles and gamma rays over a time period ranging from seconds to years.

The separated fragments experience a large Coulomb repulsion due to their nuclear charges, and they recoil from each other with kinetic energies determined by the fragment charges and the distance between the charge centres at the time of scission. Variations in these parameters lead to a distribution of kinetic energies, even for the same mass split.

The initial velocities of the recoiling fragments are too fast for the outer (atomic) electrons of the fissioning atom to keep pace, and many of them are stripped away. Thus, the nuclear charge of the fragment is not fully neutralized by the atomic electrons, and the fission fragments fly apart as highly charged atoms. As the nucleus of the fragment adjusts from its deformed shape to a more stable configuration, the deformation energy (*i.e.*, the energy required to deform it) is recovered and converted into internal excitation energy, and neutrons and prompt gamma rays (an energetic form of electromagnetic radiation given off nearly coincident with the fission event) may be evaporated from the moving fragment. The fast-moving, highly charged atom collides with the atoms of the medium through which it is moving, and its kinetic energy is transferred to ionization and heating of the medium as it slows down and comes to rest. The range of fission fragments in air is only a few centimetres.

Fission products

During the slowing-down process, the charged atom picks up electrons from the medium and becomes neutral by the time it stops. At this stage in the sequence of events, the atom produced is called a fission product to distinguish it from the initial fission fragment formed at scission. Since a few neutrons may have been lost in the transition from fission fragment to fission product, the two may not have the same mass number. The fission product is still not a stable species but is radioactive, and it finally reaches stability by undergoing a series of beta decays, which may vary over a time scale of fractions of a second to many years. The beta emission consists of electrons and antineutrinos, often accompanied by gamma rays and X rays.

The distributions in mass, charge, and kinetic energy of the fragments have been found to be dependent on the fissioning species as well as on the excitation energy at which the fission act occurs. Many other aspects of fission have been observed, adding to the extensive phenomenology of the process and providing an intriguing set of problems for interpretation. These include the systematics of fission cross sections (a measure of the probability for fission to occur); the variation of the number of prompt neutrons (see below) emitted as a function of the fissioning species and the particular fragment mass split; the angular distribution of the fragments with respect to the direction of the beam of particles inducing fission; the systematics of spontaneous fission half-lives; the occurrence of spontaneous fission isomers (excited states of the nucleus); the emission of light particles (hydrogen-3, helium-3, helium-4, etc.) in small but significant numbers in some fission events; the presence of delayed neutron emitters among the fission products; the time scale on which the various stages of the process take place; and the distribution of the energy release in fission among the particles and radiations produced.

A detailed discussion of all of these facets of fission and how the data were obtained is not possible here, but a few of them are treated to provide some insight into this field of study and a taste of its fascination.

Distribution of fragment masses

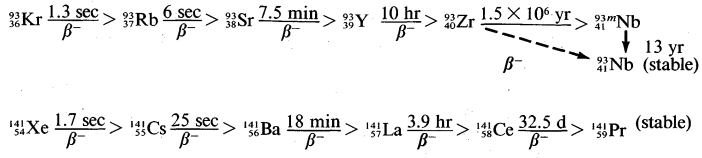
Fission fragment mass distributions. The distribution of the fragment masses formed in fission is one of the most striking features of the process. It is dependent on the mass of the fissioning nucleus and the excitation energy at which the fission occurs. At low excitation energy, the fission of such nuclides as uranium-235 or plutonium-239 is asymmetric—*i.e.*, the fragments are formed in a two-humped probability (or yield) distribution favouring an unequal division in mass. This is illustrated in Figure 28. As will be noted, the light group of fragment masses shifts to higher mass numbers as the mass of the fissioning nucleus increases, whereas the position of the heavy

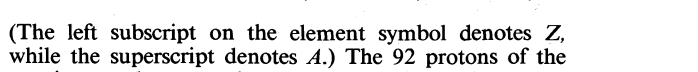
group remains nearly stationary. As the excitation energy of the fission increases, the probability for a symmetric mass split increases, while that for asymmetric division decreases. Thus, the valley between the two peaks increases in probability (yield of formation), and at high excitations the mass distribution becomes single-humped, with the maximum yield at symmetry (see Figure 29). Radium isotopes show interesting triple-humped mass distributions, and nuclides lighter than radium show a single-humped, symmetric mass distribution. (These nuclides, however, require a relatively high activation energy to undergo fission.) For very heavy nuclei in the region of fermium-260, the mass-yield curve becomes symmetric (single-humped) even for spontaneous fission, and the kinetic energies of the fragments are unusually high. An understanding of these mass distributions has been one of the major puzzles of fission, and a complete, theoretical interpretation is still lacking, albeit much progress has been made (see below).

Fission decay chains and charge distribution. In order to maintain stability, the neutron-to-proton (n/p) ratio in nuclei must increase with increasing proton number. The ratio remains at unity up to the element calcium, with 20 protons. It then gradually increases until it reaches a value of about 1.5 for the heaviest elements. When a heavy nucleus fissions, a few neutrons are emitted; however, this still leaves too high an n/p ratio in the fission fragments to be consistent with stability for them. They undergo radioactive decay and reach stability by successive conversions of neutrons to protons with the emission of a negative electron (called a beta particle, β^-) and an antineutrino. The mass number of the nucleus remains the same, but the nuclear charge (atomic number) increases by one, and a new element is formed for each such conversion. The successive beta decays constitute an isobaric, fission-product decay chain for each mass number. The half-lives for the decay of the radioactive species generally increase as they approach the stable isobar of the chain. (Species of the same element characterized by the same nuclear charge, Z [number of protons], but differing in their number of neutrons [and therefore in mass number A] are called isotopes. Species that have the same mass number, A, but differ in Z are known as isobars.)

Charge distribution in fission

For a typical mass split in the neutron-induced fission of uranium-235, the complementary fission-product masses of 93 and 141 may be formed following the emission of two neutrons from the initial fragments. The division of charge (*i.e.*, protons) between the fragments represents an important parameter in the fission process. Thus, for the mass numbers 93 and 141, the following isobaric fission-product decay chains would be formed (the half-lives for the beta-decay processes are indicated above the arrows):





(The left subscript on the element symbol denotes Z, while the superscript denotes A.) The 92 protons of the uranium nucleus must be conserved, and complementary fission-product pairs, such as krypton-36 with beryllium-56, rubidium-37 with cesium-55, or strontium-38 with xenon-54, would be possible.

The percentage of fissions in which a particular nuclide is formed as a primary fission product (*i.e.*, as the direct descendant of an initial fragment following its de-excitation) is called the independent yield of that product. The total yield for any nuclide in the isobaric decay chain is the sum of its independent yield and the independent yields of all of its precursors in the chain. The total yield for the entire chain is called the cumulative yield for that mass number.

Extensive radiochemical investigations have suggested that the most probable charge division is one that is displaced from stability about the same distance in both chains. This empirical observation is called the equal charge displacement (ECD) hypothesis, and it has been confirmed by several physical measurements. In the above example the ECD would predict the most probable charges at about rubidium-37 and cesium-55. A strong shell effect modifies the ECD expectations for fragments having 50 protons. The dispersion of the charge formation probability about the most probable charge (Z_p) is rather narrow and approximately Gaussian in shape and is nearly independent of the mass split as well as of the fissioning species. The most probable charge for an isobaric chain is a useful concept in the description of the charge dispersion, and it need not have an integral value. As the

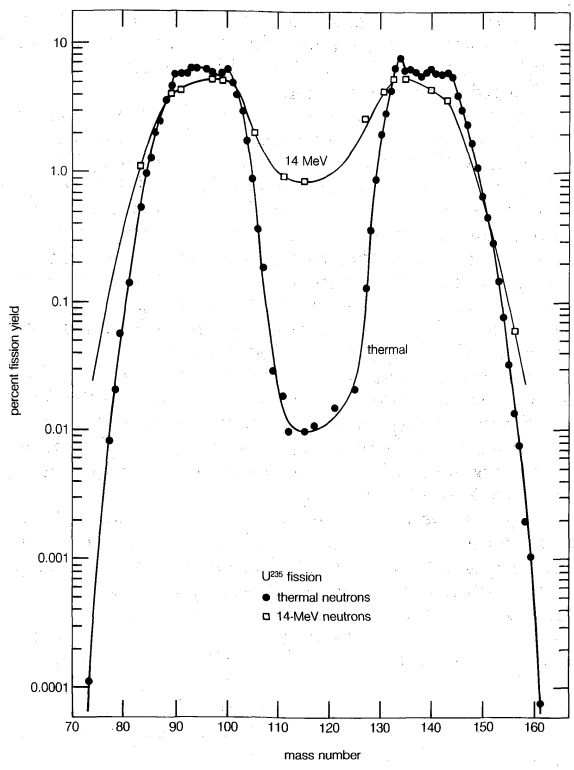


Figure 29: *Mass distribution dependence on the energy excitation in the fission of uranium-235.* At still higher energies, the curve becomes single-humped, with a maximum yield for symmetric mass splits (see text).

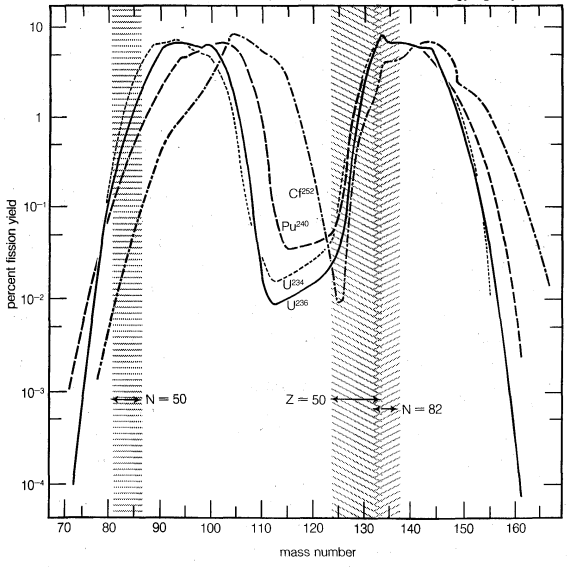

Figure 28: *Mass distributions (or fission-yield curves) for the thermal-neutron fission of uranium-233, uranium-235, and plutonium-239 and the spontaneous fission of californium-252.* The light mass group shifts to higher masses as the mass of the fissioning nucleus increases, while the heavy group remains nearly stationary. The shaded areas show the location of the closed shells of 50 protons, 50 neutrons, and 82 neutrons (see text).

energy of fission increases, the charge division tends toward maintaining the n/p ratio in the fragments the same as that in the fissioning nucleus. This is referred to as an unchanged charge distribution.

Prompt neutrons in fission. The average number of neutrons emitted per fission (represented by the symbol $\bar{\nu}$) varies with the fissioning nucleus. It is about 2.0 for the spontaneous fission of uranium-238 and 4.0 for that of fermium-257. In the thermal-neutron induced fission of uranium-235, $\bar{\nu} = 2.4$. The actual number of neutrons emitted, however, varies with each fission event, depending on the mass split. Although there is still controversy regarding the number of neutrons emitted at the instant of scission, it is generally agreed that most of the neutrons are given off by the recoiling fission fragments soon after scission occurs. The number of neutrons emitted from each fragment depends on the amount of energy the fragment possesses. The energy can be in the form of internal excitation (heat) energy or stored as energy of deformation of the fragment to be released when the fragment returns to its stable equilibrium shape.

Figure 30 shows the number of neutrons emitted per fragment as a function of the fragment mass number in the thermal neutron fission of uranium-235. The mass-yield distribution for the same isotope also is shown. This "sawtooth" neutron emission curve is typical of many fissioning systems at low excitation energy and provides another interesting phenomenon of fission. It is directly correlated with the fragment deformations at scission.

Delayed neutrons in fission. A few of the fission products have beta-decay energies that exceed the binding energy of a neutron in the daughter nucleus. This is likely to happen when the daughter nucleus contains one or two neutrons more than a closed shell of 50 or 82 neutrons, since these "extra" neutrons are more loosely bound. The beta decay of the precursor may take place to an excited state of the daughter from which a neutron is emitted. The neutron emission is "delayed" by the beta-decay half-life of the precursor. Six such delayed neutron emitters have been identified, with half-lives varying from about 0.5 to 56 seconds. The yield of the delayed neutrons is only about 1 percent of that of the prompt neutrons, but they are very important for the control of the chain reaction in a nuclear reactor.

Energy release in fission. The total energy release in a fission event may be calculated from the difference in the rest masses of the reactants (*e.g.*, $^{235}U + n$) and the final stable products (*e.g.*, $^{93}Nb + {}^{141}Pr + 2n$). The energy equivalent of this mass difference is given by the Einstein relation, $E = mc^2$. The total energy release depends on the mass split, but a typical fission event would have the total energy release distributed approximately as follows for the major components in the thermal neutron-induced fission of uranium-235:

Energy component	number per fission	total energy
Kinetic energy of fission fragments	2	170 MeV
Kinetic energy of prompt neutrons	2.5	5
Binding energy from capture of prompt neutrons	2.5	~12
Prompt gamma rays	8	8
		Total = 195 MeV

(The energy release from the capture of the prompt neutrons depends on how they are finally stopped, and some will escape the core of a nuclear reactor.)

This energy is released on a time scale of about 10^{-12} second and is called the prompt energy release. It is largely converted to heat within an operating reactor and is used for power generation. Also, there is a delayed release of energy from the radioactive decay of the fission products varying in half-life from fractions of a second to many years. The shorter-lived species decay in the reactor, and their energy adds to the heat generated; however, the longer-lived species remain radioactive and pose a problem in the handling and disposition of the reactor fuel elements when they need to be replaced. The antineutrinos that accompany the beta decay of the fission products are unreactive, and their kinetic energy (about 10 MeV per fission) is not recovered. Overall, about 200 MeV of energy per fission may be recovered for power applications.

The prompt energy release

Fission theory. Nuclear fission is a complex process that involves the rearrangement of hundreds of nucleons in a single nucleus to produce two separate nuclei. A complete theoretical understanding of this reaction would require a detailed knowledge of the forces involved in the motion of each of the nucleons through the process. Since such knowledge is still not available, it is necessary to construct simplified models of the actual system to simulate its behaviour and gain as accurate a description as possible of the steps in the process. The successes and failures of the models in accounting for the various observations of the fission process can provide new insights into the fundamental physics governing the behaviour of real nuclei, particularly at the large nuclear deformations encountered in a nucleus undergoing fission.

The framework for understanding nuclear reactions is analogous to that for chemical reactions and involves the concept of a potential-energy surface on which the reaction occurs. The driving force for physical or chemical reactions is the tendency to lower the potential energy and increase the stability of the system. Thus, for example, a stone at the top of a hill will roll down the hill, converting its potential energy at the top to kinetic energy of motion, and will come to rest at the bottom in a more stable state of lower potential energy. The potential energy is calculated as a function of various parameters of the system being studied. In the case of fission, the potential energy may be calculated as a function of the shape of the system as it proceeds over the barrier to the scission point, and the path of lowest potential energy may be determined.

As has been pointed out, an exact calculation of the nuclear potential energy is not yet possible, and it is to approximate this calculation that various models have been constructed to simulate the real system. Some of the models were developed to address aspects of nuclear structure and spectroscopy as well as features of nuclear reactions, and they also have been employed in attempts to understand the complexity of nuclear fission. The models are based on different assumptions and approximations of the nature of the nuclear forces and the dynamics of the path to scission. No one model can account for all of the extensive phenomenology of fission, but each addresses different aspects of the process and provides a foundation for further development toward a complete theory.

Nuclear models and nuclear fission. The nucleus exhibits some properties that reflect the collective motion of all its constituent nucleons as a unit, as well as other properties that are dependent on the motion and state of the individual nucleons.

The analogy of the nucleus to a drop of an incompressible liquid was first suggested by George Gamow in 1935

From J. Terrell, *Physical Review* 127, p. 892 (August 1962)

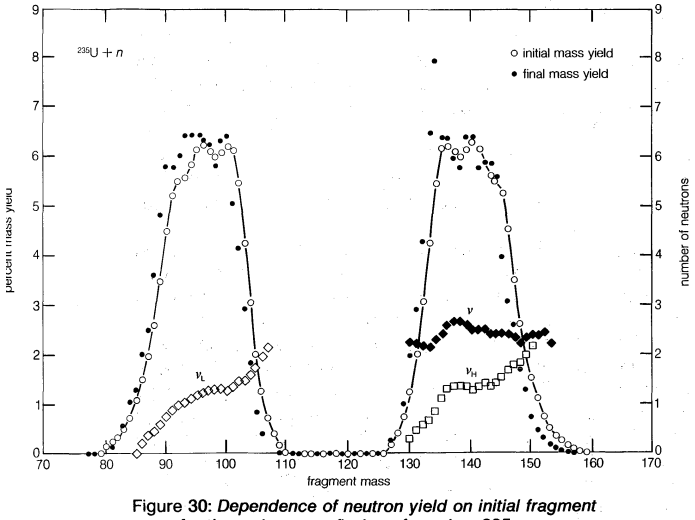

Figure 30: *Dependence of neutron yield on initial fragment mass for thermal-neutron fission of uranium-235.* Average number of neutrons emitted by light and heavy fragments are given the symbols ν_L and ν_H; the total from both fragments is ν. Also shown are the initial (fission fragment) and final (fission product) mass yields.

and later adapted to a description of nuclear reactions (by Niels Bohr [1936]; and Bohr and Fritz Kalckar [1937]) and to fission (Bohr and John A. Wheeler [1939]; and Yakov Frenkel [1939]). Bohr proposed the so-called compound nucleus description of nuclear reactions, in which the excitation energy of the system formed by the absorption of a neutron or photon, for example, is distributed among a large number of degrees of freedom of the system. This excited state persists for a long time relative to the periods of motion of nucleons across the nucleus and then decays by emission of radiation, the evaporation of neutrons or other particles, or by fission. The liquid-drop model of the nucleus accounts quite well for the general collective behaviour of nuclei and provides an understanding of the fission process on the basis of the competition between the cohesive nuclear force and the disruptive Coulomb repulsion between protons (as described above). It predicts, however, a symmetric division of mass in fission, whereas an asymmetric mass division is observed. Moreover, it does not provide an accurate description of fission barrier systematics or of the ground-state masses of nuclei. The liquid-drop model is particularly useful in describing the behaviour of highly excited nuclei, but it does not provide an accurate description for nuclei in their ground or low-lying excited states. Many versions of the liquid-drop model employing improved sets of parameters have been developed. However, investigators have found that mass asymmetry and certain other features in fission cannot be adequately described on the basis of the collective behaviour posited by such models alone.

Limitations of the liquid-drop model in describing certain fission features

A preference for the formation of unequal masses (*i.e.*, an asymmetric division) was observed early in fission research, and it has remained the most puzzling feature of the process to account for. Investigators have invoked various models other than that of the liquid drop in an attempt to address this question. Dealing with the mutual interaction of all the nucleons in a nucleus has been simplified by treating it as if it were equivalent to the interaction of one particle with an average, spherical static potential field that is generated by all the other nucleons. The methods of quantum mechanics provide the solution for the motion of a nucleon in such a potential. A characteristic set of energy levels for neutrons and protons is obtained, and, analogous to the set of levels of the electrons in an atom, the levels group themselves into shells at certain so-called magic numbers of nucleons. (For both neutrons and protons, these numbers are 2, 8, 20, 28, 50, 82, and 126.) Shell closures at these nuclear numbers are marked by especially strong binding, or extra stability. This constitutes the essence of the spherical-shell model (sometimes called the independent-particle, or single-particle, model), as developed by Maria Goeppert Mayer and J. Hans D. Jensen and their colleagues (1949). It accounts well for ground-state masses and spins, and for the existence of isomeric nuclear states (excited states having measurable half-lives) that occur when nuclear levels of widely differing spins lie relatively close to each other. The agreement with observations is excellent for spherical nuclei with nucleon numbers near the magic shell numbers. The spherical-shell model, however, does not agree well with the properties of nuclei that have other nucleon numbers—*e.g.*, the nuclei of the lanthanide and actinide elements, with nucleon numbers between the magic numbers.

Inadequacy of the shell model

In the lanthanide and actinide nuclei, the ground state is not spherical but rather deformed into a prolate spheroidal shape—that of a football or watermelon. For such nuclei, the allowed states of motion of a nucleon must be calculated in a potential having a symmetry corresponding to a spheroid rather than a sphere. This was first done by Aage Bohr, Ben R. Mottelson, and Sven G. Nilsson in 1955, and the level structure was calculated as a function of the deformation of the nucleus. A spheroid has three axes of symmetry, and it can rotate in space as a unit about any one of them. The rotation can occur independent of the internal state of excitation of the individual nucleons. Various modes of vibration of the spheroid also may take place. Since this deformed shell model has components of both the independent-particle motion and the collective motion of the nucleus as a whole (*i.e.*, rotations and vibrations), it is sometimes referred to as the unified model.

In Aage Bohr's application of the unified model to the fission process, the sequence of potential-energy surfaces for the excited states of the system are considered to be functions of a deformation parameter (*i.e.*, elongation) characterizing the motion toward fission and evaluated at the saddle point. As the system passes over the saddle point, most of its excitation energy is used up in deforming the nucleus, and the system remains "cold"—*i.e.*, it manifests little excitation, or heat, energy. Thus, only the low-lying excited states are available to the system. The spin and parity of the particular state (or channel) in which the system exists as it passes over the saddle point are then expected to determine the fission properties. In this channel (or transition-state) analysis of fission, a number of characteristics of the process are qualitatively accounted for. Hence, fission thresholds would depend on the spin and parity of the compound nuclear state, the fission fragment angular distribution would be governed by the collective rotational angular momentum of the state, and asymmetry in the mass distribution would result from passage over the barrier in a state of negative parity (which does not possess reflection symmetry). This model gives a good qualitative interpretation of many fission phenomena, but it must assume that at least some of the properties of the transition state at the saddle point are not altered by dynamical considerations in the descent of the system to the scission point. It is the only model that provides a satisfactory interpretation of the angular distributions of fission fragments, and it has attractive features that must be included in any complete theory of fission.

Application of the unified model to the fission process

The first application of the spherical-shell model to fission was the recognition that the positions of the peaks in the fission mass distribution correlated fairly well with the magic numbers and suggested a qualitative interpretation of the asymmetric mass division. Thus, a preference for the formation of nuclei with neutron numbers close to 82 would favour the formation of nuclides near the peak in the heavy group and would thus determine the mass split for the fissioning system (see Figure 28). Some extra stability for nuclear configurations of 50 protons would also be expected, but this is not particularly evident. In fact, the so-called doubly magic nucleus tin-132, with 50 protons and 82 neutrons, has a rather low yield in low-energy fission.

A more quantitative application of the spherical-shell model to fission was undertaken by Peter Fong in the United States in 1956. He related the probability of formation of a given pair of fragments to the available density of states for that pair of fragments at the scission point in a statistical-model approach. A model of this sort predicts that the system, in its random motions, will experience all possible configurations and so will have a greater probability of being in the region where the greatest number of such configurations (or states) is concentrated. The model assumes that the potential energy at the saddle point is essentially all converted to excitation energy and that a statistical equilibrium among all possible states is established at the scission point. The extra binding energy for closed-shell nuclei leads to a higher density of states at a given excitation energy than is present for other nuclei and, hence, leads to a higher probability of formation. An asymmetric mass distribution in good agreement with that observed for the neutron-induced fission of uranium-235 is obtained. Moreover, the changes in the mass distribution with an increased excitation energy of fission (*e.g.*, an increase in the probability of symmetric fission relative to asymmetric fission) are accounted for by the decrease in importance of the shell effects as the excitation energy increases. Other features of the fission process also are qualitatively explained; however, extensive changes in the parameters of the model are required to obtain agreement with experiments for other fissionable nuclides. Then, too, there are fundamental problems concerning the validity of some of the basic assumptions of the model.

Statistical-model approach

The fundamental question as to the validity of models that evaluate the properties of the system at the scission point (the so-called scission-point models of fission) is whether the system remains long enough at this point

cission-
oint
iodels

on the steep decline of the potential-energy surface for a quasi-equilibrium condition to be established. There is some evidence that such a condition may indeed prevail, but it is not clearly established. Nonetheless, such models have proved quite useful in interpreting observations of mass, charge, and kinetic energy distributions, as well as of neutron emission dependence on fragment mass. It seems very likely that the fragment shell structure plays a significant role in determining the course of the fission process.

Although the single-particle models provide a good description of various aspects of nuclear structure, they are not successful in accounting for the energy of deformation of nuclei (*i.e.*, surface energy), particularly at the large deformations encountered in the fission process. A major breakthrough occurred when a hybrid model incorporating shell effects as a correction to the potential energy of the liquid-drop model was proposed by the Soviet physicist V.M. Strutinskii in 1967. This approach retains the dominant collective surface and Coulomb effects while adding shell and pairing corrections that depend on deformation. Shell corrections of several million electron volts are calculated, and these can have a significant effect on a liquid-drop barrier of about 5 MeV. The nucleon numbers at which the shells appear depend on the deformation and may differ from the spherical model magic numbers. In the vicinity of the fission barrier, the shells introduce structure in the liquid-drop potential-energy curve, as illustrated in Figure 31. The relative heights and widths of the two peaks vary with the mass and charge of the fissioning system.

iodel

The double-humped barrier (Figure 31) provides a satisfactory explanation for a number of puzzling observations in fission. The existence of short-lived, spontaneous fission isomers, for example, is understood as the consequence of the population of states in the second well (class II). These isomers have a much smaller barrier to penetrate and so exhibit a much shorter spontaneous fission half-life. The change in shape associated with these states, as compared to class I states, also hinders a rapid return to the ground state by gamma emission. (Class II states are also called shape isomers.) The systematics of neutron-induced fission cross sections and structure in some fission-fragment angular distributions also find an interpretation in the implications of the double-humped barrier.

From R. Vandenbosch and J.F. Huizenga, *Nuclear Fission* (1973); Academic Press

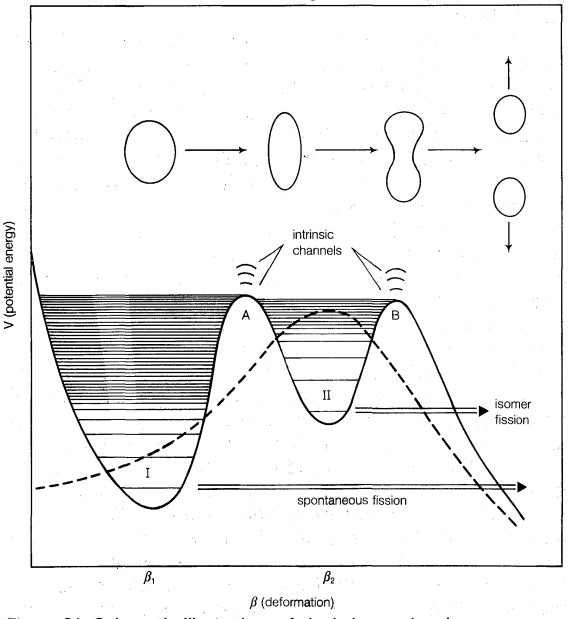

Figure 31: *Schematic illustrations of single-humped and double-humped fission barriers.*
The former are represented by the dashed line and the latter by the continuous line. Intrinsic excitations in the first and second wells at deformations β_1 and β_2 are designated class I and class II states, respectively. Intrinsic channels at the two barriers also are illustrated. The transition in the shape of the nucleus as a function of deformation is schematically represented in the upper part of the figure. Spontaneous fission of the ground state and isomeric state occurs from the lowest energy class I and class II states, respectively.

The Strutinskii procedure provided a strong stimulus for calculations of the potential-energy surfaces appropriate to fissioning systems, since it provided a consistent and useful prescription for treating both the macroscopic (liquid-drop) and microscopic (single-particle) effects in deformed nuclei. Many calculations of the potential-energy surface employing different model potentials and parameters have been carried out as functions of the shapes of the system. The work of the American nuclear physicists W.J. Swiatecki, James R. Nix, and their collaborators has been particularly noteworthy in such studies, which also include some attempts to treat the dynamical evolution of the fission process.

Calculations for the actinide elements indicate that, at deformations corresponding to the second barrier (Figure 31), the potential energy for asymmetric mass splits is lower than that for symmetric ones; hence, the former are favoured at that stage of the process. For larger deformations, however, a single potential does not represent the incipient formation of two fragments very well. In fact, a discontinuity occurs at the scission point, and the results of the calculation depend on whether the scission configuration is treated as one nucleus or as two separate nuclei.

Two-centre potential

A two-centre potential may also be used to represent the nature of the forces at work in a fissioning nucleus. In such a model, the potential energy surfaces are represented by two overlapping spheres or spheroids. It is equivalent to a one-centre potential when there is a complete overlap at small deformations, and it has the correct asymptotic behaviour as the nascent fragments separate. This approach indicates a preformation of the final shell structure of the fragments early in the process.

Although the validity of the assumptions inherent in scission-point models may be in question, the results obtained with them are in excellent agreement with observation. Representative of such a model is the Argonne Scission-Point model, which uses a macroscopic-microscopic calculation with deformed fragment shell and pairing corrections to determine the potential energy of a system of two nearly touching spheroids and which includes their interaction in terms of a neck connecting them. Models of this kind provide a simple approach to a highly quantitative and detailed study of the dependence of the probability of formation of a given fragment pair on the neutron and proton number and on the deformation in each fragment. They account very well for the mass, charge, and kinetic-energy distributions and the neutron-emission dependence on mass number for a broad range of fissioning nuclei. The scission-point models, however, do not address questions of fission probability or the angular distributions of the fragments. As the fission-excitation energy increases, the shell correction diminishes and the macroscopic (liquid-drop) behaviour dominates.

Nuclides in the region of fermium-264 have been observed to undergo symmetric fission with unusually high fragment kinetic energies. This appears to be the consequence of the stability for the magic number configurations of 50 protons and 82 neutrons. The formation of two doubly magic fragments of tin-132 is strongly favoured energetically, whereas the formation of only one such fragment in the low-energy fission of uranium or plutonium isotopes is not. The fragments of tin-132 are spherical rather than deformed, and a more compact configuration at the scission point (with the charge centres closer together) leads to higher fragment kinetic energies.

It is evident that shell effects, both in the fissioning system at the saddle point and in the deformed fragments near the scission point, are important in interpreting many of the features of the fission process. The stage of the process at which the various fragment distributions are determined is, however, not clearly established. All the components of a reasonable understanding of fission seem to be at hand, but they have yet to be synthesized into a complete, dynamic theory.

Considerations of the dynamics of the descent of the system on the potential-energy surface from the saddle point to the scission point involve two extreme points of

Dynamics of fission

view. An "adiabatic" approximation may be valid if the collective motion of the system is considered to be so slow or the coupling between the collective and internal single-particle degrees of freedom (*i.e.*, between macroscopic and microscopic behaviour) so weak that the fast single-particle motions can readily adjust to the changes in shape of the fissioning nucleus as it progresses toward scission. In this case, the changes in the system take place without the gain or loss of heat energy. The decrease in potential energy between the saddle and scission points will then appear primarily in the collective degrees of freedom at scission and be associated with the kinetic energy of the relative motion of the nascent fragments (referred to as pre-scission kinetic energy). On the other hand, if the collective motion toward scission is relatively fast or the coupling-to-particle motion stronger, collective energy can be transformed into internal excitation (heat) energy of the nucleons. (This is analogous to heating in the motion of a viscous fluid.) In such a "non-adiabatic" process the mixing among the single-particle degrees of freedom may be sufficiently complete that a statistical model may be applicable at the scission point. Either extreme represents an approximation of complex behaviour, and some experimental evidence in support of either interpretation may be advanced. As in most such instances in nature, the truth probably lies somewhere between the extremes, with both playing some role in the fission process.

Fission chain reactions and their control. The emission of several neutrons in the fission process leads to the possibility of a chain reaction if at least one of the fission neutrons induces fission in another fissile nucleus, which in turn fissions and emits neutrons to continue the chain. If more than one neutron is effective in inducing fission in other nuclei, the chain multiplies more rapidly. The condition for a chain reaction is usually expressed in terms of a multiplication factor, k, which is defined as the ratio of the number of fissions produced in one step (or neutron generation) in the chain to the number of fissions in the preceding generation. If k is less than unity, a chain reaction cannot be sustained. If $k = 1$, a steady-state chain reaction can be maintained; and if k is greater than 1, the number of fissions increases at each step, resulting in a divergent chain reaction. The term critical assembly is applied to a configuration of fissionable material for which $k = 1$; if $k > 1$, the assembly is said to be supercritical. A critical assembly might consist of the fissile material in the form of a metal or oxide, a moderator to slow the fission neutrons, and a reflector to scatter neutrons that would otherwise be lost back into the assembly core.

Critical assembly

In a fission bomb it is desirable to have k as large as possible and the time between steps in the chain as short as possible so that many fissions occur and a large amount of energy is generated within a brief period ($\sim 10^{-7}$ second) to produce a devastating explosion. If one kilogram of uranium-235 were to fission, the energy released would be equivalent to the explosion of 20,000 tons of the chemical explosive trinitrotoluene (TNT). In a controlled nuclear reactor, k is kept equal to unity for steady-state operation. A practical reactor, however, must be designed with k somewhat greater than unity. This permits power levels to be increased if desired, as well as allowing for the following: the gradual loss of fuel by the fission process; the buildup of "poisons" among the fission products being formed that absorb neutrons and lower the k value; and the use of some of the neutrons produced for research studies or the preparation of radioactive species for various applications (see below). The value of k is controlled during the operation of a reactor by the positioning of movable rods made of a material that readily absorbs neutrons (*i.e.*, one with a high neutron-capture cross section), such as boron, cadmium, or hafnium. The delayed-neutron emitters among the fission products increase the time between successive neutron generations in the chain reaction and make the control of the reaction easier to accomplish by the mechanical movement of the control rods.

Fission reactors

Fission reactors can be classified by the energy of the neutrons that propagate the chain reaction. The most common type, called a thermal reactor, operates with thermal neutrons (those having the same energy distribution as gas molecules at ordinary room temperatures). In such a reactor the fission neutrons produced (with an average kinetic energy of more than 1 MeV) must be slowed down to thermal energy by scattering from a moderator, usually consisting of ordinary water, heavy water (D_2O), or graphite. In another type termed an intermediate reactor the chain reaction is maintained by neutrons of intermediate energy, and a beryllium moderator may be used. In a fast reactor fast fission neutrons maintain the chain reaction, and no moderator is needed. All of the reactor types require a coolant to remove the heat generated; water, a gas, or a liquid metal may be used for this purpose, depending on the design needs. For details about reactor types, see ENERGY CONVERSION: *Nuclear reactors.*

Uses of fission reactors and fission products. A nuclear reactor is essentially a furnace used to produce steam or hot gases that can provide heat directly or drive turbines to generate electricity. Nuclear reactors are employed for commercial electric-power generation throughout much of the world and as a power source for propelling submarines and certain kinds of surface vessels. Another important use for reactors is the utilization of their high neutron fluxes for studying the structure and properties of materials and for producing a broad range of radionuclides, which, along with a number of fission products, have found many different applications. Heat generated by radioactive decay can be converted into electricity through the thermoelectric effect in semiconductor materials and thereby produce what is termed an atomic battery. When powered by either a long-lived, beta-emitting fission product (*e.g.*, strontium-90, calcium-144, or promethium-147) or one that emits alpha particles (plutonium-238 or curium-244), these batteries are a particularly useful source of energy for cardiac pacemakers and for instruments employed in remote, unmanned facilities, such as those in outer space, the polar regions of the Earth, or the open seas. There are many practical uses for other radionuclides, as discussed above in *Applications of radioactivity.* (E.P.S.)

Atomic batteries

NUCLEAR FUSION

Nuclear fusion is the process by which nuclear reactions between light elements form heavier elements (up to iron) and, in most cases, result in the release of energy. Such reactions constitute the fundamental energy source of stars, including the Sun. Stellar evolution can be viewed as the passing of a star through various stages as thermonuclear reactions and nucleosynthesis cause compositional changes over long time periods. Hydrogen "burning" initiates the fusion energy source of stars and leads to the formation of helium. Generation of fusion energy for practical use also relies on fusion reactions between the lightest elements that burn to form helium. In fact, the heavy isotopes of hydrogen, deuterium ($^2_1$H, or D) and tritium ($^3_1$H, or T), react more efficiently with each other and yield more energy per reaction than do two hydrogen nuclei (protons) when they undergo fusion. The deuterium nucleus has one proton and one neutron, while that of tritium consists of a proton bound together with two neutrons.

Energy source of stars

Fusion reactions between light elements, like fission reactions that split heavy elements, release energy due to a key feature of nuclear matter. A parameter called the binding energy of the nucleus is a measure of the efficiency with which its constituent nucleons are bound together. Take, for example, an element with Z protons and N neutrons in its nucleus. The element's atomic mass number or atomic weight, A, is $Z + N$ and its atomic number is Z. The binding energy is the energy associated with the mass difference between the Z protons and N neutrons considered separately and the nucleons bound together ($Z + N$) in a nucleus of mass, M. The formula is

$$B = [Zm_p + Nm_n - M(Z,N)]c^2, \qquad (10)$$

where m_p and m_n are the proton and neutron masses, and c is the speed of light. It has been determined experimentally that the binding energy per nucleon is a maximum of about 8.8 MeV at an atomic mass number of approximately 60. Accordingly, the fusion of lighter elements or the splitting of heavier ones generally leads to a net release of energy.

History of fusion research and technology. The fusion process has been studied as part of nuclear physics for much of the 20th century. In the late 1930s the German-born physicist Hans A. Bethe first recognized that the fusion of hydrogen nuclei to form deuterium is exoergic (*i.e.,* there is a net release of energy) and, together with subsequent reactions, accounts for the energy source in stars. Work proceeded over the next two decades, motivated by the need to understand nuclear matter and forces, to learn more about the nuclear physics of stellar objects, and to develop thermonuclear weapons (the so-called hydrogen bomb) and predict their performance. During the late 1940s and early 1950s, research programs in the United States, United Kingdom, and Soviet Union began to yield a better understanding of nuclear fusion, and investigators embarked on ways of exploiting the process for practical energy production. This work focused on the use of magnetic fields and electromagnetic forces to contain extremely hot gases called plasmas. A plasma consists of unbound electrons and positive ions whose motion is dominated by electromagnetic interactions. It is the only state of matter in which thermonuclear reactions can occur in a self-sustaining manner. Astrophysics and magnetic fusion research, among other fields, require extensive knowledge of how gases behave in the plasma state.

Research on plasma containment

The inadequacy of the then-existent knowledge became clearly apparent in the 1950s as the behaviour of plasma in many of the early magnetic confinement systems proved too complex to understand. Moreover, researchers found that confining fusion plasma in a "magnetic trap" was far more challenging than they had anticipated. Plasma must be heated to tens of millions of degrees kelvin or higher to induce and sustain the thermonuclear reaction required to produce usable amounts of energy. At temperatures this high, the nuclei in the plasma move rapidly enough to overcome their mutual repulsion and fuse. It is exceedingly difficult to contain plasmas at such a temperature level because the hot gases tend to expand and escape from the enclosing structure (see below).

The work of the major American, British, and Soviet fusion programs was strictly classified until 1958. That year, research objectives were made public, and many of the topics being studied were found to be similar, as were the problems encountered. Since that time, investigators have continued to study and measure fusion reactions between the lighter elements and have arrived at more accurate determinations of reaction rates. Also, the formulas developed by nuclear physicists for predicting the rate of fusion-energy generation have been adopted by astrophysicists to derive new information about the structure of the stellar interior and about the evolution of stars.

The late 1960s witnessed a major advance in efforts to harness fusion reactions for practical energy production: the Soviets announced the achievement of high plasma temperature (about 3,000,000 K), along with other physical parameters, in a tokamak, a toroidal magnetic confinement system in which the plasma is kept generally stable both by an externally generated, doughnut-shaped magnetic field and by electric currents flowing within the plasma itself. (The basic concept of the tokamak had been first proposed by Andrey D. Sakharov and Igor Y. Tamm about 1950.) Since its development, the tokamak has been the focus of most research, though other approaches have been pursued as well. Employing the tokamak concept, physicists have attained conditions in plasmas that approach those required for practical fusion-power generation (see below).

The tokamak

Work on another major approach to fusion energy, called inertial confinement fusion (ICF), has been carried on since the early 1960s. Initial efforts were undertaken in 1961 with a then-classified proposal that large pulses of laser energy could be used to implode and shock-heat matter to temperatures at which nuclear fusion would be vigorous. Aspects of inertial confinement fusion were declassified in the 1970s, but a key element of the work—specifically the design of targets containing pellets of fusion fuels—still is largely secret. Very painstaking work to design and develop suitable targets continues today. At the same time, significant progress has been made in developing high-energy, short-pulse drivers with which to implode millimetre-radius targets. The drivers include both high-power lasers and particle accelerators capable of producing beams of high-energy electrons or ions. Lasers that produce more than 100,000 joules in pulses on the order of one nanosecond (10^{-9} second) have been developed, and the power available in short bursts exceeds 10^{14} watts. Best estimates are that practical inertial confinement for fusion energy will require either laser or particle-beam drivers with an energy of 5,000,000 to 10,000,000 joules capable of delivering more than 10^{14} watts of power to a small target of deuterium and tritium (see below).

Research on inertial confinement fusion

Types of fusion reactions. Fusion reactions are of two basic types: (1) those that preserve the number of protons and neutrons, and (2) those that involve a conversion between protons and neutrons. Reactions of the first type are most important for practical fusion-energy production, whereas those of the second type are crucial to the initiation of star burning. An arbitrary element is indicated by the notation ${}^{A}_{Z}\mathrm{X}$, where Z is the charge of the nucleus and A is the atomic weight. An important fusion reaction for practical energy generation is that between deuterium and tritium. It produces helium (${}^{4}_{2}\mathrm{He}$) and a neutron (${}^{1}_{0}n$); and is written

$$\mathrm{D} + \mathrm{T} \rightarrow \mathrm{He} + n. \tag{11}$$

To the left of the arrow (before the reaction), there are two protons and three neutrons. The same is true on the right. Another reaction, that which initiates star burning, is the fusion of two hydrogen nuclei to form deuterium:

$$\mathrm{H} + \mathrm{H} \rightarrow \mathrm{D} + \beta^{+} + \nu, \tag{12}$$

where β^{+} represents a positron and ν stands for a neutrino. Before the reaction, there are two hydrogen nuclei. Afterward, there is one proton and one neutron, bound together as the nucleus of deuterium, plus a positron and a neutrino produced as a consequence of the conversion of one proton to a neutron. Both fusion reactions (11) and (12) are exoergic and so yield energy. Bethe proposed that fusion reaction (12) could occur with a net release of energy and provide, along with subsequent reactions, the fundamental energy source sustaining the stars. Practical energy generation requires reaction (11) rather than (12) for two reasons: first, the rate of reactions between deuterium and tritium is much faster than that between protons; and, second, the net energy release from reaction (11) is 40 times greater than that from reaction (12).

Energy released in fusion reactions. Energy is released in a nuclear reaction if the total mass of the resultant particles is less than the mass of the initial reactants. To illustrate, suppose two nuclei, labeled X and a, react to form two other nuclei, Y and b, denoted

$$\mathrm{X} + \mathrm{a} \rightarrow \mathrm{b} + \mathrm{Y}, \tag{13}$$

or X(a,b)Y. The particles a and b are often nucleons, either protons or neutrons, but in general can be any nuclei. Assuming that none of the particles are internally excited (*i.e.,* are in their ground state), the energy quantity called the Q-value for this reaction is defined as

$$Q = (m_{\mathrm{x}} + m_{\mathrm{a}} - m_{\mathrm{b}} - m_{\mathrm{y}})c^{2}, \tag{14}$$

where the m-letters refer to the mass of each particle and c is the speed of light. If the energy value Q is positive, the reaction is exoergic. If Q is negative, the reaction is endoergic (*i.e.,* absorbs energy). When the total proton number and total neutron number are each preserved before and after the reaction (such as in reaction 11), then the Q-value can be expressed in terms of the binding energy, B, of each particle as

$$Q = B_{\mathrm{y}} + B_{\mathrm{b}} - B_{\mathrm{x}} - B_{\mathrm{a}}. \tag{15}$$

Fusion reaction (11) between deuterium and tritium has a positive Q-value of 17.58 MeV, which is equivalent to 2.8×10^{-12} joule. Fusion reaction (12) also is exoergic, with a Q-value of 0.420 MeV, or 6.7×10^{-14} joule. To develop a sense for these figures, one might consider that one metric ton (2,205 pounds) of deuterium atoms is equal to 3×10^{32} atoms. If one ton of deuterium is consumed through burning via fusion reaction (11) with

tritium, the energy released would be 8.4×10^{20} joules. This can be compared to the energy content of one ton of coal—namely, 2.9×10^{10} joules. In other words, one ton of deuterium has the energy equivalent of approximately 29,000,000,000 tons of coal.

Rate and yield of fusion reactions. The energy yield of a reaction between nuclei and the rate of such reactions are equally important. These quantities have a profound influence in both nuclear astrophysics and practical fusion-energy considerations. When a particle of one type passes through a collection of particles of the same or different type, there is a measurable chance that the particles will interact. The particles may interact in many ways, such as simply scattering, which means that they change direction and exchange energy. Or they may undergo a nuclear fusion reaction such as (11) or (12). The measure of the likelihood that particles will interact is called the cross section, σ. The cross section depends on the type of interaction and the state and energy of the particles. When σ is multiplied by the atomic density of target particles, N, the resultant product, $N\sigma$, is denoted Σ, the macroscopic cross section. The inverse of Σ is the mean distance an incident particle will travel before interacting with a target particle and is called the mean free path. The rate of interactions of a given type is ($vN\sigma$), where v is the speed of the incident particle. Cross sections are measured by producing a beam of one particle at a given energy, allowing the beam to interact with a (usually thin) target made of either the same or a different material, and measuring deflections or reaction products. In this way it is possible to determine the relative likelihood of one type of fusion reaction versus another, as well as the optimal conditions for a particular reaction.

The cross sections of fusion reactions can be measured experimentally or calculated theoretically and have been determined for many reactions over a wide range of particle energies. They are well known for practical fusion-energy applications and are reasonably well known, though with significant gaps, for stellar evolution. Fusion reactions between nuclei, each with a positive charge of one or more, are the most important for both practical applications and the nucleosynthesis of the light elements in the burning stages of stars. Yet, it is well known that two positively charged nuclei electrostatically repel each other—*i.e.*, they experience a repulsive force inversely proportional to the square of the distance separating them. This repulsion is called the Coulomb barrier. It is highly unlikely that two positive nuclei will approach each other closely enough to undergo a fusion reaction unless they have sufficient energy to overcome the Coulomb barrier. As a result, the cross section for fusion reactions between charged particles is very small unless the energy of the particles is high, at least 10^4 eV and often more than 10^5 or 10^6 eV. This explains why the centre of a star is hot and why fuel material for practical fusion energy must be heated to 50,000,000 K or more. Only then will a reasonable fusion reaction rate and power output be achieved.

Significance of the Coulomb barrier

The phenomenon of the Coulomb barrier also explains a fundamental difference between energy generation by nuclear fusion and nuclear fission. While fission of heavy elements can be induced by either protons or neutrons, generation of fission energy for practical applications is dependent on neutrons to induce fission reactions in uranium or plutonium. Having no electric charge, the neutron is free to enter the nucleus even if its energy corresponds to room temperature. Fusion energy, relying as it does on the fusion reaction between light nuclei, occurs only when the particles are sufficiently energetic to overcome the Coulomb repulsive force. This requires the production and heating of the gaseous reactants to the high temperature state known as the plasma state.

Plasma state. Gas containing unbound electrons and an equal amount of positive charge constitutes plasma, which is commonly considered the fourth state of matter. Very high temperature plasmas are fully ionized gases, which means that the ratio of neutral gas atoms to charged particles is extremely small. For example, the ionization energy of hydrogen is 13.6 eV, while the average energy of a hydrogen ion in a plasma at 50,000,000 K is 6,462 eV. One can reasonably expect that essentially all of the hydrogen in this plasma is ionized.

Fully ionized gases

A reaction-rate parameter more appropriate to the plasma state is obtained by accounting for the fact that the particles in a plasma, as in any gas, have a distribution of energies. That is to say, not all particles have the same energy. In simple plasmas, this energy distribution is called the Maxwell–Boltzmann distribution, and the temperature of the gas or plasma is defined to be two-thirds of the average particle energy—*i.e.*, the relationship between the average energy, denoted $\bar{E}$, and temperature is $\bar{E} = (3/2)kT$. The quantity k is the Boltzmann constant, 8.62×10^{-5} eV per kelvin. The intensity of nuclear fusion reactions in a plasma is derived by averaging the quantity, $v\sigma$, over a distribution of speeds corresponding to a Maxwell–Boltzmann distribution. The cross section for the reaction depends on the energy or speed of the particles. The averaging process yields a function for a given reaction that depends only on the temperature and can be denoted $f(T)$. The rate of energy released (*i.e.*, the power released) in a reaction between two species, a and b, is

$$P_{ab} = n_a n_b f_{ab}(T) U_{ab}, \tag{16}$$

where n_a and n_b are the density of species a and b in the plasma, respectively, and U_{ab} is the energy released each time a and b undergo a fusion reaction. The parameter P_{ab} properly takes into account both the rate of a given reaction and the energy yield per reaction (see Figure 32).

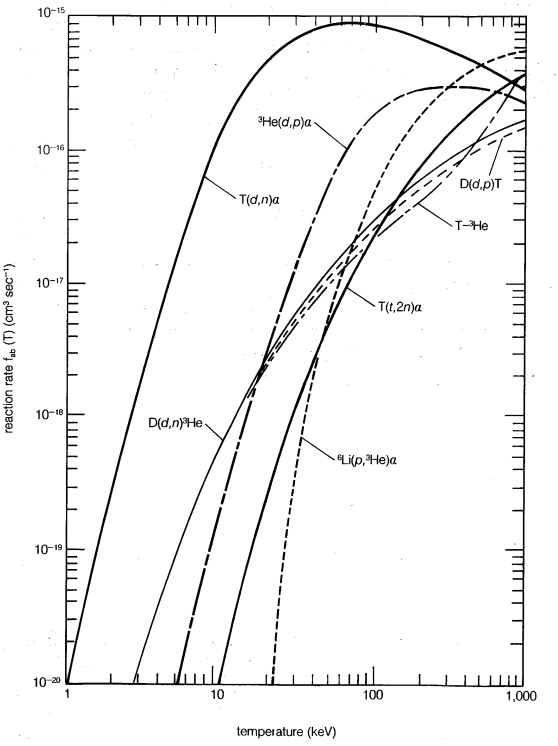

Figure 32: *The reaction rate as a function of plasma temperature, expressed in kiloelectron volts (keV).*
One keV is equivalent to a temperature of 11,000,000 K. The rate of reaction between deuterium and tritium is seen to be higher than all others and is very substantial, even at temperatures in the 5- to 10-keV range (see text).

Fusion reactions in stars. Fusion reactions are the primary energy source of stars and the mechanism for the nucleosynthesis of the light elements. The synthesis of helium from hydrogen is the main source of energy emitted by normal stars, such as the Sun, where the burning-core plasma has a temperature of less than 15,000,000 K. However, because the gas from which the star is formed often contains some heavier elements, notably carbon and nitrogen, it is important to include nuclear reactions between protons and these nuclei. The reaction chain between protons that ultimately leads to helium is the proton-proton (*pp*) chain. When protons also induce the burning of carbon and nitrogen, the CN cycle must be considered; and

Mechanism for nucleosynthesis

when oxygen is included, still another alternative scheme, the CNO bi-cycle must be accounted for.

The proton-proton nuclear fusion cycle in a star containing only hydrogen begins with the reaction

$$H + H \rightarrow D + \beta^+ + \nu; \qquad Q = 1.44 \text{ MeV}, \qquad (17)$$

where the Q-value assumes annihilation of the positron by an electron. The deuterium could react with other deuterium nuclei, but because there is so much hydrogen, the D/H ratio is held to very low values, typically 10^{-18}. Thus the next step is

$$H + D \rightarrow {}^3He + \gamma; \qquad Q = 5.49 \text{ MeV}, \qquad (18)$$

where γ indicates that gamma rays carry off some of the energy yield. The burning of the helium-3 isotope then gives rise to ordinary helium and hydrogen via the last step in the chain:

$${}^3He + {}^3He \rightarrow {}^4He + 2(H); \qquad Q = 12.86 \text{ MeV}. \qquad (19)$$

At equilibrium, helium-3 burns predominantly by reactions with itself because its reaction rate with hydrogen is small, while burning with deuterium is negligible due to the very low deuterium concentration. Once helium-4 builds up, reactions with helium-3 can lead to the production of still heavier elements, including beryllium-7, beryllium-8, lithium-7, and boron-8, if the temperature is greater than about 10,000,000 K.

The stages of stellar evolution are the result of compositional changes over very long periods. The size of a star, on the other hand, is determined by a balance between the pressure exerted by the hot plasma and the gravity force of the star's mass. The energy of the burning core is transported toward the surface of the star, where it is radiated at an effective temperature. The effective temperature of the Sun's surface is about 6,000 K, and significant amounts of radiation in the visible and infrared wavelength range are emitted.

Fusion reactions for controlled power generation. Reaction (11) between deuterium and tritium is one of the most important fusion reactions for controlled power generation, because the cross section for its occurrence is high, the practical plasma temperature required for the net energy release is moderate, and the energy yield of the reaction is high—17.58 MeV. Important reactions of this type involving deuterium include

$$D + T \rightarrow {}^4He + n; \qquad Q = 17.58 \text{ MeV}, \qquad (20)$$

$$D + D \xrightarrow{50\%} {}^3He + n; \qquad Q = 3.32 \text{ MeV} \qquad (21a)$$

$$D + D \xrightarrow{50\%} H + T; \qquad Q = 4.04 \text{ MeV}, \qquad (21b)$$

$$D + {}^3He \rightarrow H + {}^4He; \qquad Q = 18.34 \text{ MeV}. \qquad (22)$$

It should be noted that any plasma containing deuterium automatically produces some tritium and helium-3 from reactions of deuterium with other deuterium reactions. Significant too is the fact that reactions (11) and (21a) both produce a neutron, whereas reactions (21b) and (22) yield only charged nuclei as reactant products. The practical application of reactions (21a and 21b) or (22) would require plasmas that are three to 10 times hotter than a plasma burning deuterium and tritium, and the D-T plasma would burn 10 to 100 times as fast. Other fusion reactions involving elements with an atomic number (nuclear charge) above 2 can be used but with much greater difficulty. This is because the Coulomb barrier increases with increasing charge of the nuclei, leading to the requirement that the plasma temperature exceed 1,000,000,000 K. Some of the more interesting reactions are

$$H + {}^{11}B \rightarrow 3\,({}^4He); \qquad Q = 8.68 \text{ MeV}, \qquad (23)$$

$$H + {}^6Li \rightarrow {}^3He + {}^4He; \qquad Q = 4.023 \text{ MeV}, \qquad (24)$$

$${}^3He + {}^6Li \rightarrow H + 2({}^4He); \qquad Q = 16.88 \text{ MeV} \qquad (25a)$$

$${}^3He + {}^6Li \rightarrow D + {}^7Be; \qquad Q = 0.113 \text{ MeV}. \qquad (25b)$$

Reaction (24) converts lithium-6 to helium-3 and ordinary helium. Interestingly, if reaction (24) is followed by reaction (25a), then a proton would again be produced and be available to induce reaction (24), thereby propagating the process. Unfortunately, it appears that reaction (25b) is 10 times more likely to occur than reaction (25a).

Methods of achieving fusion energy. Practical efforts to achieve fusion energy involve either of two basic approaches to contain and sometimes sustain a hot plasma of elements that undergo nuclear fusion reactions: magnetic confinement and inertial confinement.

Magnetic confinement. In this approach, the particles and energy of a hot plasma are confined using magnetic fields. A charged particle in a magnetic field experiences a Lorentz force that is proportional to the product of the particle's velocity and the magnetic field. This force causes electrons and ions to spiral about the direction of the magnetic line of force, thereby confining the particles. When the topology of the magnetic field yields an effective magnetic well and the pressure balance between the plasma and the field is stable, plasma can be confined away from material boundaries. Heat and particles are transported both along and across the field, but losses can be prevented in two ways. The first is to increase the strength of the magnetic field at two locations along the field line. Charged particles contained between these points can be made to reflect back and forth, an effect called magnetic mirroring. In a basically straight system with a region of intensified magnetic field at each end, particles can still escape through the ends due to scattering between particles as they approach the mirroring points. Such end losses can be avoided altogether by creating a magnetic field in the topology of a torus (*i.e.*, configuration of a doughnut or inner tube).

External magnets can be arranged to create a magnetic field topology for stable plasma confinement, or they can be used in conjunction with magnetic fields generated by currents induced to flow in the plasma itself. Many schemes have been devised over the years, but the most successful approaches have proved to be toroidal magnetic confinement designs. Examples include the tokamak, pioneered in the Soviet Union and characterized by both a strong externally produced magnetic field and a plasma current in the toroidal direction; the stellarator, pioneered in the United States and involving the use of external magnets only; and the reversed-field pinch (RFP), pursued mainly in the United States, the United Kingdom, and Italy and employing a weak toroidal magnetic field and a strong toroidally flowing plasma current. All three approaches yield magnetic field lines that follow a helical or screwlike path as the lines proceed around the torus. In the tokamak and stellarator, the pitch of the helix is weak, passing several times around the torus before the starting point returns past the initial position. By contrast, the RFP field lines trace out a path much more like a screw, wrapping many times around the cross section before covering one full length of the torus along the toroidal axis. Magnetically confined plasma must be heated to temperatures at which nuclear fusion is vigorous, typically greater than 4,400 eV, or equivalently about 75,000,000 K. This can be achieved by coupling radio-frequency waves to the plasma particles, by injecting energetic beams of neutral atoms that become ionized and heat the plasma, by magnetically compressing the plasma, or by the Joule-heating that occurs when plasma resistance dissipates the energy of electric currents induced to flow in the plasma.

Toroidal magnetic confinement designs

Inertial confinement fusion (ICF). In this approach, a fuel mass is compressed rapidly to densities 1,000 to 10,000 times greater than normal by generating a pressure as high as 10^{17} pascals (10^{12} atmospheres) for periods as short as nanoseconds. Near the end of this time period the implosion speed exceeds about 3×10^5 metres per second. At maximum compression of the fuel, which is now in a cool plasma state, the energy in converging shock waves is sufficient to heat the very centre of the fuel to temperatures high enough to induce fusion reactions. If the product of mass and size of this highly compressed fuel material is large enough, energy will be generated through fusion reactions before the plasma disassembles. Under proper conditions, much more energy

Compressing and shock-heating fuel material

can be released than is required to compress and shock-heat the fuel to thermonuclear burning conditions. The physical processes in ICF bear a relationship to those in thermonuclear weapons and in star formation—namely, gravitational collapse, compression heating, and the onset of nuclear fusion. The situation in star formation differs in one respect: after gravitational collapse ceases and a star begins to expand again due to heat from exoergic nuclear fusion reactions, the expansion is arrested by the gravity force associated with the enormous mass of the star. In a star a state of equilibrium in both size and temperature is achieved. In ICF, by contrast, complete disassembly of fuel occurs.

Conditions for practical fusion yield. Two conditions must be met to achieve a practical yield of fusion energy. First, the plasma temperature must be high enough so that fusion reactions occur at a sufficient rate. Second, the energy content of the plasma at the required temperature must be confined long enough so that the energy released by fusion reactions, when deposited in the plasma, is sufficient to maintain the temperature against heat lost by such phenomena as conduction, convection, or radiation. When this condition is first achieved, the plasma is said to be ignited. At such a temperature or higher, the energy redeposited in the plasma from fusion reactions is capable of balancing or exceeding the rate of plasma heat loss. In the case of stars or some approaches to fusion by magnetic confinement, a steady state can be achieved and no energy beyond that from fusion reactions is needed to sustain the system. In other cases, such as the ICF approach, there is a large temperature excursion once fuel ignition is achieved. The energy yield can far exceed the energy required to attain plasma ignition conditions. The energy yielded, however, is released in a burst, and the process would have to be repeated roughly once every second.

The conditions for plasma ignition are readily derived. When fusion reactions are occurring in a plasma, the power released is given by expression (16), which is proportional to the square of plasma ion density, n^2. The plasma loses energy when electrons scatter from positively charged ions, accelerating and radiating in the process. Such radiation is called bremsstrahlung and is proportional to $(n^2T^{1/2})$, where T is the plasma temperature. Assume that all other mechanisms by which heat can escape the plasma lead to a characteristic energy-loss time denoted τ. The energy content of the plasma at temperature T is $3nkT$, where k is the Boltzmann constant (see above). The rate of energy loss by mechanisms other than bremsstrahlung is simply $(3nkT)/(\tau)$. The energy balance of the plasma is the balance between the fusion energy heating the plasma and the energy loss rate, which is the sum of $3nkT/(\tau)$ and the bremsstrahlung. The condition satisfying this balance is called the ignition condition. An equation relates the product of density and energy confinement time, denoted $n\tau$, to a function that depends only on the plasma temperature and the type of fusion reaction. For example, when the plasma is composed of deuterium and tritium, the smallest value of $n\tau$ required to achieve ignition is about 2×10^{20} (particles per cubic metre times second, or m^{-3}—s) and the required temperature is equal to about 25,000 eV. If the only energy losses are due to bremsstrahlung escaping from the plasma (meaning τ is infinite), the ignition temperature decreases to 4,400 eV. Hence, the keys to generating usable amounts of fusion energy are to attain a sufficient plasma temperature and a sufficient confinement quality, as measured by the product, $n\tau$. At a temperature equivalent to 10,000 eV, the $n\tau$ product must be about 3×10^{20} (m^{-3}—s).

Energy loss by bremsstrahlung

Magnetic fusion energy generally creates plasmas with a density of about 3×10^{20} particles per cubic metre, which is about 10^{-8} of normal density. Hence, the characteristic time for heat to escape must be greater than about one second. This is a measure of the required degree of "magnetic" insulation for the heat content. Under these conditions the plasma remains in energy balance and can operate continuously if the ash of the nuclear fusion, namely helium, is removed (otherwise it will quench the plasma) and if fuel is replenished.

ICF creates plasmas of much higher density, generally about 10^{31} to 10^{32} particles per cubic metre, or 1,000 to 10,000 times normal density. As such, the confinement time need be only about 20×10^{-12} second, or 20 picoseconds. The objective in ICF is to achieve a temperature of 4,400 eV at the centre of the highly compressed fuel mass while still having sufficient mass left around the centre so that the disassembly time will exceed the minimum burn time of 20 or more picoseconds. The requirement is usually expressed in terms of the product of the mass density, ρ, given in grams per cubic centimetre, and the radius, r, of the compressed fuel mass. An $n\tau$ value of 3×10^{20} (m^{-3}—s) is roughly equal to a value of ρr of 0.3 gram per square centimetre.

Fusion energy and electric-power production. Practical fusion reactors are not yet available because the physics of containing and heating plasmas to thermonuclear conditions in a controlled manner has proved extraordinarily difficult. Large-scale fusion experiments, however, have been conducted in various countries, and the necessary conditions of plasma temperature and heat insulation have been largely achieved, suggesting that fusion energy for electric-power production is now a serious possibility.

Commercial fusion-power stations would provide an inexhaustible source of electricity. A facility of this type would of course derive its primary energy from nuclear fusion in a hot plasma. The reaction easiest to initiate is that between deuterium and tritium, though ultimately commercial fusion-power stations may employ other reactions, such as between deuterium nuclei or between deuterium and helium-3. Perhaps some of the other reactions discussed earlier will prove feasible as well. The use of deuterium as the primary fuel seems to be the most promising option, however, since it can be extracted at relatively low cost from ordinary water.

From a practical viewpoint, the initiation of nuclear fusion in a hot plasma is but the first step in a whole sequence of steps required to convert fusion energy to electricity. The intervening steps in this process would transform the fusion energy into heat at conditions appropriate, for example, to generate steam that can be employed in a Carnot cycle to drive a turbine and produce electricity. An alternative but more difficult approach may be possible in some fusion systems. The products of fusion reactions are often energetic charged nuclei, as, for example, the doubly charged helium-4 produced in reaction (11) or the proton and helium-4 released in reaction (22). The energy of these charged particles can be converted directly to electricity. The particles must be guided magnetically to a system that decelerates their initially high energy, extracting the energy as a voltage. By decelerating the particles to a lower voltage and collecting them as a current, electric power equal to the voltage difference times the collected current can be generated. The efficiency of such direct conversion can be considerably higher than the roughly 40-percent efficiency obtained in converting steam heat to electricity. This approach of direct conversion, however, is likely to be feasible only in a few specialized approaches to fusion energy. In the end, successful fusion reactors must be capable of safely producing electricity in a cost-effective manner while yielding a minimum of radioactive material and environmental impact. (Ro.W.C.)

RAEDER *et al., Controlled Nuclear Fusion: Fundamentals of Its Utilization for Energy Supply* (1986; originally published in German, 1981), an introduction to fusion energy, its technology, and the engineering aspects of conceptual fusion power reactors; ROBERT W. CONN, "The Engineering of Magnetic Fusion Reactors," *Scientific American,* 249(4):60–71 (Oct. 1983), a descriptive article on the technology of fusion machines and future fusion-energy reactors; R. STEPHEN CRAXTON, ROBERT L. MCRORY, and JOHN M. SOURES, "Progress in Laser Fusion," *Scientific American,* 255(2):68–79 (Aug. 1986), a description of inertial confinement fusion and specifically laser fusion; and EDWARD TELLER (ed.), *Fusion,* vol. 1, *Magnetic Confinement,* 2 vol., pt. A and B (1981), a series of technical articles on confinement approaches to fusion, such as the tokamak, stellarator, and magnetic mirror, and on the technology of fusion energy. (Ro.W.C.)

Attention

Attention, in psychology, is awareness of the here and now in a focal and perceptive way. For early psychologists, such as Edward Bradford Titchener, attention determined the content of consciousness and influenced the quality of conscious experience. In subsequent years less emphasis was to be placed on the subjective element of consciousness and more on the behaviour patterns by which attention could be recognized in others. Although human experience is determined by the way people deploy attention, it is evident that they do not have complete control over such deployment. There are, for example, times when an individual has difficulty in maintaining as much attention on a task, a conversation, or other set of events as he would desire. There are other times when an individual's attention is "captured" by an unexpected event rather than voluntarily directed toward it.

Attention has to do with the immediate experience of the individual; it is a state of current awareness. There are, of course, myriad events taking place in the world all of the time, impinging upon people's senses in great profusion. There are events taking place within the body affecting attention, and there are representations of past events stored away in memory but accessible to awareness under appropriate circumstances.

At first sight it might be expected that current awareness is the totality of all those events at any given moment, but clearly this is not the case. Within this vast field of potential experiences an individual focuses upon—or attends to—some limited subset, which constitutes the subjective field of awareness. It is possible to determine the reason for this limitation. Control and coordination of the many inputs and stored experiences and the organization of appropriate patterns of response are the province of the brain. The brain has impressive processing capabilities, but it has a limited capacity. A person simply cannot consciously experience all of the events and information available to him at any one time; nor is it possible to initiate at the same time an unlimited number of different actions. The question becomes one of how an appropriate subset of inputs, intermediate processes, and outputs are selected to command attention and engage available resources.

Attention, then, may be conceived as a condition of selective awareness, governing the extent and quality of man's transactions with his environment, although it is not necessarily held under voluntary control. Some of the history of attention and the methods by which psychologists and others have come to characterize and understand it are presented in the discussion that follows.

This article is divided into the following sections:

EARLY VIEWS ON ATTENTION

Following the break between psychology and the introspective traditions of philosophy, psychologists began in the latter part of the 19th century and early years of the 20th century to emphasize attention. Those philosophers who had previously considered attention at all had usually done so within the context of apperception. Thus Gottfried Wilhelm Leibniz suggested that one's loss of awareness of the constant sound of a waterfall illustrates how events cease to be apperceived (represented in consciousness) without specific attention. He suggested that attention determines what will and will not be apperceived. The term apperception was still employed in the 19th century by Wilhelm Wundt, one of the founders of modern psychology. Wundt, however, was among the first to point out the distinction between the focal and more general features of human awareness of the world. He wrote of the wide field of awareness (which he called the *Blickfeld*) within which lay the more limited focus of attention (the *Blickpunkt*). He suggested that the range of the *Blickpunkt* was about six items or groups and speculated that attention is a function of the frontal lobes of the brain.

The concept of apperception

One of the most influential psychologists at the turn of the century was William James. In his major work, *The Principles of Psychology,* published in 1890, he says:

> Every one knows what attention is. It is the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. Focalization, concentration, of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others, . . .

James held that attention made humans perceive, conceive, distinguish, and remember more effectively and sped their reactions.

In 1906, another prominent psychologist, W.B. Pillsbury, suggested methods for measuring attention. He distinguished three separate approaches: the first relied upon tests that measured attention through performance of a task judged to require a high degree of attention; the second measured diminished attention through performance decrements; and the third gauged the strength of attention by the stimulus level required to distract the individual.

As the 20th century progressed, psychology and the study of behaviour were subject to new influences that had far-reaching consequences for notions of attention. One such area of influence originated in the work of Ivan Petrovich Pavlov who reported what is now usually referred to as the orienting response. In dogs and other animals this includes such signs of attention as pricked-up ears, turning the head toward the stimulus, increased muscular tension, and physiological changes detectable with instruments. A further influence on psychology was the work of Pavlov and that of his fellow Russian Vladimir M. Bekhterev on reflexology. Many psychologists came to regard the conditioned reflex (an involuntary response conditioned by reward), first demonstrated by these physiologists, as the basic building block of all human learning.

The influence of Pavlov

THE INFLUENCE OF BEHAVIOURISM

During this period the psychological school of behaviourism was born. Its principal advocate, John B. Watson, in 1913 defined psychology uncompromisingly as the science of human behaviour. His concern was primarily with stimulus–response relations. Attention seemed an unnecessary concept in a system of this kind, which rejected mentalistic notions, such as volition, free will, introspection, and consciousness. If used at all, the term attention was operationally defined in terms of discriminative responses to external stimuli. Ultimately it became apparent that the scientific explanations offered did not deal adequately with situations in which multiple stimuli compete with one another for attention. This led to emphasis' being placed on notions of set, attitude, and expectancy, and to a renewed interest in attention.

RELATION TO INFORMATION THEORY

Interest in attention had been subdued between World Wars I and II, and it was not until the 1940s that a true resurgence occurred. It was during this time that engineers and psychologists became involved in problems of man–machine interaction in various military contexts and found a need to formulate a new communications theory. Faced with this new range of problems, such as maintaining vigilance in soldiers watching radar systems, applied psychologists found no help in existing academic theories. As the occupational psychologist D.E. Broadbent expressed it, "attention had to be brought back into respectability." Gradually the individual came to be viewed as a processor of information, and much of the research during the 1940s and 1950s was carried out in pursuit of information theory.

Renewed interest in the 1940s and 1950s

Dependence of attention both on the unexpectedness of events and on their familiar association may seem paradoxical. This may be resolved, or at least redefined, by considering events in relation to the information they convey. Information theory suggests that the significance of any event can only be estimated in terms of what else might have happened; hence, its tendency to attract attention is considered a function of its statistical improbability. The degree of novelty, which is estimated according to the number of times an event has been experienced previously, provides a measure of its surprise value. Thus an event that has never been experienced before has a high surprise value and should attract attention, even without specific associations or consequences.

The attempts to apply information theory to a diversity of psychological problems met in the end with limited success. Nevertheless, the view of the human brain as an information processor, a type of computer, was becoming more prevalent, and the notion that one might be able to quantify the gain or flow of information proved attractive. Information itself was defined as that which reduces or removes uncertainty. The process of removing uncertainty was seen as a series of binary (yes or no) choices, rather like the game of Twenty Questions. The unit of information that expressed this primitive choice between two alternatives, or halving the residual uncertainty, was called the bit (short for binary digit). In the terms of this theory, humans are seen as a communication channel, through which information is transmitted at the rate of so many bits per second. Attempts were made to measure the capacity of this channel in many areas of human activity, but ultimately these attempts became fewer as the results were found to be too inconsistent to be useful. Finally, cognitive psychologists largely abandoned information theory, recognizing the incalculable effect of past experience on the information carried by any bit.

The brain as a computer

THE FILTER THEORY OF SELECTIVE ATTENTION

Following the decline of behaviourism in psychology, the main function of the term attention has been to provide a label for some of the internal mechanisms that determine the significance of stimuli. There is little dispute that human beings and other animals selectively attend to some of the information available to them through their senses at the expense of the remainder. One reason advanced for this is the limited capacity of the brain, which cannot process all available information simultaneously.

The perennial question arises as to whether an individual can attend to more than one thing at a time. Everyday experience leads to the conclusion that people are able to do several things at the same time. When driving an automobile they can apparently watch the road, turn the steering wheel, change gears, and apply the brakes simul-

taneously if necessary. This is not to say, however, that people attend to all of these activities simultaneously. It may be that only one of them, such as the road or its traffic, is at the forefront of awareness, while the others are dealt with relatively automatically. Another kind of evidence indicates that, when two stimuli are presented at the same time, quite frequently only one is perceived, while the other is completely ignored. In those instances when both are perceived, the responses made to them tend to be in succession, not together.

The conclusion reached and embodied in theories of the 1950s was that somewhere in the system was a bottleneck. Views differed as to where the bottleneck occurred. One of the most influential of the psychological models of selective attention was that put forward by Broadbent in 1958. He postulated that the many signals entering the central nervous system in parallel with one another are held for a very short time in a temporary "buffer." At this point the signals are analyzed for features such as their location in space, their tonal quality, their size, their colour, or other basic physical properties. They then pass through a selective "filter" that allows only those signals with the appropriate, selected properties, to proceed along a single channel for further analysis. Part of the lower priority information held in the buffer will fail to pass this stage before the time limit on the buffer expires. Items lost in this way have no further effect on behaviour. The original theory held that signals from only one source at a time could proceed. This view was modified, however, to suggest that the filter does not completely block, but simply attenuates, the nonattended signals.

Broadbent's "filter" theory

With the notion of attenuation, rather than exclusion, of nonattended signals came the idea of the establishment of thresholds. Thus threshold sensitivity might be set quite low for certain priority classes of stimuli, which, even when basically unattended and hence attenuated, may nevertheless be capable of activating the perceptual systems. Examples would be the sensitivity displayed to hearing one's own name spoken or the mother's sensitivity to the cry of her child in the night. This latter example demonstrates how processing at some level occurs even in sleep. Before attention can be said to be deployed on the activating event, however, the brain must return to a state of wakefulness. Some theorists have considered that there is no real need to postulate an early filter at all. They suggest that all signals reach central brain structures, which are, according to current circumstances, weighted to take account of particular properties. Some have a high weighting, for example, in response to one's own name; others are weighted according to the immediate task or interest. Among the concurrently active structures, that with the highest weighting gains awareness and is most directly responded to.

The information weighting system

Some critics of the above theories consider that they overemphasize the serial elements in attention. Apart from the everyday instances of tasks performed in parallel, as in the example of driving, they point to experimental evidence for highly demanding combinations of concurrent activities. As early as 1887 the French philosopher Frédéric Paulhan reported the ability to write one poem while reciting another. More recently it has been shown that some music students can sight read and play piano music while at the same time repeating aloud a prose passage. Of course it can still be held that when two such tasks are being performed together one of them is being done automatically and essentially without direct attention. An alternative explanation might be that attention alternates between them in a rapid, and frequently imperceptible, way. An analogy would be "time-sharing" on a large modern computer, where many users may be in simultaneous contact with the machine, although it is in practice servicing their demands in very rapid alternation. Each user remains relatively unaware that the interactive process is not absolutely continuous.

Another criticism of the theories already considered is that they deal only with the passive aspects of attention and that there is more to attention than mere selection. Such critics point out that there is also the question of the degree or intensity with which attention is applied to a particular task or situation. These "intensive" aspects of attention may be regarded as a subset of the broader dimension of arousal; that is to say, they relate to the continuum of awareness that extends from sleep, or even coma, at one end to alert wakefulness at the other. The topic of arousal is discussed later; for the present it is sufficient to note that the level of arousal can be determined by the demands of the task or activity in which the individual is engaged or by internal states; these are sometimes manifested as instinctive drives and frequently accompanied by high emotions, ranging from keen excitement to unpleasant stress. In the case of some drive states the high arousal may be directed to the satisfaction of a particular need. The consequences for attention can be the allocation of a high priority, or weighting, to all stimuli that relate to satisfaction of the need.

The intensity of attention

By contrast, the level of arousal associated with a particular task varies from moment to moment as the task demands change; in other words, it is very much dependent upon overall stimulus load. One of the consequences of high-demand tasks is that spare capacity decreases. At full load, virtually all attention must be concentrated on the main task, leaving little attention available for perceptual monitoring of the surrounding.

In recent years the direction of attention in response to task demands has often been spoken of in terms of the deployment of mental effort. The implication is that the intensive aspects of attention correspond to effort rather than just wakefulness. Effort, like arousal, is subject to task demands and available capacity. It is regarded as being mobilized in response to such demands, although the degree of voluntary control of effort is limited. Effort is not simply to be equated with the amount of work required by a task. Much mental activity takes place without the investment of a large amount of conscious effort.

Attempts to accommodate the selective and intensive aspects of attention and its links with both awareness and more automatic processes have led to the formulation of a number of "two-process" theories of attention. One of the most influential was that advanced by the American psychologists Richard M. Shiffrin and Walter Schneider in 1977 on the basis of experiments involving visual search. In their theory of detection, search, and attention, they distinguish between two modes of processing information: controlled search and automatic detection. Controlled search is highly demanding of attentional capacity and is usually serial in nature. It is easily established and is largely under the individual's control in that it can be readily altered or even reversed. It is strongly dependent on load. It has been suggested that it uses short-term brain storage. By contrast, automatic detection, or automatic processing, operates in long-term memory and is dependent upon extensive learning. It comes into operation without active control or attention by the individual, it is difficult to alter or suppress, and it is virtually unaffected by load. An example of controlled search would be having to identify, say, the letters *k, t,* and *v* in an array of many different letters. Automatic detection, by contrast, is exemplified by having to identify instances of, say, the number 4 in an array of letters, all of which are *c.*

The automatic and focal modes

Broadly speaking the two types of attention can be characterized as focal and automatic. Someone who is focally attentive is highly aware, consciously in control, and selective in handling sensory phenomena. A person in such a state is also employing his brain for short-term storage. (Indeed, some focal attention is almost certainly necessary for storing information in the memory at all.) Focal attention is flexible but makes great demands on brain capacity. Automatic attention makes fewer demands but is relatively inflexible. Although it deploys well-learned skills swiftly and smoothly—even when they are quite complex—it cannot cope with the unexpected. Automatic attention is largely uncontrolled, although its workings may possibly be modified by changes in the threshold at which it is triggered. The focal and automatic modes may be illustrated by a driving example: a new driver has to attend to gear-shifting in a focal way—actively thinking about it; an experienced driver, on the other hand, changes gears automatically—not having to think about it.

Attention and memory

An important aspect of the control process in many circumstances is rehearsal, meaning here the mental repetition of incoming information. One consequence of rehearsal is that input items spend an extended period of time in the short-term memory store. It is also generally the case that what is attended to and rehearsed is what is eventually stored in long-term memory, suggesting a close relationship between the conditions for awareness and those for storage in memory. Evidence for learning during sleep has sometimes been cited as contradicting this assertion that people remember only those things of which they were consciously aware at the time they occurred. It is now generally accepted, however, that the original evidence for sleep learning was suspect. In subsequent studies, when more stringent electrophysiological measures were made to ensure that individuals were in fact asleep, no clear evidence for learning during sleep could be found. There has been an indication that some type of conditioning may be possible during sleep, but, generally, awareness appears to be necessary for learning to take place.

As already noted, one of the conditions for becoming aware, or selectively engaged, is when current expectations are violated. Just as people learn skills to the point where they become subject to automatic programs of input and ouput processing, they also encode current experience into patterns of expectation that, as long as they continue to be fulfilled, need not engage focal processing resources. On entering a room a person may be aware of the regular one-second tick of a grandfather clock, but soon it fades from awareness as other things command attention. One is likely to remain unaware of it unless it stops and established expectations are violated, or unless other demands upon attention drop to the point where the person has sufficient spare focal capacity to monitor the environment more directly and again becomes at least partially aware of the sound.

Measurement of repetitive stimuli

The basic mechanism whereby response to novelty wanes with repeated and regular presentation of the same signal is usually referred to as habituation. Thus habituation may be described as a progressive loss of behavioral responsivity to a stimulus as its lack of adaptive significance is discovered. Repetition of the signal merely serves to facilitate this discovery and confirm the inappropriateness of deploying further attention upon it. In practice, the shorter the interval of time between signals the more rapidly responsiveness drops. Naturally, if the signals have special significance for the individual, they will continue to be attended to and responded to even though they may be repetitive. For example, if, to check its accuracy, a person counts the ticks of the clock, habituation to the tick will not take place. In other circumstances where stimuli have special signal properties, habituation may take place, but only very slowly. Among the factors that can affect the magnitude of response to a signal and the rate at which habituation takes place is the intensity of the signal; for example, its loudness or brightness. Although such response enhancement and resistance to habituation are primarily linked with increased stimulus intensity, they can also occur in reaction to quite faint signals, close to the threshold at which they are experienced. These observations of changes in attention with time and signal properties raise the wider question of how attention behaves over long periods of time.

VIGILANCE

Sustained attention, or vigilance, as it is more often called, refers to the state in which attention must be maintained over time. Often this is to be found in some form of "watchkeeping" activity when an observer, or listener, has continuously to monitor a situation in which significant, but usually infrequent and unpredictable, events may occur. An example would be watching a radar screen in order to make the earliest possible detection of a blip that might signify the approach of an aircraft or ship.

Attention decline during vigilance

Vigilance is difficult to sustain, however. Over any given time individuals become increasingly poor at detecting infrequent signals, and measurement of this forms the basis for studying vigilance. No single theory explains vigilance satisfactorily, probably because of its complexity. In the first place, there is a clear distinction between sustaining attention in a detection task, where the overall work load is high, and sustaining it when little is happening except for the occasional looked-for events. Under both conditions performance can show a decline over time. An important factor is the allocation of neural resources to deal with the task. These resources are to some extent fixed by virtue of the limits on processing capacity already mentioned. When the task is complex, detection difficult, time limited, and a series of decisions in using variable data is required, the brain may not succeed in coping. Long, boring, and for the most part uneventful tasks result in lowered performance with regard to both speed and accuracy in detecting looked-for events. If the task is interesting or is taking place in a stimulating environment, it is easier to sustain attention and maintain performance.

Among the factors that influence vigilance performance, the frequency with which task-relevant events occur is among the most important. Generally speaking, the more frequent the events are the better is the performance; long periods of inactivity constitute the worst case for performance. Surprisingly, the ratio of signals to nonsignal stimuli makes little difference to performance. The magnitude of the signal, however, is significant. During the course of a watch, expectancies develop about the frequency with which signals appear. If a signal occurs after an atypical interval it is less likely to be detected. Up to a point, increasing task complexity serves to improve performance, and in some vigilance situations the introduction of a secondary task can actually improve performance on the primary task. Performance is also enhanced when feedback is provided to give the individual knowledge of the results. A noisy environment can be detrimental to a vigilance task, particularly if the noise is high-pitched and loud and the task is difficult. If the task is simple and the noise is low in pitch the effect is likely to be small. Less surprisingly, lack of sleep impairs performance. Conversely, vigilance can be improved—or at least lapses prevented—by short periods of rest or by conversation or other mild forms of diversion. Monetary or other rewards tend to improve performance, as do some stimulant drugs.

THE NEUROPHYSIOLOGY OF ATTENTION

Accompanying the external manifestations of attention are physiological changes taking place within the body, particularly within the brain and nervous system. A useful starting point for examining such changes is through those circumstances where they are elicited by novel stimuli. Following the pioneering research of Pavlov, the orienting response to novel stimuli has been strongly represented in the work of Soviet neuroscientists, who have accorded it a central position in the study of mental processes. Both in the Soviet Union and in the West, the orienting response has come to be characterized less by its behavioral signs than by a broad complex of physiological changes. These embrace changes in heart rate, in the electrical conductivity of the skin, in the size of the pupils of the eyes, in the pattern of respiration, and in the level of tension in the muscles. If the novel signal is an interesting one, the heart transiently slows down; if, on the other hand, it is startling the heart transiently speeds up. Most of the other types of change reflect similar reactions. Thus, the startling signal increases the level of skin conductance and the size of the pupils of the eyes, causes respiration to pause or briefly become irregular, and increases tension in certain muscles. Closer inspection reveals many more such changes: for example, in the size of blood vessels and consequently in blood circulation, in digestive processes, and in other bodily functions. The majority of these changes are regulated by the autonomic nervous system. They prepare the individual to respond to new and potentially threatening situations. Senses become temporarily more responsive to signals from the outside world. Overall the pattern is one of preparing the individual to take in information rapidly and efficiently and of giving priority to those systems that might have to respond promptly to that information. The glands of the endocrine system come into operation, releasing hormonal agents that circulate around the body and further facilitate the preparatory process. Once the

Physical reactions during attention

novel signal has been fully assessed and classed as nonthreatening or of no continuing importance, the defenses are "stood down." As might be predicted from the behavioral evidence, repetitive signals lead to habituation of the physiological responses as novelty dissipates.

One of the crucial factors in this process is the evaluation of the signal and the assessment of its significance. Physiologically this entails shifting the level of arousal and focusing available resources (attention) on the demands the signal makes.

Signal transfers in the brain

Sensory inputs travel to the brain via primary sensory pathways that converge on a central relay structure, the thalamus, from which they are sent to relatively specific and localized receiving areas in the higher (cortical) levels of the brain. On their way from the sensory receptors to the thalamus the signals pass an area of the brain stem and midbrain to which the sensory pathways have lateral connections. This area, called the reticular formation, is important in changing the overall level of arousal. When it is damaged the individual may be unarousable. It has interconnections with the higher brain centres, and it projects pathways to the cerebral cortex. Unlike the primary sensory projections, which are limited to specific sensory modalities, many of the reticular formation cells respond to signals from any of the sensory modalities.

When this ascending reticular activating system is operating the individual is alert, aroused, and attentive. Reduction of its activity results in somnolence or inattentiveness; extreme reduction (for example, by anesthesia or concussion) may lead to confusion or unconsciousness, even though the senses still pass messages to the brain over the direct pathways. The reticular system seems to account physiologically for the sustained, tonic shifts in an individual's level of involvement with the environment, including the control of sleep-wakefulness. One nonspecific route to the cerebral cortex via the thalamus, the diffuse thalamic projection system, appears concerned with moment-to-moment fluctuations in the focus of attention. Collectively the primary sensory pathways, associated areas of the cerebral cortex, and these more diffuse projection systems cooperate in the process of registering the incoming sensory signal, evaluating its contents, and mobilizing brain resources in response to the demands made.

Inevitably this account is an oversimplification. In human beings, other brain structures, particularly the hypothalamus, are involved in regulating states of sleep and wakefulness, and limbic structures, such as the hippocampus, take part in arousal when rewards, punishments, or other emotional factors are involved. Much of our understanding of these systems and their interactions comes from the study of animal brains and from observing what happens in the human brain when things go wrong. There is, however, another important source of information about what is taking place in the healthy human brain when it processes incoming information. This is through the associated electrical changes that take place within the brain; these changes can be recorded from electrodes attached to the scalp. Such recording, known as electroencephalography, involves amplification of the very weak neuroelectric signals, often followed by computer analysis and display. Electroencephalography enables observation of the minute patterns of voltage fluctuation that take place as the brain cells process information and relay messages.

Measuring brain activity

Often the patterns of these intrinsic brain rhythms are modified by attention to external events and by thinking and other internal activity. The clearest effect of this kind is the inhibition (blocking) of so-called alpha rhythms, usually when the eyes are opened or when the person is thinking about a task, especially one involving visual imagery. Alpha rhythms are more or less regular electric oscillations at a frequency of about 10 cycles per second (hertz, or Hz), seen principally in the hindmost (visual) part of the brain. In the majority of people they tend to be most prominent when the mind is relatively blank and the eyes are closed. Absence of rhythmic features in the electroencephalogram (EEG) is generally regarded as evidence of arousal as long as there are signs of less rhythmic (asynchronous) activity; total lack of electric discharge is a serious sign of brain morbidity.

Buried within the fluctuating pattern of voltage changes are more consistent patterns that accompany the registration and evaluation of each discrete piece of sensory information. These changes are referred to as evoked potentials or, more precisely, as event-related potentials (ERP). They extend over the period of half a second or so immediately following the onset of the signal concerned. ERPs are composed of a relatively consistent pattern of positive and negative electrical peaks that vary systematically when the properties of the signal that elicits them change. The whole waveform is divided into components, which are roughly approximate to its peaks and troughs, though not exactly because there is overlap between adjacent components. Each component has its own pattern of distribution over the brain and varies according to the properties of the eliciting signal.

Use of event-related potentials (ERP)

This succession of ERP components constitutes a convenient and meaningful indicator of the various aspects of information processing being carried out on the signal. Moreover, because recording of such electrical potentials offers no insult to the brain or serious interference with the performance of a wide range of tasks, many aspects of processing can be studied in healthy as well as disordered brains. Among the components of the ERP are several related to attention in its various forms. For example, about 100 milliseconds after a novel sound is heard, a prominent negative component is produced, which, if the sound becomes repetitive, diminishes (habituates). The closer together in time the sounds occur, the smaller the component becomes. Components with similar characteristics, but varying slightly in time, are found following novel visual and tactile stimuli. In situations where the individual must pay particular attention to a signal, these electrically negative components become larger. Conversely, if the individual is not paying attention—but is, perhaps, reading a book when the sound occurs—the component is smaller. This physiological sign of selective attention can be shown to be larger to all stimuli in an attended channel than in a nonattended channel. For example, if an individual who is hearing different voices speaking simultaneously in each ear is told to listen for a particular word spoken by one voice only, all words spoken by the "attended" voice elicit a larger 100-millisecond component than those spoken by the other voice. Only the designated word, however, elicits a later prominent, electrically positive component, occurring about 300 milliseconds after it is spoken. These responses appear to offer physiological support for the behavioral view that there is an early filtering for broad characteristics, followed by a later one of the more complex task-relevant properties.

Although such an explanation is plausible, the indications are that selection is not a simple serial process taking place at two discrete stages. When the task is relatively simple, looked-for properties can be distinguished substantially earlier than 100 milliseconds. There is also evidence of a more sustained, electrically negative change that can begin before 100 milliseconds and continue for perhaps several hundred milliseconds. This overlaps several components, supporting the idea that much processing must take place in parallel. Another component with attentional properties occurs just after 200 milliseconds when the incoming signal and current expectations are mismatched.

Apart from these transient electrical links with selective attention, there are rather longer electrical changes in preparatory states when attention is directed toward making a rapid response to an expected signal. When the signal that requires the rapid response (the imperative stimulus) is preceded at a short but fixed interval by a warning or "get-ready" signal, the warning signal triggers in the cerebral cortex a slowly rising negative voltage, which reaches its maximum by the time the imperative signal arrives. (A race starter saying "on your marks, get set," may be a warning signal; the following pistol shot, an imperative stimulus.) When the response has been made the voltage returns to its normal level. This slow potential change, contingent on the association of the two stimuli and the individual's intended response to the imperative second stimulus, has been termed the contingent negative variation (CNV). It appears as a correlate of focal attention,

Contingent negative variation (CNV) factor

and it has been suggested that one of its functions may be to prime the appropriate areas of the cerebral cortex to expected stimuli. The expectation must be focal; *i.e.,* in the forefront of conscious awareness. If the preparation and response are well learned or the individual is distracted, the CNV is reduced. Conversely, if the individual concentrates on the task or is highly motivated to perform it well, the CNV increases in size. The CNV offers links with two-process theories of attention in that it seems to provide a physiological distinction between the more demanding focal, flexible mode (large CNV) and the less demanding automatic mode (small CNV). If the priming view of the CNV is correct, it may well indicate recruitment of the necessary resources to deal with the (imperative) task.

Although these are small beginnings in the quest to find a physiological basis for attention, they constitute an important first step toward the integration of behavioral and neurophysiological evidence and theory. Evidence from both humans and other animals already links the cortical CNV with similar processes taking place in the brain stem reticular formation. Several theoretical models of selective attention based on ERP evidence have been advanced. They have in common an attempt to use systematic patterns of ERP change as an index of the cerebral mechanisms underlying cognitive processes.

Chemical reactions

All of the electrical changes considered are in practice electrochemical. That is, complex chemical changes underlie the electrical correlates of attention. To take just one instance, the passage of electrical signals from nerve cell to nerve cell is dependent upon a range of neurotransmitter substances. Each of the neural systems already discussed is dependent upon the action of one—or sometimes combinations—of these neurochemicals. One transmitter substance, noradrenaline, is particularly prominent in alerting processes, along with its close relative dopamine. The total amount of another transmitter substance, acetylcholine, in the brain is found to be inversely related to the level of central nervous system activity at any given time. For example, if an individual is anesthetized, the electrical activity of the brain is reduced, and the content of acetylcholine is found to be increased. Direct electrical stimulation of the brain, or the convulsant action of certain drugs, tends to decrease brain levels of acetylcholine. This transmitter seems to be involved in a wide range of behaviour and functions. Among those related to attentional and arousal states are stress, awakening from sleep, and exploring behaviour. Certain amino acids, such as gamma-aminobutyric acid (GABA) and glycine, appear to play an inhibitory role in the brain and nervous system. Hence they too may be involved in reciprocal inhibitory processes accompanying some attentional states.

PERCEPTION AND RECALL

The vast subject of memory is beyond the scope of this survey of attention, but a few pointers to the interactions that take place between what is attended to, how it is perceived and recognized, and factors that govern its subsequent recall are relevant. Memorizing is not simply a matter of repetition; attention plays a role in organizing material in ways that can influence its later recall. One example, known as the Von Restorff effect, is that, in any given number of items to be learned, an item that is notably different from the rest in size, colour, or other basic characteristics will be more readily recalled than the others. Unfortunately there is a price to be paid for this improvement; other "standard" items will be less well recalled than they otherwise would have been.

It is also important to realize that what is actually perceived is not a neutral, objective representation of what exists in the external world. It is coloured by past experiences stored in memory and by current expectations, to the extent that substantial distortions can occur to make a perceived item fit those experiences and expectations. Perceptions are frequently formed on the basis of quite limited cues; the art of camouflage utilizes this characteristic to the benefit of both humans and other animals in certain situations. It seems that even the culture within which a person lives determines the way he perceives the world. Following a study of the Hopi and Shawnee languages, the linguist Benjamin Whorf concluded that what these American Indian peoples perceived was itself different from the perceptions of English-speaking Americans, by virtue of the way their languages were structured.

INATTENTION AND DISTRACTIBILITY

Limited processing capacity entails that there is invariably competition for attention. While awake humans are essentially always attending to something. The term inattention usually implies that, at a given moment, the thing being attended to is either not what it was intended to be or not what adaptively it ought to be. People will often report, "I was attending, but found that I was not taking in what was happening." On many such occasions, internal preoccupations (thoughts) have become the object of current attention at the expense of sensory information from the external world. Alternatively, an internal stimulus, such as a pain or hunger, may have captured attention. On other occasions, irrelevant sensory information from the external world may distract individuals from their current focus of attention. When this happens it is either because the intrusive stimulus has high priority, for example, the ringing of a telephone, or perhaps because the task engaged in is simply uninteresting.

Some individuals are more easily distracted than others, but in everyone distractibility varies with circumstances. When motivation and the level of involvement are high, an individual may totally disregard intense and persistent "outside" signals. Such inputs are either heavily filtered or dealt with only at an automatic level. Even when the competing stimulus is pain from an injury sustained, say, by a player in the early stages of a team sport, it is often scarcely noticed until the game ends and attention is no longer absorbed by the game. Nevertheless, because people's ability to focus attention varies, some report "difficulties of concentration" and may find themselves so easily distracted that they can scarcely read a book. There are indications that persons who are chronically anxious may be among those whose attention can readily be distracted by quite modest and irrelevant levels of stimuli. This feature has been noted in a number of psychiatric disorders, and it has been suggested that one cause of these disorders may be a fault in the mechanisms of attention.

Levels of distractibility

LAPSES OF ATTENTION

It has been established that, to conserve limited resources, whole sequences and hierarchies of actions can apparently be elicited without focal attention when they have been well learned or executed many times. There is reason, however, to suppose that at least a minimum level of focal attention may be necessary, if only to ensure that the correct sequence or hierarchy is initiated. Failure of this minimal monitoring can result in the phenomena usually classed as lapses of attention. For example, most people have experienced trivial behavioral slips such as finding themselves taking a regularly used route when they had meant to go in a different direction; attempting to switch off a light when leaving a room in daylight; or, perhaps, pouring tea into the sugar bowl instead of a cup. In each case a well-established action has been inappropriately triggered by partial cues and has slipped past the attentional monitor when it was otherwise engaged. A person realizes in retrospect that the error has occurred because he was "thinking about something else"; he was not paying attention to what he was doing. In many circumstances it is advantageous that automatic sequences of behaviour should be executed with only very limited reference to conscious attention. Musicians, typists, and other skilled persons are well aware that too much attention devoted to the execution of a well-learned skill can disrupt performance. Nevertheless, people cannot dispense entirely with some degree of attentional monitoring if they are to avoid errors. Another kind of lapse entails being unable to remember whether one has performed a particular action as part of a highly automated sequence: "did I or did I not put the sugar in my tea?" Yet another kind results in one automatic action's triggering another unwanted or inappropriate action: "I meant to take off only my shoes but took off my socks as well." Most lapses have in com-

Limited attentional monitoring

mon that they occur when attention has been claimed by an internal preoccupation or external distraction.

CONCLUSION

Attention has sometimes been described not as a single concept but as the name of a complex field of study. This is true only to the extent that around it have grown up a multitude of ancillary and often poorly defined constructs, many of them overlapping. Some, like consciousness and awareness, are related to subjective mental states. Others, like arousal, activation, and orientation, are thought of more in physiological terms. Still others, like alertness and expectancy, have been characterized principally in terms of behaviour and performance. Another dimension considers the process in terms of effort, intention, drive, or motivation, and, yet another, the notion of automaticity. Doubtless each of these facets contributes to the overall picture, but there would seem to be a case for treating the term as referring primarily to that state of the individual which represents the shifting, selective focus of consciousness. This is the state through which learning takes place and one that makes heavy demands upon the brain's processing capacity. Individuals recognize it subjectively in themselves, but it is becoming increasingly recognizable in others through neurophysiological activity as well as by individual behaviour. It is a state of awareness that subserves the more flexible and directable aspects of human transactions with the environment.

Augustine

Saint Augustine (in Latin, Augustinus), bishop of Hippo in Roman Africa from 396 to 430, and the dominant personality of the Western Church of his time, is generally recognized as having been the greatest thinker of Christian antiquity. His mind was the crucible in which the religion of the New Testament was most completely fused with the Platonic tradition of Greek philosophy; and it was also the means by which the product of this fusion was transmitted to the Christendoms of medieval Roman Catholicism and Renaissance Protestantism.

This unique significance would have belonged to Augustine had he never written the famous *Confessions,* in which at the age of about 45 he told the story of his own restless youth and of the stormy voyage that had ended, as he believed, 12 years before he put it in writing, in the haven of the Catholic Church. It is easy to forget that the real work of Augustine's life did not begin until the last scene of the *Confessions* was already receding for him into a remembered past. Moreover, the *Confessions* themselves are not so much autobiography as they are devotional outpourings of penitence and thanksgiving. Augustine's conscientious memory generally can be trusted for the facts: his reflections upon them are those of the bishop on his knees. This is not to say that, in any attempt to understand or appreciate the mind of the bishop, the *Confessions* can be neglected. The picture must, however, be drawn in proper proportion; it is essential to avoid giving undue prominence to what should be no more than its background.

Youth and conversion. Hippo Regius is the modern Annaba on the Algerian coast, in what was then the Roman province of Numidia. Augustine, named Aurelius Augustinus, was born on November 13, 354, of middle-class parents at Tagaste (modern Souk-Ahras), a small town about 45 miles (72 kilometres) to the south. His father, Patricius, was and remained until late in life a pagan; his mother, Monica, was a Christian of intense but simple piety, from whose early teaching Augustine retained a reverence for the "name of Christ" that never left him. But he was not baptized in infancy. He went through primary and secondary schooling and soon displayed such intellectual promise that the modest family funds were banked upon securing him an academic career that would qualify him for government service. As a 19-year-old student at Carthage he was stirred by the reading of a treatise of Cicero—the now lost *Hortensius*—and was filled with an enthusiasm for "philosophy," which meant not only a devotion to the pursuit of truth but a conviction of the superiority of a life devoted to that pursuit (the *vita contemplative*) over any aims of secular ambition. The faith of the Catholic Church seemed to him too hopelessly unphilosophical for any man of culture to entertain; and he was easily carried away by the discovery in Manichaeism of a religion that professed to appeal to reason rather than authority.

Enthusiasm for philosophy

Alinari—Art Resource/EB Inc.

St. Augustine, fresco by Sandro Botticelli, 1480. In the Church of Ognissanti, Florence.

Influence of Manichaeism. The Manichaean system as propagated in the Western Roman Empire was a materialistic dualism that accounted for the creation of the world as the product of a conflict between light and dark substances and for the soul of man as an element of the light entangled in the dark. Manichaeism claimed to be

the true Christianity, preaching Christ as the Redeemer who enables the imprisoned particles of light to escape and return to their own region. In the Manichaean Church the higher order of "elect" were strictly ascetic and celibate, all physical generation being held to serve the realm of darkness. After an adolescence that probably was no more licentious than was common in his time and country, Augustine had formed a liaison with a woman of low birth by whom he had a son and to whom he remained loyally attached throughout the nine years of his association with the Manichaeans, and he was therefore allowed to join that sect's lower order as one of the "hearers," to whom marriage was permitted as a concession to human weakness.

His first zeal for this "religion of enlightenment" did not last long, however, for the Manichaean experts were intellectually second rate and proved incapable of dealing with the questions he put to them. He became increasingly disillusioned and was already falling into a general agnosticism when, at the age of about 28, he left Carthage, where he had worked as a free-lance teacher of rhetoric, and went to Rome in search of more satisfactory pupils. There he made connections that led to an official professorship at Milan, where the Western emperor then resided.The bishop of Milan was Ambrose, the most eminent Christian churchman of the day. Augustine was introduced to Ambrose but never came to know him well. He went to hear him preach, however, and this, his first contact with the mind of a Christian intellectual, was enough to shake Augustine's prejudice against Catholic teaching. Although he had abandoned the doctrines of Manichaeism, he retained its materialistic presuppositions, which left him still a skeptic with no satisfying alternative to Manichaean notions of ultimate reality. The being of God and the nature and origin of evil remained for him problems as insoluble as they had ever been.

Contact with St. Ambrose

Influence of Neoplatonism. The solution of both problems was given to him by a chance introduction to Neoplatonic writings, for which he may well have been prepared by Ambrose's use of them in some of his sermons. Neoplatonism, in the work of the 3rd-century philosopher and mystic Plotinus, its greatest exponent, is a spiritual monism—a philosophical doctrine holding that there is only one reality—according to which the universe exists as a series of emanations or degenerations from absolute unity. From the transcendent One arises self-conscious mind or spirit; from mind comes soul or life; and soul is the intermediary between the spheres of spirit and of sense. Matter is the lowest and last product of the supreme unity; and since the One is also the real and the good, the potentiality of evil is identified with unformed matter as the point of maximum departure from the One. Evil itself is thus the least real of all things, being simply the privation or absence of good. Neoplatonic mysticism relies on the principle that the inward is superior to the outward: to reach the good, which is the real, one must "return into" oneself; for it is the spirit at the heart of man's inmost self that links him to the ultimate unity.

In the seventh book of the *Confessions,* Augustine tells how in such an act of introspection he found God—the "changeless light," at once immanent and transcendent, which is the source of every intuitive recognition of truth and goodness. This discovery of God was more than the conclusion of a process of reasoning: it was a mystical experience, a vision or touch that came and went. But it left behind it the answer to Augustine's unsatisfied questionings. God is light, and evil is darkness, as the Manichaeans said. But neither is a material substance: the changeless light of God is pure spiritual being, and the evil is nonentity, as darkness is but the absence of light.

Conversion to Christianity. Augustine's mystical experience, his awareness of God, had been momentary and fleeting. He believed that this could be only because he had not made for himself the necessary total identification of supreme value with spirit; he was still himself entangled with the flesh. In fact, Neoplatonism had reinforced the Manichaean principle that the way of return to God must be through escape from the body; and for Augustine this meant primarily and immediately escape from the ties of sexuality. The immortal story of his conversion in the eighth book of the *Confessions* tells of his coming to learn of the heroic achievements of Christian asceticism in East and West, of the self-contempt induced in him by the contrast of his own weakness, and of the final breakdown of resistance in a Milan garden, when, at the sound of a child's voice calling "*tolle, lege: tolle, lege*" ("take up and read"), he opened the New Testament Letters and read in Letter of Paul to the Romans the words, ". . . put on the Lord Jesus Christ, and make no provision for the flesh, to gratify its desires" (Rom. 13:14).

Moral struggle

This was in the late summer of the year 386. Vacation was near, and Augustine resigned his teaching chair and went with some young pupils, his son Adeodatus, and his mother Monica to a reading party at a country house lent by a friend. Out of their literary study and philosophical discussions there came the earliest of Augustine's surviving works—the dialogues, which display so little of the storm and stress of a religious conversion and so little concern with specifically Christian themes that critics have been led to question the accuracy of the *Confessions* story written many years later. It is true that Augustine's struggle against the domination of his sexual nature can be regarded as the final phase in that fluctuating pursuit of the "philosophic life" first presented to him by Cicero's *Hortensius.* But there is no sufficient reason for doubting that he was a Catholic Christian in intention when he received Baptism at the hands of Ambrose in the spring of 387. It is certain that three or four years later, when he wrote his treatise *De vera religione* (*Of True Religion*), he was still thinking of Christianity in Neoplatonic terms. In this treatise, the divine Word (Logos) in Christ is the mind or spirit of Plotinus, illuminating the reason, through whom the human soul has access to the transcendent Godhead. Christ's human life is man's example of the ascetic victory over the pains and pleasures of the flesh; Christian morals serve only to purify the soul for the life of contemplation; and Christian faith is the necessary acceptance of the church's authority in this preliminary stage of training.

Bishop and Christian philosopher. Shortly after his Baptism, Augustine left Milan, with his mother and a small party of friends, to return to Africa. At Rome's port city of Ostia, his mother died; and Augustine recorded his last talk with her, in which son led mother, through a discourse formed on the pattern of the Neoplatonic "ascent" from this world to the other, to share with him a momentary experience of the life eternal. Home again at Tagaste, the friends formed a little community devoted to the religious life of contemplation and study. But its peace was soon broken when, on a visit to Hippo in 391, Augustine was forced to accept ordination as assistant priest to its old bishop, Valerius. Five years later Valerius died, and Augustine entered the episcopate in which he was to labour until his death. The bishop in Roman Africa was not only the pastor of a parish, the busy teacher and preacher, but the presiding judge in a much-frequented court of summary jurisdiction in civil cases. Augustine never enjoyed robust health, and the vast extent of his literary output was made possible only by the constant services of stenographers and by an extraordinary capacity for the extempore formulation of ordered thought, of which at least 400 sermons remain as proof. He was not a systematic theologian. Much of his writing was in response to the appeals that his growing reputation in the Christian world brought to him for the solution of the most diverse problems. Over 200 of his letters have been preserved, many of them having the scale of minor treatises. He was tireless in controversy with heretics—Manichaeans, Donatists, and Pelagians. But his deepest thought, the real Augustinianism, is to be found in his scripture commentaries and homilies, especially his expositions of the Psalms and his writings on the Gospel and First Letter of John. The characteristic pattern he imposed upon Christian theology was not the outcome of controversy.

Pastor, teacher, and judge in Hippo

The decisive turn was given to his thinking by his ordination to the priesthood, which dragged him against his will from the *vita contemplative* into the world and at the same time diverted his studies from philosophy to Scripture. The realities of pastoral experience among the very imperfectly Christianized people of an African seaport,

Biblical and philosophical theologian

together with the rapid impregnation of his mind with the categories of biblical religion, made it impossible for him to overlook the differences between Neoplatonism and Pauline Christianity. The knowledge of God and of the soul always remained from the time of his Baptism the one and only knowledge that he desired; and Plotinus had not been mistaken in bidding him look within himself if he would find God, for the Bible also tells of a likeness to God imprinted on the soul. But although for the Neoplatonist the soul's likeness to God is that of a, so to speak, reduced divinity, for the Christian it is that of a temporal and mutable image of the "eternal and changeless." Augustine was assured that it is the task of a Christian philosophy, guided by the scriptural revelation, to seek to know God through his image in the soul; and this was the path he followed in his great treatise *De Trinitate* (*On the Trinity*). He insisted that a true knowledge of the soul's nature can be based only on the immediate awareness of self-consciousness; and the soul's awareness of itself is of a trinity in unity that reflects "as in a glass darkly" the being of its Maker. He claimed that knowledge of one's own being, of one's own thinking, of one's own willing is not open to doubt; there is an ego that exists, knows, and wills. But in none of these aspects is the ego self-sufficient or independent: it cannot maintain its own being, produce its own knowledge, or satisfy its own desires. Augustine believed that he had learned from the Platonists to find in God "the author of all existences, the illuminator of all truth, the bestower of all beatitude" (*De civitate Dei* viii, 4). But his theories of the universe, of knowledge, and of ethics were his own. The following three paragraphs summarize these theories.

Theory of the universe. Creation in Plotinus is motiveless and purposeless, the automatic by-product of the divine self-contemplation; in Augustine its source is "the will of a good God that good things should be" (*De civitate Dei* xi, 21). The outgoing energy of creative love forms the basic principle of his entire theology. Since nothing can come into being or continue in it but by this divine will to create, all that exists is good "in so far as it has being"; and because there are evidently degrees of goodness, there must also be degrees of being. But even the formless matter that is nearest to "not being" is essentially good because God made it; the origin of evil is not to be sought in material existence. Augustine persistently refused to unload upon the material conditions of human life the responsibility for human wickedness.

Theory of knowledge. Following Plato, Augustine argued that the ability to make true judgments never can be inserted into the mind from outside. The human teacher never can do more than help his pupil to see for himself what he already knew without being aware of it. Augustine's favourite examples of these intuitive judgments are the propositions of mathematics and the appreciation of moral values; they are not the construction of the individual mind, because when properly formulated they are accepted by all minds alike. The individual thinker does not make the truth, he finds it; and he is able to do so because Christ, the revealing Word of God, is the *magister interior,* the "inward teacher," who enables him to see the truth for himself when he listens to him.

Ethics. Augustine accepts the basic assumption of ancient ethical theory that conduct is properly directed to the achievement of *eudaimonia*—the happiness or well-being that is taken to be the one universal desire of humanity. Augustine's cosmos is an ordered structure in which the degrees of being are at the same time degrees of value. This universal order requires the subordination of what is lower in the scale of being to what is higher: body is to be subject to spirit, and spirit to God. Man must know his place in the order of the universe and, knowing it, must voluntarily accept it; that is, he must set upon himself and upon everything else the relative value that is properly due. Augustine's word for the ethical valuation that influences conduct is *amor* ("love"). *Amor* is the moral dynamic that impels man to action. If it is rightly directed man will never set a higher value on what is lower in the scale. All lesser goods are to be "used" as means or aids toward the higher; only the highest is to be "enjoyed" as the ultimate end on which the heart is set. The supreme good in whose fruition alone man reaches his perfection is for Augustine the God whose nature is *agapē*, love in the New Testament sense of the word. If, then, man's love, his *amor,* can rise to the enjoyment of God, it will become a participation in the divine *agapē,* love itself. God will have given himself to men, and by sharing in his love men will love one another as he loves them, drawing from him the power to give themselves to others.

Struggle with the Donatist schism. The energies of Augustine, both pastoral and literary, were for the first 15 years of his episcopate distracted by the wearisome struggle to end the schism in the African Church that had persisted for nearly a century. The Donatists, a Christian sect (named after Donatus, one of its leaders) the members of which outnumbered the Catholics in the country districts and in many towns, claimed to be the only true church on the ground that their ministry was the only one the succession of which had not been stained by apostasy in the great persecution of the years 303–313, which had begun under the emperor Diocletian. Imperial attempts to suppress the schism had stimulated the martyr spirit that had always marked African Christianity and gained Donatism the support of strong elements in the native population whose grievances were social and economic rather than ecclesiastical. The schism maintained itself by fanatical violence, and Augustine's persevering attempts to settle the questions at issue by peaceful discussion were fruitless. In the end, the imperial government became convinced that the Donatists were a danger to the security of Africa. The Donatist bishops were compelled to meet their Catholic rivals at a formal conference held under an official arbitrator at Carthage in 411, the foregone conclusion of which was a Catholic victory.

Answer to the Donatists

Donatists and Catholics agreed that the power of the Holy Spirit is conveyed to the believer through the sacraments, which are administered by the church through the clergy. The Donatists alleged, however, that the sacraments require for their validity a ministry undefiled by serious sin; for the Spirit departs from the sinner, who cannot therefore "confer what he does not possess." Augustine replied that the sacraments convey the Spirit in virtue of Christ's ordinance alone and that this validity is unaffected by the worthiness or unworthiness of the human minister. The church's unity depends on the Spirit's supreme gift of charity, of which schism is the denial. Unfortunately, Augustine, who had for long opposed the use of any means but persuasion to end the schism, eventually was induced to approve the enforcement of legal penalties upon the schismatics, in the interest, as he believed, of the many whose fear of Donatist violence had kept them from returning to the church. His famous saying, "Love, and do what thou wilt," was in fact a defense of compulsion in the service of charity.

Struggle with the Pelagian heresy. As the Donatist controversy was ending, the Pelagians were already beginning to threaten the traditional doctrines of sin and redemption in the Western Church. Pelagius had set himself to resist the slackening of Christian moral standards. Against those who pleaded human frailty in excuse for their failings, he insisted that God has made every man alike free to choose and to perform the good; that it is the essence of sin to be a voluntary act that God's law forbids and that the sinner was free to avoid; and that, were not this freedom real, there could be no justice in God's punishments and rewards. This reduction of Christianity to a bleak moralism could not avoid conflict with the plain implications of the church's sacramental and liturgical practice. Baptism had always been "for the remission of sins," and infants were held to need it because they inherit the guilt of Adam's transgression, which, as St. Paul taught, brought death upon the whole race of men. The doctrine of original sin was firmly established in the Western Church before Augustine's time; and when it was openly rejected by Pelagius' disciple Celestius, there was no escape for Pelagianism from being branded as a heresy. The prevarications of Pelagius were able to persuade Pope Zosimus (417–418) to reverse the condemnation pronounced by his predecessor, Innocent I. But in the spring of 418 the African bishops

obtained from the emperor Honorius an edict banishing the heretics; and Zosimus was obliged to come into line.

Augustine was the soul of the Church's resistance. He had seen Pelagianism at once as not merely a denial of the virtue of Christian Baptism but also as a fatal misconception of the relationship between God and man. For to assert that man can achieve righteousness by his own effort is to contradict the fundamental truth that God is the giver of all good.

Original sin and its propagation

Before the controversy began, Augustine had worked out his own rationalizations of the doctrines of original sin and divine grace—rationalizations that the church was to prove unwilling to accept fully. He accepted the traditional belief in the fact and in the penal consequences of Adam's transgression, defining the fact as man's refusal to accept his place in the created order, and the consequences as a dislocation of the order of man's own nature—the revolt of flesh against spirit. He argued that not only are all men involved in Adam's guilt and punishment but also that this involvement takes effect through the dependence of human procreation on the sexual passion, in which the spirit's inability to control flesh is evident. It was this linking of original sin with human sexuality that exposed Augustine in his old age to the most damaging criticisms of the Pelagian bishop Julian of Eclanum, who boldly asserted the moral neutrality of the instincts that belong to man's created nature and charged Augustine with relapsing into Manichaeism in his argument that an impulse that a man is bound to fight and conquer must therefore be evil.

For Augustine the fall of man means that in all men the true order of love has been violated. Departing from the love of God above him, man has followed the love of self and become subject to what is below him. Man has fallen by the act of his own will. He cannot by a similar exercise of will reverse the consequences of that fall. The subjection of spirit to flesh is a slavery from which the perverted will has no power to deliver itself, just because it cannot will the deliverance. What is needed is a kind of reversal of gravity—the substitution of an uplifting for a down-dragging love. And Augustine believed that this could happen only by that gracious descent of the divine love to dwell within the sinner: the gospel of the incarnation and of Pentecost.

Pelagius, on the other hand, argued that all men have been created free to do what is right when they see it, and that Christians have received the needed moral enlightenment in Christ's teaching and example. Augustine knew the unreality of the Pelagian conception of freedom as an innate and absolute power of choice, unaffected by circumstances. He pointed to the inescapable conditioning of all moral activity by the situation of the agent—outside whose control are in general not only the presentation of an object but also the kind of feeling that the presentation excites. Moreover, the act of will is dependent on feeling as well as on cognition. In Augustine's words:

> Men will not do what is right, either because the right is hidden from them or because they find no delight in it. But that what was hidden may become clear, what delighted not may become sweet—this belongs to the grace of God" (*De peccatorum meritis et remissione*).

Augustine insisted that without this delight in righteousness there can be no true freedom in well-doing, but only a servile obedience to law. The love of God, which is the motive of the Christian life, must be free. Yet love of God, as St. Paul said, enters man's heart by the gift of the Holy Spirit; and Augustine found it increasingly difficult to leave room in his doctrine of grace for a genuinely free response on man's part to the Spirit's gift. The unexamined assumption that everything in human life must be ascribed either to God's or to man's working compelled him to hold that God alone is the cause of every human movement toward good. In the first year of his episcopate, the study of St. Paul's argument in Rom. 9–11 had convinced him that no event in time can alter the eternal setting of God's will toward any human soul: his elect are chosen before the foundations of the world. God knows—not before, but apart from, the time process—how each individual in the course of time will respond to the particular form in which grace is offered to him; and the elect alone receive the grace that will win their acceptance.

The City of God

The rigour of this doctrine did not soften in face of the Pelagian challenge. In *De civitate Dei* (*The City of God*), the masterpiece on which Augustine was working throughout the Pelagian controversy, he drew a picture, as majestic as it is appalling, of the "beginnings, course and destined ends" of the two invisible societies of the elect and the damned. The work seems to have been in his mind before the capture of Rome by the Visigoths in 410 had shaken the empire; but it took the form of a Christian apologetic against the pagan claim that the disaster was consequence and punishment of Rome's apostasy from its ancestral religion. Augustine's two cities are not to be identified with the Christian Church and the pagan or secular state. They are symbolic embodiments of the two spiritual powers that have contended for allegiance in God's creation ever since the fall of the angels—faith and unbelief, "the love of self extending to contempt for God, and the love of God extending to contempt of self." Neither power is embodied in its purity in any earthly institution; in this world the heavenly and earthly cities are inextricably intermingled. If there is a philosophy of history in the *De civitate Dei,* it is the religious philosophy of predestination.

Augustine found it difficult in his old age to reassure some of his own disciples, to whom his doctrine seemed to make moral effort futile and praise and blame alike groundless. But he would retract nothing. His last completed treatises drew out the logic of predestination to its most ruthless conclusions. Though his doctrine in its final form was never accepted by the church, it reappeared virtually unmodified in the writings of both St. Thomas Aquinas and John Calvin, the most acute thinkers, respectively, of Scholasticism and Reform. It may indeed be regarded as product of the too audacious attempt of the time-bound human mind to contemplate existence with the eye of the eternal God.

The influence of Augustine. The end of Roman civilization in Africa was near and the Vandal armies were besieging Hippo when Augustine died there on August 28, 430. Not many years later, Vincent of Lérins defined Catholic orthodoxy in the famous phrase, *Quod ubique quod semper quod ab omnibus creditum est* ("What is everywhere, what is always, what is by all people believed"). He dared not call Augustine a heretic in so many words, but it was against the extravagances that he rightly detected in Augustinian doctrine that his definition was aimed. That these extravagances have been a noxious legacy to theology because of their author's authority cannot be denied. But that should not prevent the grateful acknowledgment of the debt that Christian thinking has owed through the centuries to Augustine's influence, which has spanned and may one day reconcile the divisions of Western Christendom. The secret of that influence is to be found not so much in the brilliance and profundity of his intellect, the magic of his style, or the validity of his constructions as in the unique power of his religious genius. St. Anselm of Canterbury, St. Bernard of Clairvaux, the makers of *The Book of Common Prayer,* St. Francis de Sales, Blaise Pascal, Jacques-Bénigne Bossuet, Joseph Butler, Jacques Maritain, Reinhold Niebuhr, and Paul Tillich—all these have in their different ways drawn inspiration from one in whom they have been compelled to recognize "the heart of the matter." *Verus philosophus est amator Dei* ("The true philosopher is the lover of God"). In those words from the *De civitate Dei,* Augustine has left at once the best portrait of himself and the fullest justification of his life's work.

St. Augustine has been revered as a doctor of the church since the early Middle Ages. His feast is celebrated on August 28.

MAJOR WORKS

TEXT AND TRANSLATIONS: Modern critical editions of St. Augustine's works in the original Latin are in process of publication in the *Corpus Scriptorum Ecclesiasticorum Latinorum* and in the *Corpus Christianorum;* but the only available edition complete except for the Sermons is still that of the Benedictines of Saint-Maur (1670–1700), reprinted in Migne's

Patrologia Latina. There are no complete English translations of all St. Augustine's works. The largest separate collection is in the series "Nicene and Post-Nicene Fathers of the Christian Church" (N.P.N.F.). Translations of most of the Major Works listed below can be found either in this collection or in one or other of the following more recent series: "Ancient Christian Writers" (A.C.W.); "The Fathers of the Church" (F.C.); "The Library of Christian Classics" (L.C.C.).

GENERAL: *Confessiones* (*c.* 400; *The Confessions,* L.C.C.); *De doctrina Christiana* (397–428; *Christian Instruction,* F.C.); *De Trinitate* (400–416; *On the Trinity,* N.P.N.F.); *De civitate Dei* (413–426; *The City of God,* F.C.); *Enchiridion ad Laurentium de fide, spe, et caritate* (421; *Enchiridion to Laurentius on Faith, Hope, and Love,* L.C.C.); *Sermones* (from 391; *Selected Sermons,* ed. by *Quincy Howe,* 1966); *Epistolae* (from 386; *Letters,* F.C.).

EXEGETICAL: *De Genesi ad litteram* (401–415), a commentary on the first three chapters of Genesis; *De sermone Domini in monte* (393–394; *Commentary on the Lord's Sermon on the Mount,* F.C.); *Enarrationes in Psalmos* (391–420; *Expositions on the Book of Psalms,* 1847–57; A.C.W. incomplete); *Tractatus in Joannis Evangelium* (407–418; *Homilies on the Gospel of John,* N.P.N.F.); *Tractatus in Epistolam Joannis ad Parthos* (*c.* 415; *Homilies on St. John's Epistle,* L.C.C.).

CONTROVERSIAL: (ANTI MANICHAEAN): *De vera religione* (*c.* 390; *Of True Religion,* L.C.C.); *De libero arbitrio* (389–395; *On Free Will,* L.C.C.). (ANTI-DONATIST): *De Baptismo, contra Donatistas* (400–401; *On Baptism, Against the Donatists,* N.P.N.F.); *Contra litteras Petiliani* (400–403; *Answers to Letters of Petilian,* N.P.N.F.). (ANTI-PELAGIAN): *De spiritu et littera* (412; *The Spirit and the Letter,* L.C.C.); *De natura et gratia* (415; *On Nature and Grace,* N.P.N.F.); *De gratia Christi et de peccato originali* (418; *On the Grace of Christ, and on Original Sin,* N.P.N.F.); *De gratia et libero arbitrio* (426 or 427; *On grace and Free Will,* N.P.N.F.).

BIBLIOGRAPHY. A comprehensive bibliography of works dealing with St. Augustine is CARL ANDRESEN (ed.), *Bibliographia Augustiniana,* 2nd ed. (1973); TARSICIUS J. VAN BAVEL and F. VAN DER ZANDE, *Répertoire bibliographique de Saint Augustin* (1963), covers material that appeared between 1950 and 1960; for the years 1970–80, see TERRY L. MIETHE, *Augustinian Bibliography: 1970–1980* (1982). Annual bibliographies are provided in *L'Année philologique* (1924–); *Revue des études augustiniennes* (quarterly); and *Recherches augustiniennes* (1958–).

Biography: WARREN T. SMITH, *Augustine: His Life and Thought* (1980), is a good introduction. A scholarly and readable biography is PETER R.L. BROWN, *Augustine of Hippo* (1967). GERALD BONNER, *St. Augustine of Hippo: Life and Controversies* (1963), is also valuable. Of literary interest is REBECCA WEST, *St. Augustine* (1933). See also KARL ADAM, *Saint Augustine: The Odyssey of His Soul* (1932; originally published in German, 1931); and HUGH POPE, *Saint Augustine of Hippo* (1937, reissued 1961). The problems concerning the chronology and nature of Augustine's conversion, especially as related in his *Confessions,* are dealt with in PAUL AUBIN, *Le Problème de la "Conversion"* (1963); J.M. LE BLOND, *Les Conversions de Saint Augustin* (1950); A.M. LA BONNARDIÈRE, *Recherches de chronologie augustinienne* (1965); PIERRE P. COURCELLE, *Recherches sur les Confessions de Saint Augustin,* new ed. (1968); JOHN J. O'MEARA, *The Young Augustine* (1954, reissued 1980); and MICHELE PELLEGRINO, *Les Confessions de Saint Augustin* (1961). Augustine's maturity is described in FREDERIK VAN DER MEER, *Augustine the Bishop* (1961; originally published in Dutch, 1947).

Thought: A general outline of Augustine's thought is provided in PROSPER ALFARIC, *L'Évolution intellectuelle de Saint Augustin* (1918); also good introductory texts are HENRI I. MARROU, *St. Augustine and His Influence Through the Ages* (1957; originally published in French, 1956), and *Saint Augustin et la fin de la culture antique,* 4th ed. (1958); and EUGÈNE PORTALIÉ, *A Guide to the Thought of Saint Augustine* (1960, reprinted 1975). His philosophy is considered in JAKOB BARION, *Plotin und Augustinus* (1935); and ÉTIENNE GILSON, *The Christian Philosophy of St. Augustine* (1960; 2nd French ed., 1943). His political theory and view of history, especially as propounded in *De civitate Dei,* is the subject of REGINALD H. BARROW, *Introduction to St. Augustine: The City of God* (1950); JOHN H.S. BURLEIGH, *The City of God* (1949); HERBERT A. DEANE, *The Political and Social Ideas of St. Augustine* (1963); and GORDON L. KEYES, *Christian Faith and the Interpretation of History: A Study of St. Augustine's Philosophy of History* (1966). See also ROBERT A. MARKUS (ed.), *Augustine: A Collection of Critical Essays* (1972); and ROBERT E. MEAGHER, *An Introduction to Augustine* (1978), an anthology of passages extracted from Augustine's writings, with commentary.

Theology: For general accounts of Augustine's theology, see JOHN BURNABY, *Amor Dei: A Study of the Religion of St. Augustine* (1938, reprinted 1960); HENRI DE LUBAC, *Augustinianism and Modern Theology* (1969; originally published in French, 1965); and E.A. TESELLE, *Augustine the Theologian* (1970); and PAUL HENRI, *The Path to Transcendence: From Philosophy to Mysticism in Saint Augustine* (1981; originally published in French, 1938).

Special topics: For Christology, see TARSICIUS J. VAN BAVEL, *Recherches sur la Christologie de Saint Augustin* (1954); for the Eucharist, GASTON LECORDIER, *La Doctrine de l'eucharistie chez S. Augustin* (1930); for biblical exegesis, MAURICE PONTET, *L'Exégèse de S. Augustin, prédicateur* (1946); for predestination and grace, HENRI RONDET, *Essais sur la théologie de la grâce* (1964).

Augustus

Gaius Octavius, subsequently known as Gaius Julius Caesar Octavianus and still later as Augustus or Caesar Augustus, was the first Roman emperor, following the republic, which had been finally destroyed by the dictatorship of Julius Caesar, his great-uncle and adoptive father. His autocratic regime is known as the principate because he was the *princeps,* the first citizen, at the head of that array of outwardly revived republican institutions that alone made his autocracy palatable. With unlimited patience, skill, and efficiency, he overhauled every aspect of Roman life and brought durable peace and prosperity to the Greco-Roman world.

Gaius Octavius was born on September 23, 63 BC, of a prosperous family that had long been settled at Velitrae (Velletri), southeast of Rome. His father, who died in 59 BC, had been the first of the family to become a Roman senator and was elected to the high annual office of the praetorship, which ranked second in the political hierarchy to the consulship. Gaius Octavius' mother, Atia, was the daughter of Julia, the sister of Julius Caesar; and it was Caesar who launched the young Octavius in Roman public life. At the age of 12 he made his debut by delivering the funeral speech for his grandmother Julia. Three or four years later he received the coveted membership of the board of priests (*pontifices*). In 46 he accompanied Caesar, now dictator, in his triumphal procession after his victory in Africa over his opponents in the Civil War; and in the following year, in spite of ill health, he joined the dictator in Spain. He was at Apollonia (now in Albania), completing his academic and military studies when, in 44 BC, he learned that Julius Caesar had been murdered.

Rise to power. Returning to Italy, he was told that in his will Caesar had adopted him as his son and had made him his chief personal heir. He was only 18 when, against the advice of his stepfather and others, he decided to take up this perilous inheritance and proceeded to Rome. Mark Antony (Marcus Antonius), Caesar's chief lieutenant, who had taken possession of his papers and assets and had expected that he himself would be the principal heir, refused to hand over any of Caesar's funds, forcing Octavius to pay the late dictator's bequests to the Roman populace from such resources as he could raise. Caesar's assassins, Brutus and Cassius, ignored him and withdrew to the east. Cicero, the famous orator who was one of Rome's principal elder statesmen, hoped to make use of him but underestimated his abilities.

Celebrating public games, instituted by Caesar, to ingratiate himself with the city populace, Octavius succeeded

Augustus, bronze sculpture from Meroe, Sudan, 1st century AD. In the British Museum.

in winning considerable numbers of the dictator's troops to his own allegiance. The Senate, encouraged by Cicero, broke with Antony, called upon Octavius for aid (granting him the rank of senator in spite of his youth), and joined the campaign of Mutina (Modena) against Antony, who was compelled to withdraw to Gaul. When the consuls who commanded the Senate's forces lost their lives, Octavius' soldiers compelled the Senate to confer a vacant consulship on him. Under the name of Gaius Julius Caesar he next secured official recognition as Caesar's adoptive son. Although it would have been normal to add "Octavianus" (with reference to his original family name), he preferred not to do so. Today, however, he is habitually described as Octavian (until the date when he assumed the designation Augustus).

The Second Triumvirate

Octavian soon reached an agreement with Antony, as well as with another of Caesar's principal supporters, Lepidus, who had succeeded him as chief priest. On November 27, 43 BC, the three men were formally given a five-year dictatorial appointment as triumvirs for the reconstitution of the state (the Second Triumvirate—the first having been the informal compact between Pompey, Crassus, and Julius Caesar). The east was occupied by Brutus and Cassius, but the triumvirs divided the west among themselves. They also drew up a list of "proscribed" political enemies, and the consequent executions included 300 senators (one of whom was Antony's enemy Cicero) and 2,000 members of the class immediately below the senators, the equites or knights. Julius Caesar's recognition as a god of the Roman state in January 42 BC enhanced Octavian's prestige as son of a god.

He and Antony crossed the Adriatic and under Antony's leadership (Octavian being ill) won the two battles of Philippi against Brutus and Cassius, both of whom committed suicide. Antony, the senior partner, was allotted the east (and Gaul); and Octavian returned to Italy, where difficulties caused by the settlement of his veterans involved him in the Perusine War (decided in his favour at Perusia, the modern Perugia) against Antony's brother and wife. In order to appease another potential enemy, Sextus Pompeius (Pompey the Great's son), who had seized Sicily and the sea routes, Octavian married Sextus' relative Scribonia (though before long he divorced her for personal incompatibility). These ties of kinship did not deter Sextus, after the Perusine War, from making overtures to Antony; but Antony rejected them and reached a fresh understanding with Octavian at the treaty of Brundisium, under the terms of which Octavian was to have the whole west (except for Africa, which Lepidus was allowed to keep) and Italy, which, though supposedly neutral ground, was in fact controlled by Octavian. The east was again to go to Antony, and it was arranged that Antony, who had spent the previous winter with Queen Cleopatra in Egypt, should marry Octavian's sister Octavia. The peoples of the empire were overjoyed by the treaty, which seemed to promise an end to so many years of civil war. In 38 BC Octavian formed a significant new link with the aristocracy by his marriage to Livia Drusilla.

But a reconciliation with Sextus Pompeius proved abortive, and Octavian was soon plunged into serious warfare against him. When his first operations against Sextus' Sicilian bases proved disastrous, he felt obliged to make a new compact with Antony at Tarentum (Taranto) in 37 BC. Antony was to provide Octavian with ships, in return for troops Antony needed for his forthcoming war against the empire's eastern neighbour Parthia and its Median allies. Antony handed over the ships, but Octavian never sent the troops. The treaty also provided for renewal of the Second Triumvirate for five years, until the end of 33 BC.

Military successes. In the following year the balance of power began to change: whereas Antony's eastern expedition failed, Octavian's fleet, commanded by his former schoolmate, Marcus Agrippa, who, although unpopular with the influential nobles, was an admiral of genius, totally defeated Sextus Pompeius off Cape Naulochus (Venetico) in Sicily. At this point the third triumvir, Lepidus, seeking to contest Octavian's supremacy in the west by force, was disarmed by Octavian, deprived of his triumviral office, and forced into retirement. Ignoring Antony's right to settle his own veterans in Italy and recruit fresh troops, Octavian discharged many legionaries and founded settlements for them. His deliberate rivalry with Antony for the eventual mastership of the Roman world became increasingly apparent. Octavian's marriage two years earlier had begun to win over some of the nobles who had previously been Antony's supporters. Octavian also launched elaborate religious and patriotic publicity, centring on the classical god of order, Apollo, in contrast to Antony's more un-Roman patron, Dionysus (Bacchus). In addition, Octavian had started to prefix his name with the designation "Imperator," to suggest that he was the commander *par excellence;* and now, although he continued to use his triumviral powers, he omitted all reference to them from his coins, gradually concentrating on the plain, emotive name "Caesar Son of a God."

Retirement of Lepidus

But if Octavian was to compete with Antony's military seniority, successes in a foreign war were necessary; and so Octavian between 35 and 33 BC fought three successive campaigns in Illyricum and Dalmatia (parts of the modern Yugoslavia) in order to protect the northeastern approaches of Italy. With the help of Agrippa, he also lavished large sums on the adornment of Rome. When Octavian fomented public clamour against Antony's territorial gifts to Cleopatra, it was clear that a clash between the two men was imminent.

In 32 BC the triumvirate had officially ended, and Octavian, unlike Antony, professed no longer to be employing its powers. Amid a virulent exchange of propaganda, Antony divorced Octavia, whereupon her brother Octavian seized Antony's will and claimed to find in it damaging proofs of Cleopatra's power over him. Each leader induced the populations under his control to swear formal oaths of allegiance to his own cause. Then, in spite of grave discontent aroused by his exactions in Italy, Octavian declared war—not against Antony but gainst Cleopatra.

Defeat of Antony and Cleopatra

Accompanied by her, Antony had brought up his fleet and army to guard strongpoints along the coast of western Greece; but in 31 BC Octavian dispatched Agrippa very early in the year to capture Methone, at the country's southwestern tip. His enemies were taken by surprise; and after Octavian himself arrived—leaving his Etruscan friend and adviser Maecenas in charge of Italy—he and Agrippa soon shut Antony's fleet inside the Gulf of Ambracia (Arta). At the Battle of Actium Antony tried to extricate his ships in the hope of continuing the fight elsewhere. Though Cleopatra and then Antony succeeded in getting away, only a quarter of their fleet was able to follow them. She and Antony fled to Egypt and committed

suicide when Octavian captured the country in the following year. Executing Cleopatra's son Ptolemy XV Caesar (Caesarion)—whose father she had claimed was Caesar—he annexed Egypt and retained it under his direct control.

The seizure of Cleopatra's treasure enabled him to pay off his veterans and made him finally master of the entire Greco-Roman world. From this point on, by a long and gradual series of tentative, patient measures, he established the Roman principate, a system of government that enabled him to maintain, in all essentials, absolute control. Gradually reducing his 60 legions to 28, he retained approximately 150,000 legionaries, mostly Italian, and supplemented them by about the same number of auxiliaries drawn from the provinces. A permanent bodyguard (the Praetorians), based on the bodyguards maintained by earlier generals, was stationed partly in Rome and partly in other Italian towns. A superb network of roads was created to maintain internal order and facilitate trade; and an efficient fleet was organized to police the Mediterranean. In 28 BC Octavian and Agrippa held a census of the civil population, the first of three during the reign. They also reduced the Senate from about 1,000 to 800 (later 600) compliant members; and Octavian was appointed its president.

Master of the Greco-Roman world

Government and administration. Remembering, however, that Caesar had been assassinated because of his resort to naked power, Octavian realized that the governing class would welcome him as the terminator of civil war only if he concealed his autocracy beneath provisions avowedly harking back to republican traditions. From 31 until 23 BC the constitutional basis of his power remained a continuous succession of consulships, but in January 27 BC he ostensibly "transferred the State to the free disposal of the Senate and people," earning the misleading, though outwardly plausible, tribute that he had restored the republic. At the same time he was granted a ten-year tenure of an area of government (*provincia*) comprising Spain, Gaul, and Syria, the three regions containing the bulk of the army. The remaining provinces were to be governed by proconsuls appointed by the Senate in the old republican fashion. Octavian, however, believed that his supreme prestige—crystallized in the meaningful term *auctoritas*—safeguarded him against any defiance by these personages; and he was indeed able, more or less indirectly, to influence their appointments, just as he was able (on the rare occasions when he regarded it as desirable) to influence the appointments to the consulships and other metropolitan offices that continued to exist in "republican" fashion.

Autocracy in republican guise

Four days after these measures, his name Caesar, acquired through adoption in Julius' will, was supplemented by "Augustus," an appellation with an antique religious ring, believed to be linked etymologically with *auctoritas* and with the ancient practice of augury. The word *augustus* was often contrasted with *humanus;* its adoption as the title representing the new order cleverly indicated, in an extraconstitutional fashion, his superiority over the rest of mankind. With the aid of writers such as Virgil, Livy, and Horace, all of whom in their different ways shared the same ideas, he showed his patriotic veneration of the old Italian faith by reviving many of its ceremonials and repairing numerous temples.

Military operations continued in many frontier areas. In 25, recalcitrant Alpine tribes were reduced, and Galatia (central Asia Minor) was annexed. Mauretania, on the other hand, was transferred from Roman provincial status to that of a client-kingdom, for such dependent monarchies, as in the later republic, bore a considerable part of the burden of imperial defence. Augustus himself visited Gaul and directed part of a campaign in Spain until his health gave out; in 23 he fell ill again and seemed on the point of death. Feeling, amid reports of conspiracies, that new constitutional steps were necessary, he proceeded to terminate his series of consulships in favour of a power (*imperium majus*) which was separated altogether from office and its practical inconveniences. This power raised him above the proconsuls; it was never referred to on the official coinage or in Augustus' political testament but was intended to be exercised mainly in emergencies and on personal visits. He was also awarded the power of a tribune (*tribunicia potestas*) for life. Earlier, he had accepted certain privileges of a tribune. The full power he now assumed carried with it practical advantages, notably the right to convene the Senate. But, more particularly, the office of a tribune, because of the ancient character of the annually elected tribunes of the people as defenders of the *plebs,* surrounded him with a "democratic" aura, one which, perhaps, was needed all the more because Augustus himself—while admittedly supporting the interests of poorer people by a great extension of the right of judicial appeal—tended to back the established classes as the keystone of his system.

Agrippa, too, was granted superiority over proconsuls, presumably in order to ensure that the armies would be in safe hands in case one of Augustus' recurrent illnesses proved fatal. The next to die, however, was the emperor's young nephew Marcellus, who had been married to his daughter Julia and might eventually have been envisaged as his successor. In the same year, 23 BC, Agrippa was sent out to the east as deputy *princeps;* two years later he became Julia's second husband. Meanwhile Augustus himself travelled in Sicily, Greece, and Asia (22–19). Important reorganizations were put into effect wherever he went; and immense satisfaction was caused by an agreement in 20 BC with Parthia, under which the Parthians recognized Rome's protectorate over Armenia and returned the legionary standards captured from Crassus 33 years earlier. In 19 Agrippa completed the subjugation of Spain. In this year there was some adjustment of Octavian's powers to allow him to exercise them more freely in Italy, and the two following years witnessed social legislation attempting to encourage marriage, regulate penalties for adultery, and reduce extravagance. In 17 there were resplendent celebrations of ancient ritual, known as the Secular Games, to purify the Roman people of their past sins and provide full religious inauguration of the new age.

Although the principate was not an office which could be automatically handed on, Augustus seemed to be indicating his views regarding his ultimate successor when he adopted the two sons of his daughter Julia, boys aged three and one who were henceforward known as Gaius Caesar and Lucius Caesar. Their father Agrippa, whose powers had been renewed along with his master's, returned to the east. But now Augustus also gave important employment to his stepsons—his wife Livia's sons by her former marriage—Tiberius and Drusus the elder. Proceeding across the Alps, they annexed Noricum and Raetia, comprising large parts of what are now Switzerland, Austria, and Bavaria, and extended the imperial frontier from Italy to the upper Danube (16–15).

Reform of the administration

It was probably during these years that an executive, or drafting, committee (*consilium*) of the Senate was established in order to help Augustus to prepare senatorial business. His administrative burden was also lightened by the expansion of his own staff (knights, who could also now rise to a number of key posts, and freedmen) to form the beginnings of a civil service, which had never existed before but was destined to become an essential feature of the imperial system. Gradually, too, a completely reformed administrative structure of Rome, Italy, and the whole empire was evolved. The financial system that made this possible was evidently far more effective than anything the empire had ever seen until then. The system was based on the central treasury (*aerarium*), but the details of its relationship with the treasuries of the provinces, and particularly the *provincia* of Augustus, are still imperfectly understood, partly because, although the emperor proudly recorded his gifts to the central treasury, he did not report what funds passed in the opposite direction.

The taxation providing these resources apparently included two main direct taxes: a poll tax (*tributum capitis*), paid in some provinces by all adults and in others by adult males only, and a land tax (*tributum soli*). There were also indirect taxes, which (as in the past) were farmed out to contractors because their yield was unpredictable and the embryonic civil service lacked the resources to handle them. The republican customs dues continued; but its rates were low enough not to hamper trade, which, in the peaceful conditions created by Augustus, flourished in

wholly unprecedented fashion. Industries did not exist on a very large scale, but commerce was greatly stimulated by a sweeping reform and expansion of the Roman coinage. Gold and silver pieces, their designs reflecting many facets of imperial publicity, were issued in great quantities at a number of widely distributed mints; and from about 19 (or perhaps 23) BC onward the absence of bronze token coinage, which had been sparse for many decades, was remedied by the creation of abundant mintages in two bright new metals, yellow brass and red copper. In the West, the principal mint for these pieces, besides Rome, was Lugdunum (Lyon), whose coins displayed a view of the Altar of Rome and Augustus that formed a model for other provincial capitals. The Roman citizen colonies of the West, many of them established by Augustus to settle his veterans, supplemented this output by their own local coinages, and in the East, particularly Asia Minor and Syria, numerous Greek cities were also allowed to issue small change.

Expansion of the empire. The death in 12 BC of Lepidus, who had lived on in retirement for 24 years, enabled Augustus finally to succeed him as the official head of the Roman religion, the chief priest (*pontifex maximus*). In the same year, however, another death came as a severe blow to him, for Agrippa, too, died. Augustus compelled his widow Julia to marry Tiberius against the wishes of both of them. During the next three years, however, Tiberius was away in the field, reducing Pannonia (Yugoslavia and Hungary) up to the middle Danube, while his brother Drusus crossed the Rhine frontier and invaded Germany as far as the Elbe, where he died in 9 BC. In the following year Augustus lost another of his intimates, Maecenas, who had been the adviser of his early days and was an outstanding patron of letters.

Tiberius, who replaced Drusus in Germany, was elevated in 6 BC to a share in his stepfather's tribunician power. But shortly afterward he went into retirement on the island of Rhodes. This was attributed to jealousy of his stepnephew Gaius Caesar, who was introduced to public life with a great fanfare in the following year; and the same compliments were paid to his brother Lucius in 2 BC, the year in which Augustus received his climactic title "father of the country" (*pater patriae*). Gaius was sent to the East and Lucius to the West. Both, however, soon died, Lucius in AD 2 and Gaius in 4. Tiberius returned home in 2, and in 4 Augustus realized that he had to make him his heir.

Tiberius named heir

He adopted Tiberius as his son, who in turn was required to adopt Germanicus, the son of his brother Drusus. The powers conferred upon Tiberius made him almost Augustus' own equal in everything except prestige.

Tiberius' next task was to consolidate the invasion and provincial organization of Germany (4–5); and now that the Elbe was the frontier instead of the Danube, Augustus instructed him to establish a shorter frontier line incorporating Bohemia, which had become the nucleus of a German (Marcomannic) empire ruled by King Marobodduus. An invasion of Bohemia, therefore, was planned, and had already been launched, from two directions, when news came in 6 that Pannonia and Illyricum had revolted. It took three years for the rebellion to be put down; and this had only just been completed when Arminius raised the Germans against their Roman governor Varus and destroyed him and his three legions. As Augustus could not readily replace the troops, the annexation of western Germany and Bohemia was postponed indefinitely; Tiberius and Germanicus were sent to consolidate the Rhine frontier.

Although Augustus was now feeling his age, these years in association with Tiberius were marked by administrative innovations: the annexation of Judaea in AD 6 (its client king Herod the Great had died 10 years previously); the establishment at Rome (in the same year) of a fire brigade with police duties—supplemented seven years later by a regular police force (*cohortes urbanae*); the creation of a military treasury (*aerarium militare*) to defray soldiers' retirement bounties from taxes; and the conversion of the hitherto occasional appointment of prefect of the city (*praefectus urbi*) into a permanent office (AD 13). When, in the same year, the powers of Augustus were renewed for 10 years—such renewals had been granted at intervals throughout the reign—Tiberius was made his equal in every constitutional respect. In April, Augustus deposited his will at the House of the Vestals in Rome. It included a summary of the military and financial resources of the empire (*breviarium totius imperii*) and his ingenious political testament known as the "Res Gestae Divi Augusti" ("Achievements of the Divine Augustus"). The best preserved copy of the latter document is still to be seen on the walls of the Temple of Rome and Augustus at Ankara, Turkey (the Monumentum Ancyranum). In 14 Tiberius was due to leave for Illyricum but was recalled by the news that Augustus was gravely ill. He died on August 19, and on September 17 the Senate enrolled him among the gods of the Roman state. By that time Tiberius had succeeded him as the second Roman emperor, though the formalities involved in the succession proved embarrassing both to himself and to the Senate because the "principate" of Augustus had not, constitutionally speaking, been heritable or continuous. Like other emperors, Tiberius assumed the designation "Augustus" as an additional title of his own. Agrippa Postumus, who had been named his co-heir but was later banished, was put to death. The order to kill him may already have been given by Augustus, but this is not certain.

Personality and achievement. Augustus was one of the great administrative geniuses of history. The gigantic work of reorganization that he carried out in every field of Roman life and throughout the entire empire not only transformed the decaying republic into a new, monarchic regime with many centuries of life ahead of it but created a durable Roman peace, based on easy communications and flourishing trade. It was this Pax Romana that ensured the survival and eventual transmission of the classical heritage, Greek and Roman alike, and provided the means for the diffusion of Judaism and Christianity (Jesus Christ was born during Augustus' reign). Although his regime was an autocracy, Augustus, being a tactful and imaginative master of propaganda of many kinds, knew how to cloak that autocracy in traditionalist forms that would satisfy a warworn generation—perhaps, most of all, the upper bourgeoisie immediately below the leading nobility, since it was they who benefitted from the new order more than anyone. He was also able to win the approbation, through the patronage of Maecenas, of some of the greatest writers the world has ever known, including Virgil, Horace, and Livy.

Pax Romana

Their enthusiasm was partly due to Augustus' conviction that the Roman peace must be under occidental, Italian control. This was in contrast to the views of Antony and Cleopatra, who had envisaged some sort of Greco-Roman partnership such as only began to prevail three or four centuries later. Augustus' narrower view, although modified by an informed admiration of Greek civilization, was based on his small-town Italian origins. These were also partly responsible for his patriotic, antiquarian attachment to the ancient religion and for his puritanical social policy.

Augustus was a cultured man, the author of a number of works (all lost): a pamphlet against Brutus, an exhortation to philosophy, an account of his own early life, a biography of Drusus, poems, and epigrams. The conventional view of his character distinguishes between his cruelty in early years and his mildness in later life. But there was not so much need for cruelty later on, and when it was needed (notably in the suppression of alleged plots), he was still ready to apply it. It is probable that nothing short of this degree of political ruthlessness could have achieved such enormous results. His domestic life, however, was simple and homespun. Within his family, the successive deaths of those he had earmarked as his successors or helpers caused him much sadness and disappointment. His devotion to his wife Livia Drusilla remained constant, though, like other Romans, he was unfaithful. His surviving letters show kindliness to his relations. Yet he exiled his daughter Julia for offending against his public moral attitudes, and he exiled her daughter by Agrippa for the same reason; he also exiled the son of Agrippa and Julia, Agrippa Postumus, though the suspicion that he later had him killed is unproved. As for Augustus' male relatives who were his

helpers, he was loyal to them but drove them as hard as he drove himself. He needed them because the burden was so heavy, and he especially needed them in the military sphere because he was not a great commander. In Agrippa and Tiberius and a number of others he had men who supplied this deficiency, and although, on his deathbed, he is said to have advised against the further expansion of the empire, he himself, with their assistance, had expanded its frontiers in many directions.

His physical condition was subject to a host of ills and weaknesses, many of them recurrent. Indeed, in his early life, particularly, it was only his indomitable will that enabled him to survive—a strange preliminary to an unprecedented and unequalled life's work. His appearance is described by the biographer Suetonius.

> He was unusually handsome and exceedingly graceful at all periods of his life, though he cared nothing for personal adornment. His expression, whether in conversation or when he was silent, was calm and mild . . . He had clear, bright eyes, in which he liked to have it thought that there was a kind of divine power, and it greatly pleased him, whenever he looked keenly at anyone, if he let his face fall as if before the radiance of the sun. His teeth were wide apart, small and ill-kept; his hair was slightly curly and inclining to golden; his eyebrows met . . . His complexion was between dark and fair. He was short of stature, but this was concealed by the fine proportion and symmetry of his figure, and was noticeable only by comparison with some taller person standing beside him.

Augustus' countenance proved a godsend to the Greeks and Hellenized easterners who were the best sculptors of the time, for they elevated his features into a moving, never to be forgotten imperial type, which Napoleon's artists, among others, keenly emulated. The contemporary portrait busts of Augustus, echoed on his coins, formed part of a significant renaissance of the arts in which Italic and Hellenic styles were discreetly and brilliantly blended. Still extant at Rome are the severe yet delicate reliefs of the Ara Pacis ("Altar of Peace"), depicting a religious procession in which the national leaders are taking part; there are also scenes from the Roman mythology. The altar was dedicated by the Senate and people of Rome in 13 BC to commemorate the pacification of Gaul and Spain.

The architectural masterpieces of the time were also numerous; and something of their monumental grandeur and classical purity can be seen today in the remains of the Theatre of Marcellus at Rome and of the massive Forum of Augustus, flanked by colonnades and culminating in the Temple of Mars the Avenger—the Avenger of Julius Caesar. Outside Rome, too, there are abundant memorials of the Augustan age; on either side of the Alps, for example, there are monuments to celebrate the submission and loyalty of the local tribes, an elegant arch at Segusio (Susa) and a square stone trophy, topped by a cylindrical drum, at La Turbie. From Livia's mansion on the outskirts of Rome, at Prima Porta, comes a reminder that not all the art of the day was formal and grand. For one of the rooms is adorned with wall paintings representing an enchanted garden; beyond a trellis are orchards and flower beds, in which birds and insects perch among the foliage. Augustus himself had no interest in personal luxury. Yet if ever he or his associates had any spare time, such were the rooms in which they spent it.

(M.Gr.)

BIBLIOGRAPHY. The principal ancient literary sources are GAIUS SUETONIUS TRANQUILLUS, *De Vita Caesarum,* in Latin, which describes the lives of the Roman emperors from Julius Caesar to Domitian; and books 52–56 of CASSIUS DIO COCCEIANUS, *Romaika,* a history of Rome, written in Greek. Both exist in several English translations, including, respectively, SUETONIUS, *The Twelve Caesars,* trans. by ROBERT GRAVES, rev. ed. (1979); and DIO CASSIUS, *Dio's Roman History,* trans. by EARNEST CARY, 9 vol. (1914–27, reprinted 1961), which includes the Greek text. *Inscriptions: Res Gestae Divi Augusti: The Achievements of the Divine Augustus,* ed. by P.A. BRUNT and JOHN M. MOORE (1967, reprinted 1979); VICTOR EHRENBERG and A.H.M. JONES (comps.), *Documents Illustrating the Reigns of Augustus and Tiberius,* 2nd ed. (1955, reprinted with addenda, 1976). *Coins:* CAROL H.V. SUTHERLAND, *Coinage in Roman Imperial Policy, 31 B.C.–A.D. 68* (1951, reprinted 1978); MICHAEL GRANT, *From Imperium to Auctoritas* (1946, reprinted 1969). *Art:* JOCELYN M.C. TOYNBEE, *The Art of the Romans* (1965); AXEL BOËTHIUS and J.B. WARD-PERKINS, *Etruscan and Roman Architecture* (1970). Modern sources include several books by RONALD SYME: *The Roman Revolution* (1939, reprinted 1974), a scholarly analysis of Augustus' creation of the Roman imperial system; *History of Ovid* (1978), which deals with Augustus' motives for Ovid's exile; and *Roman Papers,* 2 vol. (1979). Other works include ARNOLD H.M. JONES, *Augustus* (1970); MASON HAMMOND, *The Augustan Principate in Theory and Practice During the Julio-Claudian Period,* new ed. (1968); *The Cambridge Ancient History,* vol. 10, *The Augustan Empire, 44 B.C.–A.D. 70* (1934, reprinted 1966); DONALD C. EARL, *The Age of Augustus* (1968, reissued 1980); JOHN M. CARTER, *The Battle of Actium: The Rise and Triumph of Augustus Caesar* (1970); HOWARD H. SCULLARD, *From the Gracchi to Nero,* 5th ed. (1982), and *Roman Britain* (1979); JOHN C. STOBART, *The Grandeur That Was Rome,* 4th ed. (1961, reprinted 1971), a survey of Roman culture and civilization; HERMANN BENGTSON, *Kaiser Augustus: sein Leben und seine Zeit* (1981), an illustrated biography; HELMUT SIGNON, *Agrippa* (1978), which explores Marcus Vipsanius Agrippa's friendship and collaboration with Augustus; COLIN M. WELLS, *The German Policy of Augustus: An Examination of the Archaeological Evidence* (1972); MAX CARY and HOWARD H. SCULLARD, *A History of Rome Down to the Reign of Constantine,* 3rd ed. Australia

Australia is located in the Southern Hemisphere between the Indian Ocean and the South Pacific, on an island continent that has been called both the Oldest Continent and the Last of Lands. Although possibly poetic, neither description is accurate. It is the oldest continent only in the senses that much of Australia is formed of rocks laid down during the Precambrian (4,600,000,000 to 570,000,000 years ago), and that it has altered relatively little since life first appeared on Earth. It is the last of lands only in the sense that it was the last continent (excluding Antarctica) to be discovered and explored by Europeans. Thousands of years before the explorers Abel Tasman and James Cook sailed into the South Pacific, the Aborigines had crossed the land bridge from Asia formed by the Malay Archipelago and had spread throughout the mainland and Tasmania. They remained, however, a sparse, primitive, and nomadic people. When Capt. Arthur Phillip of the British Royal Navy landed with the First Fleet at Botany Bay in 1788, the event that marks the true beginning of modern Australia, there were probably not more than 300,000 Aborigines altogether, and there was no man-made structure on the continent more solid than a bark hut.

The most striking characteristics of the vast, 3,000,000-square-mile (8,000,000-square-kilometre) landmass are its isolation, its low relief, and the aridity of much of its surface. Its isolation from other continents explains much of the strangeness of Australian plant and animal life; its low relief results from the long and extensive erosive action of the forces of wind, rain, and the heat of the Sun during the great periods of geological time when the continental mass was elevated well above sea level.

A member of the Commonwealth of Nations, the Commonwealth of Australia is a prosperous, independent nation united under one government. Australians are in many respects fortunate in that they do not share their continent—which is only a little smaller than the United States—with any other nation. Their nearest neighbours are Papua New Guinea and Indonesia to the north, the Polynesians and Melanesians of the Pacific Islands to the east, and New Zealand, which, like Australia, is a member of the Commonwealth of Nations, to the southeast. On the other hand, Australia is extremely remote from its two principal allies: it is 12,000 miles (19,000 kilometres) from Australia to Great Britain via the Indian Ocean and the Suez Canal; it is 7,000 miles across the Pacific to the West Coast of the United States.

Like Canada and the United States, contemporary Australia is a political federation with a central government (the Commonwealth) and six constituent states (New South Wales, Victoria, Queensland, South Australia, Western Australia, and Tasmania), each of which has its own government enjoying a limited sovereignty. There are also two internal territories: the Northern Territory was established as a self-governing territory in 1978, and the Australian Capital Territory, seat of the federal capital city Canberra, is administered directly by the Commonwealth, which also governs the external territories of Norfolk Island, Cocos (Keeling) Islands, Christmas Island, Ashmore and Cartier Islands, Coral Sea Islands, and Heard and McDonald Islands and claims the Australian Antarctic Territory. The Cocos Islands was a non-self-governing territory until 1984, when it was integrated with Australia following an act of self-determination approved by the Cocos Malay people. Papua New Guinea, which formerly was an Australian external territory, became an independent nation in 1975.

The article is divided into the following sections:

PHYSICAL AND HUMAN GEOGRAPHY

Geological history

A popular misconception about the observed peculiarities of Australia is that it is the oldest of continents. The statement is, in fact, unjustified: the cores of all of the continents are of approximately the same age, and rocks of all geological ages, of sedimentary as well as volcanic origin, are found in Australia. The misconception about its age stems partly from its relative paucity of surface relief, the result of relative stability and the absence of recent strong movements of the Earth's crust, rather than the old age of its rocks. The geologically young mountain-building forces, such as those that formed the Himalayas in Asia, the Alps in Europe, the Rocky Mountains in North America, and the Andes in South America, have bypassed Australia.

Australia resembles the continents of Eurasia and Africa in being strikingly different from the landmass of North America, which consists basically of an old core, the Canadian Shield, surrounded by mountain zones formed from belts of folded rocks of varying ages, all younger than the central core. Australia is strikingly asymmetric, with a folded belt of rocks bordering its east coast only and extending westward to no more than one-fourth of the continent's width.

Like the other continental masses, Australia is built of three types of structural units. In the west is the Western Australian Shield (Western Craton), a comparatively stable and resistant block consisting mainly of ancient rocks that have not been folded during at least the last 1,000,000,000 years. In the east is an ancient fold mountain belt, greatly eroded but relatively uplifted again. Between these two lies the platform-like area occupied by the central plains, a region where crystalline or folded rocks are overlain by relatively thin sequences of flat-lying or gently deformed sediments. Each of these major units is complex. The Western Australian Shield, for example, includes, in addition to extensive outcrops of crystalline rocks in the core area itself, blocks of sedimentary strata deposited in troughs and basins within this structural unit. The central platform consists of several basin structures. The Eastern Uplands include both upfaulted and depressed structural blocks, along with large, exposed, formerly molten intrusions (batholiths) of granite formed within the past 50,000,000 years, and extensive lava flows formed during the Cenozoic Era.

The outline of the Australian continent, unlike those of South America and Africa, and the Indian subcontinent, is not roughly triangular with an apex pointing southward, though some resemblance to this distinctive configuration of the other continents and subcontinents can be seen in the shape and position of Tasmania. This island is part of the continent if the base of the shallow peripheral submarine area known as the continental shelf is taken as its outer boundary. The continental shelf and the slope separating it from the ocean depths are moderately wide in the south and southwest and spectacularly wide in the northwest from Exmouth Gulf to the Timor Sea, where the distance of the slope base from the shore exceeds 300 miles (470 kilometres), and the line marking depths that exceed 650 feet (200 metres) is more than 250 miles from the shore. To the north of Australia, the continental shelf extends to the island of New Guinea. The shelf is narrow along the east coast, where the Great Barrier Reef marks its edge. A trough, with depths of about 3,000 feet (900 metres), separates the Great Barrier Reef from the largely submerged Queensland Plateau, where only a few small islands and reef tops reach sea level. Off Brisbane and Sydney, the continental shelf is only some 30 miles (48 kilometres) wide, and the slope plunges steeply to the floor of the Tasman Sea.

The discovery of vast and varied mineral deposits in Australia stimulated intensive studies of its geological history and structure. At the same time, new developments in general geological theory, including the concepts of continental drift and ocean-floor spreading, have led to renewed speculation regarding possible former land connections between Australia and other continents, particularly Antarctica. As a result, the answer to the problem of how the history of the Australian continent fits into the picture of the development of the Earth's crust as a whole will have to come from a deeper understanding not only of the geology of the continent but also of that of the ocean surrounding it.

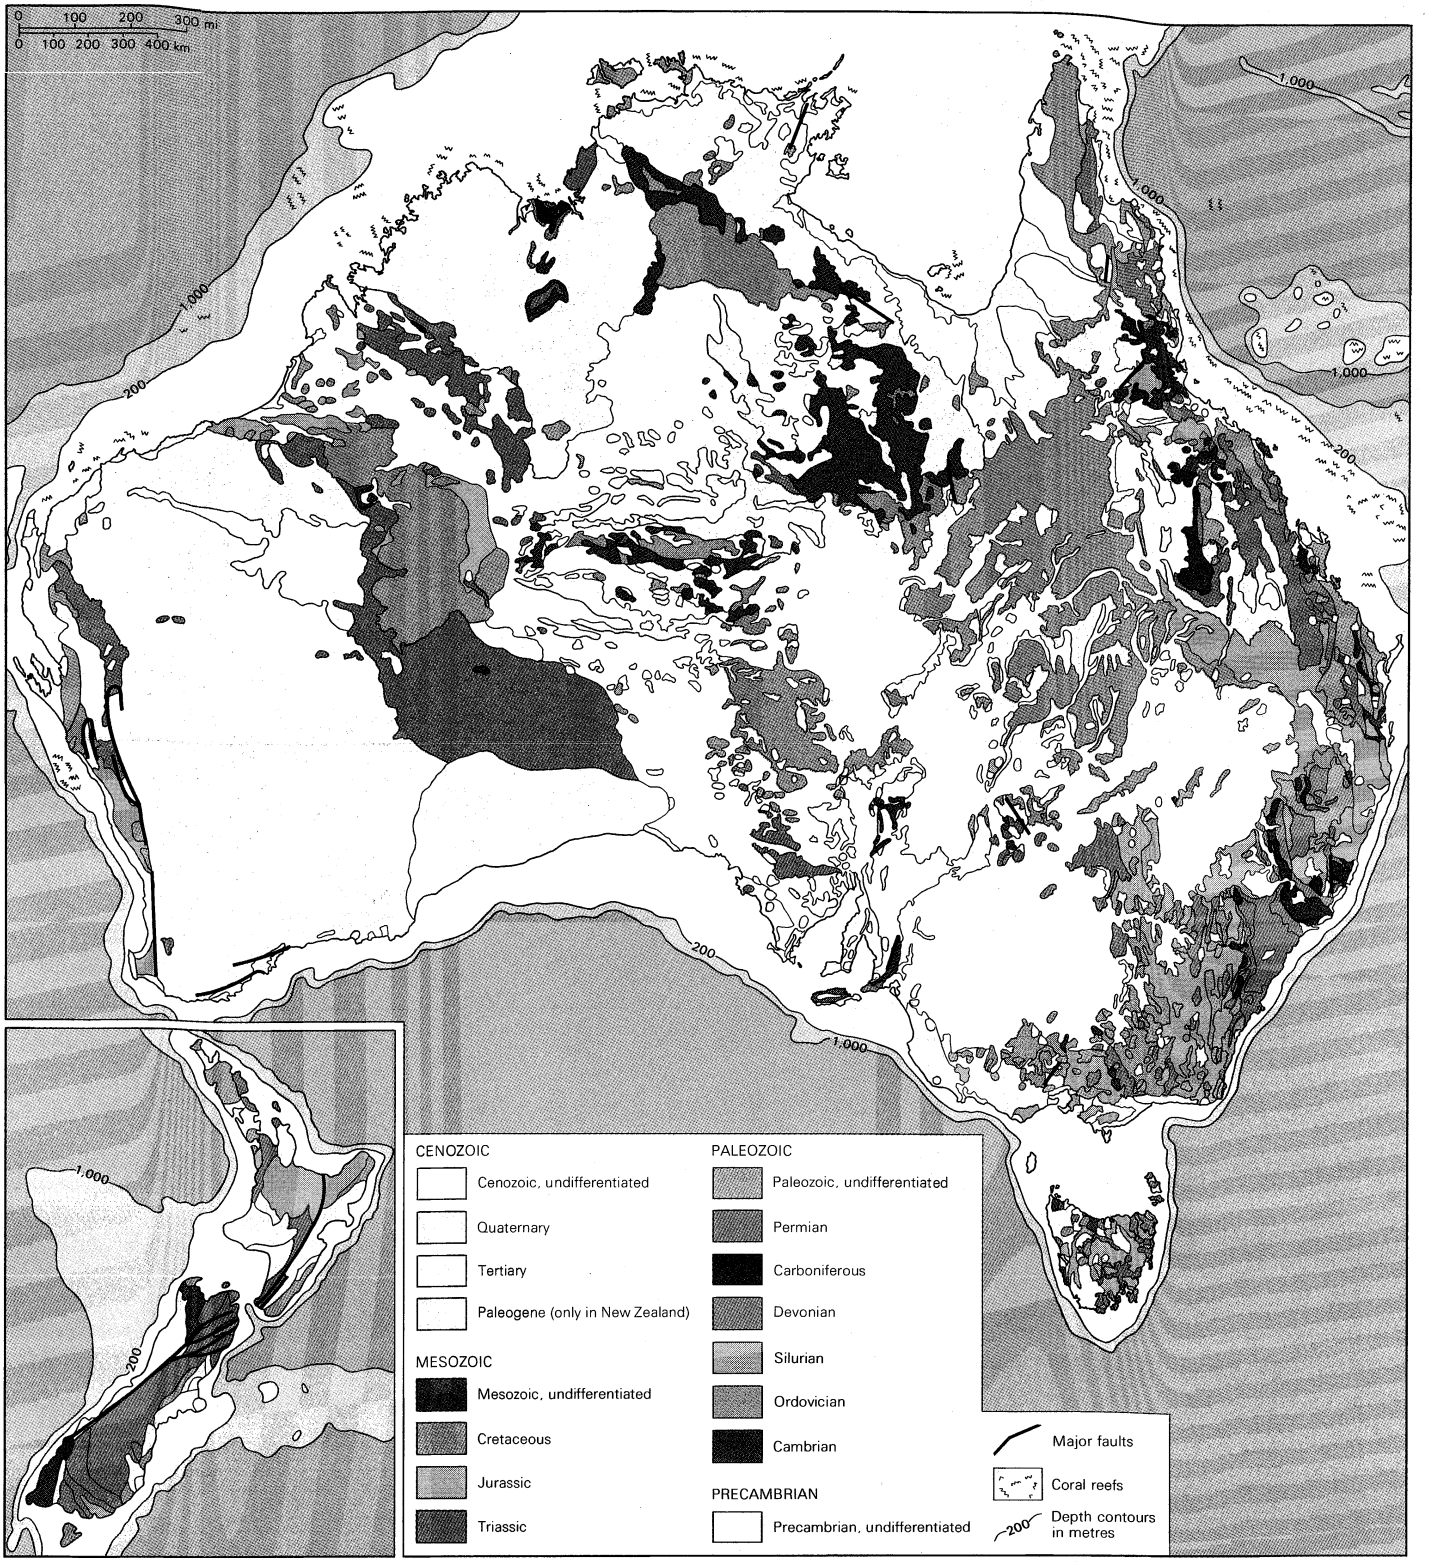
THE OLDEST ROCKS: THE PRECAMBRIAN

The oldest rocks of the continent occur in the southwest, where they form part of the Western Australian Shield, an area underlain by rocks that have not been folded since early Precambrian (Archaean) time. These oldest rocks are now thought to be about 3,000,000,000 years old. The Yilgarn nucleus of the Western Australian Shield extends over 230,000 square miles (600,000 square kilometres) and consists mostly of granite, with belts of altered sedimentary rocks (metasediments) and greenstones, the latter including ancient rocks rich in economically important mineral deposits, as well as basic intrusions of formerly molten rocks. Similar to metal-bearing greenstone rock belts occurring in the nuclei of the ancient shield areas of other continents, these Australian formations are being studied in the hope that the origin of these rock belts and their ore bodies will be explained in terms of the state of the Earth's crust and mantle at the beginning of geological time. The conditions under which the continental crust was formed and then reworked are not yet known, but geologists believe that some of the peculiarities of ancient rocks, their structure, and their composition can be explained only by assuming that the Earth's crust was originally much thinner than it is today.

Formation of the continental crust

The Yilgarn nucleus does not extend as far as the west and south coasts of Western Australia, where younger Precambrian rocks occur. Those on the west coast are separated by the Darling Fault, which forms the western margin of the shield near Perth, and by the Perth Basin. The Frazer Fault apparently marks the boundary between rocks of the main shield area that were metamorphosed by heat and pressure more than 2,500,000,000 years ago and others to the southeast that were similarly affected less than 2,000,000,000 years ago. Each of these major fault lines is about 600 miles (960 kilometres) long and is considered as a major lineament in the continental structure. The older rocks appear again in the Pilbara nucleus in the northwest, where some granites are more than 3,000,000,000 years old and where altered volcanic, greenstone, and sedimentary rocks also occur.

Large platforms and basins separate the Yilgarn and Pilbara nuclei of the Western Australian Shield from other occurrences of ancient rocks in the northwest and north of the continent and in central Australia. It is not yet known whether a major part of these other instances of



Geological structure of Australia and (inset) New Zealand.

ancient rocks are as old as those that have been dated as Archaean in the west. Therefore, the earliest geographic configuration of the Australian continent cannot be reliably reconstructed; it could have extended northward and eastward far beyond the limits of the present Western Australian Shield.

Old (Archaean) rocks on the margins of the Kimberley Block form its basement; they occur also in the Katherine–Darwin area of the Northern Territory, in the Rum Jungle Complex. No definite datings of rocks in the east indicate ages as great as those of the oldest shield rocks, although part of the Arunta Complex, north of Alice Springs in the centre of Australia, may be approximately 2,250,000,000 years old.

The post-Archaean geological history of Australia can be seen in a clearer framework; the general terms Early, Middle, and Late Proterozoic, or the regional terms Nullaginian, Carpentarian, and Adelaidean, are used to identify intervals in the time scale of this period and are documented by sedimentary rock sequences.

Post-Archaean regional rock units

The Nullaginian System comprises platform cover south of the Pilbara nucleus, including the vast banded iron ore formations of the Hamersley Ranges (notably the Mt. Bruce supergroup, which also contains volcanic rocks dated at 2,200,000,000 to 1,950,000,000 years ago) and the rocks in the east Kimberley area. The Carpentarian System comprises a belt of sedimentary rocks—the McArthur Basin, southwest of the Gulf of Carpentaria—that may be 1,500,000,000 to 1,800,000,000 years old; younger granites in the Katherine–Darwin region; and the sediments and intrusive granites of the Mt. Isa–Cloncurry region. The rocks of these regions are rich in mineral deposits. In South Australia, the basement rocks (gneisses) of Eyre Peninsula in the west and the Mt. Painter Complex in the northeast, and extending to Broken Hill in New South Wales (Willyama Block), may be of the same age as those of the Carpentarian System, although the iron formations of the Middleback ranges have been considered to be as old as the early Proterozoic iron formations found in the Pilbara region.

The Adelaidean System is made up of rocks of Late Precambrian age. Consolidation of the Musgrave Block in central Australia and intrusion of various molten rocks took place during the time interval 1,400,000,000 to 1,000,000,000 years ago, forming an extension of the Western Australian Shield. At the same time, sedimentary rocks were laid down in the Adelaide Geosyncline, a vast downwarping of the Earth's surface lying to the southeast. Sedimentation continued into mid-Cambrian time in a shallow marine trough extending from the coast south of Adelaide at least 400 miles (640 kilometres) northward, through the Mt. Lofty and Flinders ranges, and measuring 640 miles (1,025 kilometres) from west to east, from Lake Torrens to beyond Broken Hill. These rocks, with a total maximum thickness of more than 10 miles (16 kilometres), formed in an intermittently sinking trough in which the accumulating sediments were subjected to moderately strong folding and faulting in Late Precambrian and Early Paleozoic time. This Adelaidean sedimentary sequence has characteristic features of outstanding importance for Earth history: most of the sediments, which have remained unaltered, contain definite evidence of a major glacial period; they also contain the oldest known rich and varied assemblage of fossil animals, all of which were essentially soft-bodied. Rocks of similar age also occur in the Peake and Denison ranges west of Lake Eyre, in the Amadeus Basin, and on the margins of the Kimberley Block. In the area there is also clear evidence of a Precambrian glaciation. Its earlier phase has been dated at about 740,000,000 years, while the later phase was little older than 660,000,000 years. This is the likely time range of glaciation in the Adelaide Geosyncline and probably also of related glaciations in other continents: it was probably one of the most extensive periods of cold in the Earth's history. No definite Precambrian animal remains are known from rocks that have been identified as older than the onset of this glaciation; on the other hand, primitive aquatic plant fossils have been found abundantly in earlier Precambrian strata.

The Adelaide Geosyncline

PALEOZOIC HISTORY OF EASTERN AUSTRALIA

The Adelaide Geosyncline is often considered as a precursor of the more extensive fold belts of eastern Australia. These form another great downwarp known as the Tasman Geosyncline. While the rocks of the Adelaide Geosyncline were folded in Late Cambrian time, about 500,000,000 years ago, and elevated so that sedimentation ceased, the Tasman Geosyncline began to form in Cambrian time, the first period of the Paleozoic Era, which was to last for the next 300,000,000 years.

The Tasman Geosyncline

Australian landscapes.
(Top left) St. Mary Peak, Flinders Range, South Australia. Mineral traces are evident in upper crests. (Top right) Macdonnell Ranges, west of Alice Springs, Northern Territory. The low parallel ridges, cut in folded strata, run practically unbroken for 150 miles. (Bottom left) Simpson Desert, central Australia, one of the most desolate areas of the continent, contains neither water nor habitation. In the foreground are sand humps covered with spinifex, the scattered vegetation characteristic of the desert. (Bottom right) Mt. Olga, a huge red sandstone monolith, rises 1,500 feet above the plain, south of Lake Amadeus in the Northern Territory.

Cambrian strata. Cambrian strata, containing marine fossils indicating their age, are known only from a few areas in eastern Australia: Tasmania, central Victoria, and northeast of Broken Hill in western New South Wales. It is possible that Cambrian rocks outcrop also on the coast of southern New South Wales. These few occurrences are insufficient to support any well-founded reconstruction of the geography of the Australian continent in Cambrian time, but they do indicate a fundamental difference in conditions of sedimentation in the east, where the rocks are similar to those deposited in deep geosynclinal troughs generally, and the large areas in southern, central, and northern Australia, including the Amadeus and Georgina basins, where the Cambrian rocks were mostly formed in shallow water. These differences are the expression of the relative stability of the western areas as compared with the greater geological mobility of eastern Australia during Paleozoic time, although any boundary between these two areas is likely to be gradational rather than a definite line.

An attempt at a generalized western margin of the Tasman Geosyncline might be drawn from the north Queensland coast, at about longitude 144° E and latitude 14° S, around the Precambrian Georgetown area to Charters Towers, south-southwestward to near Wilcannia on the Darling River, and thence either due south or southwestward to Kangaroo Island. The discontinuous folded and granite-intruded Paleozoic rocks east of this somewhat hypothetical boundary are now separated by generally flat-lying younger rocks deposited in separate sedimentary basins. Because there is no obvious continuity of folded zones and of belts of contemporaneous folding from the south coast to the north of eastern Australia, it has been suggested by some that a Lachlan Geosyncline in the southeast (mainly in Victoria and south central New South Wales) should be distinguished from the New England Geosyncline, the western boundary of which extends from Newcastle to south of Townsville. They are two component parts of the Tasman geosynclinal belt and are similar in rock types, but they are different in age and geographic position.

Ordovician rocks. In contrast with the paucity of information on Cambrian Australia, the geography of eastern Australia in Ordovician time, from 500,000,000 to 430,000,000 years ago, is sufficiently well known to permit some general statements. The Lachlan Geosyncline was the site of sedimentation that took place in a series of troughs separated by rising upwarped ridges. No western shoreline can be defined, but the characteristics of Ordovician rocks in the Broken Hill region, and the evidence of bores in northeastern South Australia, indicate that these localities lay outside the geosynclinal belt in platform areas where subsidence was less intense. The geosynclinal nature of most of the rocks of Victoria, and southern and central New South Wales, is indicated by the great thicknesses of marine rocks deposited partly in deep quiet water (as in the case of black shales) and partly by mud-laden currents flowing from higher areas of the sea floor, producing the muddy sandstones known as graywackes. The rocks in the central part of the geosyncline were altered by heat and pressure, and volcanic rocks are widely distributed. In many parts of the Lachlan Geosyncline, folding movements (known as the Benambran orogeny, or mountain-building movement) occurred at the end of Ordovician and in early to mid-Silurian time. Accompanied by granite intrusions, these movements are thought to have caused the changes in composition and texture of the Ordovician rocks in the Snowy Mountains.

The Lachlan Geosyncline

Silurian rocks. The Benambran mountain-building movements changed the geographic framework of the sedimentation that occurred during Silurian times (from 430,000,000 to 395,000,000 years ago). The eastern margin of the Lachlan Geosyncline now extended from the Melbourne area northward through Cobar to the Adavale Trough. In the Melbourne Trough there are thick Silurian graywackes and mudstones with graptolites and other fossils, and the area of sedimentation extended southward into Tasmania, where shallow-water rocks were laid down. Farther east, in southern New South Wales, the Yass Shelf was an area of volcanic rocks and sedimentary rocks, including limestones and shales that are now famous for their fossils. Silurian rocks are not well known in the New England Geosyncline and in southern Queensland, but farther north there is another peripheral shelf development, with Silurian limestones occurring along the western margin of the Tasman geosynclinal belt and the Chillagoe Shelf and its southward extension.

Devonian rocks. Deposition in the Lachlan Geosyncline generally continued from Silurian into Lower and Middle Devonian Periods, from 400,000,000 to 350,000,000 years ago, although the earth-movements of the Bowning orogeny occurred at the end of the Silurian and through early Devonian. Evidence of this can be seen as an unconformity, or break, in the rock layers of the sedimentary series of the Canberra–Yass area: molten rocks were intruded into the sedimentary rocks during this period. This activity again changed the geography of sedimentary areas in the Lachlan Geosyncline. In particular, a shallow-water platform with limestone deposition extended from eastern Victoria (Buchan Caves) to the Yass–Taemas area. Geosynclinal deposition during early and mid-Devonian time was widespread in the New England Geosyncline and its extension in southeastern Queensland, but only corals preserved in isolated limestones permit precise dating of the rock layers.

The Tabberabberan earth movements

The Tabberabberan period of earth movements, which occurred at the end of mid-Devonian time, had a profound effect on the geographic development of eastern Australia. Marine sedimentation in the Lachlan Geosyncline ended, and nonmarine rocks, in part red sandstone beds resembling similar sandstones found in northern Europe, were deposited. Discoveries of abundant fossil remains of armoured fishes—notably the widely distributed *Bothriolepis,* which is also found in central Australia, North America, Eurasia, and Antarctica—have been made in western New South Wales. Remains of the scale-tree *Leptophloeum* are also common. Erosion of the rocks of uplifted areas in central Australia, Victoria, and most of New South Wales must have produced the material for extensive Late Devonian and Early Carboniferous lake and river deposits. These include sandstones of the Grampian Mountains in western Victoria.

Carboniferous and Permian rocks. In the eastern troughs, from New England to eastern Queensland, geosynclinal deposition continued under the influence of volcanic activity. In the Carboniferous Period, about 300,000,000 years ago, nonmarine rock deposition occurred in the south and west, while marine sediments accumulated in the east. The central part of New England was uplifted. The earliest FIleozoic glaciations in eastern Australia are of Late Carboniferous age and have been considered as the result of mountain glaciation.

The youngest rocks in the New England Geosyncline that were deposited before final deformation are of Permian age (about 280,000,000 to 225,000,000 years ago) and of marine origin. In Middle and Late Permian time the great New England batholith was emplaced in the older rocks, which were heavily folded toward the west. A line extending from the mouth of the Hunter River near Newcastle in the south to the eastern margin of the Bowen Basin in the Rockhampton–Bowen area marks the western limit of the Hunter–Bowen orogeny, which was the last of the major mountain-building phases in the Tasman geosynclinal belt and which terminated its existence as a belt of troughs of sedimentation.

The Hunter–Bowen earth movements

SEDIMENTARY BASINS AND MESOZOIC HISTORY

Quite distinct from the history of the successive, more or less elongated, highly mobile (in geological terms) troughs discussed above is the development of sedimentary basins over the Australian continent. Some of these developed at various times on the Precambrian basement of the western and central parts of the continent, while in other areas this type of sedimentation followed the consolidation of folded belts of Paleozoic rocks and interrupted their continuity. Others are superimposed on differently shaped preexisting basins.

Like the Perth Basin, which adjoins it to the south, the Carnarvon Basin of Western Australia began to form in Silurian time and contains Late Paleozoic deposits, including Early Permian glacial sediments, followed by Lower Triassic and, in places, nearly 13,000 feet (4,000 metres) of Jurassic sediments, dating from about 180,000,000 to 140,000,000 years ago. During the Upper Cretaceous Period, about 100,000,000 years ago, sedimentation in the Carnarvon Basin changed from sands and shales to limestones and chalks, and this may be related to a change to warmer water conditions, which continued in the north until Miocene time, less than 25,000,000 years ago. The west coast of the continent was, to varying extents over the course of the last 400,000,000 years, a geologically mobile shelf area; it exhibits an alternation of marine and nonmarine deposits representing successive transgressions and regressions of the sea.

In northwestern Australia the shallower Canning Basin with the adjoining deeper Fitzroy Trough formed a large subsidence area between the Western Australian Shield and the Kimberley Block. The Joseph Bonaparte Gulf and Ord basins extend along its northern and eastern margins on the West Australian–Northern Territory border. These basins date back to Ordovician time. The Canning Basin may have been linked eastward, through the Officer and Amadeus basins of central Australia, with the Tasman geosynclinal belt in the east, and, again in Permian time it may have extended southeastward in a similar manner. Such temporary configurations are exceptional in ancient Australian geography. As a rule, the structural independence of the basins is supported by differences in their fossil remains. An outstanding development of Devonian reef complexes is known from the northern edge of the Canning–Fitzroy basins, while Permian glacial deposits occur on its southern margin and continue into South Australia, Victoria, and New South Wales.

The Amadeus Basin. The Amadeus Basin in central Australia is a large depression extending east–west for 450 miles (720 kilometres) and north–south for no more than 160 miles (260 kilometres) and filled with many varieties of ancient sedimentary rocks. It is situated between the so-called Musgrave structural block in the south and the Arunta structural complex in the north, and both have moved toward, and folded sediments of, the basin at different times. Some sediments were deposited during the folding of the Macdonnell Ranges near Alice Springs, which later erosion shaped into spectacular scenery. The isolated sandstone masses of Ayers Rock and Mt. Olga are now considered to be of Cambrian age.

The Canning Basin continued to exist as a depositional trough during Jurassic time, when only its northwestern margin received marine sediments, and also through the early Cretaceous Period. During the early Cretaceous a great marine transgression joined it again southeastward with the Eucla and Officer basins and eastward with the Great Artesian Basin.

The Eucla and Officer basins. The Eucla Basin is a large but shallow depression lying between the Western Australian Shield and the basement rocks of Eyre Peninsula. Permian and Cretaceous rocks are known to exist from the evidence of bores. Above them lie Tertiary limestones, which are no more than a few hundred feet thick, perfectly flat-lying, with their surface forming the arid Nullarbor Plain. They are riddled with caves, many of which remain unexplored. The Officer Basin, south of the Musgrave Block, is filled with late Precambrian and Cambro-Ordovician rocks.

The Great Artesian Basin. The Great Artesian Basin is a large (670,000 square miles [1,735,000 square kilometres]) and complex, generally slowly subsiding area, in which, by Jurassic time, several previously separate basins (such as the Cooper Basin, with its rich gas-bearing Permian sands) had been incorporated. The Jurassic nonmarine sands of the Great Artesian Basin, which spread from the eastern highlands to the western margins of the basin, provide its most important sources of water. By mid-Cretaceous time the sea invaded the basin from the northeast and southwest, but the early Upper Cretaceous is represented by marine fossil-bearing deposits only near the northern coasts. The northernmost part of the Great Artesian Basin is separated from its main body by a basement ridge that hardly reaches the surface; north of it only Cretaceous and younger rocks are found. The southern boundary is formed by extensive basement outcrops in the Broken Hill–Wilcannia–Cobar areas, and the lowlands to the south are considered a separate unit, the Murray Basin. Permian and Mesozoic rocks play only a minor part in its filling. Its rocks are mostly of Tertiary age, marine in the west and mainly nonmarine in the east. A range of granitic hills in the south, the Padthaway Ridge, extending southeastward from Murray Bridge, forms a persistent boundary between the Murray and Otway basins. The Otway Basin, which extends into western Victoria and the continental shelf offshore, contains much greater thicknesses than the Murray Basin, of Cretaceous and Tertiary rocks in alternating marine and nonmarine development. Oil exploration in the Murray and Otway basins had not been commercially successful by the late 20th century, but the adjoining submarine Bass Basin between Victoria and Tasmania had become a major petroleum-producing region along with the early Tertiary age rocks of the offshore Gippsland Basin, which was Australia's largest petroleum-producing region.

The Murray and Otway basins

The Sydney Basin. The Sydney Basin was superimposed on a part of the folded rocks of the Tasman geosynclinal belt in Permian time and was filled with a considerable thickness of Permian and Triassic marine and nonmarine rocks. Overlapped by the Great Artesian Basin in the northwest, it continues southeastward under the continental shelf. The Permian begins with shallow-water marine sediments with erratic blocks indicating continued glaciation of the adjoining land, and volcanic material. The plant fossils are typical of the Permian of the southern continents. Coal deposition followed, and after another marine interlude, the Permian Period ended with the formation of further coal-bearing sediments, while volcanic activity and some earth movements continued. The Triassic sequence of the Sydney Basin consists of the Narrabeen Group of sandstones and shales, the Wianamatta Group, and the Hawkesbury Sandstone, which forms conspicuous cliffs around Sydney Harbour and is much used as a building stone.

The Clarence–Moreton and Maryborough basins. On the border between New South Wales and Queensland, from south of Grafton to north of Brisbane, the Clarence–Moreton Basin developed in Triassic time as an offshoot of the Great Artesian Basin. It contains basic volcanic rocks and coal measures that were laid down in several ages. The Maryborough Basin is the easternmost of the Australian sedimentary basins. It is filled with nonmarine Triassic and coal-bearing Jurassic strata, followed in order by volcanic rocks, Lower Cretaceous marine sediments, and coal measures. These beds are the most strongly folded post-Paleozoic rocks in eastern Australia. It is now known that in other basins the Mesozoic and Tertiary rocks are slightly folded, but it is believed that the observed folds, such as those in the central part of the Great Artesian Basin, are due to movements of the underlying older rocks. The more intense folding on the eastern seaboard has been thought to be related to intrusions of Jurassic granites and to a late structural phase in the development of eastern Australia.

Tasmania. The most important Mesozoic event in Tasmania was the large-scale (2,000 cubic miles) intrusion of dark, layered volcanic rocks in Early to mid-Jurassic time. This process produced rocks similar to those in the Karroo region of South Africa, in Brazil, in Antarctica, and also in the Palisades of the New York area, in the Northern Hemisphere.

CENOZOIC HISTORY OF THE AUSTRALIAN CONTINENT

During the Cenozoic Era, occupying the last 60,000,000 years of geological time down to the present, true mountain-building movements were confined to the island arcs in the north and east. Nonetheless, the Australian continent was not altogether stable. On the mainland, movements of the basic structural blocks produced some folding in the sedimentary cover of the basins, and uplifts

ate
olcanic
ctivity

and downwarps restricted or extended their boundaries. Faulting in the southeast and east led to outpouring of large fields of basalts in Victoria in mid-Cenozoic and Late Cenozoic time, and also to scattered but important volcanicity along the east coast. The mid-Miocene (20,000,000 years old) volcanoes of the Warrumbungle Mountains and the Tweed River areas in northern New South Wales and the spectacular Glass House Mountains in southeastern Queensland are the most important examples of this activity. In Victoria and parts of New South Wales, basaltic lava flows followed ancient valleys and buried their stream-deposited gravels. Known as "deep leads," they are locally gold bearing.

The relative ages of the geological events that took place during Cenozoic time are still under study. There is no doubt about the Late Cenozoic age of the uplift of the eastern highlands and also of the Flinders Ranges in South Australia, and the corresponding retreat of the sea from the Murray Basin. This process seems to have occurred intermittently throughout Tertiary time, perhaps culminating in a Pliocene–Pleistocene phase that has been named the Kosciusko Epoch, after the highest mountain on the continent. During the Pleistocene ice age, an area of some 400 square miles around this mountain and some surrounding valleys were glaciated, as were large areas of the Tasmanian highlands. This weak but obvious expression of a worldwide climatic change is only one phase in a sequence of changes that affected Australia during Cenozoic time. Like the sequence of structural movements with which it is likely to be connected, the history of climatic changes is still disputed. The evidence of plant and animal fossils, together with determinations of the temperatures of the period, indicate that the climate in Early Tertiary (Eocene) time, some 50,000,000 years ago, was temperate in the south to tropical in the north. It was also humid, with rivers flowing to the south coast and coal-forming swamps existing in the areas of Eyre Peninsula and south Gippsland. Currents warmer than at present reached the south coast in early Miocene time (some 25,000,000 years ago), while during the late Miocene and Pliocene epochs there was a fall in temperature and a change in the plant life. This came to be dominated by eucalypts and acacias, replacing the southern beech (*Nothofagus*) that had been dominant in Early and mid-Tertiary time. Climatic change is also reflected by other evidence, for example by the large extent of lateritic weathering, causing the formation of red, iron-rich residual deposits as the result of alternating wet and dry seasons. Whether the change to the present arid conditions of the inland regions was gradual and progressive is uncertain. Some soil scientists and biologists have postulated a period of greater aridity than the present, dated a few thousand years ago, but this is disputed by others. There is no doubt about changes of sea level as well as earth movements during the Pleistocene ice age: the eastern highlands were uplifted by some 2,600 feet, as was the western plateau, and there were corresponding changes of wind and ocean water-current patterns. These factors combined in an intricate manner with worldwide climatic changes to alter the climate during the last few million years. The last of the great hippopotamus-like marsupial herbivores (*Diprotodon, Nothotherium*) and giant flightless birds (*Genyornis*) died out when the great lakes in the centre of the continent (Lake Eyre, Lake Callabonna, etc.) turned into salt pans only a few thousand years ago.

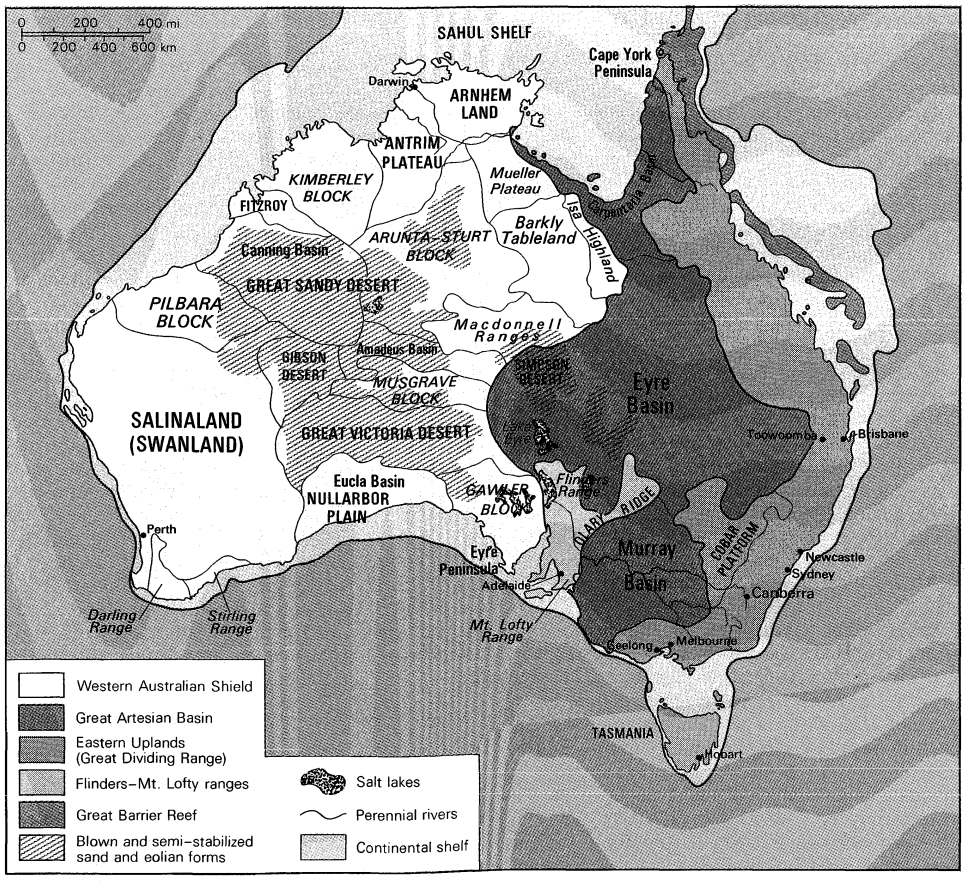
Recent climatic changes

(M.F.G.)

Physical geography

THE LAND

Australia is both the flattest continent and the driest. Seen from the air it is hard to believe that its vast plains, sometimes the colour of dried blood, more often tawny like a lion's skin, are not one huge desert. One can fly the 1,900 miles to Sydney from Darwin in the north, or the 2,000 miles from Perth in the west, without seeing a single town or anything but the most scattered and minute signs of human habitation. A good deal of the central depression and western plateau is indeed desert. Yet appearances can be deceptive. The red and blacksoil plains of Queensland



Physiographic regions of Australia.

and New South Wales have long supported the world's greatest wool industry, while recent discoveries have revealed that some of the most arid and forbidding areas of Australia conceal great mineral wealth.

Moreover, the coastal rim is, almost everywhere, an exception to these rules. In particular the east coast, where European settlement began and where the majority of Australians now live, is hilly, well watered, and fertile.

Inland from the coast runs a chain of highlands known as the Great Dividing Range, from Cape York in northern Queensland to the southern seaboard of Tasmania. From the coast itself this range, which may be anything from 20 miles (32 kilometres) to 200 miles (320 kilometres) distant, often appears as a bold range of mountains, though few of its peaks exceed 5,000 feet (1,500 metres). In fact, it is more like the escarpment of a giant plateau, formed of gently rolling hills, which then slopes imperceptibly down to the western plains. There are similar, though smaller, stretches of hilly, well-watered land all around the rim of the continent except on the south coast where the Nullarbor Plain stretches to the sea; but everywhere the rainfall diminishes rapidly as one penetrates further from the coast.

The "Outback"

To Australians the land beyond the Great Dividing Range and the coastal rim is the Inland, or the "Outback." For them it still retains some of the mythical quality it had for the first explorers searching for inland seas and great rivers. It is their Frontier: the land of hope and adventure. Yet in fact it is still very sparsely populated and perhaps always will be. The real heart of Australia lies in the industrial cities of the east and west coasts.

In this huge continent there are wide variations in scenery and climate. The thickly wooded ranges of the Great Divide have little in common with the treeless, sun-dried plains of the Inland. There is a vast difference between the red rocks and monumental hills of central Australia and the tropical rain forests and sugar plantations of north Queensland. Yet visitors to Australia usually detect a certain uniformity created, perhaps, more by the red earth, the brilliant light, and the drab, olive-coloured leaves of the ubiquitous eucalyptus than by any real resemblance. And if visitors from the Northern Hemisphere are at first repelled, as the English novelist D.H. Lawrence was, by "the vast, uninhabited land and by the grey charred bush . . . so phantom-like, so ghostly, with its tall, pale trees and many dead trees, like corpses," they should remember that to Australians born in the country the bush is friendly and familiar. Australia is not a pretty country, but it has a unique and haunting beauty that exerts a powerful fascination on those who get to know it.

If there is no real uniformity in the Australian landscape, there is certainly uniformity among the Australian people. No marked regional differences have emerged in the 200 years of European development, and steadily improving means of transport and communication have constantly worked to erase such differences as did exist. Today there is a strong similarity in the speech, manners, and customs of all Australian states, and everywhere the culture of white Australia is immediately recognizable as characteristic of Anglo-Saxon culture in Britain and North America.

Relief. *Overall characteristics.* Australia is a land of great plains. The island continent is almost 3,000,000 square miles in area, but of this, only 6 percent is above 2,000 feet elevation. Its highest peak, Mt. Kosciusko, rises to only 7,310 feet (2,228 metres). This situation stems in part from Australia's position at the edge of a zone of significant and recent earth movement and in part from the long periods of geological time during which Australia has been subject to weathering and erosion.

Patterns of faulting and folding in large measure control the distribution and attitude of rocks and thus play a significant part in determining the shape of the land surface. But the nature and intensity of the processes at work at and near the land surface also give rise to characteristic assemblages of forms. Australia is an arid continent; fully one-third of its area is occupied by desert, another third is steppe or semidesert, and only in the north, east, and southeast is rainfall adequate to support a vegetation that significantly protects the land surface.

The Western Australian Shield. The ancient west Australian core area, known geologically as a shield, or craton, is subdivided, most obviously in the north and west, by long, straight (or only gently arcuate) fractures called lineaments. These fractures delineate prominent rectangular or rhomboidal blocks, some of which have been raised to form uplands, others of which have been depressed to form lowlands or topographic basins. The lineaments display strong northwest–southeast and northeast–southwest trends in the northern, northwestern, and southeastern parts of the shield, but east–west alignments are prominent in the centre, and major structural lines are more nearly meridional in the west and southwest. In all areas, however, trends other than those locally dominant can be discerned.

The role of lineaments

Within such structurally defined areas as the Kimberleys, the Isa highlands, and the Pilbara, the nature of the land surface varies according to the type and disposition of the rock outcrops. In the Kimberleys and the Mueller Plateau there are extensive outcrops of flat-lying massive sandstone that have been dissected to give rise to the striking isolated rock features known variously as plateau, mesa, and butte. Under these circumstances, local joints and bedding planes in the rocks, combined with the permeable nature of the bedrock, control the local landforms. Similar plateau forms dominate the Pilbara and Arnhem Land, though in the former region horizontally bedded or only gently warped massive ironstone formations, together with massive sandstones, give rise to prominent bluffs bordering the plateau assemblages; and in the latter karst landforms (greatly eroded by solution) are developed where limestone occurs at the surface. At the margins of the Kimberleys (in the Fitzroy region and in the Durack Range) and in the southern part of the Pilbara, in the Ophthalmia Range, dipping rock strata have been differentially eroded to form ridges and valleys. Such features are also extensively and well developed in the uplands of central Australia (the Macdonnell, James, and Kirchauff ranges), in the Isa highlands, and in the Stirling Range of the southwest. In all of these areas it is the sandstones and quartzites that underlie the upstanding ridges, the intervening valleys being eroded in siltstones or shales; and in all these areas the pattern in plan of ridge and valley reflects the pattern of folding in the underlying rocks.

In the far southwest, the Darling Range forms an upfaulted block underlain mainly by granite but capped by laterite, a reddish, iron-rich product of weathering rock. The Gawler Block, in the southeast, is complex. There are crystalline and sandstone uplands in the east, sandstone plateaus in the northeast, and, in the centre and north, the rounded Gawler Ranges built of Precambrian lava flows. Much of Eyre Peninsula is occupied by a rolling plain traversed by fixed sand dunes, but in the northwest numerous low isolated granite rocks of spectacular appearance, called inselbergs, stand above the plain. These epitomize the isolated ranges and hills widely developed in the northwest of South Australia, in the Musgrave, Everard, Birksgate, Mann, and Tompkinson ranges.

Isolated inselbergs

The lowlands between these raised blocks also display varied topography. The so-called Barkly Tableland is in reality a high plain of remarkable flatness, partly eroded in Cambrian sedimentary rocks and partly underlain by Tertiary swamp deposits. The Nullarbor Plain is approximately coincident with the Eucla Basin. A vast area of the southwest of Western Australia is occupied by Salinaland, an extensive high plain traversed by elongate ribbons encrusted with salt, the desiccated and disrupted remnants of former river courses. The Gibson Desert consists in large part of a laterite-capped plain, but huge areas of the plains of central and northern Australia are occupied by active sand dunes, and large areas of southern South Australia and Western Australia are covered by fields of fixed dunes.

Actively developing and moving sand ridges occupy the Canning Basin (the Desert Basin), the Great Victoria Desert, the Amadeus depression and large areas of the Arunta–Sturt Complex. The dune fields extend to the east into the Great Artesian Basin, where the dunes constitute the well-known Simpson Desert. These dune deserts reflect the

prevailing aridity of most of Australia, and the dune trend displays a huge swirl around the centre of the continent.

But even in these most arid areas—the area around Lake Eyre averages less than five inches of precipitation per year—rain falls from time to time, and the rivers run occasionally. Because of the scarcity of vegetational protection, and because of the common development of impermeable rock layers of various types, runoff in the arid lands tends to be rapid and to achieve dramatic and significant results. Hillslopes are scoured and washed bare of weathered debris; streams erode gullies and transport large volumes of sediment from the uplands to the plains; broad braided river channels are developed; and extensive alluvial plains are formed. It is the alluvium, carried to the lowlands by rivers and deposited on the plains, that is, in large measure, the source of the sand out of which the desert dunes are molded by the wind.

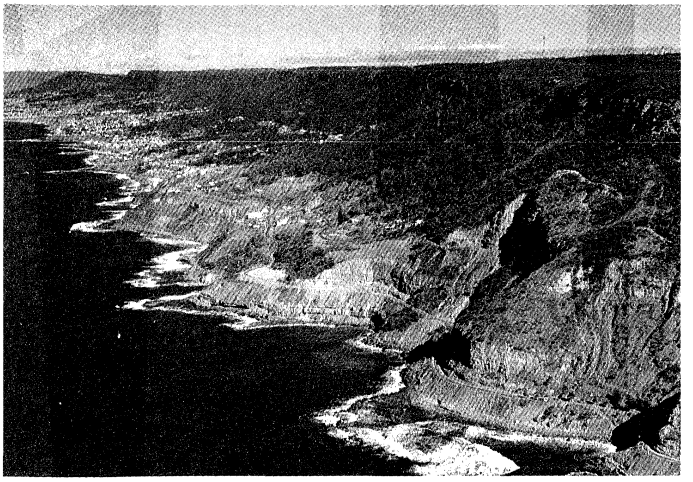
Effects of rapid water runoff

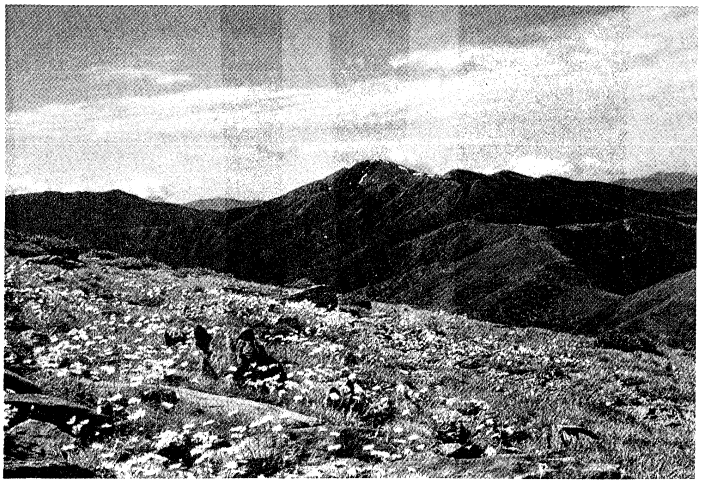
In the far southwest of the shield, and especially in the northern areas, rainfall is sufficient to support a considerable vegetation and is regular enough for streams to flow seasonally. Here the work of rivers in shaping the land surface is more obvious and widespread; the landscape consists essentially of valleys and intervening divides, the precise form of each depending on local structure. But in such areas the rate of landscape change is more rapid than in the arid zones.

Many of the landforms of the shield are inherited from the past, when different climatic conditions obtained. Remnants of laterite are widespread in many parts of Australia: the Darling Range, Salinaland, the Isa highlands and Mueller Plateau, the Darwin area, southern Eyre Peninsula. Clearly, at some time or times in the Tertiary Period, these areas had been reduced to low relief, and humid tropical climates prevailed, for laterite is at present forming only under such conditions in such areas as Southeast Asia and the Congo Basin. The disrupted former drainage system of Salinaland has already been referred to, and remnants of similar old stream networks occur in the Amadeus depression, on the Nullarbor Plain, and in the Great Victoria Desert. A large swamp formerly occupied the south of the Barkly Tableland; and Lake Woods, near Newcastle Waters, is now dry, with a bed of some 70 square miles in extent, but shorelines indicate that the lake formerly occupied some 1,100 square miles. Fossil remains also suggest wetter climates in the past in many parts of Australia, and subsequent deterioration toward aridity. But in the south the occurrence of dunes now fixed by vegetation shows that the climate there has recently become moister.

Finally, in several parts of the shield remnants of eroded surfaces, planed off and covered with hard, silicified crusts of weathered rock, cut across local bedrock and are either preserved high in the relief or buried beneath later sedimentary deposits. They attest to changes in the disposition of the land surface (either base-level changes or regional warping or faulting) and also indicate that, in the past, surfaces of low relief similar to present ones were widely developed. Reference has already been made to the distribution of the laterite surface. At the eastern margin of the shield there are remnants of a still older surface, of late or middle Mesozoic age, which has been warped by subsequent earth movements and now disappears beneath the sediments of the Great Artesian and similar basins. Evidence of the existence of this surface has been forthcoming from northwestern Queensland, central Australia, and South Australia.

The Flinders–Mt. Lofty ranges. Adjacent to the southeastern extremity of the shield, these uplands occupy the





Eastern Highlands (Great Dividing Range).

site of the Adelaide Geosyncline, or downwarp in the Earth's surface. These sediments were folded and faulted, principally in the early Paleozoic, though recurrently since. The Flinders Ranges are a much-eroded fold mountain belt characterized by ridge and valley forms in which sandstone ridges and bluffs are dominant. The Willochra Plain occupies an elongate intermontane basin excavated from a major upwarped structure and achieved through the erosion of some 20,000 feet of sediments. There are remnants of old land surfaces of low relief, and, in the north, extremely rugged relief developed on a much-shattered granite outcrop.

'he Villochra 'lain

To the south, the Mt. Lofty Ranges are a much dissected and complex horst, or ancient uplifted structural block. Bounded on both east and west by meridional or gently arcuate fault scarps, which developed initially in the Early Paleozoic but which have suffered recurrent movements since (and which indeed are still active), the ranges are surmounted in many areas by the remnants of a lateritic plain. In many other areas, such a hard capping of rock, if ever present, has been eliminated by stream erosion. Sandstones again form prominent ridges and residuals (isolated relief features), like Mt. Lofty itself; small granite outcrops give rise to boulder-strewn surfaces; and exposures of gneiss form slablike blocks known as tombstones, monk stones, or penitent rocks.

Between the Mt. Lofty and the Flinders ranges is the midnorth, a region of broad simple folds in which the sandstone ridges run for the most part north–south and in which the broad open valleys were in some instances occupied by lakes during the Tertiary Period, some 50,000,000 years ago. Similar upland areas of low relief, but with domes of crystalline rock standing above the general level, dominate the Olary Arc, which swings northeastward from the midnorth region.

The Great Artesian Basin. This platform area consists of three major basins, the Carpentaria Basin, the Eyre Basin, and the Murray Basin. Between the Carpentaria and Eyre basins the Euroka–Kynuna Plateau barely rises to reach the surface in such minute residual relief elements as Mt. Brown and Mt. Fort Bowen, in northwest Queensland. The Wilcannia threshold separates the Eyre and Murray basins, and the latter is separated from the Otway Basin and the Southern Ocean by the Padthaway Ridge. The two southern basins are entirely terrestrial, but the Carpentaria is partly inundated by the sea.

The Carpentaria plains, occupying the basin of the same name, form a narrow lowland corridor between the Isa highlands and the Einasleigh uplands (part of the Eastern Uplands). They are drained by the Leichhardt, Flinders, and Gilbert rivers, and in the south take the form of broadly rolling plains underlain by heavy gray lime-enriched (pedocalcic) soils and known as the Rolling Downs. In the north, however, there are extensive flat depositional plains, some of them related to Pleistocene swamps, some associated with the present floodplains of the braided river systems. Standing above the plains, for example around Normanton, are considerable plateau and mesa remnants of the Tertiary laterite surface.

Similar rolling plains with laterite residuals standing above them occur in the Eyre Basin, particularly around the headwaters of the Diamantina, near Kynuna. But to the south, toward the more arid interior, the plains become flatter and are protected by a veneer of stones—the well-known stony desert with its mantle of gibber (hammada, serir, desert armour). In many parts of southwestern Queensland, northeastern South Australia, and northwestern New South Wales there are plateau and related relief remnants similar to those found in other parts of the lowlands, although these are capped and protected not by laterite but silcrete, another hard rock residue. This region is folded in places, and the subsequent dissection by erosive forces has brought about disintegration of the silcrete, which is of Middle Tertiary age and which formerly extended over vast areas of central Australia. This process provided much stony debris for the gibber plains so characteristic of much of central Australia and particularly of the Lake Eyre depression.

Lake Eyre

The catchment of Lake Eyre extends over some half million square miles of central and northern Australia. It occupies the lowest point of the Australian continent (46 feet [14 metres] below sea level) and many large river systems drain into it. These rivers drain the driest part of the continent. But no desert is rainless, and floodwaters cover the bed of Lake Eyre about twice each century, the waters deriving not only from central Australia but also from the higher rainfall areas drained by the headwaters of the Georgina, Diamantina, Thomson, Barcoo, and similar rivers. It is now clear that during the late Pleistocene period, more than 10,000 years ago, the rainfall of central Australia was heavier than it is now; as a consequence, these rivers, past and present, have brought vast quantities of sediment and salt to the interior drainage basin. As a result, there is ample source material for the Simpson Desert dunes, and many of the normally dry lake beds, including all the large ones, are encrusted with salt. Most of the very large salinas, or salt pans (Eyre, Frome, Torrens, Gregory, Blanche), are, at least in part, of structural origin, having been formed by downfaulted blocks. Torrens and Gregory are surfaced mainly by gypsum, but the remainder carry a crust of sodium chloride, common salt. Around the major salinas there are extensive alluvial plains.

Under the prevailing arid conditions, fine dust is winnowed from the surface sediments and can be carried high into the air in dust storms. Some is carried long distances, even reaching New Zealand from time to time. The sand of the alluvium is molded into dune ridges.

Sand dunes also occupy large areas of the Murray Basin.

They are, by contrast, fixed (or "fossil") dunes, which developed at some time in the recent past and have since been stabilized by higher rainfall conditions. In the east of the basin, near the foothills of the Eastern Uplands, there is evidence of former higher rainfalls in the numerous abandoned river channels of the Riverina. But the western Murray plains are a stony as well as a climatic desert. The plains are underlain by Miocene limestones and, in many areas, by calcrete, a calcareous soil accumulation. There are instances of water-dissolved sinkholes and enclosed depressions, and lack of surface drainage characteristic of this type of topography. Only the Murray, which originates outside the area in a different environment, crosses the basin, flowing in a narrow trench in its lower reaches.

In the east of this region there are extensive alluvial plains associated with major tributaries of the Murray. One feature of interest is the diversion of the Murray, near Echuca, by a rising structural block bounded by fault zones and known as the Cadell Fault Block.

The Eastern Uplands. This complex series of high ridges, high plains, plateau, and basins extends from Cape York Peninsula in the north to Bass Strait in the south, with a southerly extension into Tasmania and one extending westward into western Victoria. The uplands are the eroded remnants of an ancient mountain range recently rejuvenated by block faulting. They occupy the site of the Tasman geosynclinal belt, the sediments of which were folded and faulted in late Paleozoic times. Granite batholiths were intruded into this region, and during the Cenozoic Era lavas appeared extensively in areas as far apart as north Queensland and Tasmania. Characteristic features associated with this process were lava fields, with stony rises, soil-filled depressions, and lava caves. Extinct cones and craters survive in southeastern Queensland, in the Monaro district of New South Wales, and in western Victoria.

Volcanic landforms

The landforms, in considerable measure, reflect these various geological events. Uplifted structural blocks, many of them trending north to south, are common in some areas, while straight river courses reflect the control exercised by fault zones. Ridge and valley forms, as found in the Grampians of Victoria, reflect the differential erosion of broken and folded rock strata. On the exposed granitic batholiths, massive domes or clusters of boulders are common. The lava plains and plateaus display stony rises, shallow alluvial depressions, and volcanic vents and plugs of various types and ages.

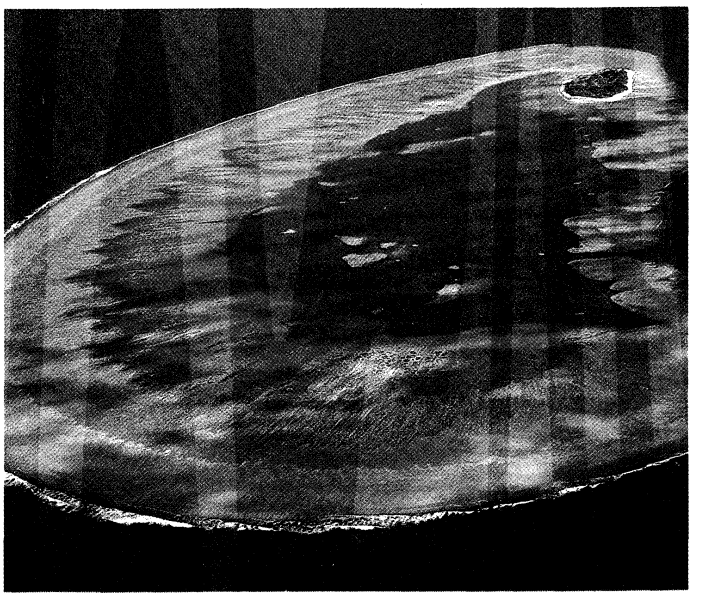
Other features reflect the erosional history of the region. Wide areas of the upland had been reduced to a uniform low relief by the time of the later Mesozoic Era, about 100,000,000 years ago, and many remnants of this ancient surface, exhumed by erosive action from beneath a Later Cretaceous cover, survive in the landscape, notably in north Queensland. The Middle Tertiary leaching of rocks by weathering in humid climates with the formation of iron-rich residuals (laterization) also affected the uplands, from northern Queensland to Tasmania.

Lastly, during the Pleistocene Epoch, some 2,000,000 years ago, small glaciers developed in the Kosciusko area of New South Wales and the central plateau of Tasmania. Small, ice-scoured hollows and small moraines (ridges of glacial debris) attest to these events, while over rather wider areas frost shattering of rocks and resulting downslope flowage of soil (solifluction) have helped shape the surface. No snow normally survives through summer in either of these areas now, but in winter the snowfields of the Kosciusko area alone are more extensive than those of all of Switzerland.

The Great Barrier Reef influence

The Great Barrier Reef is related in important respects to the Eastern Uplands. Lying off the Queensland coast, this great system of coral reefs and atolls owes its origin in part to Pleistocene changes in sea level but in most part to long-continued subsidence, related to faulting, of the offshore region. This slow subsidence has enabled a great thickness of coral to develop, and it is on this basement that the present reefs and coral atolls have grown in the clear warm waters of the Coral Sea.

The coming of man. Though neither aboriginal man nor the later European settlers have been long in Australia, they have already achieved widespread, and in most ways deleterious, effects on the landscape. European man in particular has been responsible for initially minor, but later significant and widespread, changes, notably considerable soil erosion. The clearing of vegetation for agricultural purposes, overgrazing, the introduction of exotic plants and animals, the making of tracks and roads, even the clearing of stones from paddocks—all have rendered the land surface more susceptible to soil erosion. Man has set in train his own great cycle of erosion, similar to that which beset many parts of western Europe in the 18th century and which has assailed many parts of the American West since late in the 19th century.



A portion of the Great Barrier Reef, lying off the coast of northeastern Australia and forming the largest coral structure in the world.

Climate. Australia is the arid continent. Over two-thirds of its landmass rainfall per annum averages less than 20 inches (500 millimetres) and over one-third of it is less

than 10 inches. Only just over 10 percent receives more than 40 inches per annum. As has been noted, in winter the snowfields of Tasmania and the Kosciusko area can be far more extensive than those of Switzerland, but on the whole Australia is a very hot country with a high incidence of heat waves, in consequence of which evaporation losses are high and the effectiveness of the rainfall received is reduced. In addition, the severity of climate, the predominance of the outdoors in the minds and lives of many, and the national importance of agricultural and pastoral pursuits, all make Australians perhaps more climate-conscious than most. In no country of comparable development do climate, the weather map, and the latest forecast loom so large in the lives and conversation of the common people.

Major influences on climate

The principal features of Australia's climate stem from its position, shape, and size. Australia is a compact tropical and near-tropical continent located between latitudes 10°41′ S and 43°39′ S. No major arms or embayments of the sea penetrate far into the landmass. The only extensive uplands occur near the east coast, and even they are not, by world standards, very high.

In summer, when the sun is directly overhead in northern Australia, temperatures are extremely high. The sea exerts little moderating influence, and the uplands are not sufficiently extensive or high to have more than local effects. Because of the lack of cloud over most of the interior, however, while temperatures commonly soar over the 100° F (38° C) mark, there is considerable radiation loss at night, and daily temperature ranges are quite high. But, on the whole, high temperatures dominate the Australian summers in all but Tasmania. Heat waves are common, and though the highest amounts of radiation are received in northern South Australia, the highest temperatures and longest heat waves are recorded in the northwest of Western Australia. Marble Bar, for instance, has recorded a maximum temperature of 100° F or more on 162 consecutive days. Temperatures in winter remain moderate except in the uplands of Tasmania and southeastern Australia, where snow is common. Night frosts are common in winter throughout southern Australia and in the interior.

Because of its latitudinal position, Australia comes under the influence of the southeast trade winds in the north and the westerlies in the south. Northern Australia is affected by a northerly monsoon, partly because of the latitude and the seasonal migration of planetary wind zones and partly because of the summer heating of the continent and the indrawing of surface winds. The monsoon brings summer rains to the northern coastal area and extends inland for variable distances. These summer rains are all the more important because most of northern Australia is in the sheltered rain shadow of the Eastern Uplands so far as the southeast trades, which are dominant in winter, are concerned. The trades, forced to rise by the uplands, bring heavy rains to the Pacific coast of Queensland and of northern New South Wales. These areas, which are also

affected by tropical cyclones, receive the heaviest rains of any part of Australia, and, within this coastal fringe, the north Queensland area around Cairns is the wettest.

Southern Australia receives winter rains from depressions associated with the west-wind zone. Again there are local topographic controls, with uplands receiving more than the adjacent plains. Parts of the southern Mt. Lofty Ranges, in South Australia, average more than 40 inches of rainfall per annum, but Adelaide, to the west, averages only 21 inches, while the Murray plains, in the rain shadows of the ranges, receive 15 inches or less rainfall annually.

The dry interior

In the great mass of the interior of Australia, rainfall averages less than 20 inches per annum, and over vast areas the total is less than 10 inches; the Lake Eyre region averages less than 5 inches. Rainfall in these areas is unreliable and capricious, with long droughts broken by damaging rains and floods. Over Australia as a whole, rainfall is indeed extremely variable. Only in the far north, around Darwin, in the southwest of Western Australia, in southern South Australia and Victoria, in Tasmania, and in eastern New South Wales is the recorded annual rainfall not more than 10 percent above or below the long-term average in different years.

Drainage. Permanently flowing rivers are found only in eastern Australia and in Tasmania. The major exception is the Murray, a stream that rises in the Kosciusko region in the Eastern Uplands and is fed by melting snows. As a result, it acquires a volume sufficient to survive the passage across the arid and semi-arid plains that bear its name and to reach the Southern Ocean southeast of Adelaide. All other rivers in Australia are seasonal or intermittent in their flow, and those of the arid interior are episodic.

Many areas—notably the Nullarbor Plain, underlain by limestone, and the sand ridge deserts—are without surface drainage. A map of Australia can be misleading; though many "lakes" are depicted in the interiors, the fact is that many of them are now salt lakes that contain no water for years on end (see also below, *Natural resources: water resources*).

Soils. In broad view, the continental pattern of soils is closely related to climatic factors; mineral or skeletal soils exist over much of arid Australia, with virtually no organic content and little development to any depth. They may consist merely of a rough mantle of weathered rock. Gypsum is present in many of the desert loams and arid red earths. The soils of the semi-arid regions (where annual rainfall is from 8 to 15 inches) are also alkaline, with gypsum and lime a common feature. The organic content of the soils is again low in the solonized (salt-enriched) brown soils and the gray and brown soils of heavy texture that are common in these areas.

In both the arid and semi-arid regions gilgai—patterns of swells and depressions due to the alternate swelling and contraction following wetting and drying of clay soils—have developed. They are especially well represented in areas of seasonal rainfall. In areas with 15 to 25 inches of annual rainfall, black earths, brown soils, and red-brown earths are the most common soils. In the wetter areas the leaching out of minerals is a prominent feature of the soils. Podsols—sandy, with much humus at the surface and acid throughout—are the characteristic soil types. In the alpine regions humus soils—surface peats over a mineral—are noteworthy.

Local soil variations

Superimposed on these broad, climatically determined, soil patterns are local variations due to topography, groundwater conditions, and parent materials. For example, red soils of one kind (krasnozems) are developed on the basalt outcrops so common in eastern Australia, and those of different composition (terra rossas and rendzinas) on calcareous bedrock. In addition, laterite and silcrete originated in remote geological times, when conditions were very different from those of today. Laterite is represented in every state, including Tasmania, though it is forming nowhere in Australia at the present time, while silcrete is restricted to arid Australia and parts of subhumid Western Australia, South Australia, and Queensland.

(C.R.T./J.D.Pr.)

PLANT AND ANIMAL LIFE

Overall characteristics. Less than 200 years ago, Australian vegetation was still in its primal stage; the older plants in its present woodlands and forests began their

lives before the continent was invaded by Europeans. So close is the continent's prehistory that many a eucalypt still bears the great scar of a canoe or shield cut from its bark by Aborigines. Others can be found bearing blazes and inscriptions dating back to the first years of exploration and settlement.

In the short history of modern Australia, vast changes have been wrought in the continent's vegetation. Agricultural expansion stripped whole regions, substituting introduced crops, pastures, and plantations, while uncleared areas near the new settlements, ranging from the densest forest to the sparsest woodland, were cut through for timber. Enormous central and northern areas too arid for agriculture or too remote for timber getting were stocked with millions of sheep and cattle. In addition, many weeds were introduced, along with rabbits, other herbivorous vermin, and frequent bush fires. The native vegetation is still in that moment of destructive upheaval that marks the passing from aboriginal man to technological man and domestic flocks. Reserves and wilderness areas hold some native vegetation as national heritage, although it is doubtful if these are adequate or sufficiently protected.

Plant life. Australian federal and state governments maintain institutions for the scientific collection and study of the kinds (or taxa) of plants. Cumulative knowledge of Australia's flora stems mainly from these endeavours and is partly available in handbooks (Floras) listing species, together with appropriate "keys" for their recognition. G. Bentham's *Flora Australiensis* (1863–78), based on 19th-century collections sent to Europe, remains—although much outdated—the only comprehensive survey of Australian flora. More up-to-date information, scattered in the botanical literature, is not easily accessible except to professionals.

Australia's phanerogamic (seed plant) flora is estimated at 15,000 to 20,000 species, believed to be a blend of elements from various original sources and the outcome of a long and complicated history. One contribution to the present plant patterns is thought to have originated, in the remote past, from some southern landmass that then linked all the present southern continents. There is evidence to support this view: Australia shares with South Africa, Madagascar, New Zealand, and South America such plants as the southern beech (*Nothofagus*) and characteristic genera in other families, which constitute an Antarctic element.

Plant origins

Australia also shares many more kinds of plants with its northern neighbours. Also, typically Australian genera such as *Callitris* (native pine), *Banksia,* and *Eucalyptus* (gum tree), extend into the Indo-Malaysian area, some as far as the Celebes. This evidence has given rise to the idea of an Indo-Malaysian element in the Australian plant life, in a process that involved some two-way exchanges. These, and other links with plant life elsewhere, have prompted various hypotheses invoking the development of species, migrations, and extinctions throughout geological time, along with changes in the disposition of land, sea, and climate.

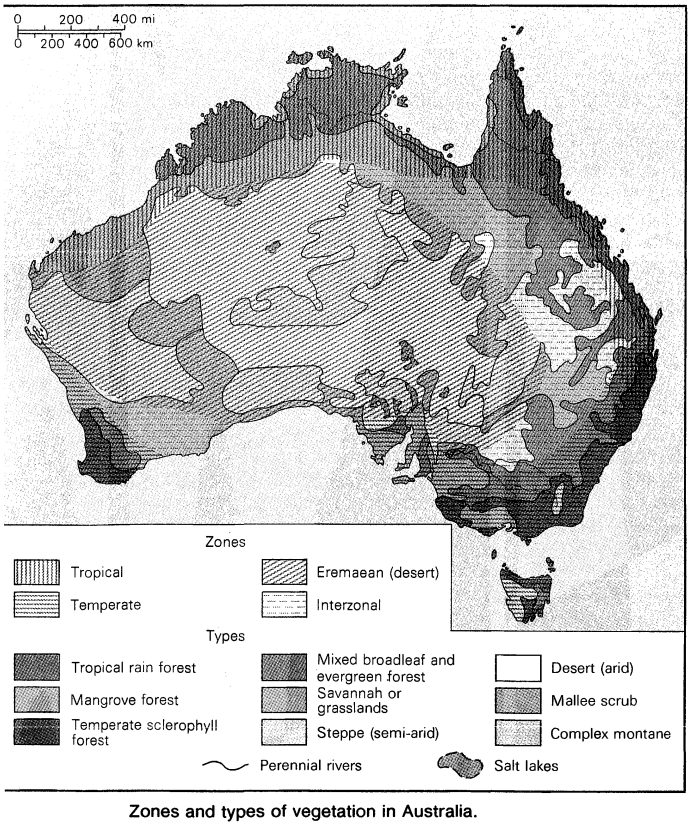
That characteristic part of Australia's plant life that is not much shared with other lands, together with those specialized characteristics that apparently originated in the continent long ago, form what has been designated as an Australian (or autochthonous) element. It includes many of the plants lending character to typical Australian vegetation scenery. It also shows a marked tendency to sclerophylly (formation of hard leaves) and wide-ranging adaptation in many genera, extending their species throughout the whole range of the continent's environmental habitats. Most obvious to the visitor are the *Eucalyptus,* which are represented by over 600 species, ranging in size from diminutive mallees, smaller than a man, to forest giants matching in bulk and height the world's biggest plants. Their habitat is similarly varied, ranging from rain forest to snowfield to hot desert fringe. *Acacia* has undergone similar adaptive radiation; its species range from mulga and myall—the dominant trees of vast areas—to small leafless blades at ground level. The banksias and hakeas (Proteaceae), the grass trees and blackboys (Xanthorrhoeaceae), and the kangaroo-paws (Haemodoraceae) are examples of the many other characteristically Australian plants.

Vegetation. Vegetation, as opposed to plant life, implies the structure and communal relations of the landscape's plant cover, whether it be forest, grassland, or marsh. There is no standard, or worldwide, classification system (such as exists for describing flora) for this aspect of the environment. Initial attempts to apply European and American classification ideas and methods to Australia were not particularly satisfactory, as a result of the peculiarities of the continent's vegetation and environment. For example, climatic control of local vegetation zones was often found insufficient to support vegetation analysis; on the contrary, soil patterns and geological history quite override climatic control in many localities. Similarly, structural descriptive schemes useful for Northern Hemisphere coniferous and deciduous vegetation proved quite inappropriate when confronted by the great variety of evergreen vegetation—notably mallees and scrubs—found in Australia. The mapping of Australian vegetation is based largely on factual descriptive features, and by this means such comprehensive and detailed accounts and maps as those contained in the *Atlas of Australian Resources* and *The Australian Environment* (see *Bibliography*) have been produced. Scientific vegetation analysis, not to be confused with mapping, is also well advanced in Australia, contributing modern ideas equal to those anywhere else in the world.

Classification difficulties

Modern Australian plant life is distributed in three main zones—the Tropical, the Temperate, and the Eremian—which reflect overall climatic conditions. The first zone, arced east and west across the north margin of the continent and extending halfway down the eastern seaboard, has a mainly dry monsoonal climate, with very wet patches. The second, with a cool to warm temperate to subtropical climate and mostly winter or nonseasonal rainfall, is arced across the southern margin, embracing Tasmania and extending up the eastern seaboard to overlap slightly with the Tropical Zone. The third zone covers the whole of central Australia, through to the central west coast; its climatic characteristic is aridity.

The major structural units comprising this geographical distribution are rain forest, sclerophyll forest (dominated by hard-leaved plants such as eucalypts), woodland,



Zones and types of vegetation in Australia.

scrub, savanna, and grassland forms, each with a range of subforms. The bulk of the Tropical Zone carries mixed deciduous woodland and sclerophyll low-tree savanna, with areas of tussock grassland, coastal mangrove complexes, and tropical rain forest. There is a high occurrence of exotic vegetation, particularly in the northeastern part of Cape York Peninsula, in Queensland, and a strong Indo-Malaysian influence occurs throughout the entire zone. The rain forests—with large trees with stem buttresses and multiple vegetation layers with interlaced canopies of lianas and epiphytes growing parasitically on the trees—qualify technically as jungles.

The Temperate Zone

The Temperate Zone is characterized by dry and wet sclerophyll forests, temperate mixed woodlands, savannah woodlands, mallees, and scrubs, with areas of Alpine vegetational complexes, temperate rain forest, and sclerophyll heath. Native plants form a much higher proportion of the vegetation cover, much of which is typically and recognizably Australian. Within this zone the southwest corner of Western Australia is outstanding, both for the high proportion of Australian plants and for the richness of the plant life, while the vegetation of Tasmania is notable for its southern beech forests and for its links with New Zealand and South America. In marked contrast to the tropical rain forests, the predominant trees throughout the majority of the Temperate Zone communities are either *Eucalyptus* or *Acacia.* Much of the Temperate Zone vegetation has been cleared for agricultural purposes, leaving only the vegetation communities of infertile or inaccessible localities.

The vegetation of the Eremian Zone ranges from barely vegetated desert sand hills through a variety of semiarid shrub savannas, shrub steppes, semiarid tussock grassland, and sclerophyll hummock grasslands. Many shrubs have adapted themselves similarly to the arid conditions so that in their vegetative state representatives of numerous families look alike. *Acacia, Eremophila,* and *Casuarina* are examples of genera that tend to displace *Eucalyptus* as the dominant tree shrub. Much of this vegetation is badly degraded. (R.T.La.)

Animal life. Human activities had a modifying and generally destructive influence on Australian animal life, or fauna. The arrival, about 30,000 years ago, of the Aborigines was in this respect less significant than European occupation, which has had profound effects over a period of only two centuries. The Aborigines brought only the dingo, a placental carnivore that must have affected the native marsupials. The Aboriginal hunters and food gatherers lived in ecological balance with their environment, and their demands were not large enough nor their technology sufficiently developed to upset it. There is even less scientific evidence to link them with the extinction of the large Pleistocene mammals than there is in other continents. All this changed with the advent of the Europeans: their cats, rats, foxes, rabbits, cattle, and sheep and their technology modified and largely destroyed important habitats of the Australian fauna. The inhabited coastal region (and even part of the arid inland regions) of the continent now contain a very much modified fauna compared with the indigenous life of only 200 years ago, which cannot now be reconstructed.

Destructive effects of Europeans

The Australian fauna is markedly different from that of the nearest land areas, the islands of Indonesia. A 19th-century biologist, Alfred Russel Wallace, designated an Australian zoogeographic region in 1876 and drew the boundary separating it from the Oriental region of Southeast Asia between Bali and Lombok and between Borneo and Celebes. This division, which became known as Wallace's line, is still recognized in modern biogeography as the boundary of a transitional zone, across which animals spread according to their ability to cross narrow seaways. These passages were much narrower during the Pleistocene glacial periods of the last 600,000 years, when so much oceanic water was frozen at the poles that the sea level fell to or beyond the edges of the continental shelf that now fringes Australia. At such times, the continent had land connections with New Guinea and Tasmania, while remaining separated from the Indonesian Archipelago during all of Cenozoic time (*i.e.,* for the last 50,000,000 years). The history and origin of the distinctive Australian fauna has led to much controversial speculation and searching for relationships among the southern continents.

A published count indicates the existence of 108 placental mammal species, 119 marsupials (125 according to a later count), 2 monotremes (egg-laying primitive mammals), 520 birds, about 380 reptiles, 122 frogs, and 180 freshwater fish. There are also more than 54,000 species of insects (Mackerras, 1970; see *Bibliography*) and about 750 species of mollusks. The placental mammals (apart from those introduced by humans) belong to groups that can swim (seals), fly (bats), or drift on logs (rodents).

The marsupials are considered distinctive Australian animals because they are more abundant and more differentiated on the Australian continent than in America, where few remain, and in Europe, where none has survived. They are not closely related to any fossil or living species found elsewhere. Their history in Australia has been traced back to fossil remains not more than 25,000,000 years old; that is, for less than one-half of the time of their presumed existence in isolation in Australia. There, isolation from placental predators and competitors gave them time to differentiate. The kangaroos, herbivores of the open woodlands and grasslands (occupying the habitat of horses or antelopes elsewhere); the tree-dwelling cuscuses (*Phalanger*) and flying phalangers, or gliders (*Petaurus*), resembling flying squirrels; the "native bear," or koala (*Phascolarctos*), which is specialized to live on eucalypt leaves; the burrowing wombat (*Vombatus*); the native cats (*Dasyurus*); the marsupial mice (*Sminthopsis* and *Antechinus*); the numbat, or banded anteater (*Myrmecobius*); the dog-sized Tasmanian wolf (*Thylacinus*); and, finally, the marsupial mole (*Notoryctes*) are examples of the adaptive differentiation of these mammals.

The role of marsupials

There are two types of monotreme extant, and both are wholly protected by Australian law. The duck-billed platypus (*Ornithorhynchus anatinus*) is common in streams and lakes throughout eastern Australia. The short-nosed echidna (*Tachyglossus aculeatus*) is also common but is widely distributed throughout Australia, including Tasmania. (A related anteater, the long-nosed echidna [*Zaglossus bruijni*], is found only in New Guinea.)

There has been much concern among nature lovers and conservationists in Australia about the obvious losses suffered by the marsupial fauna. These losses have been due both to increases in rangeland agriculture and to the largely uncontrolled exploitation of the kangaroos. According to one observer,

> The lands of arid Australia have been grazed by sheep, cattle and rabbits for periods varying from a few years in the most recently occupied areas to a little over a century in the oldest settled parts, a period short in comparison with most other arid lands of the world. In that short period we have caused far more degeneration of land resources than the aborigines caused in twenty to thirty millennia. Australia is fortunate indeed that the period has been so short. (From R.O. Slatyer and R.A. Perry [eds.], *Arid Lands of Australia;* Australian National University Press, 1969).

To this progressive destruction of habitat has to be added the effect of loosely controlled, or uncontrolled, shooting of kangaroos for meat and fur. Though it was banned from 1973 to 1975, the export of kangaroo products has become increasingly profitable. On the other hand, popular opinion had forced the government to take measures for the strict protection of the koalas in the 1920s. Many small marsupials are also endangered, and some have been eliminated in their original habitats by marauding cats and foxes. Conservationists hope that the increasing number of national parks and reserves will assist in the preservation of the native fauna, though supervision in the vast, almost uninhabited inland areas, where natural conditions remain least disturbed, is a serious problem.

Australian birds

Dangers similar to those threatening the marsupials also affect the birds of Australia, many of which are also unique to the continent and, therefore, of great scientific interest. The best known typically Australian birds are the flightless emu (*Dromaeus*), the mallee fowl (*Leipoa,* which builds a mound-shaped nest for hatching its eggs and actively controls the mound's temperature), the spectacularly

abundant cockatoo (*Cacatuinae*), the lyrebird (*Menura*), the fairy wren (*Malurus*), the honey-eaters (Meliphagidae), the Australian magpie (Cracticidae), and the bowerbird (Ptilonorhynchidae).

Australia has one freshwater crocodile (*Crocodilus johnstoni*), which lives in the tropical north but is also represented in rock engravings made by Aborigines in South Australia. There are 10 freshwater tortoises belonging to a family (Chelyidae) that is also known from South America. Lizards include geckos, skinks, legless lizards, and goannas, or monitor lizards (*Varanus*), which have relatives in Southeast Asia and Africa. There are many poisonous snakes, of which the taipan (*Oxyuranus scutellatus*), the tiger snake (*Notechis scutatus*), the death adder (*Acanthophis antarcticus*), and the brown snake (*Pseudonaja textilis*) are most dangerous to man.

The isolation and predominant aridity of Australia makes its freshwater fish fauna an interesting object for study. The Queensland lungfish (*Neoceratodus*) has lived in Australia without change for millions of years and is very much like its European ancestors of 200,000,000 years ago; it is very different from African and South American lungfishes. European fishes introduced recently into some Australian rivers and streams seem to be a danger to the survival of native species.

Insects have been as successful in Australia as in other continents, showing many adaptations to hot and dry conditions, particularly by adjusting the timing of drought-resistant developmental stages. Leaf-eating insects, including locusts, may be plagues in pasture regions. Other insects attack timber, and the destructive, as well as the constructive, activities of the widespread termites are well known. Bloodsucking insects attack cattle and sheep, and some are disease carriers. The larvae of blowflies (Calliphoridae) attack the living tissues of sheep and continue to cause losses of millions of dollars. (M.F.G.)

SETTLEMENT PATTERNS

Australia did not yield easily to development by Europeans. Even on the relatively favoured eastern seaboard, the first settlers found it hard to cross the rugged mountains of the Great Divide. When they did so they had to fight an endless battle against savage droughts, sudden floods, and fierce bush fires. Though they had little to fear from the Aborigines or from the gentle and harmless Australian animals, the land itself often appeared as a harsh and implacable foe. The long struggle by these settlers to tame the Australian Outback helped to form the tough and independent character of modern Australians just as the struggles of the pioneers and frontiersmen helped to mold the national character of the United States.

By the second half of the 20th century the automobile, the airplane, and the radio had greatly eased the harshness of life in country districts. Although many families still live in astonishing isolation by the standards of most other countries—it is nothing for a grazier to live 50 miles from the nearest country town and perhaps 10 or 15 miles from the nearest neighbour—most of them are linked by telephone and by well-surfaced roads. Even those who live on the great sheep and cattle stations beyond the Darling in New South Wales or in northwestern Queensland are linked by radio and can call the radio doctor and the flying ambulance in emergency. Many of the bigger stations own their own airplanes.

heep nd cattle ations

In Australia a sharp distinction was made in the past between the grazier, who runs sheep or cattle on his "station" or "property," and the small farmer who grows wheat or fruit or raises dairy cattle on the coast or in the irrigation areas. That distinction has been blurred since World War II by the subdivision of the biggest properties and by the fact that many graziers, faced by rising costs and the falling price of wool, have been forced to grow wheat or other crops to supplement their income. But Australia is still one of the last countries where one can find huge properties of 100,000 acres (40,500 hectares) or more where sheep and cattle graze over land unbroken by the plough. Life on a big sheep station is still a privileged one where a comfortable income, the pride of owning wide acres, and the spacious dignity of life on the sunburnt plains more than compensates for the loneliness and the inevitable hazards of drought and bush fires.

The life of the small farmer in Australia is less attractive and, consequently, less envied. Most of them struggle against the same hazards of drought and fire without the reassurance of broad acres to fall back on. Very often their homes are modest, and their cash income may not equal that of an industrial worker on the basic wage. Many of them could not survive or compete with imported produce without generous government subsidies.

Because of the vast distances and sparse settlement, nothing like the European village has ever developed in Australia. Instead, there are country towns that serve a wide area and vary a great deal in size and amenities. Many of the Outback towns are dusty little settlements with one wide main street, a store, two or three hotels, and not much else. But in the areas of closer settlement nearer the coast, many substantial country towns have grown to a point where they offer excellent medical and educational services and first-class shopping. Very few towns in the Outback, however, have more than 25,000 inhabitants.

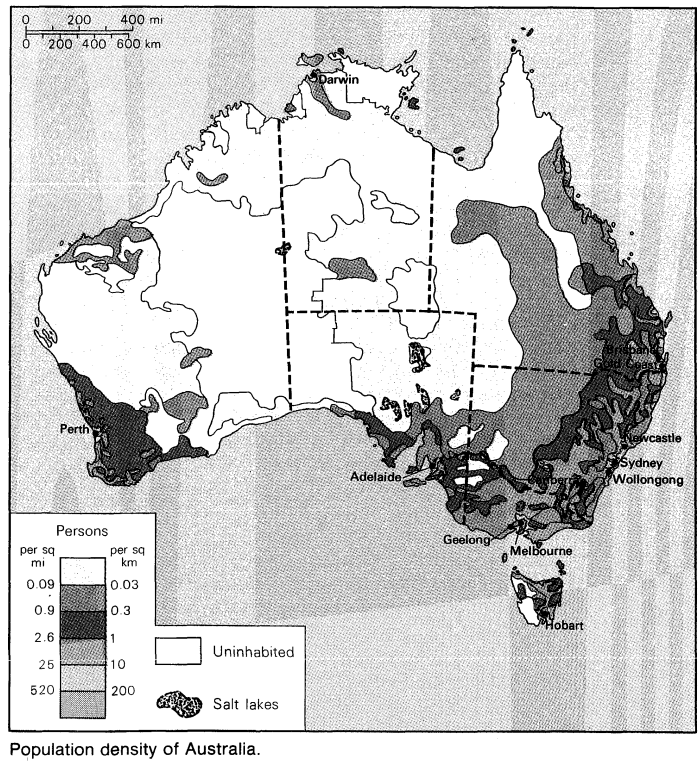
The great paradox of Australia, however, is that in this huge continent with its small population, relatively few people live in the country at all. The majority of the population lives in the seven capital cities. Many Australians regard this balance of the population as unhealthy, and most politicians pay lip service to the principle of decentralization from time to time; but historical, climatic, and economic reasons all suggest that this situation will not change much in the future.

Urbanization

Yet there are compensations in this imbalance. Both Sydney and Melbourne are large, modern, sophisticated cities that can compare in the services and amenities they offer with any city in the world except, perhaps, London, New York City, and Paris. Although neither is the federal capital, they are still the most important cities in Australia, the natural centres of both business and the arts. After Sydney and Melbourne the largest cities are the state capitals of Queensland (Brisbane), South Australia (Adelaide), and Western Australia (Perth).

All of these cities grew naturally as centres of local trade and commerce. Canberra, on the other hand, was artificially created as the federal capital of Australia. Although building did not begin until 1913, by the late 20th century it had become the most rapidly growing city in Australia.

The original plan for Canberra was designed by Wal-



Population density of Australia.

ter Burley Griffin, an American architect of the Chicago School, as the result of a competition held for the purpose. Though Griffin's plan was later modified, Canberra is still a conspicuously well-planned city, with broad avenues lined with trees and an artificial lake in the centre of the city. Some of the most important public buildings include the National Library, the High Court, the National Gallery, and the Parliament Building.

For all its advantages of site and plan, Canberra has not quite escaped the main criticism levelled against Australian cities—that they have allowed suburbia to run riot. Because of the availability of land and the determination of the average Australian to own his own house and garden, all the main cities stretch for miles around their centres, putting an inevitable strain on public transport and services. The rising price of land, particularly in Sydney, has slowly brought a change to apartment dwelling and higher density housing, but most Australians still live in suburbs, and some critics have found in this an explanation for a certain suburban outlook in contemporary Australia.

Human geography

THE PEOPLE

The population of Australia is remarkably homogeneous. The largest percentage is of British heritage, while other Europeans make up most of the balance, and only a small percent of the total population is nonwhite. This includes more than 150,000 Aborigines, of whom only one-third are full bloods. There is also a significant Asian minority, including many refugees from Vietnam and a few thousand Chinese Australians, the descendants of Chinese coolies and diggers who entered Australia during the gold rush of 1851 before the White Australia policy was adopted.

Until the end of World War II almost all immigrants to Australia came from the British Isles. The ancestry of present-day Australians has been estimated as about half English, one-fifth Irish, and one-tenth Scottish, with only a few Welsh. (The remainder are of non-British origin, largely from continental Europe.)

After World War II it was decided to try to increase the population of Australia by encouraging migrants from other European countries, including refugees who had been rendered homeless by the war. Missions were sent to many of these countries, and government aid was extended to European as well as British immigrants. As a result, a steady stream of migrants arrived from Europe after 1945, about half of them from Britain.

Australia's immigration program has been remarkably successful. On the whole, European immigrants have been easily assimilated, and most apply for Australian citizenship after the statutory five years residence. Few return to their homelands, though, curiously enough, it has been estimated that one of every six British families who came to Australia after World War II returned to the United Kingdom.

The White Australia policy

This homogeneity, of course, was achieved only by enforcing a White Australia policy. Strictly speaking, there was no such policy. The phrase did not appear in any act of Parliament. In fact, from 1901 to 1966 all Australian governments saw to it that black, yellow, and brown immigrants (politely called non-Europeans) were not admitted to permanent residence in Australia. From 1966 onward, however, a limited number of non-Europeans and people of mixed descent were admitted.

In 1973 the Labor government of Gough Whitlam declared an end to all racial discrimination in immigration policy, though the actual numbers of non-Europeans admitted each year remained about the same. Since then a large proportion of immigrants have come from Asia, many from Indochina, the Philippines, and Malaysia. On the whole this historic change in Australia's traditional immigration policy, carried out by successive governments somewhat furtively and without much public debate, has been accepted by the majority of Australians.

Australia has one nonwhite minority that is too often forgotten. That is the Aborigines, who have survived two centuries of white persecution and indifference. (There is no true definition of an Aborigine, but anyone with a recognizable amount of Aboriginal blood tends to be counted as an Aborigine.)

Aborigines

These people have had little share in Australia's growth and prosperity. Most of the full bloods are to be found in the Northern Territory, the north of Queensland, and Western Australia, where some of them still live in tribal societies and a few—a very few—still follow the nomadic, hunting life of their ancestors. Others find appropriate employment as stockmen on the cattle stations. But most of them live in Aboriginal communities, outstations, mission stations, or government reserves, depending on social security or earning a little money as casual workers. The same is largely true of the part-Aborigines in the southern states, although they have had greater opportunities for employment. There are few Aborigines in Tasmania, where they were largely exterminated early in the 19th century.

Official federal policy is to help the Aborigines assume responsibility for their own affairs while improving the services available to them. So far, however, they have been held back by white prejudice or indifference, by their own deep suspicions, and, most of all, by the vicious circle of poverty, ignorance, and disease in which they are trapped. Their birth rate is high, but infant mortality during the late 20th century rose as high as five times that for white Australian children. Those who survive tend to suffer from malnutrition and other diseases, which gravely handicap their development at school and afterward.

Several measures that give some hope of improvement have been taken by the federal and state governments. All acts discriminating against Aborigines have been repealed except in Queensland; Aborigines now have the right to vote in all federal and state elections. Moreover, in 1976 the federal government for the first time granted the Aborigines living in the Northern Territory freehold over part of the territory's land area. Since then South Australia has granted the Pitjantjatjara people land rights over part of that state, and other states, some more reluctantly than others, have been considering legislation granting Aborigines the right to own the reserves on which most of them live.

The Aborigines themselves, whose numbers are increasing rapidly in spite of their high rate of infant mortality, are becoming more politically aware and more outspoken in their demands for land rights and full equality. While there is much sympathy for them among urban white Australians, there have also been some signs of reaction among white Australians living in country towns with a high proportion of Aborigines. It can no longer be claimed that there is no racial conflict in Australia.

Major religious groups

If Australia is largely white and predominantly Anglo-Saxon, it is far from being overwhelmingly Protestant. Many of the European immigrants have been Roman Catholic. Sectarian feeling between Roman Catholics and Protestants has at times played an important part in Australian political and social life, and it cannot yet be said to be entirely extinct. From the beginning, the Roman Catholic Church has played an important part in Australia, and its adherents make up about one-third of the total population, almost as large a portion as the membership of the Anglican Communion. There are also Jewish and Muslim communities in Australia, and in some areas of the country the Aboriginal religion survives. (J.D.Pr./Ed.)

THE ECONOMY

Australia's traditional world reputation as a predominantly farming country has changed. Its meteoric rise after World War II to a major mining nation has attracted much world attention. It has come to be realized that beneath this vast continent and its offshore areas lies a wealth of mineral riches. Australia has become one of the chief sources of minerals for the leading industries of Japan.

The minerals boom, the impressive progress of industrialization, and the growth of service industries and other features of a sophisticated economy have added new dimensions of economic strength and transformed the nation's traditional image of a predominantly agricultural and pastoral country with vast open spaces into that of

a bustling industrial nation. In the Pacific Basin area, Australia plays a vital role in trade, commerce, and investment. By the late 20th century, Australian living standards were comparable to those of the advanced economies.

Australia exports to all the important world markets and it imports goods from most countries, particularly the leading industrialized nations. (E.I.U.)

Resources. *Mineral resources.* The first settlers, who arrived in Australia at the beginning of the Industrial Revolution in Europe, soon reported the existence of coal near Sydney and elsewhere. Discoveries of alluvial gold west of Sydney, later in Victoria, and finally in Western Australia led to great movements of population across the continent and to extensive immigration. Prospectors discovered many rich mining areas throughout the continent, particularly in the west, the area around Adelaide, Victoria, Tasmania, western and central New South Wales, northern New England, coastal and western Queensland, and the Northern Territory. In 1949, Australia began a period of almost continuous mineral discoveries. This period continued into the late 20th century, the rate of discoveries and, more importantly, of mineral production, rapidly increasing.

Australia is endowed with resources of all the major minerals, particularly coal, oil, natural gas, iron ore, lead, zinc, copper, bauxite, uranium, tin, gold, silver, nickel, and beach-sand minerals. Australia's iron ore and bauxite reserves are among the world's largest. Its reserves of lead, zinc, copper, and the rare minerals rutile, zircon, and ilmenite are also very large by world standards.

Australia's significant mineral reserves are located in Western Australia (iron ore, nickel, bauxite, diamonds, and gold), Queensland (bauxite, lead, zinc, and silver), New South Wales (coal, lead, zinc, silver, and beach-sand minerals), and off the coast of Victoria (oil and natural gas).

The coal resources of eastern Australia have attracted much interest from overseas buyers, and new mining ventures have been undertaken. Black coal is found in the Permian sediments—some 250,000,000 years old—in the Sydney Basin and in Queensland. Western Australia has a small Permian coal basin at Collie, and South Australia has a Triassic coalfield—dating from 200,000,000 years ago—at Leigh Creek. Large brown-coal deposits are exploited for electricity production at Yallourn and Morwell in Victoria, and west of Melbourne.

Commercial gas fields

The fuel supply situation in Australia changed fundamentally with the discovery of commercial gas fields and the opening of pipelines to capital cities in 1969. The Roma area of Queensland supplies gas to Brisbane; the Gippsland offshore area supplies Melbourne; gas from the Gidgealpa–Moomba area is brought to Adelaide and Sydney; while the Dongara field in the Perth Basin and the offshore Barrow Island fields on the northwestern coast are connected by pipeline with Perth. The Mereenie and Palm Valley fields of the Northern Territory are large gas reserves, located in the Ordovician sandstone (some 450,000,000 years old). The Palm Valley field is linked by pipeline to Alice Springs.

The first commercial oil discoveries in Australia were made, in 1961 and 1964, respectively, at Moonie and Alton, in the Surat Basin. By the late 20th century indige-

Mineral resources of Australia.

nous production was meeting more than two-thirds of the continent's crude oil requirements.

Uranium. Post-World War II exploration efforts, linked to the world demands of a growing atomic energy industry, led to the discovery and opening of uranium mines in northwest Queensland, South Australia, and the Northern Territory.

Major uranium deposits

During the early 1980s the Mary Kathleen uraninite deposit, situated in northwestern Queensland between Mt. Isa and Cloncurry, closed down, leaving the Ben Lemond deposit, near Townsville on the eastern coast, as the country's major producer of uranium. The Radium Hill mine, located near Olary in South Australia, was based on a deposit discovered in 1906 and worked from 1954 to 1960, producing uranium in the form of davidite. In the Northern Territory four large deposits in the Alligator River area were discovered: the Jabiluka; Ranger; Koongara; and Narbleck. The first large discovery of a sedimentary uranium deposit in Australia was made at a shallow depth, under the Lake Frome plains in South Australia, and is clearly derived from the uranium-bearing Mt. Painter Complex in the adjoining northern Flinders Ranges. In Western Australia the Yeerlirrie deposit has sizable reserves.

Iron ore. Iron ore is produced in Australia for iron and steel production and for export; the physical and chemical properties of the iron ores control the value of the ore for modern technological processes. These processes facilitate the use of otherwise valueless fine-grained ore, although strict control of phosphorus and nickel content is required.

The old ore-producing areas are in the Middleback Range on Eyre Peninsula in South Australia, and in Yampi Sound and Koolyanobbing Range in Western Australia. The Middleback Range contains numerous ore bodies of banded hematite-jaspilite iron formation.

Iron ore discoveries

Discoveries are on a vast scale: the newly developed Hamersley iron province contains thousands of millions of tons of ore in iron formations. The largest high-grade ore deposits are Mt. Tom Price, with reserves totalling hundreds of millions of tons of ore; Mt. Whaleback; and Mt. Newman. Other ores occur in vast quantities in the Robe River area; reserves are estimated at a few billion tons, with an iron content of 56–57 percent. The Savage River iron deposits, in Tasmania, were also developed during the late 20th century.

Ferroalloy metals. Tungsten has been produced in Australia since the end of the 19th century, and in the late 20th century its contribution to world output has been substantial, generally exceeding one-twentieth of world production. It is produced from wolframite and scheelite found primarily on King Island (in Bass Strait) and in Queensland. Manganese has been mined from many small deposits, but between one and two million tons of ore are produced annually from the deposits on Groote Eylandt in the Gulf of Carpentaria. One of the most significant of the many economic mineral occurrences discovered in Australia is that of nickel. The Kambalda deposits, the country's largest producer of nickel, lying 35 miles south-southeast of Kalgoorlie, were discovered in 1964. Many other similar deposits in the old goldfields area of the Western Australian Shield were also explored. Later finds are located in the Windarra area, in the northern part of the nickel belt. The Greenvale operation in Queensland is the second largest producer of nickel. In addition, there are large areas of lower grade nickel ores in the Musgrave Block, near the borders of Western Australia, South Australia, and the Northern Territory.

Nonferrous base metals. The Australian continent has long been one of the world's principal producers of lead and zinc. The Broken Hill lode, in western New South Wales, discovered in 1883, was, a century later, still producing roughly half of the country's annual production of lead and zinc. At Mt. Isa, in western Queensland, important lead–zinc and copper ore bodies were discovered in 1923. During the late 20th century another lead–zinc deposit was developed in the McArthur River area of northern Australia, as was a deposit in Tasmania.

Copper production

Copper is widely distributed in the Precambrian and Paleozoic rocks of the continent, although most occurrences are small. Among Australia's principal producing copper mines in the late 20th century, Mt. Isa accounted for roughly three-quarters of the total output. Mt. Morgan in Queensland, Mt. Lyell in Tasmania, Tennant Creek in the Northern Territory, and Cobar in New South Wales produced most of the remaining copper ore. The South Australian copper mines, at Wallaroo–Moonta and Burra, although of great importance to the early economic development of that state, were maintained as reserve mines in the late 20th century. Vast resources of bauxite for aluminum production have been discovered at Weipa (on the Gulf of Carpentaria), at Gove (Arnhem Land) in northern Australia, and at the Darling Range in Western Australia. Tin is produced in eastern and western Australia and in Tasmania; it occurs in lodes connected with granites and as alluvial deposits. Rutile (titanium oxide) and zircon are heavy minerals that are extensively mined from beach sands, mainly on the east coast.

Precious metals. Gold discoveries—which first occurred near Orange, in New South Wales, in the mid-19th century, and later in Victoria, north Queensland, and Western Australia—were important stimulants for the growth of population in Australia. From a peak production of nearly 4,000,000 fine ounces in 1904, annual output had declined by the late 20th century to about one-seventh of that level, most of it coming from the Kalgoorlie–Norseman area of Western Australia. Silver occurs in the rich lead–zinc ores, most of it found in Broken Hill and Mt. Isa, and small amounts of platinum and palladium have been found during the search for nickel.

Nonmetallic deposits. As can be expected from its size, the Australian continent has abundant deposits of such industrial minerals as clays, mica, salt, dolomite, building materials of all kinds, refractories, abrasives, talc, and asbestos. An intensive search for phosphates to offset the declining production of Nauru and Ocean Island led to the discovery of large deposits in the Cloncurry–Mt. Isa area, but it has not been economical to develop these deposits.

Mining of gems

Gem minerals occur in many localities, and mechanized industrial prospecting and mining is in operation. The Australian white and "black" opals, mainly from Andamooka and Coober Pedy in South Australia and White Cliffs and Lightning Ridge in New South Wales, are world famous. The sapphires and topaz from Queensland and the New England district are also well known. In 1979 a vast deposit of diamonds was discovered in the Kimberley region of Western Australia.

Water resources. If not the oldest continent, Australia is certainly the driest. The average annual rainfall is less than 20 inches, with less than 10 inches falling in more than one-third of the continental area. The more significant index is of average variability from average annual rainfall, which is more than 20 percent, and reliable rainfall occurs only in the southeast, southwest, and in the north around Darwin. In the interior, the low and unreliable rainfall, the high evaporation rate, and the flat topography combine to reduce the streamflow. The catchment area of the Murray River system, the largest in Australia, is almost a third that of the Nile, but the average annual flow is only one-sixth (18,000,000 acre-feet). The control of water runoff and the general development of storage dams are of great importance in the management of water resources in Australia. An elaborate development scheme for the waters of the southeastern highlands for storage, irrigation, and power, the Snowy Mountains hydroelectric scheme, was completed in 1974; it is one of the greatest projects of this kind ever undertaken. Some of the waters of the Snowy River, which takes the meltwaters of snow from the eastern highlands straight to the sea, are turned into the Murray Basin to be used for irrigation. The total storage capacity of the many large dams of the Snowy Mountains scheme is more than 6,000,000 acre-feet.

The Snowy Mountains scheme

In the Great Artesian Basin there are about 25,000 recorded water bores. The quantity of water drawn from the basin apparently exceeds the rate of recharge, but the need for further investigations and reassessment of data on the hydrology of the Great Artesian Basin is recognized. The underground water resources of the Murray Basin and of other sedimentary basins are significant but insufficient-

ly known. Considerable underground water supplies are available for the development of Alice Springs in central Australia, and drilling has also supplied sufficient water for the mining developments in the northwest. An important problem—at least until desalination becomes economically feasible—is the quality of underground water; the water from the Great Artesian Basin bores is used only for livestock. The groundwater at Kalgoorlie, in Western Australia, is as salty as the sea, and at Norseman the salinity is twice as high. Investigations are in progress to promote the better use of Australia's water resources as knowledge of their limited amount increases.

Biological resources. The natural biological resources of the Australian continent, as distinct from introduced plants and animals, are limited. Native timber resources in the form of eucalypts are used for papermaking, and the jarrah and karri forests of southwestern Australia provide valuable sawmilling timber. In many parts of the country the virgin native plants still provide the principal pasture component, but in the more arid parts of the country overstocking has destroyed much of this resource and damaged the soil. The arid part of the continent carries only one-third of the total livestock, but introduction of types of cattle more suited to the country and a greater awareness of the limits of its carrying capacity have improved the utilization of these regions. In the zones of better climate, introduced pasture plants such as lucerne and clover, together with the use of superphosphate as fertilizer and of trace elements for soil improvement, have greatly improved Australian pasture resources.

Hydroelectric and other power resources. By the late 20th century Tasmania was one of the few states with sufficient water resources to permit the continuous operation of large hydropower stations. Its hydroelectric potential has been estimated to be half of Australia's total. Although the use of hydropower is expected to grow, the country's potential for this form of energy is small because of generally flat topography and low rainfall.

Petroleum and black coal are Australia's most important energy sources. About three-quarters of the total installed electric capacity comes from thermal power equipment; well over three-quarters of the electric power actually generated is thermal in origin.

Livestock, agriculture, forestry, and fisheries. Australia is the world's largest wool producer and a major supplier of cereals, dairy products, meat, sugar, and fruit. The vast majority of the wool and over a third of most of the other rural products are exported. In contrast with most other countries, by the last quarter of the 20th century more than 90 percent of the utilized land area in Australia remained in its natural state or was capable of very limited improvement; *i.e.,* was land used solely for rough grazing. The area cultivated for agriculture and intensive grazing is about 10 percent of all the utilized land. The main limiting factor in this respect is lack of water, but unsuitable soil and topography are also important determinants. Australia's rural holdings have a combined land area equal to about two-thirds of the total land area. (A rural holding in Australia is defined as a piece of land of one acre or more in extent used for the production of agricultural products or for the raising of livestock and the production of livestock products.)

Livestock. The sheep industry accounts for about one-half of Australia's total farming area. By the late 20th century Australian sheep made up about one-sixth of the world's wooled sheep, producing more than one-fourth of the world's wool supplies. Merino sheep form the basis of the Australian wool industry, making up about three-quarters of total sheep numbers. The Merino, which produces a fine quality wool, is well adapted to the extreme vagaries of climate in Australia's wool-producing areas. Australia's other types of sheep are crossbred and comeback varieties and dual-purpose Australian and British breeds, raised mainly for fat lamb production.

Sheep

A dramatic rise in producton since 1950 is attributable to a number of factors: success of a myxomatosis campaign; pastureland flock improvement; improved methods of pest and disease control; better management of sheep farms; and improved breeding techniques.

Sheep are run throughout Australia under a wide range of climatic conditions and environments, but about a third of Australia's sheep are reared in those areas with an annual rainfall of less than 15 inches (380 millimetres), generally known as the pastoral zone, where lack of water and fodder usually limits development. Dry conditions in the pastoral zone make the adaptable Merino the main breed. In areas of higher rainfall, up to 25 inches, sheep are often reared in conjunction with wheat and other cereals. About 40 percent of Australia's flock are found in these wheat–sheep zones, and breeds other than Merinos constitute a high proportion of the flocks. The rest of Australia's sheep are reared in the areas of relatively high and reliable rainfall, which produce most of the country's superfine wool. Victoria is the most important producer of mutton and lamb, using crossbred sheep raised in areas of high rainfall and fertility. Most of this type of grazing in Victoria is part of a mixed farming operation, where wheat is often the other principal product.

The breeding and fattening of cattle are usually carried out in different climatic zones. The better quality pastures in the relatively high rainfall areas are usually reserved for the fattening of cattle, which are often purchased seasonally and moved to rich natural pastures. Most of Australia's beef cattle are raised in Queensland and New South Wales in regions of warm and coarse pastures. In the northern parts of Australia herds of the more recently introduced zebu and Brahman cattle are thriving and increasing; they are well adapted to the generally poor tropical pastures and resistant to heat and insects. An introduction from the United States, the Santa Gertrudis breed, also offers good prospects of development. Australia's dairy industry is mainly located in the temperate zones of high rainfall in coastal New South Wales and Victoria.

Cattle

Agriculture. Wheat is the most important grain crop grown in Australia; other grain crops are barley and oats. Wheat is usually grown in the medium rainfall belt in all states, and it has become increasingly integrated with sheep grazing and cultivation of other crops. Wheat, barley, and oats are often grown on the same farm for grain and green fodder or hay for livestock. Most of these cereal crops are grown for grain. Sugar, Australia's most important crop after wheat, is grown from cane in coastal areas of Queensland and in northern New South Wales. The former area accounts for nearly all of the Australian sugar crop. The sugar industry is based on small farms.

Other important crops grown in Australia include tobacco, citrus fruit, grapes, apples, cotton, bananas, potatoes, and sorghum.

Forest and fisheries. Australia is estimated to have several millions of acres of commercial or potentially commercial areas of forest, in addition to large regions of low-grade forest suitable only for the production of small quantities of forest products for use in the immediate vicinity.

The main commercial forests are in the areas of high rainfall on the coast or near the coastal highlands of southeastern and eastern Australia, Tasmania, and the southwestern coast of Western Australia. The main type of tree in Australian forests is the eucalyptus, a broad-leaved genus that provides timbers of great strength and durability for building and packaging. The rain forests of the wetter regions, with many species of broad-leaved trees, are also important.

It has been estimated that there are about 2,000 species of fish (including freshwater species) in Australia and the waters surrounding it. The resources include mullet, cod, bream, perch, tuna, snapper, whiting, flathead, abalone, mackerel, and Australian salmon. New South Wales and Western Australia are the most important producing states, the latter being famous for its crayfish. There has not been much change in the types of fish caught in Australian coastal waters over the years, but lobster and crayfishing have been expanded. In 1978 Australia established a 200-mile fishing zone that encompassed the continent and the External Territories. By establishing this zone the Commonwealth assumed responsibility for the management of fisheries and other living resources within the region.

(E.I.U./M.F.G./Ed.)

Depression in rural industry

Industry. *Rural industry.* Although the rural sector still makes a substantial contribution to Australia's national income, its importance has declined sharply. By the late 20th century the gross annual value of rural production totalled about 5 percent of gross national product, a substantial drop compared with a 15-percent contribution to GNP during the middle of the century. Despite a declining rural labour force, agricultural output has increased by nearly 80 percent since World War II. One of the main reasons for this improvement is the use of fertilizers. Wool production accounts for almost 10 percent of the total export earnings. Because of recurrent droughts, wheat production has fluctuated. As a result, the value of beef production has exceeded that of wheat, and Australia has become one of the world's largest exporters of meat. Wheat is Australia's most important rural crop in terms of area and production. Forestry and fishing contribute only an insignificant proportion, less than 1 percent, of Australia's gross national product.

Mining and quarrying. The story of Australia's mineral industry is one of strong expansion and development. Australia has achieved self-sufficiency in most minerals of economic importance except for petroleum and natural gas. Domestic supplies of petroleum and natural gas, however, fulfill much of Australia's needs. There also are adequate reserves and production to allow exports of many minerals, and the contribution to national income and exports from the nation's mineral industry has increased at a spectacular rate. The two most important contributors to mineral output are the coal and iron-ore industries. Other minerals of major economic significance, as mentioned above, are silver, lead, zinc, the construction materials group (road metal, gravel, clays, limestone, and building stone), copper, gold, tin, mineral sands, nickel, and bauxite. Australia is one of the world's largest exporters of iron ore along with Brazil, Canada, and the Soviet Union. Coal and iron ore account for about three-quarters of the total value of primary mineral exports.

Manufacturing. A vital sector of the Australian economy, manufacturing, has grown spectacularly since 1950. Australia's limited home market will not support certain types of industry, such as the manufacture of highly sophisticated machines, heavy fabricating, certain types of electrical equipment, some industrial chemicals, and highly specialized scientific instruments and equipment. With the exception of these special classes of goods, however, the domestic market is well supplied with products of local manufacturers, which include the full range of items required in a modern country. Most of the industries are soundly based; only a few are carried out at an excessive cost, and require high tariff protection.

About one-fifth of the nation's workforce is employed in Australia's manufacturing industries. Since World War II the expansion of manufacturing industries has been widely spread throughout the industrial structure, but it has been particularly strong in the engineering, vehicle, oil-refining, petrochemical, and construction materials industries.

The motor vehicle industry is a vital sector of the Australian economy, directly employing more than 5 percent of the manufacturing workforce, and numerous other industries are dependent upon demand created by its level of activity. Its importance is underlined by the fact that Australia has one of the world's highest per capita motor vehicle ownership, while most of these vehicles are locally produced or assembled.

The motor vehicle industry

Iron and steel production is a virtual monopoly in the hands of one company, the Broken Hill Proprietary Co. Ltd. Other major manufacturing industries include oil refining, chemicals, textiles, and domestic appliances.

Energy. The main source of power used in Australian homes, factories, and other buildings is electricity. There has been a strong rise in the domestic use of electricity because of the increased use of appliances, extension of electricity supply into rural areas, and the high rate of home building. Thermoelectric power, based on either brown or black coal, is the main source of electrical energy in Australia.

Finance. Australia has a well-developed banking system broadly similar to that operating in Britain. The system is made up of the Reserve Bank of Australia (the central bank), the trading (commercial) banks, the savings banks, the Commonwealth Development Bank of Australia, the Australian Resources Development Bank, and the Primary Industry Bank of Australia.

The government-owned Commonwealth Banking Corporation operates a trading bank, a savings bank, and a development bank. Some of the savings banks are owned by state governments. These savings banks operate within the borders of a particular state only, and some offer checking-account facilities. The major banks in Australia operate under a branch-banking system, and most of them have branches throughout Australia.

The Australian Resources Development Bank was set up to provide finance mainly for the development of Australia's mineral projects. One of its aims is to provide finance in order to maintain a substantial proportion of Australian equity in these mineral enterprises. The Primary Industry Bank of Australia provides loans to primary producers for longer terms than are otherwise generally available.

The banking system in Australia is an important repository for savings, the most important source of finance, and the medium through which most commercial and financial transactions are settled. The trading banks provide two types of facilities: current accounts operated on by checks and payable on demand (similar to checking accounts of U.S. banks), and fixed deposits, which are lodged for specific periods.

The Reserve Bank of Australia applies its monetary policy to regulate the economy through the banking system, which usually bears the brunt of monetary and credit restraints during periods when the authorities consider it necessary to dampen inflationary pressures in the economy.

Another important source of finance in Australia is finance companies, which grew strongly after the 1950s, largely as a result of the restraining influence of official monetary policy on the banking system. All of the major Australian banks have substantial shareholdings in finance companies, which in some instances are subsidiaries of the banks. A number of foreign banks also have acquired interests in finance companies in order to enter the Australian financial market, because Australian government policy prohibits the establishment of foreign banks in Australia, the exceptions being the long-established ones.

Finance companies

Australia has a well-developed short-term money market. There are also several merchant banks performing such functions as underwriting, company flotations, mergers and takeovers of companies, portfolio management, lending, and general financial and allied services.

Other important institutions in the financial system are the insurance companies (fire, marine, and general), life insurance companies, credit unions, pastoral finance companies, and the building societies.

Each state capital has its independent stock exchange, but a nationwide coverage is achieved by reciprocal arrangements with brokers in other capitals and agents in country centres.

The system is well developed and sophisticated, and the stock exchanges provide a ready market for shares of listed companies and government securities. Quotations are distributed widely and quickly by special teleprinter channels and by radio and newspaper services.

Trade. By the late 20th century Australia's exports made up about one-seventh of the gross national product. Minerals contributed about one-fifth of Australia's export income; other important sources of export income were wool, meat, wheat, and manufactured goods. Australia's principal imports were machinery, transport equipment, chemical and petroleum products, foods and beverages, and crude oil and gas. Japan was Australia's most important export customer and a principal import supplier. Other important customers and suppliers were the United States, the European Economic Community countries (particularly the United Kingdom), New Zealand, and Asia, as a whole.

Administration of the economy. The Australian economy is essentially one based on private enterprise, although government plays an important role in influencing economic conditions.

Most capital expenditure in Australia is undertaken by private business enterprises and persons. There is only limited public ownership of business enterprises. Major enterprises owned and run either directly by federal or state governments or by government corporations include the post office, Australia's international airline, one of the two major domestic airlines, the Commonwealth Banking Corporation, the Australian Shipping Commission, and the electricity and gas distribution organizations in the various states.

The government regulates economic activity through fiscal policies embodied in its annual budget and through monetary policy. The Reserve Bank and the federal government's Treasury Department are the government's chief source of economic advice.

Taxation

In Australia taxes are levied by federal, state, and local governments. The main taxation authority is the federal government, which levies income taxes, customs and excise duties, and sales taxes. There are also a number of minor taxes imposed for specific purposes. There is no general duplication of taxes by the three tiers of government. The states impose a wide variety of taxes that include stamp duties, taxes on motor vehicles, payroll taxes, land taxes, liquor taxes, and probate duties.

The trade-union movement is well organized in Australia. Most workers are members of trade unions; in a number of instances membership is virtually mandatory. Industrial disputes are common and often disruptive in terms of loss of production. Australia has a unique arbitration system for settling disputes, but there have been signs of this system breaking down, and the trend is increasingly toward direct negotiations with employers. (E.I.U.)

Transportation. Because of the great size and small population of Australia, transport has always been costly and has absorbed an unduly high proportion of the total work force. Moreover, the main lines of road and rail transport were laid down in the second half of the 19th century,

Fragmentation of transport system

when Australia was a collection of separate colonies, each of which looked to Britain for most of its trade. The transport system was therefore designed to maintain this trade, with roads and railways radiating from the main ports. Little thought was given to internal transport between the separate colonies. An unfortunate relic of this is the existence of three different railway gauges in the continent. It was not until 1970 that it became possible to go by train from Sydney on the east coast to Perth in the west without changing trains.

In spite of these historical and geographical handicaps, Australia is fairly well equipped with roads and railways, especially in the southeastern states. It is one of the most highly motorized countries in the world.

Australia is almost entirely lacking in internal waterways. For a short period during the 19th century the Murray–Darling river system was widely used to transport produce (mostly wool) from the country districts of New South Wales and Victoria to the coast, but the variable flow of water in these rivers always made this method hazardous and unreliable. With the coming of the railways it was quickly abandoned.

On the other hand, Australia is in many ways ideally suited to air transport. The great distances, lack of mountains, and fine prevailing weather make flying safe and economical.

For the historical reasons already outlined, roads and railways are mainly the responsibility of the six state governments, although the federal government has taken over railway systems in some states. Shipping and air transport between the states are the responsibility of the federal government. Since 1946 the Australian Transport Advisory Council, including the federal minister for shipping and transport and the six state ministers for transport, has provided machinery for coordinating transport on national lines.

Component systems. As has been noted above, the main road networks in Australia radiate from the ports, and especially from the capital cities of Sydney, Melbourne, Brisbane, Adelaide, and Perth. Most of the states, aided by federal grants, have also made progress in sealing thousands of miles of country roads.

The most serious lack is still adequate highways between the state capitals. Both the Hume Highway between Sydney and Melbourne and the Pacific Highway between Sydney and Brisbane are far too narrow for the heavy traffic they carry. A federal government bicentennial program has been successful in making significant improvements to major highways.

The provision of adequate expressways and throughways in the great conurbations of Sydney and Melbourne has also fallen behind. Like the industrialized nations of the West, Australia is finding it hard to keep up with the insatiable demands of the automobile.

Railways

Five of the six state governments own and operate a railway system, and the federal government operates the Australian National Railways. Private rail companies operate in each state in order to serve mining, agricultural, and industrial complexes. The largest private railway operations are those serving iron-ore mines in northwestern Western Australia.

Australian railways have a hard struggle to pay their way against the competition of road and air services, but rail transport still plays an important part in the development of the Australian economy. New capital is being spent in providing standard-gauge lines between the different state capitals and industrial centres and in building new branch lines where mineral discoveries justify it, as in the case of northwestern Australia. Sydney and Melbourne have major electrified underground and suburban railway systems.

There are about 70 ports of commercial significance in Australia, of which the great majority are on the east coast. The rest of Australia is notably lacking in good natural harbours. The most important port is Sydney, which has one of the finest harbours in the world. Sydney (with Botany Bay) discharges and ships the largest amount of freight tons annually, followed by Port Hedland, Melbourne, Fremantle, Newcastle, Brisbane, Hay Point, Port Walcott, Gladstone, Port Kembla, and Port Adelaide.

Shipping is still the lifeblood of Australia. Most of this shipping is in foreign hands, although Australian companies have a monopoly of interstate trade around the Australian coast.

Air transport

Australia has one international airline, Qantas Airways, Ltd., which is owned by the federal government. It is one of the world's leading air carriers. Many foreign-owned international airlines operate regularly in and out of Australia. Sydney has long been the site of the main international airport, and a new terminal was opened there in 1970. The same year Melbourne opened a new international airport at Tullamarine.

Several airlines operate domestic services throughout Australia. The two major companies are Trans-Australia Airlines (TAA), owned by the federal government, and Ansett-Airlines of Australia (Ansett), owned by private enterprise. Competition between the two is strictly controlled and regulated by federal legislation. Australia is well served by its internal airways, which offer a service that compares favourably in safety, cheapness, and extent with any in the world.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. The constitution of Australia may be described crudely as an amalgam of the constitutional forms of Great Britain and the United States. Like Britain it is a monarchy, and the king or queen of Britain is also the king or queen of Australia. Like Britain, too, the governments both of the Commonwealth and of the states are chosen from the majority party in Parliament. Like the United States, on the other hand, it is a federation, and the duties of the federal government and the division of powers between the Commonwealth and the states are laid down in a written constitution that can be altered only by a referendum that gains the consent of a majority of all the electors and a majority in at least four out of the six states.

Any disputes arising out of the constitution are decided by the High Court of Australia.

Although the monarch of Britain is also monarch of Australia, Australia is wholly independent. Except when the monarch is in Australia, his or her functions, which are

largely formal and decorative, are exercised by a governor general, who resides in the federal capital in Canberra, and by governors in each of the six states. Though formally the governor general and the governors are appointed by the monarch, they are invariably recommended by the Australian governments concerned, and in recent years there has been a growing tendency to choose Australians. By convention, the prime minister (the leader of the party or coalition of parties victorious in the general election) is the nation's chief executive.

Due to a past constitutional crisis that developed between a prime minister and the governor general, there have been proposals for various constitutional amendments that would define, and limit, the powers and duties of the governor general. Some Australians, although they are clearly in a minority, favour severing all remaining ties with Great Britain and declaring Australia a republic, thus abolishing the post of governor general altogether.

The constitution defines the form and duties of the federal government in some detail. The most important of these are defense, foreign policy, immigration, customs and excise, and the post office. Those powers not given to the federal government in the constitution—the residual powers—are left to the states. The state governments are the direct descendants of the colonial governments of the 19th century. Originally they owed their powers to an act of the British Parliament, but these acts are short documents that lay down only the form that the parliaments shall take, not the sort of legislation they may pass.

State and territorial government

In theory the states are sovereign, with real and important powers. They are responsible for justice, education, health, internal transport, and, indeed, for most of the things that most closely concern the citizen. In practice, however, their powers have been greatly weakened by the federal government's decision in 1942, at the most dangerous point of World War II, to collect all income taxes itself and then to reimburse the states on an agreed formula. This temporary arrangement has become permanent, in spite of many political and legal challenges, so that the states, deprived of any equivalent "growth tax," have become largely dependent on federal grants for their revenues.

The Northern Territory was established as a self-governing territory in 1978 when the Commonwealth government transferred most of its powers to the government of the territory. The government of the territory has powers similar to the governments of the states but has an administrator instead of a governor and a chief minister instead of a prime minister. Members of the Legislative Assembly are elected for a period of four years.

Australia is a true parliamentary democracy. Both the federal upper house (the Senate) and the lower house (the House of Representatives) are directly elected by universal adult suffrage, with a voting age of 18. All state lower houses are similarly elected.

The political process

Preferential voting (placing the candidates in order of preference on the ballot paper) is used for all parliamentary elections. In elections for the House of Representatives the alternative vote system is used; the 64 senators (10 from each state and two from each of the territories) are elected by proportional representation. Voting in both federal and state elections is compulsory.

Since federation the political struggle in Australia has been between the Australian Labor Party (ALP) and a coalition of anti-Labor parties under different names. For most of the years after 1949 the federal government was formed by a coalition between the Liberal Party, which broadly represents the interests of private enterprise, and the National Party (formerly the Country Party), which represents the interests of the farmers and graziers in rural constituencies. The ALP is a typical Western social-democratic party, based firmly on the support of the trade unions, and normally preferring practical reforms to socialist theories. It has, however, always had a left wing retaining a belief in Marxist principles.

Another political party of some significance, the Australian Democrats Party, was formed by a former Liberal minister, Donald L. Chipp, in 1977. The Australian Democrats Party appeals to many middle-class voters with liberal or radical views.

The Communist Party of Australia, split into several different factions, is insignificant in numbers. It has retained a disproportionate influence in some trade unions.

Voting in state elections does not necessarily follow voting in federal elections. During the long rule of the Liberal–Country Party coalition in the federal Parliament after 1949, Labor governments at different times held office in five of the six states. But with a few minor exceptions the lines of battle are the same, though local issues play a larger part. State Liberal and Labor governments, once elected, though on different sides politically, often find themselves in alliance against the Commonwealth either in defending states' rights or in seeking more money from the federal government.

Justice. The law of Australia is based on the common law of England, and many laws are identical with those laid down in acts of the British Parliament. The administration of the law is largely in the hands of the states, each of which has a series of courts culminating in a supreme court. Between them these courts have a comprehensive jurisdiction that extends to all matters of state, and to most matters of federal, jurisdiction. The states are also responsible for the police, although there is a federal police force that performs general police duties in the Australian Capital Territory and is the principal agency for the enforcement of federal laws.

The High Court of Australia, established by the constitution, is the federal supreme court. It has a general appellate jurisdiction over all other federal and state courts, and has a special duty to decide disputes involving the interpretation of the federal constitution and acts of the federal Parliament. The High Court of Australia has a high reputation among legal authorities both inside and outside Australia.

The federal Court of Australia was created to exercise the jurisdictions formerly exercised by the Federal Court of Bankruptcy and the Australian Industrial Court.

Armed forces. Australia has a proud military tradition dating from the landing of the first Australian Imperial Force on the Gallipoli Peninsula during the Dardanelles campaign of World War I. Since then Australian armed forces have served with distinction in World Wars I and II and in Malaysia, Korea, and Vietnam. The Royal Australian Navy, the Army, and the Royal Australian Air Force are separate services with distinctive uniforms and separate commands.

The Royal Australian Navy is a small but compact, flexible force with an emphasis on antisubmarine warfare.

The first aim of the army is to provide a highly trained field force for limited warfare in Southeast Asia. Compulsory national service was introduced in 1964 but was abandoned in 1972.

The Royal Australian Air Force has five operational elements: strike/reconnaissance, tactical fighter, air transport, tactical air support, and maritime forces.

Health, welfare, and education. Australia may be described as a modified welfare state. The federal and state governments have not gone so far as some European countries in providing free health and other services for its citizens but have gone further than the United States. Government benefits include pensions for the aged, invalids, widows, and single parents; unemployment and sickness benefits; health insurance provisions; maternity allowances; and child endowment. Benefits are paid from the National Welfare Fund, which is financed from consolidated revenue.

On the other hand, there is a strong tradition in Australia that one should buy or build one's own house. There are relatively few state or municipal houses and apartments for rent, though there are various federal and state financial schemes to help citizens purchase their own homes.

Education

Responsibility for education lies primarily with the states. Free education at government schools is provided at the primary and secondary levels, though there is also a considerable private sector formed by schools run by the churches (mostly Roman Catholic) and a few grammar schools for children of the wealthy. The principle of giving some state aid to Roman Catholic schools has now been accepted by all the main political parties.

Since 1974 tertiary education has been free both at universities and at colleges of advanced education that are oriented toward practical training and technology. Universities are mainly, and colleges of advanced education wholly, financed by the Commonwealth government. Australia has 19 universities, most of them located in the capital cities, and some colleges of advanced education, some of the latter quite small.

Health services are everywhere excellent. The method of financing these services has been changed several times. The states provide free hospital treatment in public hospitals, but patients may also insure to cover the cost of better accommodations, choice of doctor, and other variable costs.

Australia's most interesting contribution to the welfare of the ordinary citizen is the arbitration system, which has roused much interest in other countries. In brief this is an attempt, unique to Australia and New Zealand, to fix wages and working conditions by law.

Wage fixing

The constitution gives the federal government the right to undertake conciliation and arbitration in industrial disputes. Armed with this power, the first federal government set up the Commonwealth (now Australian) Conciliation and Arbitration Commission, which began by establishing a basic wage necessary to keep in "frugal comfort" the average family of an unskilled worker. From this beginning an elaborate system has been built up, involving both federal and state arbitration courts, conciliation commissioners, and wage boards, the aim of which is to prevent or mitigate industrial disputes.

If a dispute cannot be solved by collective bargaining or conciliation, then either the employers or the trade union concerned may take the dispute to the relevant court for a judicial decision that has the force of law. Strikes are not forbidden, but a union that strikes in defiance of a judicial award may be held to be in contempt of court and fined accordingly. In practice, therefore, the judges on the Australian Conciliation and Arbitration Commission, after hearing argument from both sides, fix minimum wages and conditions over a large section of Australian industry.

This system has frequently been criticized as excessively cumbrous and, more recently, complaints have been heard that the judges who make the awards are not always equipped to appreciate the economic consequences of their decisions. On the whole, however, it has worked reasonably well over the years though it has certainly not prevented industrial unrest in Australia. It is still supported, with reservations, by both employers and trade unions.

Both Australia's welfare services and arbitration system spring from a deep concern for the common man. From the earliest days Australians have been strongly egalitarian in outlook, quick to resent any claims to privilege either by a class or an individual. This has not prevented class distinctions in Australia—there is a stronger class system than is often admitted—or wide differences in wealth, but it has greatly eased the conflicts inherent in a capitalist society. Australian trade unions are as militant as any in the world in the pursuit of higher wages and better conditions, but the Australian working man is well paid, well cared for, and living in a prosperous, democratic, and expanding country. He is widely judged to be no wage slave but rather the master of his own fate.

CULTURAL LIFE

The cultural milieu. For the first 100 years of white settlement the arts were naturally neglected. Settlers were too busy exploring and developing this harsh land to have much time or energy left for the graces of life. This neglect was never total. There were always Australians who wrote poems or novels or who painted the landscape of their adopted country, but for the most part they were content to take their art and culture secondhand from England.

Early developments in the arts

The first sign of an Australian consciousness in the arts was the emergence of a small group of writers and artists in the 1890s associated with the Sydney *Bulletin*. Most of them—though not all—tended to express the radical, egalitarian, and nationalist views that were then beginning to stir political life in the colonies. Of these writers the most important were Joseph Furphy (1843–1912), author—under the pseudonym Tom Collins—of the long novel *Such Is Life* (1903), and Henry Lawson (1867–1922), whose short stories are still worth reading. The *Bulletin* also provided an opportunity for a remarkable collection of artists working in black and white, among whom Norman Lindsay (1879–1969) was the best known.

But Australia's great leap forward in the arts did not take place until World War II, when the growing wealth and sophistication of the cities, and isolation from Britain and Europe, provided a powerful stimulus. This movement began with painting and poetry and later spread to all the arts in turn. Since 1954 the federal and state governments have subsidized the arts on an increasing scale.

The arts. The first of the arts to attract attention outside Australia was painting. Starting in Melbourne during World War II, a group of painters—of whom George Russell Drysdale, Sidney Nolan, and Arthur Boyd are the best known—developed an original school of Australian painting by means of adapting contemporary techniques to depict Australian myths and Australian landscape. Since that time the influence of that school in Australia itself has dwindled, and young Australian painters prefer to paint in the international styles of their contemporaries in Paris, London, and New York City; in spite of this, their work is distinguished by a freshness and vigour that are characteristic of their young nation.

Australian poets have also revealed a new maturity and sophistication, though, unlike painters, they have tended to turn their backs on the more revolutionary developments overseas and to prefer traditional metrical forms. This may be due to the powerful influence of A.D. Hope and James McAuley (1917–76), both professors of literature as well as poets, who consciously set and maintained classical standards in their own work. More recognizably "modern" in their very different ways are Geoffrey Lehmann and the remarkably gifted Les A. Murray, who almost alone has managed to find an authentic Australian idiom. But many other younger Australian poets, such as Bruce Dawe, Bruce Beaver, Peter Porter, and David Malouf, deserve mention.

Australian novelists have, on the whole, been less original and creative, though Patrick White, who won the Nobel Prize for Literature in 1973, has received acclaim worldwide for his lyric and visionary contemporary novels *The Tree of Man* (1955), *Voss* (1957), and *Riders in the Chariot* (1961). Thomas Keneally has enjoyed international success with his historical novels, *Gossip from the Forest* (1975), *Confederates* (1979), and *Schindler's Ark* (1981). Christina Stead (1902–83) and Shirley Hazzard, two other distinguished novelists, have not always been recognized as Australian because of their long residence in the United States.

The performing arts are more dependent on financial support and suffer from the fact that outstanding artists can always go overseas to Britain or the United States where a wealthier market offers greater rewards. This is particularly true of actors and singers, many of whom, from Dame Nellie Melba to Dame Joan Sutherland, have won international fame. In recent years, however, increasing financial support, the growing wealth and population of the larger cities, and the building of Sydney's spectacular Opera House (designed by the Danish architect Jørn Uzton) and new arts centres in Melbourne and Adelaide have led to a remarkable revival of the theatre in Australia, which has provided opportunities for dramatists, such as David Williamson, as well as for actors, singers, and dancers. Australia now has first-class national opera and ballet companies, and the Australian Broadcasting Commission (ABC) maintains symphony orchestras in all the capital cities.

Even more remarkable has been the revival of the moribund Australian film industry, which has been turning out a number of excellent films that have won international recognition. Australia's young film industry has also produced one director, Peter Weir, of outstanding talent. His best known films include "Picnic at Hanging Rock" (1976), "Gallipoli" (1980), and "The Year of Living Dangerously" (1983).

The Australian popular arts follow too closely develop-

ments in Britain and America to deserve special mention, and the remarkable Aboriginal arts, notably dancing and painting on bark, must be considered dead though efforts are being made to preserve and revive them.

Cultural institutions. The first serious attempt to organize the arts in Australia was the formation of the Elizabethan Theatre Trust in 1954. It was this body that formed the Australian Opera and Australian Ballet companies. The trust still administers the opera and ballet orchestras, but its main functions have been taken over by the Australia Council, established in 1975, which advises the Commonwealth government on the arts and allots government funds to various bodies. The Arts Council of Australia, a separate and independent body, has a division in each state that takes the performing arts to school and adult audiences in rural areas and coordinates community arts activities.

The Australia Council

Australia has many festivals devoted solely or largely to the arts, of which Perth's annual festival and Adelaide's biennial festival attract both overseas and Australian artists and companies.

The state governments have long provided museums and art galleries in their respective states. In 1982 the National Gallery was opened in Canberra to house the national collection. Since it is accepted that it is now impossible for such a gallery to compete with the great galleries of Europe and America in collecting European painting and sculpture from the past, this gallery concentrates on Australian art past and present, art of the Pacific and Asian areas, and international art of the 20th century.

Press and broadcasting. The press of Australia is free, independent, competitive, and vigorous. It has long reached high standards in such papers as *The Sydney Morning Herald* and the Melbourne *Age,* both of which date from the mid-19th century, though Australia has also always had and still has popular papers that are more noted for sensationalism than for sober reporting or informed comment. All of these papers circulate only in the states in which they are published. In 1964 *The Australian* was first published with the aim of becoming a national paper. It is printed in several states and has won a small but influential readership. The Australian *Financial Review* (daily) and the *National Times* (weekly) also have a national readership.

Broadcasting and television are shared between the ABC, a national service dependent on federal government grants, and a number of commercial radio and television stations operating under licenses granted by the postmaster general and dependent on advertising for their revenues. In general it may be said that while the ABC provides a high quality service, especially in the broadcasting of music, it attracts only a small part of the available audience. The commercial stations, on the other hand, attract large audiences with rather second-rate programs. Commercial television in Australia is heavily dependent on material imported from Britain and the United States. (J.D.Pr.)

HISTORY

Aboriginal Australia

The ancestors of the Aborigines of Australia arrived on the continent some 25,000 years ago. These people, whether in one or several periods of migration, probably travelled by way of the now submerged Sahul Shelf or, where land connections were absent, by rafts or canoes. They came from Southeast Asia, but whether they derived from one or more racial stocks is still unknown. They brought with them the dingo, a species of dog. Before the arrival of Europeans in Australia, Aborigines occupied the northern and eastern coasts of the continent, the Murray River Valley, and part of Tasmania. The estimate of their numbers at that time is about 300,000. Population density was highest in more fertile riverine and coastal areas; in arid zones, the exigencies of gaining a livelihood made distribution over much larger territories necessary. These broad environmental differences had direct sociocultural implications for mobility and for control over natural resources. Aborigines in the drier inland moved camp more frequently, had a narrower margin of survival in bad seasons, and relied more directly on ritual supplication as a necessary aid to everyday living.

There were approximately 500 tribes and subtribes—a tribe being a constellation of interacting groups, the members of which acknowledge certain features in common. Most tribes had specific names for themselves; other names, sometimes less flattering, were applied to them by their neighbours. They occupied recognized territories and were distinguished by features in culture or language.

Early writers on the subject of Aboriginal Australia spoke of "nations," usually referring to a group of tribes identifying themselves by the same word for "man." Although there did exist interaction between neighbours, there was no direct social communication across the continent, and the Aborigines were certainly not a nation in the modern sense of the word: they had no overarching political system and no overall name.

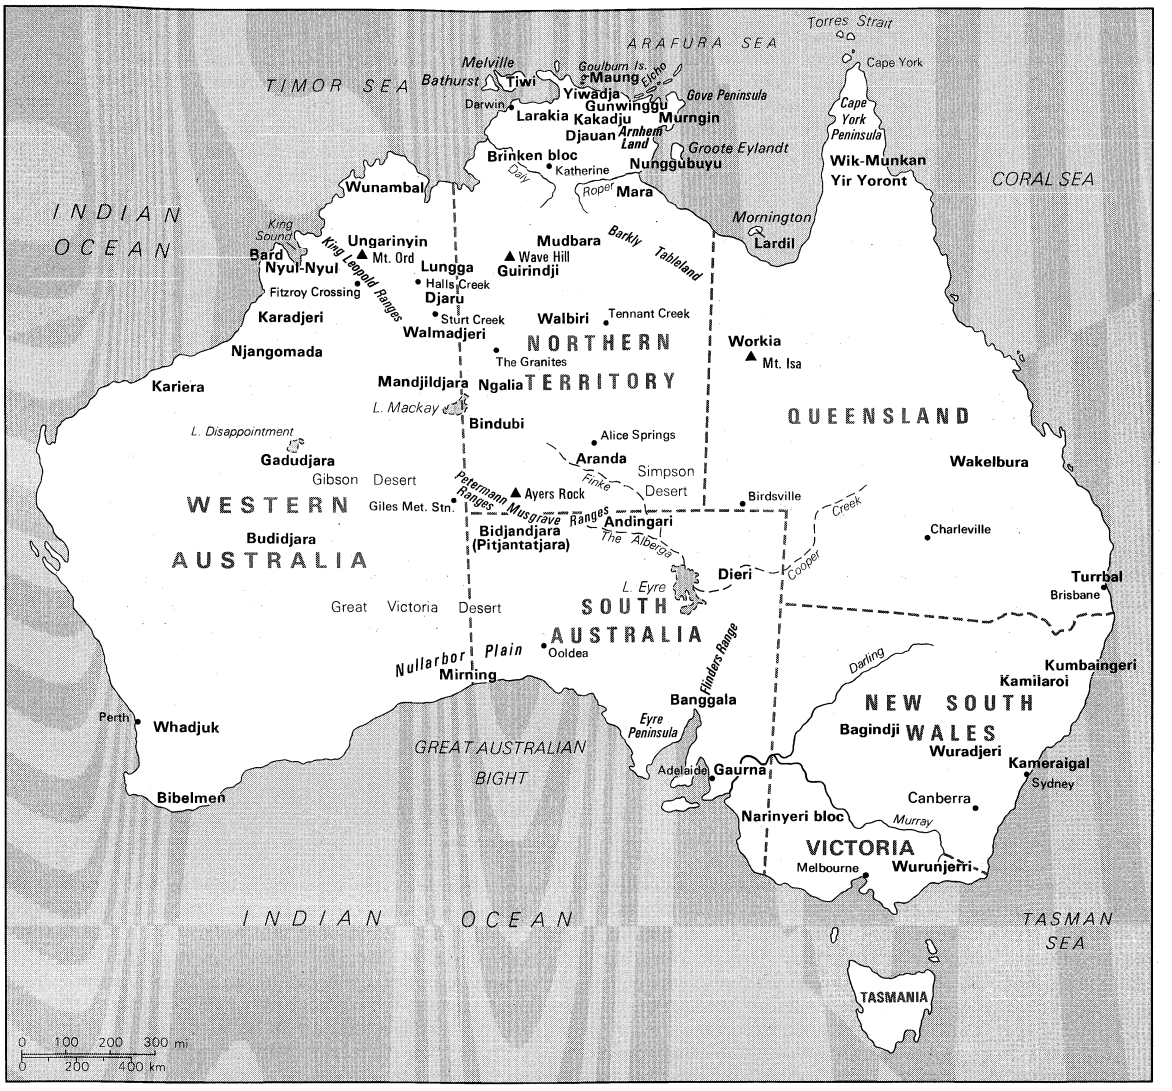
TRADITIONAL SOCIOCULTURAL PATTERNS

All Aborigines, coastal and inland, were directly dependent on their natural environment. They were seminomadic, wandering across limited stretches of the country, hunting, and collecting food. This basic economic circumstance had several concomitants: (1) food-gathering groups were fairly small and usually scattered, and all members of a tribe rarely came together, even for ritual occasions; (2) cooperation was essential; (3) over and above particular techniques and skills, Aborigines believed that religion was required for survival.

The Aborigines' view of their place in the world was summarized in their concept of "the Dreaming," or "eternal Dreamtime." This does not refer to dreams in an ordinary sense. In one of its meanings the Dreaming was the formative or creative period at the dawn of time, when mythic beings shaped the land, brought various species into life, and established human life and culture. Although these mythic beings died or were transformed, they lived on eternally in spirit. They left tangible evidence of their physical presence on earth and were actually identified with or manifested through particular species and natural elements. The Aborigines also believed that these spirits were manifested through and in human beings, that the mythic creatures of the Dreaming were not basically different from humans, and that humans, supernatural beings, and natural species were interdependent and mutually sustaining. Hence, Aborigines were never isolated; they saw themselves as acting with others, and the bonds of kinship were extended outward, embracing the nonhuman and nonempirical world.

Aboriginal cosmogony

Social groups and categories. The principal issues in Aboriginal social life were religion and economics; these elements were regarded as interdependent and were reflected in the two kinds of social units to which all Aborigines traditionally belonged. One of these social units was the local descent group, which was always patrilineal (descent through the male line), exogamous (marrying outside the group), and associated with a particular stretch of territory—the "estate." The adult males of a local descent group were responsible for the upkeep of the traditional sacred sites and for the appropriate ritual—that is, for renewing and sustaining the land. Ownership of land was nontransferable: its members held land in trust collectively by means of an unwritten charter deriving from the Dreaming. The second, larger kind of unit was the horde or band, the group concerned with the ordinary practical business of getting a living. This was a land-occupying and land-utilizing group, exploiting all the available natural resources. Fluctuating in size and composition, it comprised members of several families—that is, of more than one local descent group; and the range over which they normally travelled included several estates.



Original distribution of the larger Aboriginal tribes.

In addition to membership in a local descent group and horde, individuals identified themselves by reference to larger social groups: moieties, semimoieties, sections, subsections, and clans. A moiety is one of two basic complementary parts into which a tribe divides itself. Sections and subsections are further subdivisions, splitting the tribe into four and then eight parts. Such social divisions among the Aborigines governed marriage and other contracts. A person in one moiety, for instance, could marry only a person in the other moiety. When there were section or subsection systems, everyone was incorporated in such a system from before birth. The main advantage was that it represented a widely understood grid for categorizing everyone a person was likely to meet. With this went a shorthand statement of basic rules or conventions, which was a simple guide to behaviour, especially useful for classifying distant kin and strangers. Close, genealogically traceable kinship virtually always took precedence over nominal kinship when priorities were at issue.

Aboriginal Australia was not socially stratified in the sense of having more or less fixed classes or strata arranged hierarchically on the basis of descent or acquired status. Status was clearly marked only within the religious sphere; females, for example, were mostly excluded from an executive role in secret-sacred ritual, and areas of privilege were further defined by graded acceptance of youths and adults passing through rites of learning. Essentially, however, Aboriginal society was "open"—there were no social barriers operating against a man becoming a leader in religious matters. Such achievement depended primarily on his own efforts, his kin's, and his observance of ritual. Men acquired prestige through knowledge of religious practices and expertise in directing ritual. Entrepreneurial leaders had considerable status in one or two areas—among the Tiwi and Murngin, for example—but this was derived not so much from commercial activities as from their ability to manipulate certain kin, to arrange polygynous marriages for themselves and remunerative betrothals for their children, and to establish a network of alliances.

Kinship, marriage, and the family. As noted, the Aborigines were deeply conscious of social relations, especially kinship. All Aboriginal kinship systems were basically classificatory—that is, a limited number of terms was extended to cover all known persons: terms for lineal relatives, such as "father," also referred to collateral relatives, such as uncles. This did not mean that one could not recognize his actual father, mother, son, or other relative. The terms simply suggested the appropriate behaviour—filial, brotherly or sisterly, fatherly, or whatever.

Function and significance of kin terms

Kin terms were behavioral signals, indicating, for example, the expectation of sexual access, restraint, avoidance, or responsibilities. Affines (relatives by marriage) were often classified with consanguineous (blood) relatives, although qualifying terms might be used. Certain terms indicated potential spouses or affines. A husband and wife were ideally, before marriage, always related to each other as kin, either actual or classificatory. Some relationships were more prominent than others. The brother–sister relationship, for example, was one of the most emotionally charged and often marked by some form of avoidance. The most outstanding avoidance relationship was between a man and his actual or potential mother-in-law—not just

his wife's mother but all women and girls who on the basis of kinship and the recognition of preferred potential spouses, might become his mother-in-law.

Reciprocity was a fundamental rule in Aboriginal kinship systems and also in marriage. Marriage was not simply a relationship between two persons; it linked two families or groups of kin, which, even before the union was confirmed and most certainly afterward, had mutual obligations and responsibilities. Generally, throughout Aboriginal Australia those who received a wife had to make repayment either at the time of marriage or at some future time. In the simplest form of reciprocity, men exchanged sisters; and women, brothers. Such exchanges took place between different moieties, clans, or local descent groups or between certain types of kin. Most kinship-and-marriage systems provided for the possible replacement of spouses and for parent surrogates. At any one time, a man or woman had available a number of persons, who, because of their kinship, were termed spouses. Access to them depended on several factors, but, as far as premarital and extramarital liaisons were concerned, it was conventionally in this direction that partners should be sought.

Infant betrothal was common. If arranged before the birth of one or both of the prospective spouses, it was a tentative arrangement subject to later ratification, mainly through continued gift-giving to the girl's parents. In some Aboriginal societies, parents of marriageable girls played one man against another, although this was always a potentially dangerous game. Also, there might be a considerable age discrepancy between an affianced pair. Generally, a long-standing betrothal, cemented by gift-giving and the rendering of services, had a good chance of surviving and fostering a genuine attachment between a couple.

For a marriage to be recognized it was usually enough that a couple should live together publicly and assume certain responsibilities in relation to each other and toward their respective families; but it might be considered binding only after a child was born. All persons were expected to marry. A girl's marriage should be settled before she reached puberty, and, ideally, a husband should be older than his wife.

Apart from formal betrothal, there were other ways of contracting marriages, such as elopement, capture during feuding or fighting, and redistribution of widows through the levirate (compulsory marriage of a widow to her deceased husband's brother) or patriate (distribution of a father's widows to his sons, unless they were actual or close mothers). Elopement was often supported by love magic, which emphasized romantic love, as well as by the oblique or direct approval of extramarital relations.

Polygynous marriage

Although most men had only one wife at a time, polygyny was considered both legitimate and "good." The average number of wives in polygynous unions was two or three. The maximum, in the Western Desert, was five or six; among the Tiwi, 29; among the Murngin, 20 to 25, with many men having 10 to 12. In such circumstances, women had a scarcity value. Having more than one wife was usually a matter of personal inclination, but economic considerations were important; so were prestige and political advantage. Some women pressed their husbands to take an additional wife (or wives), since this meant more food coming into the family circle and more baby-sitters. To terminate a marriage, a woman might try elopement. A man could bestow an unsatisfactory wife on someone else or divorce her. A formal declaration or some symbolic gesture on his part might be all that was necessary. In broad terms, a husband had more rights over his wife than she had over him. But, taking into account the overall relations between men and women, their separate and complementary spheres of activity in marriage and in other aspects of social living, the status of women in Aboriginal society was not depressed.

Socialization. A child's spirit was held to come from the Dreaming to animate a fetus. In some cases, this was believed to occur through an action of a mythic being who might or might not be reincarnated in the child. Even when Aborigines acknowledged a physical bond between parents and child, the most important issue for them was the spiritual heritage.

In his early years a child's focus was on his actual parents, and especially on his mother, but there were others close at hand to care for him. Weaning occurred at about two or three years of age but occasionally not until five or six for a youngest child. Through observation of camp life around him and informal instruction, a child built up his sociocultural perspective, learning through participation. At the same time, he became familiar with his natural environment. Small children often went food collecting with their mothers and other women; as girls grew older, they continued to do so, but boys were thrown more on their own resources. Parents were, on the whole, very indulgent. Infanticide, even in arid areas, was much rarer than has been suggested.

Children learned quite early with whom they were allowed to play and whom they must avoid; brothers and sisters, for instance, or "mothers-in-law" and "sons-in-law," would not normally play together. Betrothal put special restraints on a girl, and, at or even before puberty, she normally went to live with her husband, assuming the status of a married woman.

With initiation, a boy's life changed drastically. His formal instruction as a potential adult began, and he was prepared for his entry into religious ritual. His future was henceforth in the hands of older men and ritual leaders who exercised authority in his community. But he was not among strangers: the relatives who played an active role in his initiation would also have significant roles in his adult life. A boy's age at the first rite varied: in the Western Desert it was about 16; in the Kimberleys, about 12; in northeastern Arnhem Land, six to eight; and among the Aranda 10 to 12 or even older. Generally, once he had reached puberty and facial hair had begun to show, he was ready for the initial rituals.

Initiation in Aboriginal Australia was a symbolic reenactment of death in order to achieve new life as an adult. As a novice left his camp, the women would wail and other noises would be made, symbolizing the voice of a mythic being who was said to swallow the novice and later vomit him forth into a new life. The initiation rites themselves were a focal point in discipline and training; they included songs and rituals having an educational purpose. All boys were initiated, and traditionally there were no exceptions.

Initiation rites

Circumcision was one of the most important rites over the greater part of Australia. Subincision (incisure of the urethra) was especially significant in its association with secret-sacred ritual. Other rites, according to the area, included piercing of the nasal septum, tooth pulling (in New South Wales this was central in initiation), and the blood rite, which involved bloodletting from arm vein or a penis incisure—the blood being used for anointing or sipping (red ochre was used as a substitute for blood in some cases). Hair removal, cicatrization (scarring), and playing with fire were also fairly widespread practices. Among the Aranda, fingernails were torn out and heads gashed open and bitten. All such rites were usually substantiated by mythology.

For girls, puberty was marked by either total or partial seclusion and by food taboos (also applied to male novices). Afterward, they were decorated and ritually purified. Ritual defloration and hymen cutting or both were widespread (in the Western Desert, for instance), while on Groote Eylandt the labia majora were removed.

Boys, after circumcision, became increasingly involved in adult activities. Although they were not free to marry immediately, even if they had reached puberty, they might do so after undergoing certain rites, such as subincision. Initiation was a prelude to the religious activity in which all men participated. It meant, also, learning a wide range of things directly concerned with the practical aspects of social living. Adulthood brought increased status but added responsibilities. A vast store of information had to be handed down from one generation to the next. Initiation served as a medium for this, providing a basis of knowledge upon which an adult could build. This was a process that continued through life and that was especially marked in men's religious activity.

For Aborigines birth and death were an open-ended continuum: a spiritual religious power emerged from the

Dreaming, was harnessed and utilized through initiation (as symbolic death–rebirth) and through subsequent religious ritual, and finally, on death, went back into the Dreaming. Life and death were not seen as being diametrically opposed: the Dreaming provided a thread of life, even in physical death.

Social control. Pressures toward conformity began and were formalized during initiation. There were rules and standards, right and wrong ways of doing things, and some allowance for variation. Sanctions upheld the accepted codes and were either positive or negative or a combination of both. Probably the strongest were fear of supernatural punishment and fear of sorcery.

Traditionally, most dissension arose over women, religious matters, and death. Women had trouble with husbands, eloped, and engaged in unsanctioned extramarital liaisons. Such behaviour could mean serious fighting, involving relatives of the parties concerned. Infringement of sacred law was less direct in its social repercussions but was nevertheless regarded as the most serious of all. In many cases, an ordinary or accidental death had wide ramifications, particularly if there were accusations of sorcery. An inquest was held, and, through divination, a supposed "murderer" was found. Punitive measures might or might not be taken against him.

Maintenance of law and order

The maintenance of law and order was quite narrowly localized. Authority was limited and qualified by kinship claims. Precedents were sought in order to guide or influence actions resulting from a breach, and in all tribes there were approved procedures for maintaining the peace. There were no judicial bodies as such, though on the lower Murray River a formal council, or *tendi,* of clan headmen and elders did arbitrate disagreements between adjacent tribes. Generally, simple informal meetings of elders and men of importance dealt with grievances and other matters. There was also settlement by ordeal—the most outstanding example of this sort being the *magarada,* or *maneiag,* of Arnhem Land. During a ritualized meeting, the accused ran the gauntlet of his accusers, who threw spears at him; guilt was proved if the accused was wounded in the thigh.

Although it is inaccurate to speak of a gerontocracy in Aboriginal Australia, men of importance were easily distinguished. They were usually "elders," who had this status not necessarily because of their age or grey hair but because of their religious position and personal energy. This gave them considerable control over the affairs of others in matters not directly related to religion.

Economic organization. Dependence on the environment and on its resources was reflected in seminomadic living. The Aborigines had to be intimately acquainted with all the country within their range of movement. At the same time, their economic system was not conceptually separate from their religious system. Both before and after initiation, graphic stories (or myths) served as guides to specific localities, detailing what people could expect to find there. In other words, information used in obtaining a living was preserved and transmitted in a religious context. Religious ritual, furthermore, was believed to ensure the maintenance of the natural species and the proper fluctuation of the seasons.

Before modification of their economic organization as a result of contact with Europeans, large groups of people did not remain in the same camp over a prolonged period. There were two basic patterns. Generally, in fertile regions of Aboriginal Australia, time-honoured camping areas were recognized, always in close proximity to water and usually with mythological associations; they were places where people always camped at certain times of the year. Camps were bases from which people made forays into the surrounding bush for food, returning in the late afternoon or spending a few days away. The second pattern involved a much larger territory in arid or desert areas across which Aborigines moved from waterhole to waterhole along well-defined tracks in small family groups. The whole camp moved and rarely established bases. Only in good seasons and at sizable permanent waters was it possible for a large number of people to remain for an extended period.

These two patterns were reflected in domestic arrangements. In the north, people made bark shelters, and during the monsoonal rains used caves and stilted huts as protection against flood, mosquitoes, and sandflies. In the desert, windbreaks—bough shelters or saplings covered with brush or bark—were common. During fine weather most Aborigines preferred to sleep in the open, with a windbreak; when it was too cold, dogs helped to provide warmth. Fires were kept alight, and, when moving from one place to another, or even when hunting, people carried live fire sticks.

Aborigines, with rare exceptions (southwest of Darwin and northeastern Arnhem Land, for example), had no form of cultivation and no domestic animals, except the tamed dingo. They preferred to go naked, except for small pubic coverings or decorations. In certain areas, fur cloaks were a protection against cold.

Tools and artifacts

Outside the sphere of religion, material objects were minimal. Grinding stones and platters were left at certain camps, ready for use. Men carried spears and spear throwers and, in some areas, boomerangs. There were bark canoes and rafts and dugout log canoes, some with pandanus-mat sails. Women's digging sticks could double as fighting weapons. Their large deep wooden dishes held seeds, vegetables, or water, even babies. In some areas, painted bark baskets, plaited pandanus bags, and net bags served the same purposes. Rarer objects were the kangaroo-skin waterbags of the arid central areas and the skull drinking vessels of the Coorong in South Australia. Implements included a large selection of stone tools, wedges, bone needles, bobbins, and sharkskin files.

Aboriginal spearfishing near Darwin, Northern Territory.

Generally, men were hunters, women food collectors; and, unless they were on the move, they carried out these tasks separately. A woman's economic pursuits were focussed on her own family and children. A man's obligations were wider. Providing for his own family was often of secondary importance: ideally, his ritual duties and his network of reciprocal obligations took priority. He was expected to provide meat for his family; but women bore the main responsibility, supplying vegetable foods and small game or shellfish. Although this was primarily a subsistence economy, even life in the desert was not reduced to a constant struggle for the bare essentials. It nevertheless called for skill, tenacity, and continuing social involvement. A person could not "opt out" and survive. Reciprocity was basic to economic life, and all adults were caught up in a web of rights and duties.

As far as trading was concerned, goods passed along defined routes from one group to another in an intricate crisscross patterning over the continent. Boomerangs, for

example, went in one direction, red ochre in another; pearl shells from the Kimberleys found their way, gradually, to the Great Australian Bight; and central Australian shields appeared in the Canning Stock Route area.

In traditional Aboriginal society acquisition and gain were important, but the idea of making a profit was almost irrelevant. What really counted was the social relationship inherent in the exchange. The more organized trading partnerships entailed a debtor–creditor association; but prestige still hinged on retaining an equitable balance in the exchanges, on "solvency," and on not dropping out of the network. Private property was recognized, the claims of others upon an item not affecting an individual's right to exclusive use of it until such time as he decided to relinquish it. Traditionally, however, land was inalienable, being held in trust by members of various local descent groups.

BELIEF AND AESTHETIC VALUES

Religion. The Aborigines were concerned that the seasons should come and go in an orderly, predictable way; that human life should continue; and that they themselves should go on living in much the same way as they had always done. Religious beliefs and values gave tradition its power and force in influencing life in the present.

Totemism

Both before and since the French sociologist Émile Durkheim's study of *The Elementary Forms of the Religious Life* (1915), much has been written about Australian totemism. The concept rests on the belief that human beings are an integral part of nature, like all other living things. Totemism has been defined as a representation of the universe, seen as a moral and social order; as a philosophy that regards man and nature as one corporate whole; or as a set of symbols forming a conventional expression of the value system of a society. Such symbols provided intermediate links, both personal and social, between man and the mythic beings. Many of the mythic beings in Australia were "totemic" in the sense of exemplifying in their own persons, in their outward form, the common life-force pervading particular species. Others, originating in human or near-human form, at the end of their wanderings entered some physiographic feature or were metamorphosed as hills or rocks or turned into various creatures or plants. Totemism is another illustration that a sharp dichotomy between sacred and mundane cannot be drawn in Aboriginal Australia, where religion was directly relevant to everyday living.

Among most Aboriginal tribes, the main ritual roles in the big religious sequences were reserved for men. Ordinarily, in such cases, women were forbidden to enter ritual grounds, and what went on there was secret and sacred. But women usually had complementary actions to perform or observed special taboos. In other rituals both men and women participated. Among some tribes, women had their own secret-sacred rites. Generally, any large ritual affair concerned a whole community and involved all its members in some measure.

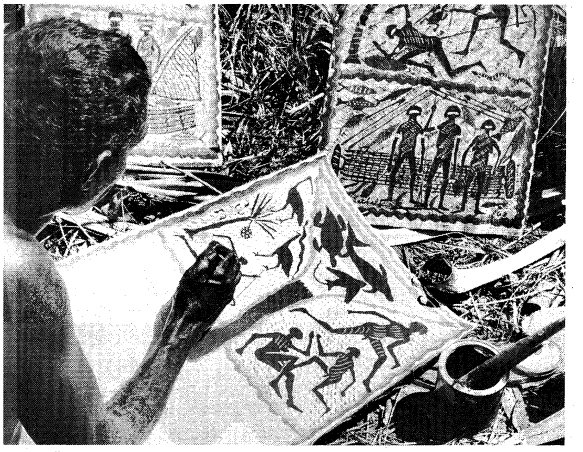
Aesthetics. Sacred ritual provided immense scope for aesthetic expression, especially in dramatic performances with stylized posturing and complicated dance movements. Less intense but sometimes almost as elaborate were the nonsacred ceremonies (or corroborees) designed for entertainment and relaxation. Songs ranged in style from the succinct verses or couplets of central Australia and the Western Desert, which were made up of three, four, or more words repeated in linked sequences, to the more elaborate songs of northeastern Arnhem Land, which were long verses building up complex word pictures through symbolic allusion and imagery. There was no poetry in terms of spoken verse, but there were chants, some of them outstandingly beautiful. The majority of secret-sacred songs comprised mythic cycles, each containing several hundreds of verses. There was also a wide repertoire of songs on everyday events, such as the "gossip" songs of western Arnhem Land, composed by songmen with the aid of spirits. Instrumental music in the north was provided by the didgeridoo (drone-trumpet) and by clapping sticks. In southern and central regions, boomerangs or clubs were rhythmically beaten together or pounded on the ground; in southeastern Australia, women used skin beating pads. Tunes and rhythms varied greatly from area to area.

Songs, chants, and instrumental music

Oral literature was rich. In addition to sacred mythology, there were ordinary stories and tales, either historically true or presumed to be true. Some existed in several versions, depending on the situation in which they were told and on the individual background of the storyteller.

Each cultural area had its own distinctive style of art. *Tjurunga* (sacred object) art, consisting of incised patterns on flat stones or wooden boards, was representative of a large area of Australia, although centralized in Aranda territory. In central Australia, body decoration and elaborate headdresses on ritual occasions, using feather down, blood, and ochres, were especially striking. Everywhere, sacred ritual provided the incentive for making a large variety of objects—mostly impermanent, because the act of making them was itself one of the appropriate rites. In western Arnhem Land, *maraiin* objects—realistic and stylized carved representations of various natural species—were made. The *rangga,* or ceremonial poles, of eastern Arnhem Land, many of durable hardwood, bore ochre designs and long pendants of feathered twine. For mortuary rituals, the Tiwi made large wooden grave posts, and shaped and decorated receptacles for bones were common in eastern Arnhem Land. Also common were carved wooden figures of mythic beings and of contemporary persons, some used in sacred ritual, others as memorial posts for the dead.

Douglass Baglin



Aboriginal artist working on a bark painting, Queensland.

Paintings in ochre on sheets of bark were indigenous to Arnhem Land, although examples could be found in the Kimberleys and in southeastern Australia. They were used mostly on the initiation ground for the instruction of novices. In western Arnhem Land, naturalistic patterns showing figures against an open background were the norm; there was also a unique kind of "X-ray" art that depicted the internal organs of animals and human beings. Also found in various parts of Australia were cave and rock paintings or engravings.

For an outstanding artist or songman, the rewards lay mainly in prestige and in religious advancement. He was not absolved from earning a living in the ordinary way and shouldering routine responsibilities.

ABORIGINES IN AUSTRALIAN SOCIETY

The heritage of early alien contact. Traditionally, the Australian Aborigines had little knowledge of other peoples and were ill-equipped to withstand the rapid inroads of an alien and culturally different people.

Early contact with Indonesians

Two qualifications are necessary here. First, the Aborigines excelled in adjusting themselves to their natural environment. Secondly, in the north they came into contact with Indonesians at an early date (at least two to four centuries ago). The visitors came as sea-going traders to the Arnhem Land coast and made a powerful impact on local art, music, ritual, and material culture. On Cape York Peninsula, the influence of New Guinea and the Torres Strait Islands was evident in the adoption of masked ritual dancing and the use of the drum.

But the coming of Europeans, in 1788, was entirely different. Initially, many Aborigines were willing to welcome them, even regarding them as returning spirits of the dead or as manifestations of the mythic beings. European settlement soon expanded, however, making inroads into tribal territory and interfering with natural resources, excluding the Aborigines from their sacred and other areas and drawing them—often forcibly, always uncomprehendingly—into the life of the developing colony. Communication was minimal. Clashes marked virtually all situations in which Aborigines and Europeans pursued conflicting interests. In the period of "pacification by force," up to the 1880s, a large number of Aborigines were killed. Others were driven into the bush or remained in small pockets subject to the "civilizing" influence of missions, or were left to fend for themselves in the fringe settlements of cities and towns; still others remained in camps or pastoral and cattle stations to become the nucleus of a labour force. Diseases took their toll. The Colonial Office in London had instructed that the Aborigines' rights should be safeguarded and that they were to be accorded the benefits of British subjects. The actual situation was different.

The Aborigines reacted with spasmodic guerrilla warfare and stock killing or with passive resistance. But they soon learned that the only alternative was to adapt, at least to some extent. The result was pauperization. Gradually, missionaries and government welfare agents began to have some effect, and questions of humane treatment came to have a more practical meaning. But in outlying areas, maltreatment and violence lingered on into the early 1940s. Further, wherever European settlement was intensive, miscegenation took place, and part-Aborigines came to replace the full-blooded population. Their traditional life ceased to exist as a living reality over much of the southwestern, southeastern, and middle eastern areas of the continent. In the central and northern regions traditional life remained, even on some pastoral, mission, and government stations, although in a modified form. In more remote areas it was still possible for Aborigines to live approximately in the way they had before but with notable modifications, particularly in the sphere of law and order. It was for some time believed that the Aborigines would eventually die out, and reserves were established in the late 1920s and early 1930s to serve as a buffer between them and Europeans. But many were attracted to the fringe settlements, where they formed tribally and linguistically mixed communities. This meant the emergence of a new form of living, structurally linked to the wider Australian society.

Developments since World War II. From the early 1940s, government policies have been changing. But growing support for the goal of assimilation (in effect, Europeanization) did not include adequate programs for achieving it. Many Aborigines were resistant, skeptical, and disillusioned—the aftermath of neglect and the not-too-distant memory of the traumatic events of early contact. In the early 1950s, some sought withdrawal and a magico-religious escape in the *kurangara* (Kimberleys) or in a revival of quasi-Aboriginal religion (as on the north coast of New South Wales). The Pindan Cooperative at Port Hedland in Western Australia is a further example of a movement concerned with maintaining group cohesion on a quasi-traditional basis.

No Aborigines exist who have not had some contact with modern Australian society. By 1960 only about 7,500 Aborigines still kept even a modified traditional orientation. The great majority of the total population of some 111,000 persons (1981) who identified themselves as Aborigines or Torres Strait Islanders (Aborigines of Papuan ancestry) were living in southern cities and country towns—more European both in physical appearance and in manner of living. Generally, within recent years, the emphasis has been on drawing Aborigines more closely into the wider Australian society and, in the process, erasing unfavourable forms of discrimination. All Aborigines are now Australian citizens, eligible to vote, to receive social service benefits, and to drink liquor. Facilities for primary and secondary education and for technical training have been improved, and more people of Aboriginal descent are taking advantage of this. Nevertheless, many remain poorly trained and educated, caught in the lowest socioeconomic level of Australian society. Prospects are brighter for the younger generation, but social acceptance by many white Australians is still limited.

Population figures

Two major developments are significant. A Commonwealth (Federal) conference in 1965 nominally redefined assimilation policies by giving Aborigines a choice between an Aboriginal and an Australian–European orientation. The trend toward social and cultural alteration has actually proceeded so far that, in most areas, such choice is unreal. But it has left the door open in some areas where Aborigines still have an informed appreciation of the value of their traditions. The other development has been an increasing uniformity between state and Commonwealth policies, partly a result of the Commonwealth Department of Aboriginal Affairs, which serves in an overview capacity and provides economic aid. In 1973 the National Aboriginal Consultative Committee (NACC), composed of Aborigines and Torres Strait Islanders elected throughout Australia, was established to advise the minister of Aboriginal affairs on Aboriginal needs, desires, and policies. The NACC was replaced by the National Aboriginal Conference (NAC) in 1977. The NAC was composed of elected Aborigines and Torres Strait Islanders from each state and territory, and it met annually on a national basis and quarterly on a territorial or state basis.

Articulate part-Aboriginal groups have emerged in the south; they insist on integration rather than assimilation—that is, on retaining Aboriginal identity as a unique status symbol marking them off from other Australians. This movement toward pan-Aboriginality has implications for all people of Aboriginal descent. In the north, the focus has been on questions of land ownership and control, including compensation (and not just royalties) for and a share in the mineral exploitation that is occurring on Aboriginal reserves. The Aboriginal Land Rights Act (1976) gave traditional Aborigines the right to hold reserve land in the Northern Territory. By the late 20th century more than 139,000 square miles of the Northern Territory had reverted to Aboriginal ownership. Minerals on the Aboriginal lands, however, remained the property of the federal government, but royalties from mineral exploitation are paid to the Aboriginal communities holding title to the land. The act also provides the framework for Aborigines to lay claim to other lands if a strong traditional link can be proved. Aborigines are also assisted by the Aboriginal Development Commission in the purchase of non-reserve land for settlement and business. Despite these accomplishments in Aboriginal representation and land ownership, there is still wide dissatisfaction with the progress of socioeconomic development. A likely consequence of this is a reinforcement of the movements mentioned above toward maintaining what remains of the traditional life, reflecting a belief that the last significant aspects of the Aborigines' social and cultural identification should not be dissipated. (R.M.B.)

Australia to 1900

EARLY EXPLORATION AND COLONIZATION

Early contacts and approaches. Prior to documented history, there may have been further Asian contacts. Chinese astronomers are said to have made observations in Australia during the 6th century BC; firmer evidence argues for a Chinese landing near Darwin in 1432. The incursion of Islām into Southeast Asia came within 300 miles (480 kilometres) of Australia, and adventure, wind, or current might have carried some individuals the extra distance. Both Arab and Chinese documents tell of a southern land, but with such inaccuracy that they scarcely clarify the argument. Similarly, the "jave la Grande" shown on some 16th-century European maps may or may not be a genuine representation of Australia. Bugis (Macassar) seamen certainly fished off Arnhem Land, in the Northern Territory, from the late 18th century and may have done so for generations. Perhaps only effective resistance by the Aborigines against the Bugis reserved Australia for white colonization.

The Portuguese. The quest for wealth and knowledge might logically have pulled the Portuguese to Australian shores; and the assumption has some evidential support, including a reference that Melville Island, off the northern coast, supplied slaves. Certainly the Portuguese debated the issue of a *terra australis incognita* ("unknown southern land")—an issue in European thought in ancient times and revived from the 12th century onward. Yet hard, clinching evidence of contact is lacking.

The Spanish. Viceroys of Spain's American empire regularly sought new lands. One such expedition, from Peru in 1567, commanded by Álvaro de Mendaña, discovered the Solomon Islands; excited by finding gold, Mendaña hoped that he had found the great southern land and that Spain would colonize there. In 1595 Mendaña sailed again but failed to rediscover the Solomons. One of his officers—Pedro Fernández de Quirós, a man of the Counter-Reformation, who desired that Catholicism should prevail in the southland, of whose existence he was certain—won the backing of King Philip III for an expedition under his own command. It left Callao, Peru, in December 1605 and reached the New Hebrides. Quirós named the island group Austrialia del Espiritu Santo, and he celebrated with elaborate ritual. He (and some later Catholic historians) saw this as the discovery of the southern land. But Quirós' exultation was brief; troubles forced his return to Hispanic America. The other ship of the expedition, under Luis de Torres, went on to sail through Torres Strait but almost certainly failed to sight Australia; and all Quirós fervour failed to persuade Spanish officialdom to mount another expedition.

Oceanic exploration. The exploration and settlement of Australia began early in the 17th century.

The Dutch. Late in 1605 Willem Jansz. of Amsterdam sailed from Bantam in search of New Guinea. He reached Torres Strait a few weeks before Torres himself and unknowingly saw, and also named, part of the Australian coast—Cape Keer Weer, on the west of Cape York Peninsula. More significantly, from 1611 some Dutch ships sailing from the Cape of Good Hope to Java inevitably carried too far east and touched Australia: the first and most famous was Dirck Hartog's "Eendracht," from which men landed and left a memorial at Shark Bay, Western Australia, October 25–27, 1616. Pieter Nuyts explored almost 1,000 miles of the southern coast in 1626–27, and other Dutchmen added to knowledge of the north and west.

The first landing

Most important of all was the work of Abel Tasman, who won such respect as a seaman in the Dutch East Indies that in 1642 Governor General Anthony van Diemen of the Indies commissioned him to explore southward. In November, having made a great circuit of the seas, Tasman sighted the west coast of what he called Van Diemen's Land (latterly Tasmania). He then explored New Zealand before returning to Batavia. A second expedition of 1644 contributed to knowledge of Australia's northern coast; thenceforth, New Holland was the name for the landmass.

The British. But the Netherlands spent little more effort in exploration, and the other great Protestant power in Europe, England, took over the role. In 1688 the English pirate William Dampier relaxed on New Holland's northeastern coast. On returning to England, he published his *Voyages* and persuaded the Admiralty to back another venture. He traversed the western coast for 1,000 miles (1699–1700) and reported more fully than anyone previously, but in terms so critical of the land and its people that another hiatus resulted.

The middle decades of the 18th century saw much writing about the curiosities and possible commercial value of the southern seas and *terra australis incognita.* This was not restricted to Great Britain, but it had especial vigour there. The British government showed its interest by backing several voyages. Hopes flourished for a mighty empire of commerce in the eastern seas.

This was the background for the three voyages of Capt. James Cook on behalf of the British Admiralty. The first, that of the "Endeavour," left England in August 1768 and had its climax April 20, 1770, when Lieut. Isaac Hicks sighted southeastern Australia. Cook landed several times, most notably at Botany Bay, and at Possession Island in the north, where on August 23 he claimed the land, naming it New South Wales. Cook's later voyages (1772–75, 1776–79) added only a little to Australian exploration but were both symptom and cause of strengthening British interest in the eastern seas.

Captain Cook's voyages

Later explorations. Cook's voyages led to settlement but did not complete exploration of the Australian coasts. Marion Dufresne of France skirted Tasmania in 1772, seeing more, at least of the western coast, than had Tasman. The Comte de La Pérouse, another French explorer, made no actual discoveries in Australia, but his visit to Botany Bay early in 1788 was notable. In 1791 the British navigator George Vancouver traversed and described the southern shores discovered by Pieter Nuyts years before; A.-R.-J. de Bruni, chevalier d'Entrecasteaux, of France also did significant work, especially in southern Tasmania.

Two Britons—George Bass, a naval surgeon, and Matthew Flinders, a naval officer—were the most famous postsettlement explorers. Together they entered some harbours on the coast near Botany Bay in 1795 and 1796; and Bass ventured farther south in 1797–98, pushing around Cape Everard to Westen Port. Flinders, too, was in that region early in 1798, charting the Furneaux Islands. Late that year Flinders and Bass in the "Norfolk" circumnavigated Tasmania, establishing that it was an island and making further discoveries. Several other navigators, including merchantmen, filled out knowledge of the Bass Strait area; most notable was the discovery of Port Phillip in 1802.

Meanwhile, Flinders had returned home and in 1801 was appointed to command an expedition that would virtually complete the charting of Australia. Over the next three years Flinders proved equal to this task. Above all, he left no doubt that the Australian continent was a single landmass. Appropriately, Flinders urged that the name Australia replace New Holland, and this change received official backing from 1817.

France sponsored an expedition, similar in intent to Flinders', at the same time. Under Nicolas Baudin, it gave French names to many features (including "Terre Napoléon" for the southern coast) and gathered much information but did little completely new. It was on the northern coast, from Arnhem Land to Cape York Peninsula, that more work was needed. Two Admiralty expeditions—under P.P. King (1817–22) and J.C. Wickham (1838–39)—filled this gap.

European settlement. The British government determined on settling New South Wales in 1786, and colonization began early in 1788. The motives for this move have become a matter of some controversy. The traditional view is that Britain thereby sought to relieve the pressure upon its prisons, a pressure intensified by the loss of its American colonies, which hitherto had accepted felons. Convicts went to the settlement from the outset, and official statements put this first among the colony's intended purposes. But some historians argue that this glossed a scheme, likely to provoke concern both within Britain and at the diplomatic level, to provide a bastion for British trade in the eastern seas. Supporters of the commercial-strategic view emphasize that Cook had extended hopes that the South Pacific would provide essential naval stores, especially mast timber and flax. (Its lack of documentary support notwithstanding, the argument makes considerable sense.)

British motives for settlement

Whatever the deeper motivation, plans went ahead, with Lord Sydney (Thomas Townshend), secretary of state for home affairs, as the guiding authority. Arthur Phillip served as commander of the expedition; he was to take possession of the whole territory from Cape York to Tasmania, westward as far as 135° and eastward to include adjacent islands. Phillip's power was to be near absolute within his domain. The British government planned to develop the region's economy by employing convict labour on government farms, while former convicts would subsist on their own small plots.

The First Fleet sailed May 13, 1787, with 11 vessels, including six transports, aboard which were about 730 convicts (570 men and 160 women). More than 250 free persons accompanied the convicts, chiefly marines of var-

ious rank. The fleet reached Botany Bay on January 19–20, 1788. Crisis threatened at once. Botany Bay was poor in soil and water and even as a harbour. Phillip therefore sailed northward on January 21 and entered a superb harbour, Port Jackson, which Cook had marked but not explored. He moved the fleet there; the flag was hoisted on January 26 and the formalities of government begun on February 7. Sydney Cove, the focus of settlement, was deep within Port Jackson, on the southern side; around it was to grow the city of Sydney.

The first settlement

Phillip at once established an outstation at Norfolk Island. Its history was to be checkered—settlement was abandoned in 1813 and revived in 1825 only to provide a jail for convicts who further misbehaved in Australia. (The island served a new purpose from 1856 as a home for the descendants of the "Bounty" mutineers, who by then were too numerous for Pitcairn Island.)

Phillip remained as governor until December 1792, seeing New South Wales through its darkest days. The land was indifferent, disease and pests abounded, few convicts proved able labourers, and the Aborigines often were hostile. The nadir came in autumn 1790 as supplies shrank; the arrival of a second fleet brought hundreds of sickly convicts but also the means of survival.

An authoritarian society. While much change proceeded throughout this period, authoritarian and hierarchical elements remained strong. The reception of convicts continued and was a major fact in social and economic life. Entrepreneurs strove hard but did not yet develop a staple industry. Farmers and graziers began to fill out an arc 150–200 miles (240–320 kilometres) around Sydney: this area was designated as the Nineteen Counties in 1829, and settlement beyond that limit was discouraged. Following the discovery of Bass Strait, and in concern to secure southern waterways, new settlements were made in the south.

From Britain, David Collins sailed in 1803 to settle Port Phillip; his sojourn there was unhappy, and in mid-1804 he moved to the River Derwent in southern Tasmania, already settled (September 1803) by a group from Sydney under John Bowen. Collins resettled the amalgamated parties at Hobart. In November 1804 William Paterson founded a settlement in northern Tasmania, the precursor of Launceston. These settlements united in 1812; they were still under supervision from Sydney, although only nominally from 1825. Among penal outstations settled from Sydney were those at Newcastle (1804) and Moreton Bay (1824), the forerunner of Brisbane. Britain extended its possession over the whole of the continent in the mid-1820s, again suspecting French (or even American) intervention. The western boundary of the governor's commission shifted to 129° in 1825 to include Bathurst and Melville islands in the far north, and there was a small settlement in this region (1824–29). At Western Port, east of Port Phillip, another settlement was made (1826–27), while in January 1827 Edmund Lockyer began permanent settlement at Albany, Western Australia. His instructions stated that Britain now claimed all Australia.

British possession of the whole continent

Structure of the government. As remarked above, the constitutional structure was authoritarian. The governors were all military officers. There were no representative institutions; but the Judicature Acts of 1823 and 1828 provided for executive and legislative councils, with the major officers of government serving in both and an equal number of private individuals, chosen by nomination, in the latter. More significant at this stage was articulation of a judicial system, especially the establishment of supreme courts (New South Wales, 1814; Tasmania, 1824); normal trial by jury did not obtain.

Sociopolitical factions. Within this rigid structure, sociopolitical factions developed and affected events. Most important in the early years was the leadership of the New South Wales Corps, stationed at Sydney from 1791. Some officers of the corps sought power and profit with an avidity that led to clash after clash with the early governors; this culminated on January 26, 1808, when John Macarthur, a former officer of the corps, led a rebellion that deposed Gov. William Bligh (served 1806–08), earlier famous for the "Bounty" mutiny. In due course, the imperial government reacted and recalled the corps; but Gov. Lachlan Macquarie (served 1810–21) also clashed with the colony's "exclusives"—former officers and a handful of wealthy free immigrants. Conversely, he associated himself with the "emancipist" faction—a group that argued in favour of erstwhile convicts having a particular claim upon government and the colony's resources.

The "emancipists"

Macquarie's attitude disturbed the imperial government. After an official inquiry (1819–21) by J.T. Bigge, it encouraged the migration of men of some standing and wealth to both New South Wales and Tasmania. Such men received substantial grants of land and appeared the natural leaders of social and economic development. The emancipists continued to be strong, however, especially through the leadership of W.C. Wentworth (himself the son of a convict woman), whose newspaper, the *Australian* (founded 1824), was the spearhead of opposition, especially to Gov. Ralph Darling (served 1825–31). In Tasmania factions never formed so clearly, but there, also, the press led criticism of the government.

The convicts. By 1830 about 58,000 convicts, including almost 50,000 men, had come to Australia (the rate increasing rapidly after 1815). Many were more or less habitual urban thieves. There were a few political prisoners, while a substantial proportion of the Irish convicts (a third of the total) had become offenders through sociopolitical unrest. In Australia the convicts were either employed by government or "assigned" to private employers. Broadly speaking, conditions were not especially harsh or repressive, and "tickets of leave" and pardons provided relatively quick routes to freedom; assignment to the new settlers of the 1820s, however, often had an element of slavery. Most convicts committed some further misdeeds, although only about one-tenth were charged with serious offenses. Those found guilty went to secondary penal stations, the (sometimes exaggerated) horror spots of Australian history—Macquarie Harbour, Newcastle, and Moreton Bay in this period and, later, Norfolk Island and Port Arthur. The convicts gave Australia a large *Lumpenproletariat,* yet success stories were common enough, and many led decent lives. There were only a few militant protests—the most remarkable was an uprising among Irish convicts outside Sydney in March 1804. Altogether, the convict impact was less grim and ugly than might be expected.

Economic activity. The maintenance of convicts was essentially the economic resource of the colony for many years; this function caused very considerable expenditure by the British government. Wealth was won by supplying government stores with food and grain, or by controlling internal trade (especially in rum), which ultimately depended on the government maintaining the settlements, or by both. The officers of the New South Wales Corps were skilled in filling these roles, although civil officers, private settlers, former convicts, and even serving convicts all had their own means of doing business, and the amount of petty commercial activity was large. Farming was pursued on a widely ranging scale. John Macarthur was most notable of those who early believed that wool growing would be a major economic resource; he himself received a substantial land grant in 1805 to pursue this hope, and he persuaded Bigge of its validity. By 1830 these hopes were yet to be decisively confirmed. Sealing and whaling returned a little more, although the richest seal fields (especially in Bass Strait) were soon thinned; and not until the 1820s did colonists have the wealth to engage seriously in whaling, although British and Americans early used Australian ports for this purpose. Maritime adventure led early colonists to make contact with Pacific islands, most importantly Tahiti.

The growth of commerce

Exploration. The period saw some notable exploration by land. From early days in Sydney men sought a way over the mountains, 50–100 miles west. The task was accomplished in 1813; the journalist W.C. Wentworth led the party. A surveyor, George William Evans, followed their route to Bathurst (founded 1815) and reported rich pastoral country. John Oxley further mapped the inland plains and rivers, especially the Lachlan and Macquarie, and also explored the southern coasts of future Queensland (1823), while Allan Cunningham was the great pioneer of that state's hinterland (1827). Meanwhile, in 1824–

25, Hamilton Hume and William Hovell went overland southward to the western shore of Port Phillip. Charles Sturt, in 1828–30, won still greater fame by tracing the Murray–Murrumbidgee–Darling river system down to the Murray's mouth.

Culture. The writings of explorers and pioneers were Australia's first contributions to literary culture. While catering to the European appetite for natural history, they sometimes achieved literary grace. Pictorial illustrations of the new land, some by convicts, also dated from the earliest years. David Collins' *An Account of the English Colony in New South Wales* (1798) and W.C. Wentworth's *Description of New South Wales* (1817) were literate, informed, and impressive. Wentworth showed skill as a versifier, too, especially in his *Australasia* (1823). Newspapers were founded as early as 1803, and they contributed to cultural as well as political history. Outstanding was the architecture of Francis Greenway, a former convict, who, under Macquarie's patronage, designed churches and public buildings that remain among the most beautiful in Australia.

THE GREAT SHIFT: 1830–60

The three decades between 1830 and 1860 saw the most rapid change in Australia's history. The impact was most evident in politics, but the economy and culture were no less affected. Patterns then established persisted.

Settlement. Four of Australia's six states were formed between 1829 and 1859. A British naval captain, James Stirling, examined the Swan River in 1827 and interested English capitalist-adventurers in colonization. Two years later he returned to the Swan as governor of the new colony of Western Australia. The Colonial Office discouraged schemes for massive proprietorial grants; still the idea persisted, with Thomas Peel—kinsman of the future prime minister Sir Robert Peel—investing heavily. But colonization was grim work in a hot, dry land, with the government reluctant to spend a penny. Western Australia's story for decades was survival, not success.

Yet the same enthusiasm quickly generated around proposals to establish a colony in South Australia, inspired by a British social reformer, Edward Gibbon Wakefield, who argued that if land were sold at a "sufficient" price, its owners would be forced to maximize its value by cultivation, while labourers would have to lend their energies to that task before being able to become landowners themselves. Highly doctrinaire, Wakefieldianism appealed to the liberal intelligentsia and to dissenting groups in England who also backed nascent South Australia. The first colonists arrived in July 1837, and Adelaide was settled soon afterward. The colony experienced many hardships, but lasting significance resulted from its founders' stress on family migration, equality of creeds, and free market forces in land and labour.

The northern and southern portions of New South Wales formed separate colonies. Settlement into the Port Phillip district in the South proceeded very quickly from the mid-1830s, colonists coming from both north of the Murray and from Tasmania; Melbourne's history began in 1835 and boomed immediately. Throughout the 1840s there were calls for constitutional independence, granted in 1851, when the Port Phillip District took the name Victoria. Northward, the Moreton Bay District was never quite so buoyant; and the creation of Queensland had to wait until 1859. Short-lived settlements included Port Essington (1838–49) and Gladstone (1847).

Development of responsible self-government

Politics. All colonies except Western Australia gained responsible self-government. New South Wales led the way when an imperial act of 1842 created a two-thirds elective legislature. The Australian Colonies Government Act (1850) extended this situation to Victoria, South Australia, and Tasmania. The act made allowance for further revision of the colonial constitutions, and in 1855–56 this took effect in the four colonies, Tasmania then abandoning the name Van Diemen's Land. Queensland followed, at its separation from New South Wales. All had bicameral legislatures, with ministers responsible to the lower houses, which by 1860, except in Tasmania, were elected on a near-democratic adult-male franchise.

While the imperial power often responded to colonial cries for self-rule, there were some tense moments. Virtually all colonists abhorred paying taxes for imperial purposes, including the costs of maintaining convicts locally; a good many disliked convictism altogether; most disputed the imperial right to dictate land policy; and many, especially in South Australia, disapproved of the imperial government directing that aid be given to religious denominations. These were the main issues, coalescing with that of increased self-rule, which stoked sometimes quite violent debate.

From the outset of the period, the imperial government fostered a freer market in land and labour throughout the colonies, not merely in South Australia. Thus grants of land ceased in 1831, replaced by sale. Attempts to create a satisfactory system caused much friction, with colonists generally hostile to any demand for payment. In New South Wales in 1844, new regulations even prompted talk of rebellion.

Friction over convicts

With regard to labour, colonists agreed with imperial encouragement of free migration, but friction arose over the convicts. British opinion in the 1830s became increasingly critical of the assignment of convicts to private employers as smacking of slavery; it was abolished in 1840, and with it transportation of convicts to the mainland virtually ceased, although more than before were sent to Tasmania. The end of assignment removed the chief virtue of transportation from the colonists' viewpoint and so contributed to a very vigorous movement against its continuation. The British government terminated it for eastern Australia in 1852; in Western Australia transportation commenced in 1850, at the colonists' behest, and continued until 1868. Altogether some 151,000 convicts were sent to eastern Australia and nearly 10,000 to Western Australia.

In the early 1850s the most dramatic political problem arose from the gold rushes. Diggers (miners) resented tax imposition and the absence of fully representative institutions. Discontent reached a peak at Ballarat, Victoria, and in December 1854, at the Eureka Stockade, troops and diggers clashed, with loss of life. The episode is the most famous of the few occasions in Australia's history involving violence among Europeans.

Common suspicion of the imperial authority modified but did not obliterate internal tension among the colonists. Divisions of ideology and interest were quite strong, especially in Sydney, where a populist radicalism criticized men of wealth, notably the big landholders. The coming of self-government marked a leftward, although far from revolutionary, shift in the internal power balance.

The economy. This period saw the first and greatest booms of the two bonanzas of Australian economic growth—wool and minerals.

Wool. Only now did men, money, markets, and land availability interact to confirm that Australia was remarkably suited for growing fine wool. Occupation of Port Phillip was the most vital part of a surge that carried sheep raising 200 miles and deeper in an arc from beyond Adelaide in the south, north, and east to beyond Brisbane. The "squatter" pastoralist became an archetype of Australian history. Although pastoralism contributed to depression in the early 1840s, the industry kept growing, and the whole eastern mainland benefitted consequently.

Pastoral expansion had one grim corollary—disaster for the Aborigines. Relations between the two races were always tense. The early governors all ordered and even practiced benevolence, but to little effect. When the European spread inland, the Aborigine fought hard, but that only strengthened the European's arm. The Tasmanians moved rapidly toward extinction, but the Australians, with further room for withdrawal, evaded that fate. Philanthropists, missionaries, and administrators stood aghast but found no remedy.

Minerals. The first significant mineral discovery was that of copper in South Australia (1842 and 1845). The discovery had the effect, to be repeated time and again, of suddenly redeeming an Australian region from stagnation. Much more remarkable, however, were a publicized series of gold discoveries made from 1851 on, first in east central New South Wales; this ignited the gold years and

spread into and throughout Victoria. As a result, Australia changed from a land of exile to one of golden attraction. The Victorian economy benefitted from the flood of men and money, although the smaller colonies suffered. Despite the Eureka Stockade incident, the diggers proved quite moderate and responsible.

Culture. Governments and citizens paid considerable heed to improvement of soul and mind. From the mid-1830s, generous aid helped all Christian churches to expand. The Church of England had the highest nominal allegiance, but in the eastern mainland colonies Roman Catholicism was notably strong; Methodism had vigorous advocates throughout; Congregationalism and other forms of dissent dominated in South Australia; and Presbyterianism had its chief strength in Victoria. Most churches attended to education, especially the provision of superior schools, while the state struggled to provide a primary system. The universities of Sydney and Melbourne were founded in 1850 and 1853, respectively. Mechanics' institutes, museums, and botanical gardens were also built.

Architects created much beauty in early Australia. Artists and writers were active; drama and music developed in all towns. The first Australian novel, *Quintus Servinton* (1830–31), was by a convict, Henry Savery; Henry Kingsley's *Geoffrey Hamlyn* (1859) is often judged the first major Australian novel. John West's *History of Tasmania* (1852) was a work of remarkable scope and insight.

Further exploration

Various forms of science had their investigators, but land exploration remained the richest field of discovery. Sir Thomas Livingstone Mitchell confirmed Sturt's work on the river systems and first opened the way from New South Wales to the rich lands of western Victoria (1836). The West Australian coastal regions were mapped by George Grey (1837–40) and by Edward John Eyre, who went overland from Adelaide to Albany (1840). Eyre and Sturt both vainly attempted to reach midcontinent from Adelaide; this was at last achieved in April 1860 by John McDouall Stuart, who in 1862 went still farther, to Darwin. Meanwhile, the central north and the northeast had been penetrated from Sydney; the most famous explorer was Ludwig Leichhardt, who led two successful expeditions (1844, 1846–47) before disappearing in an attempted traverse from the Darling Downs to Perth. An equal and more celebrated tragedy ended the expedition of Robert O'Hara Burke and William John Wills, who crossed from Melbourne to the Gulf of Carpentaria in 1860–61 but starved to death on the return. Later explorations of Western Australia in the 1870s added the names of John Forrest and Ernest Giles to the pantheon of explorer-heroes.

SEVERAL SMALL DEMOCRACIES: 1860–1900

During this period the colonies had little formal relation with each other; instead they concentrated their attention inward on their capitals. New Zealand had more in common with the eastern colonies than did Western Australia. Federation came about in 1901, but the more striking fact was its tardiness. Nevertheless, the colonies did follow similar, if independent paths.

Politics. Democracy was largely fulfilled, save that the upper houses remained elitist in franchise and membership. Governments changed rapidly over long periods, but the constitutions survived. Political groupings were extremely intricate, often personal or power seeking in origin, but allowing some expression for liberal or conservative ideology.

Social reform

The liberals made the colonies quite advanced in matters of social reform, if not the average man's paradise that some glib publicists pictured. Breaking up the large "squatter" estates and replacing them with yeoman farming was a constant concern, meeting many difficulties yet achieving some effect where market and environment allowed. Reformers put much faith in education and strove toward providing adequate primary schooling for all. "Free, secular, and compulsory" was a slogan and roughly the final result; this entailed savage controversy with the Roman Catholic Church, which scorned the godless schools and made enormous efforts to provide its own. Other forms of state aid to religion tapered away. Factory legislation and rudimentary social services presaged the welfare state; restriction of nonwhite, especially Chinese, immigration belonged to this context, for Europeans feared these labourers would reduce living standards, but the restriction was also a matter of sheer racism.

The economy. Overall the economy prospered. Wool and metals continued as the great export income earners. Pastoralism flourished, especially up to the mid-1870s; despite land legislation, this was the heyday of the squatter "aristocracy." Expansion of sheep and cattle growing into the more distant hinterland continued the heroic-pioneer theme of earlier years. Railway construction aided rural industry and proceeded remarkably fast, notably in the 1880s: between 1875 and 1891 the mileage rose from 1,600 to above 10,000 and reached as far as 500 miles inland. Most of the required capital was raised overseas on behalf of governments, contributing to the extremely important role played by the public sector in economic growth.

Gold and copper discoveries

Mining. Victoria's gold and South Australia's copper maintained their significance as new techniques allowed more sophisticated exploitation. Gold was found in southern Queensland in the later 1860s, then in the Northern Territory, and in tropical Queensland: the Palmer River goldfield pulled men to the far north in the mid-1870s. By then Cobar, in central New South Wales, had proved the most important of many new copper fields. Tin also became significant, Mt. Bischoff in Tasmania being the world's largest lode at its discovery in 1871. The 1880s was predominantly the decade of silver; western New South Wales proved richest, and in 1883 Charles Rasp, a German migrant, first glimpsed the varied riches of Broken Hill, which were to make that city almost fabulous and to prompt the establishment of Broken Hill Proprietary Company Ltd.—in time, Australia's largest private enterprise. Also from 1883 dated another big and ramifying discovery, the gold of Mount Morgan, Queensland. Gold also became Western Australia's great bonanza in the early 1890s, the Kalgoorlie and Coolgardie fields winning world attention; the copper of Mt. Lyell, Tasmania, was another highlight of that decade. These discoveries were both product and instigator of much wider activity, creating speculation, mobility, boom, and slump of extraordinary impact.

Industry. Urban expansion and the growth of secondary industry, while less distinctively Australian and contributing little to export income, were remarkable. By the criteria of investment, employment, and relative acceleration, the growth of secondary industry outstripped that of primary industry. Secondary industry multiplied its growth some ten times over during the period, so that manufacturing and construction accounted for 25 percent of the national product in the 1880s. The population ratio shifted decisively from country to town, establishing an extreme capital-city concentration and eventually putting Melbourne and Sydney among the world's large cities. Urban building and services attracted much capital; and most manufacturing was directed to providing food, furniture, and clothing for the relatively affluent townsman. City speculation contributed more than its share to a general overcapitalization, which, in company with worldwide forces, produced a depression in the early 1890s, the main impact of which was in the urban-secondary sector.

The colonies. The history of the respective colonies sharpens some points in this general background. For further treatment of the history of an individual state, see below under state name. In the later 19th century, regional characteristics consolidated, and they changed little at least until the 1960s.

Victoria. Victoria retained the impetus of the 1850s for a full generation. This was most evident in its capital, Melbourne, which had a vigorous cultural and social life. Ardent and ideological liberalism was evident in the colony's education controversy and, with greater novelty, in its adoption of protection as a means of developing its industries and living standards. Disputes between the upper (conservative) and lower (radical) houses of the parliament were frequent and sharpened political feeling. A famous clash occurred in 1865–66 over a protective tariff; another, in 1877–78, over payment of members—the liberal cause triumphed on both occasions.

Adoption of protection

New South Wales. With its longer background, New South Wales changed less in this period. Its master politician, Henry Parkes, first came into prominence in the 1840s. Parkes was involved in sectarian disputes, which were especially vigorous in the colony. Another major theme of political debate was protection versus free trade—the latter retaining greater favour, in contrast to Victoria. Sydney had its share of scandals and scalawags, especially late in the period, contributing to a rumbustious image.

Queensland. Physical expansion westward and northward dominated the history of Queensland. Cattle and sugar became industries of substantial importance. A class of small farmers was established that aspired to settle the tropics, which were usually considered unsuitable for small-scale farming by Europeans. Conversely, the established "kings" of the region used Kanakas (labourers from the Pacific islands). Thus the continued immigration of such labour provoked hot debate, which was not resolved until after federation, when the young commonwealth imposed an absolute prohibition. The Kanaka question contributed to regional feeling antagonistic to the capital.

South Australia. South Australia enjoyed less prosperity than its eastern neighbours. Agriculture remained significant in its economy but saw much disappointment; in the decade around 1870 farmers pushed out into semiarid country, hopeful that rain would follow the plough, only to learn with cruel certainty that it did not. Settlement drew back toward Adelaide, the sole sizable town. Landholding did prompt South Australia's most famous contribution to reform: that land transfer proceed simply by registration, rather than through cumbrous title deeds.

Woman suffrage

Another notable contribution was the institution of woman suffrage (1894), which effectively brought nationwide application of the principle at federation; appropriately, South Australia was the home of Catherine Helen Spence, the most remarkable Australian woman of the time, who published a significant novel, *Clara Morison* (1854), and became active in many social and political movements.

In 1863 South Australia took over the administration of the area thenceforth known as the Northern Territory, which earlier had remained technically part of New South Wales; the change entailed adjustment of boundaries. (The Northern Territory became the concern of the federal government in 1911.) South Australia set up its administrative centre at Darwin. In 1872 the construction of an overland telegraph line linked Australia with the outside world via Darwin.

Tasmania. The 1860s imprinted a "sleepy hollow" image on Tasmania, which persisted. The mineral discoveries at Mt. Bischoff and elsewhere were correspondingly important in reviving the economy. Nevertheless, living standards remained lower than in Victoria, and in Tasmania there were still property qualifications for voting in 1900. The colony contributed to democratic practice, however, by experimenting with proportional representation.

Western Australia. Western Australia ceased to receive convicts in 1868; it gained a partly elected legislature in 1870 and responsible government in 1890. Premier throughout the 1890s was John Forrest, as adept at politics as at exploration. Until the gold rushes, economic growth was slow and primitive; in the 1890s the colony was fastest in relative growth, and little short of that in absolute terms. Farming (in the southwest), town and railway building, and social legislation all followed.

Social movements. Working class and radical movements stretched back to the 1830s, although substantial trade union organization came only after midcentury.

Labour. The unions won some job benefits, including widespread adoption of the eight-hour day. The 1870s and 1880s saw extensive mass unionism, notably among miners and sheep shearers. Trades halls arose in the cities, and organization, extending beyond colonial boundaries, began to knit together. The unions early considered using political pressure and gaining political representation. This inclination strengthened in the early 1890s, helped by tougher times and by employers' stiffening resistance to union demands. Thus arose the labour parties, which gained quick success, especially in New South Wales and Queensland. At first the labourites' aim was simply to influence ministries, but for a few days in December 1899 Anderson Dawson was Labor premier in Queensland.

Rise of the labour parties

Other radicals reacted differently to the pressures of the 1890s. A few hundred of them set off for Paraguay in 1895 to establish there a Utopian "New Australia"; they failed. Republicanism was probably stronger in the 1890s than at any other time, sometimes accompanying a Marxist-like militance.

Movement toward federation. Federation was another ideal of the times. Most important politicians supported the cause, with more or less altruism. They could operate on more positive factors than common background and apparent common sense. Since the Crimean War (1853–56) Australians had feared incursion from the north by Europeans or Asians or both; the most emphatic result came early in 1883, when the government of Queensland, fearful of Germany, took possession of Papua, forcing Britain's reluctant connivance. Better defense was one motive for association, and so was the prospect of more effective Asian immigration restriction; intercolonial free trade was another desideratum. The Australian Natives Association (Australian-born comprised 64.5 percent of the population in 1901) rallied to the cause.

Yet the mills ground slowly. A federal council existed from 1885, but this was only a standing conference, without executive power. New South Wales never joined the council; the senior colony was jealous of a movement that would reduce its autonomy, the strength of which was in Victoria. Conventions met in 1891 and 1897–98 to prepare draft constitutions. These then went to referenda, which gained "yes" majorities. The Commonwealth of Australia came into existence on January 1, 1901.

The Commonwealth of Australia

The constitution was federal, with the states (as the colonies now became) forsaking only limited and specified power to the commonwealth government—these included defense, immigration, customs, marriage, and external affairs. While the lower house, the House of Representatives, was elected by single-member constituencies of roughly equal size, each state had an equal number of representatives in the upper house, the Senate. Ministers were to be members of Parliament. A high court would interpret the constitution.

Culture. Men of learning had contributed to the nationalist surge. Especially in the 1890s and through the Sydney *Bulletin,* verse and prose portrayed the "Outback" as the home of the true Australian—the bush worker: tough, laconic, and self-reliant, but ever ready to help his mate. The *Bulletin* was nationalist, even republican, and much more radical than the federalist politicians. Henry Lawson and Joseph Furphy were the supreme writers of the nationalist school. Painters and poets also extolled the nationalist ideal.

Not all cultural achievement belonged to the nationalist context, however. Henry Kendall was a lyricist of nature, and A.L. Gordon wrote of horses and countryside with a skill that won him a memorial in Westminster Abbey. "Rolf Boldrewood" (Thomas Alexander Browne) wrote tales of outback adventure, while the great 19th-century Australian novel was Marcus Clarke's *For the Term of His Natural Life* (1874), based upon convict records and legends. The older universities remained small, but with some outstanding men on their faculties; the universities of Adelaide (1874) and Tasmania (1890) were new foundations. Ferdinand von Mueller was an outstanding botanist who worked primarily at the Botanic Gardens, Melbourne. That city was the home of the great coloratura soprano Nellie Melba (Helen Porter Mitchell, born 1861), not quite the first but certainly the most famous Australian singer to achieve international renown.

Popular culture followed the British model, with music halls, novelettes, and especially sport to the fore. Australian rules football developed first in Melbourne and became strong throughout southern Australia; in cricket, a victory over the mother country in 1882 established one area of colonial equality. Admiration combined with fear to create a sporadic cult of the bushranger (rural desperado-thief): its most famous expression came with the capture of Ned Kelly's gang and Kelly's execution in 1880. Urban youths joined in gangs, or "pushes," and won the epithet larrikin.

Popular culture

Australia since 1900

NATIONHOOD AND WAR: 1901–45

The world's passions and conflict of the early 20th century were to shape the new nation's history, despite its physical distance from their epicentres. By many standards, this was the least attractive of the five major periods of Australian history. Nationalism strengthened, but it killed and sterilized rather more than it inspired; egalitarianism tended to foster mediocrity; dependence on external power and models prevailed. Yet creativity and progress survived.

The economy. Drabness was most evident in economic affairs. At the broadest level of generality, the period did little more than continue the themes of the 1860–90 generation. The most important such themes were the improvement of communications (railways reached their peak of 27,000 miles in 1941, and meanwhile came the motor boom) and increasing industrialization. In the primary field, there was significant expansion of exports, with wheat, fruits, meat, and sugar becoming much more important than hitherto. But just as manufactures received increasingly high tariff protection, so the marketing of these goods often depended on subsidy; and so the sheep's back continued to be the nation's great support in world finance. Metals, gold especially, were important in the early years; but thereafter this resource conspicuously failed to provide the vitality of earlier and later times. The worldwide economic depression of the 1930s affected Australia, especially its primary industries; otherwise the overall rate of growth, and probably of living standards, too, scrambled upward—a little more quickly than average in the mid-1920s and perceptibly so in the 1940s.

Politics and government. In national politics, men fought for office with increasing vigour and resource, while their administrative performances generally began well but then ebbed. Retrospect can espy a strangely regular pattern wherein four crisis episodes—the establishment of national policies, World War I, depression, World War II—alternate with three periods dominated by a political party enjoying its climacteric. The Labor Party filled this role in 1904–15; the Country Party, 1919–29; and the United Australia Party, 1931–41. At the state level politics were more confused, if not impenetrable.

Strengthening of the central government

A constant theme was the strengthening of the central government as against the states. This complemented the high degree of homogeneity, especially in personal and social matters, that extended through Australia's great physical spread; it was expressed primarily through the commonwealth's financial powers—at first especially relating to customs but later by direct taxation. From World War I both levels of government imposed such taxes, but in 1942 the federal government virtually annexed the field, with the high court's approval. The establishment of a national capital at Canberra, where Parliament first sat in 1927 after meeting in Melbourne since federation, symbolized this situation.

Culture. The period produced not only Furphy's *Such Is Life* but also the work of Henry Handel Richardson (H.H.R.; pseudonym of Ethel F.L. Richardson, later Robertson), another contender for "the great Australian novelist." In *The Fortunes of Richard Mahony* (three volumes, 1917, 1925, 1929), H.H.R. told the anguish of the central character, modelled on her father, as he sought to come to terms with Australian life. The tension of dual loyalties to Britain and Australia was a major concern also of Martin Boyd, whose long career as a novelist began in the 1920s. A more exclusively nationalist tone pervaded many tales of outback life and historical novel sagas. The first notable novel of urban life was Louis Stone's *Jonah* (1911); a later contributor to this genre was Vance Palmer (especially *The Swayne Family,* 1934), who, with his wife Nettie, won fame as a literary critic and selfless patron of the aspiring young.

The most significant contribution in poetry came from a group in Sydney influenced by the German philosopher Nietzsche and the late-19th-century French innovators. Outstanding was Christopher John Brennan, a major theorist of symbolism. While calling on the Australian background, these men gave a sophistication to their poetic world that lifted it far from outback balladry. Associated with this group was Norman Lindsay, an artist, novelist, sculptor, and seer.

In art, the rural landscape held domination. Revolutionary changes in European art were markedly slow in affecting Australia, but a few artists did produce some notable work of imaginative technique. Musical composition was hackneyed and mediocre, although in Percy Grainger Australia produced (but did not retain) a musician of remarkable originality and ability. Architecture promised an interesting chapter with the selection of the American Walter B. Griffin's design for the city of Canberra; in practice this was much mutilated, but Griffin did do some interesting work in both Melbourne and Sydney.

Education

One outstanding area to which the universities contributed was anthropology; a chief protagonist was A.R. Radcliffe-Brown (professor of anthropology at Sydney, 1925–31). Australians increasingly filled faculty posts, although most who did so had Oxbridge degrees, while some of the most able native intellects worked overseas. The University of Western Australia, founded in 1911, drew on one of the most substantial philanthropic bequests in Australian history (from the newspaperman Sir Winthrop Hackett) and initially charged no fees. Other university foundations were Queensland (1909) and colleges at Canberra and Armidale. The states developed their own secondary schools throughout the period, although the achievement was scarcely comparable to the development of primary education in the early period.

Australia was in the forefront of filmmaking early in the century, but this early promise soon faded. A.B. Paterson's "Waltzing Matilda" became Australia's best known song—part folk hymn and part national anthem. Radio had an impact in Australia equal to that elsewhere; radio stations became a mark of medium-town status, and the Australian Broadcasting Commission became a major force in culture and journalism. Radio helped make the 1930s probably the most sports-conscious decade in Australia's history. Cricket, tennis, swimming, boxing, and horse racing were areas of athletic excellence. Aviation moved from sport to enterprise to business; Charles Kingsford-Smith was the most famous hero and Qantas the most successful airline.

Growth of the commonwealth. The first two prime ministers were Edmund Barton (served 1901–03) and Alfred Deakin (served 1903–04), who had led the federation movement in New South Wales and Victoria, respectively. They were liberal protectionists. Their ministries established the "White Australia" (*i.e.,* exclusion of Asians) immigration policy, a tariff, an administrative structure, the high court, and a court of conciliation and arbitration that carried probably to the highest point anywhere in the world the principles of industrial arbitration and judicial imposition of welfare and justice through wage and working-condition awards.

Early ministries

In 1904 J.C. Watson led the first, brief Labor cabinet, followed by G.H. Reid's conservative free-trade ministry. Deakin led again (1905–08); then Andrew Fisher was Labor's second prime minister (1908–09), his ministry defeated when liberals and conservatives "fused" in Deakin's third term (1909–10). Then Labor won its first clear majority at election, which it barely lost in 1913 and regained, still under Fisher, in 1914. This kaleidoscope did not hinder—perhaps it even prompted—ambitious governmental policies. Social services were extended with old-age pensions (1908) and maternity grants (1912); protection rose markedly in a 1908 tariff; the Commonwealth Bank was established; and an army and navy developed.

The new nation was psychologically as well as physically prepared for war. Fear of attack became increasingly directed against Japan, and it prompted pressure on Great Britain for a firmer policy in the New Hebrides (since 1886 supervised jointly by Britain and France)—achieved in 1906–07. Although many Australians criticized Britain when the latter appeared negligent of local interests, the dominant note was overweening loyalty to the empire. Colonial troops had fought in both the Sudan and Boer wars. In 1914, when World War I began, politicians of all hues rallied to the imperial cause.

World War I. Some 330,000 Australians served in

World War I; 60,000 died, 165,000 suffered wounds—few nations made such relatively heavy sacrifice. The most famous engagement of the Australia and New Zealand Army Corps (ANZAC) was in the Dardanelles campaign (1915); the day of the landing at Gallipoli—April 25—became a day of national reverence, honoured far beyond any other. Even before Gallipoli, Australian troops had occupied German New Guinea, and the Australian vessel "Sydney" sank the German cruiser "Emden" near the Cocos Islands (November 9, 1914). After the Dardanelles, Australians fought primarily in France—Ypres, Amiens, and Villers Bretonneux were among the battles, all redolent with slaughter. In Palestine, the Australian light horse and cavalry corps contributed to Turkey's defeat.

Effects of war

The war profoundly affected domestic affairs. In economic development, it acted as a supertariff, benefitting especially textiles, glassmaking, vehicles, and the iron and steel industry. Such products as wool, wheat, beef, and mutton found a readier market in Britain, at inflated prices. But the shock of war affected politics much more, especially by giving full scope to the furious energy of W.M. Hughes, who supplanted Fisher as Labor prime minister in October 1915. Soon afterward he visited Britain. There his ferocity as a war leader won acclaim, and he became convinced that Australia must contribute still more. He advocated military conscription for overseas service; but a referendum in October 1916 declared negatively for this proposal, and immediately afterward the Labor parliamentary caucus moved no confidence in Hughes's leadership. But he continued as prime minister of a "national" government, even after losing a second conscription referendum in December 1917. The referenda in particular and war stress in general made these years uniquely turbulent in Australian history. The Labor Party lost other men of great ability along with Hughes. The split cemented a long-standing trend for Roman Catholics to support the party. Hughes's enemies also included the small but growing number of extremists—most notably the Sydney section of the Industrial Workers of the World (IWW)—who opposed the war on doctrinaire grounds.

The postwar years. The aftermath of war echoed, but finally resolved, this turbulence. Some radicals hoped that returning servicemen would force social change; but instead, the Returned Servicemen's League became a bastion of conservative order, its supporters ready to use physical force against local people they considered "Bolsheviks." The Labor Party faltered, its members adopting a more radical socialist type of platform in 1921, but with far from uniform conviction. When the challenge came to Hughes's leadership early in 1923, it arose partly from the conservative-business wing of Hughes's own Nationalist Party (its representative S.M. Bruce becoming prime minister) and partly from the Country Party, which from late 1922 held a crucial number of parliamentary seats. Although led by wealthy landowners, the Country Party won support from many small farmers: it benefitted too from its former-soldier image and from widespread country-versus-city feeling. Its leader, E.C.G. Page, had considerable, if erratic, force.

"Men, Money, Markets"

Bruce continued as prime minister until 1929, with Page his deputy in Nationalist–Country coalitions. Bruce declared his policy to be the discovery of "Men, Money, Markets" and worked hard toward this end. The cost was high, however: tariffs, bounties, prices, and public indebtedness all rose. There was considerable administration innovation—*e.g.,* the Loan Council regulated all governments' overseas borrowing—and the successful Council for Scientific and Industrial Research (later, the Commonwealth Scientific and Industrial Research Organisation [CSIRO]) was established in 1926 to apply scientific expertise to developmental problems. The worldwide development of consumer industry had its impact: the revolution in transportation provided by the automobile is the best example, although full-scale car production was still in the future.

With much economic activity subsidized—the exception being one primary product (wool)—Australia was particularly vulnerable to the Great Depression of the 1930s. It struck hard: unemployment exceeded 25 percent of the work force and imposed a degree of social misery unknown in Australian history. The rate of recovery was uneven, manufactures doing better than primary industry. Population growth slowed; at the nadir, emigration exceeded immigration.

Politics reflected the impact. J.H. Scullin succeeded Bruce as prime minister in 1929, and his Labor ministry suffered the real squeeze of events; within the Labor Party there was considerable division as to how government should react to the Depression. Some favoured a generally inflationist policy, with banks facilitating credit issue and governments extending public works. Right-wing Labor men distrusted such a policy; radicals would have gone further, by renouncing interest payment on overseas loans. Orthodox opinion argued for deflationary policies—curtailed government expenditure, lower wages, balancing the budget, and the honouring of interest commitments. In June 1931 the commonwealth and the state governments agreed on a plan—the Premiers' Plan. Albeit having some inflationary features, this foreshadowed a one-fifth reduction in government spending, including wages and pensions—a considerable affront to Labor's traditional attitudes.

Against this background, the government disintegrated. Before the Premiers' Plan, some right-wingers, led by J.A. Lyons, had crossed to the opposition. In November some leftist dissidents voted against Scullin, forcing his resignation. In the elections that followed, Labor suffered a heavy defeat. The new prime minister was J.A. Lyons, whose followers had coalesced with the erstwhile Nationalists to form the United Australia Party (UAP). Lyons led a wholly UAP government until 1934 and UAP–Country coalitions until his death in 1939.

The governments of J.A. Lyons

The Lyons governments provided stability and not much more. Recovery was uneven and sporadic, quicker in manufacturing than in primary industry, aided more by market forces than by governmental planning. Two policies failed badly to fulfill expectations—the Imperial Economic Conference, held at Ottawa, Ontario, in 1932, improved trade slightly, but the integrated economic community for which some had hoped never developed; and Australia's "trade diversion policy" of 1936, which tried to redress the imbalance of imports from Japan and the United States, offended those countries and actually reduced exports further. A plan for national insurance, the Lyons governments' most ambitious social legislation, also aborted. These mishaps did not much bother the electorate; improvement, even if meagre, was enough to retain favour.

Internal division was the greater threat to the government. This became manifest after Lyons' death. The UAP elected Robert Menzies as its new leader (and therefore prime minister); but the decision was hard fought, and it was criticized publicly and vehemently by Page, still leader of the Country Party. Nevertheless, Menzies retained office; but internal division persisted, the coalition's parliamentary majority was tiny, and Menzies resigned in August 1941. A.W. Fadden, the new leader of the Country Party, then took office, but in October he gave way to John Curtin and a Labor ministry.

Communist and Fascist movements

While the electorate generally voted conservative, Australia shared the common Western experience of the interwar years in the rise of a small, vigorous Communist movement. Founded in 1922, the Australian Communist Party made most headway in the big industrial unions and in Sydney; it also had some influence and supporters among the intelligentsia, especially in the 1930s. The party suffered a share of internal factionalism but for the most part was able to present a united face to the public.

Fascism achieved no formal political recognition in Australia, but there were hints of sympathy toward Fascist attitudes—D.H. Lawrence wrote of such in his novel *Kangaroo,* based on a brief visit in 1922; and an "Australia First" movement began in literary nationalism but drifted into race mystique and perhaps even treason. An intellectual movement of more lasting force developed among a group of young Roman Catholic intellectuals in Melbourne in the mid-1930s. They developed a commitment to social justice and against Communism somewhat in the manner of G.K. Chesterton. This was the "Catholic Social Movement," which had considerable influence on Australian Catholics.

Whereas Australia had been virtually spoiling for war before 1914, passivity became the international keynote after 1920. At the Paris Peace Conference that formally concluded World War I, Hughes was his fire-eating self, especially in defense of Australia's interests in the Pacific; thus he won a mandate for erstwhile German New Guinea and Nauru (an atoll in the central Pacific) and effectually opposed a Japanese motion proclaiming racial equality, which he thought might presage an attack on Australia's immigration laws. In the League of Nations, Australia was an independent member from the outset. Bruce's succession as prime minister marked a new emphasis. Very much an Anglo-Australian, Bruce led the nation into a period when "the empire" became the object of yet more weighty rhetoric and more desperate hope than earlier. Australia did not ratify the Statute of Westminster (1931, embodying the 1926 Balfour Declaration as to the constitutional equality of the Dominions) until 1942. The UAP governments followed Britain closely concerning the totalitarian expansion of the 1930s; if Australian influence counted for anything, it was to strengthen appeasement of Germany and Japan. Although fear of Japan continued, that country's accession to the Fascist camp did not provoke a tougher governmental line. The Labor Party meanwhile was even more incoherent and variable in matters of foreign policy than were its social-democratic counterparts elsewhere in the Western world: isolationism and anti-Fascism were equal and opposing forces.

World War II. When war came again, however, the nation's response was firm—some 30,000 Australians died in World War II and 65,000 were injured. From early in the war, the Royal Australian Air Force was active in the defense of Britain. The Australian Navy operated in the Mediterranean (1940–41), helping to win the Battle of Cape Matapan (March 1941). Australian troops fought in the seesaw battles of North Africa. In mid-1941 Australians suffered heavy losses both in the Allied defeats in Greece and Crete and in the victories in the Levant. Meanwhile, the German general Erwin Rommel was scoring his greatest triumphs in North Africa; out of these emerged the successful Allied defense of Tobruk, substantially by Australians (April–December 1941).

After the Japanese attacked the United States naval base at Pearl Harbor, Hawaii (December 7, 1941), however, the focus shifted homeward. The Japanese victories of the following months more than fulfilled the fantasies that fear and hate long had prompted in Australia. On February 15, 1942, 15,000 Australians became prisoners of war with Singapore's fall, and four days later war came to the nation's shores, when Darwin was bombed. Then came a Japanese swing southward, by August threatening Port Moresby, New Guinea.

Relations with the United States

The United States became Australia's major ally. In a famous statement (December 1941), Prime Minister Curtin declared: "I make it quite clear that Australia looks to America, free from any pangs about our traditional links of friendship to Britain." A sharper note of independence from Britain came when Curtin insisted (February 1942) that Australian troops recalled from the Middle East should return to Australia itself and not help in the defense of Burma, as British prime minister Winston Churchill wished. Conversely, American needs prompted total response to Curtin's call. U.S. general Douglas MacArthur established his headquarters first in Melbourne and then in Brisbane; the Australian Navy assisted in the U.S. victory in the Battle of the Coral Sea in May, which retrospectively appears a turning point in the war; and the two nations' troops thereafter fought in many joint land battles. The American soldier became a common figure in the Australian capitals, forging the biggest single link in the social relations between the two countries (although not always a harmonious one, as competition for girls and grog sparked jealousy).

On land, the fortunes of war turned against the Japanese in August–September 1942, beginning with an Allied victory at Milne Bay, New Guinea. More prolonged—and of more heroic dimension in Australian eyes—was the forcing back of the Japanese from southern New Guinea, over the Kokoda Trail. Then followed a long attrition of Japanese forces elsewhere in New Guinea and the islands, with Australia playing a role secondary to American forces but nevertheless significant—initially in New Guinea, and at war's end especially in Borneo. Australian volunteers and conscripts fought in these campaigns, the government and people having accepted the legitimacy of sending conscripts as far as the Equator and between the 110th and 159th meridians.

The war brought some passion into domestic affairs, albeit less than that of 1914–18. Curtin's government exercised considerable control over the civilian population, "industrial conscription" being scarcely an exaggerated description. Overall this was accepted—partly because of the sheer crisis, partly because the government showed purposefulness and capacity. Curtin easily won the 1943 elections; thereafter his ministry and the bureaucracy gave considerable thought to postwar reconstruction, hoping to use war-developed techniques to achieve greater social justice in peace.

Wartime growth

The war carried industrialization to a new level. The production of ammunition and other matériel (including airplanes), machine tools, and chemicals all boomed. Meanwhile, primary production lost prestige, aids, and skills, so that the 1944 output was but two-thirds that of 1939–40. Urban employment was bountiful, and concentration in capitals became more marked than ever; many families had two or more income earners. Thus affluence quickened; federal child endowment from 1940 and rationing of scarce products helped distribute this wealth. The gross national product, estimated at $1,089,000,000 in 1918–19 and $1,860,000,000 in 1938–39, rose to $2,936,000,000 in 1942–43.

The states. As noted above, the period saw a steady loss of state power to the federal centre and a general lessening of local consciousness. Nevertheless, repeated referenda showed the people reluctant to expand commonwealth powers formally. At many levels state loyalties and state governments still mattered most.

New South Wales. New South Wales resumed its primacy as the most populous, wealthy, and industrialized area. Most of the generalizations made in any account of Australia derive from the particular experience of New South Wales; the federal Labor and Country parties both drew their major strength from it. Its internal politics illustrated the common theme that Labor did much better in state than in commonwealth elections. The dominant Labor figure, J.T. Lang, as premier of New South Wales in 1925–27, emphasized child endowment and other welfare services. Again in office in 1930–32, Lang refused to endorse the play-safe policies with which the federal and other state governments responded to the Depression; feeling became high and a "New Guard" organization, led by military officers from World War I, pledged itself to save the state from Lang's radicalism. Finally, the state governor dismissed Lang, who broke also with the federal Labor Party and fought it for years afterward.

Federal parties' major strength

Victoria. Victoria offered much less drama; the dynamism of the colony's first half-century never returned. Deakin, Bruce, and Menzies were all Melbourne men, and Lyons had his power base there—indicative that this city remained the bastion of financial interests. Yet in state politics the Labor and Country parties generally supported one another and the Nationalists did poorly. The generation of electricity from brown coal deposits in eastern Victoria was especially important in maintaining economic development.

The smaller states. The smaller states probably lost economically by federation. Interstate free trade meant that there could be no local tariffs to offset Sydney's and Melbourne's advantages in industrial production. As fiscal matters generally became more complex, the states were left farther behind the commonwealth and more at its mercy. Tension developed, most famously in Western Australia, where in a referendum the people voted for secession in 1933. The federal government then established the Commonwealth Grants Commission, which thereafter administered subsidies intended to ensure approximate equality in living standards.

Each of the smaller states strove vigorously, if not very

effectually, to close the gap between itself and New South Wales–Victoria. Chief reliance fell on sugar and cattle in Queensland; timber and gold in Western Australia; apples, other fruit, and hydroelectric power in Tasmania. South Australia sank into deepening gloom until the mid-1930s; revival then came through the success of a campaign to attract industry.

AUSTRALIA SINCE 1945

Social and economic history. The rate of change in Australia after 1939 was greater than that during the preceding 80 years (in both centuries the '50s were especially dynamic). Sheer affluence was an important factor. Australians had long been among the world's wealthy, and, relatively speaking, this situation remained much as before. In absolute terms, however, the average Australian acquired appreciably more consumer goods and comforts. Large-scale *embourgeoisement* was all the more significant in a society in which working-class attitudes had always set overall norms. By 1980 about one-half of the population owned automobiles, and more than two-thirds of all families owned their domiciles. These basic possessions were the lodestones of Australian life.

In the midst of Australia's prosperity and its relative freedom from tensions and problems, there were those who bewailed the mediocrity of its ruling elites—business, academic, administrative, political. This criticism had considerable force. Wealth seemed as often to dampen as to inspire a drive for excellence. Yet there were many exceptions to mediocrity. Canberra—with its buildings and its institutions, as developed from the mid-1950s—probably had the most excellence to offer: the federal public service was efficient and skilled, while the Australian National University and the National Library of Australia reached international calibre.

The affluence of the 1960s did not reach rural industry. The economic role of both the small farmer (his life often a grim compound of debt, drought, and disaster) and the big farmer (who had been a member of a wealthy caste) seemed certain to diminish. Australian leaders had long encouraged industrialization, and the masses had preferred urban living; still, the "bush" had meant much in national mythology, and the shrinkage of its economic importance was thereby significant for all.

Immigration

Second to affluence in shaping a new Australia was the federal government's assistance of mass European-wide immigration from 1946 until restrictions were imposed in December 1974. Roughly 100,000 immigrants entered Australia each year; fewer than one-third came from Britain, about one-sixth from Italy, and almost one-tenth each from Germany and The Netherlands. Thus not only did migration ally with increasing birthrates to increase the population, but the traditional homogeneity of British background (often exaggerated in vernacular, but sizable enough in fact) ended. The inner suburbs of Melbourne and Sydney became polyglot communities. Far-reaching changes were made in Australia's immigration policies and procedures in 1978, effectively raising immigration quotas and changing the rules for selecting immigrants.

At other points, too, ties with Britain loosened. After 1941–42 the Royal Navy was no longer Australia's shield against the world. The United States and Japan became trading partners and investors of comparable weight—and the West Indies became a more stimulating opponent at cricket. Thus, no longer could an Australian speak of Britain as "home" without appearing ridiculous. The change was not absolute—Australia remained an active member of the British Commonwealth—but it was enough to leave a vacuum in Australian life.

Discoveries of minerals accelerated in the 1960s. Iron in Western Australia was the most considerable; bauxite, especially in north Queensland, and nickel, in Western Australia, ranked next. Uranium was a more exotic but transitory resource, while tin, copper, lead, and zinc all rallied. Petroleum and natural gas were discovered in substantial quantities in southern Queensland and off the coast of southeastern Victoria. Japanese capital was particularly important in the development of these resources.

Stock exchange speculation became commonplace in talk and action. The scale of business multiplied. In terms of economic activity and profitability, Australia placed high among the world's second-rank nations.

Government played a part of some significance. The Labor governments before 1949 believed in fiscal supervision as a matter of ideology, and this tendency survived the change of administration. "Protection all around" remained a basic policy, although it had some opponents, and in 1973 the Labor government reduced import tariffs by 25 percent. Tariff preferences for less developed nations were instituted in 1974. Through membership in the General Agreement on Tariffs and Trade (GATT) and other organizations, the government sought beneficial trade agreements, especially for primary resources. Marketing boards and commissions even came to include wool in 1970–71, markets for wool being scarce. Yet investors and managers, including those from overseas, went comparatively without restraint. Legislation directed against monopolies, for example, was insignificant, and overseas investors were not obliged to reinvest profits. Restrictions on foreign investment were imposed by the Labor administration early in 1973, but they were canceled in August 1974.

Protective tariff policy

Industrial relations became a matter of enormous complexity, involving executive and judicial arms of government as well as employer and employee organizations. They seemed to work, with generally less controversy than in earlier periods and in other places, although a strike in the petroleum industry in 1972 was especially disruptive. In May 1975 Australian workers began a trial period of wage indexation, imposed by the Conciliation and Arbitration Commission, to be based on the consumer price index; but indexation was abolished in 1981 following trade union protests and strikes against the rigidity of the system. The Australian Council of Trade Unions was one of the nation's powers.

Change in attitudes toward Asia

Attitudes toward Asia also changed in ways difficult to generalize. Arrogant antipathy diminished; sympathy, interest, and knowledge increased. Relations with Japan became vital to the economy, many Asian students attended Australia's universities, and revisions of immigration policy caused an increasing number of Asians to be allowed to enter. In the late 1970s Australia became one of the UN's designated countries of resettlement for refugees from Indochina, and by 1980 some 45,000 refugees had settled in Australia. Yet foreboding remained; its bases were Australia's heritage of Western history and Eastern geography and the end of European, especially Anglo-Saxon, world supremacy.

Not everyone shared in the nation's affluence. Some European immigrants worked hard at unpleasant jobs. Overall, about one-tenth of the population might be considered underprivileged, with old-age pensioners suffering most. Social services, though expanded considerably by the Labor government in 1973–75, were not adequate to meet these problems. After 1975 the national health scheme was improved, culminating in the institution of a national medical plan in 1984.

The Aborigines' experience remained the nation's atrocious scandal. A mining boom in northern Australia extended the long history of territorial expropriation, but the Aboriginal Lands Rights Act (1976) in the Northern Territory offered new hope (see above *Aboriginal Australia: Developments since World War II*). A mere handful of Aborigines achieved distinction—the best known were Lionel Rose, who became a world bantam-weight boxing champion, and Evonne Goolagong, women's tennis champion. In politics, the professions, or the academy, they had no counterparts.

State boundaries and loyalties suggested a division in internal affairs. The crises of the nation's first half-century had forced unity, or at least the acceptance of federal power. The relative calm of later years was accompanied with growing antagonism to "dictation" from Canberra. Growing wealth in Western Australia especially reduced the economic dominance of the southeast corner.

Culture. Painting, sculpture, poetry, and the novel all flourished in the postwar period. The writing of Australian history produced some notable prose. Ray Lawler might

have produced "the great Australian play" with *The Summer of the Seventeenth Doll* (1955), its heroes two Queensland sugarcane cutters. Affluence enabled architects to build more private homes of distinction. Construction of an opera house in Sydney was begun in 1957 and finally completed in 1973. Melbourne had its cultural centre that housed an art gallery of splendid quality.

louse

The Commonwealth government assisted theatrical work; national opera and ballet companies developed considerable reputations. The Australia Council was established in 1975 as a statutory authority to advise the Commonwealth on the arts and to sustain and promote the arts. In the late 1960s a small group of established writers and composers was invited to compose a new national anthem; "Advance Australia Fair" was chosen in 1974 to replace "God Save the Queen." The soprano Joan Sutherland achieved overseas fame almost comparable to that of Nellie Melba.

Universities grew enormously after World War II with the admission of former servicemen. The effort overextended resources, and not until the late 1950s did federal government expenditure redress the situation. The large cities acquired two or three universities, while in the late 1960s colleges of advanced education began to diversify higher education. Meanwhile, governments had reversed the generations-old policy of refusing aid to nonstate (*i.e.*, denominational and especially Roman Catholic) schools. Considerable sums were spent on education, but the system remained far from perfect.

Medical research advanced notably. The first Australians to win Nobel Prizes, Macfarlane Burnet (1960) and J.C. Eccles (1963), both worked in this area. Astronomy also merited particular emphasis: the Mt. Stromlo observatory was another of Canberra's world-ranking institutions, and Australian scientists were in the forefront of radio and X-ray astronomy. This was one of several fields in which the Commonwealth Scientific and Industrial Research Organisation (see above *Growth of the commonwealth: The postwar years*) contributed much, departing from narrow limits of applied research. The CSIRO and the universities dominated research, but some smaller institutions were important: Burnet directed one such, the Walter and Eliza Hall Institute of Medical Research.

esearch

Australia was one of the few countries to participate in all the modern Olympic Games; and in 1956, when Melbourne was host city, Australian swimmers dominated the scene. From time to time, golf, track and field sports (especially for women), cycling, and pugilism occupied the spotlight in Australia. European immigrants played soccer, but the old Australians still flocked to see Australian rules football, especially in Melbourne.

Television, introduced in 1956 and so able to capitalize on interest in the Olympic Games, soon became dominant in everyday entertainment. Many programs came from Britain and the United States, but the Australian contribution slowly increased. Radio diminished as television boomed but later found a continuing audience. The cinema was forced to accept a more modest role until the late 1970s, when international interest in Australian films grew. Popular live entertainment benefited much from the boom, with clubs that provided liquor, gambling (poker machines), and variety shows.

Domestic politics. J.B. Chifley succeeded John Curtin as Labor prime minister in mid-1945, Curtin having died in office. A growing efficiency and enthusiasm in pursuit of social justice led to extended social welfare, national development, the establishment of the National University, and the provision of university scholarships. Public servants provided the expertise for more sophisticated supervision of the economy. The party won the elections of 1946 fairly comfortably, although the government's majority fell.

But the Australian Labor Party soon became the victim of the Cold War. During World War II Communists had increased their influence throughout Australian society and especially within the labour movement. Many believed that the Labor Party itself was Socialist. This judgment exaggerated the truth, but Chifley's belief in controlling the economy gave it some force; when he planned to nationalize all banks (1947), the reaction was accordingly intense. Although declared unconstitutional in 1948, this banking nationalization counted heavily against the government in the electorate's eye.

Meanwhile, Communist influence was in large measure responsible for many strikes; the culmination came in the coalfields of New South Wales in 1949. These strikes also aroused public concern and hostility. The Labor government suffered heavy defeat in the election of December 1949. The defeat was intensified by a restructured electoral system: thenceforth the House of Representatives had about 120 members, representing single-member electorates of approximately equal size; the Senate had 60 members, each state electing five members every three years by proportional representation, the members serving for six-year terms.

Liberal and Country party coalition governments ruled continuously after the 1949 election until 1972. The Liberal Party, formed in the mid-1940s, was largely based on the erstwhile United Australia Party. Its founding genius was Robert Menzies, and as its head he was prime minister from 1949 until 1966.

Menzies and the Liberal Party

Reverberations of the Cold War helped Menzies stay in office. In 1954 the defection from the Soviet Embassy in Canberra of the Soviet agent Vladimir Petrov led to a royal commission into alleged espionage within Australia. This not only revitalized the Communist threat, which Menzies often invoked, but prompted the Labor opposition to defend some of those implicated in the commission's inquiries. This in turn antagonized the right-wing and Roman Catholic elements in the Labor Party—the groups that had been the most vigorous elements within the party in opposing Communists in the trade unions. In 1955 this group established the Democratic Labor Party (DLP); although it won few parliamentary seats, the DLP took enough votes from the Labor Party to lessen the latter's chance of federal office.

The DLP contributed what little ideology there was in Australian politics after 1950. The Labor Party increasingly disowned any Socialist belief but found no alternative doctrine; two successive party leaders, Herbert Vere Evatt, from 1951 to 1960, and Arthur Aloysius Calwell, from 1960 to 1967, were frustrated leaders of the opposition. The Communist Party split between small pro-Soviet and pro-Chinese factions.

In the late 1960s politics took a different turn. Harold Holt, Menzies' successor as prime minister, had scarcely established himself when he died by accidental drowning (December 1967). There followed a Byzantine contest for his office, won by John Gorton. But Gorton failed to provide solid, consistent leadership, and early in 1971 the Liberal Party replaced him with William McMahon. In December 1972 a new Labor government under Gough Whitlam took power and entered upon a program of social, economic, and political reform.

Labor Party in power again

The Labor program included a large increase in appropriations for social welfare, including a national health service, urban development, a doubling of aid to education, and the removal of investment incentives for the mining industry. Opposition to Whitlam's program was effective in the Senate as early as the following May in its defeat of his electoral reform bill; in December 1973 the nation defeated a referendum that would have permitted federal price and wage controls. Increased spending meant increased inflation, and this became a campaign issue in April 1974 when Whitlam dissolved Parliament in the hope of winning a majority in the Senate. He succeeded in eliminating the DLP from the Senate and increasing his numbers so that he could pass his program through a joint sitting of Parliament. A sudden increase in unemployment in July 1974, a 16 percent loss in state elections in Queensland in December, and a financial scandal in the Cabinet in early 1975 plagued the Labor government.

New leadership came to the opposition in March 1975 with the election of Malcolm Fraser to head the Liberal Party. By October 1975 Labor strength in the Senate had been reduced, two states having filled vacancies with members from the opposition parties (an unconventional practice). Fraser took advantage of the situation by refusing to pass necessary appropriations bills, thereby forcing

another election. Whitlam refused to submit to this pressure, so the governor general, Sir John Kerr, originally nominated to the post by Whitlam, dismissed the prime minister—the first time a representative of the crown had dismissed a prime minister in 200 years. With assurances from Fraser that the appropriations bills would be passed, he was made caretaker prime minister, and a new election for both houses was set for December 13. A bitter campaign ensued, with inflation and unemployment as the primary issues. The results were sweeping majorities for the Liberal–Country party coalition. With the loss of more than 30 seats, Labor was reduced to a weak opposition, and the equilibrium of the Menzies era of the 1950s and early 1960s was returned.

Liberal–Country party coalition

Fraser was successful in reducing inflation and foreign indebtedness, but the unemployment rate remained high. Despite internal dissension, which had resulted in the formation of a splinter party—the Australian Democrats led by Donald Chipp—the coalition dominated the 1977 elections. Problems continued, however, as rifts grew deeper, and controversies arose involving individual party members. In 1983, leadership changes strengthened the Labor opposition so that it gained the majority in elections and returned to power with Robert J. Hawke as prime minister. Hawke led the Labor Party to victory in the general elections of 1984, 1987, and 1990.

Foreign affairs. The Labor governments of the 1940s, and especially that of Labor minister H.V. Evatt, hoped that Australia would play an independent, substantial part in creating a stable international situation. Thus it was active in support of the United Nations, Evatt himself serving as president of the General Assembly in 1948–49. Support of Indonesian independence was another important policy, and there was movement toward building a civil service expert in international affairs.

These positive trends continued with the Liberal victory of 1949. The next year, for example, Australia signed the Colombo Plan, under which substantial aid, especially through education, was sent to Asian countries. Australia remained an active supporter of the United Nations. Menzies, especially, was a great admirer of the United Kingdom and its empire/commonwealth.

Meanwhile, the movement of world politics soured the optimism of the 1940s. Turbulence in Asia, especially a Communist victory in China, gave a new edge to Australia's long-standing fear of attack from the north. In response the country moved increasingly close to the United States, which alone offered the possibility of replacing the United Kingdom as a protector. Thus Australians fought along with UN troops in Korea; in 1951 the country accepted the U.S. view of Japan as a bulwark against Communism, while the ANZUS (Australia, New Zealand, United States) Pact promised U.S. help in case of attack; and in 1954 Australia joined the Southeast Asia Treaty Organization (SEATO), which extended U.S. responsibility throughout the area. The United States built missile bases throughout Australia, and Australia's increasingly large defense expenditure bought much U.S. equipment. Australia also supported the United States in Vietnam; it sent troops (including conscripts) to fight there, but these troops were withdrawn between August 1971 and February 1972.

With the return of Labor to power in December 1972, a greater emphasis was put on relations with Asia. The People's Republic of China was recognized immediately, and North Vietnam was recognized in February 1973. Whitlam visited Indonesia and India and stated that the Indian Ocean "should be free from international tensions, Great Power rivalry, and military escalation." A visit to China followed in November. Closer relations with the new Labor government of New Zealand began at the outset, and ties to the United Kingdom were lessened, including reduced military support in Singapore and Malaysia. In 1974 Whitlam toured six nations in Southeast Asia, reemphasizing his government's interest in the Eastern Hemisphere. At the end of the year, Whitlam visited members of the European Economic Community, declaring that Australian prime ministers had neglected this important area, second only to Japan as Australia's trading partner. Hawke continued Fraser's style of personal diplomacy, improving relations with Indonesia and Vietnam.

Asian foreign policy

Papua New Guinea, which was composed of the Australian external territory of Papua and the Australian-administered UN Trust Territory of New Guinea, became a self-governing state in 1973. After there had been several postponements, it achieved complete independence in 1975. After independence Papua New Guinea continued to receive substantial amounts of Australian aid.

Foreign policy after 1975 shifted its emphasis from defense and security to economic matters, particularly the relationship between trade and foreign policy. (MI.R./Ed.)

For later developments in the history of Australia, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

AUSTRALIAN CAPITAL TERRITORY

A separate political entity of the Commonwealth of Australia, the Australian Capital Territory is situated within the confines of the state of New South Wales and comprises the national capital, Canberra, and some surrounding land. The area of the Capital Territory was ceded to the commonwealth in 1911 by the state of New South Wales. Four years later the additional area of Jervis Bay was also ceded to the Capital Territory.

Like certain other federal cities, Canberra was deliberately chosen and planned as a capital, on a site formerly occupied by a sparse population of sheep raisers, along the banks of the Molonglo River. The area was first entered by Europeans in 1820. A small permanent settlement was established, probably in 1824, when stockmen squatted at Canberry (or Canbury), as it was called.

Physical and human geography

THE LAND

The 925 square miles (2,395 square kilometres) of the Capital Territory are situated on the open and gently undulating Limestone Plains, explored and named by Charles Throsby in 1820. The Murrumbidgee River passes through the territory from the southeast to the northwest along with its tributaries the Cotter and the Naas. Another tributary of the Murrumbidgee, the Molonglo, runs through Canberra. Beyond the Murrumbidgee, to the west and south, the terrain becomes much more rugged, rising to the Brindabella Range, the northernmost extension of the Snowy Mountains. Along this range and within the Capital Territory are some of the highest peaks in Australia, such as Mounts Bimberi (6,274 feet [1,912 metres]), Morgan (6,144 feet [1,873 metres]), Murray (6,040 feet [1,841 metres]), Tidbinbilla (5,114 feet [1,559 metres]), Franklin (5,400 feet [1,646 metres]), McKeahnie (4,915 feet [1,498 metres]), and Coree (4,657 feet [1,419 metres]). During the winter months, the higher parts of the mountains are covered with snow. The mountains are densely forested with eucalyptus and pine trees. The mean height above sea level in the region is 1,900 feet (580 metres), while the lowest point is about 1,500 feet (460 metres).

The climate of the Capital Territory produces temperatures colder than those of most of the state capitals of Australia. The annual mean temperature is 55° F (13° C). Monthly figures for average temperatures provide a better picture of the climate, ranging from 82.4° F (28° C) in January to 42.8° F (6° C) in July. Minimum average temperatures for the same months are about 55° F (13° C) for January and 32° F (0° C) for July. Frost is common on most winter nights, but the days are usually sunny and often warm. During the summer, temperatures are high in the daytime but not extreme, while the nights are

The climate

invariably cool. In the autumn, conditions are pleasant with long periods of sunshine and moderate temperatures. The average annual rainfall for the Capital Territory is about 25 inches (628 millimetres). In the mountains of the territory the average rainfall rises to about 60 inches (1,514 millimetres) each year.

THE PEOPLE

The early population

In 1841 the county of Murray, which includes present-day Canberra, had a population of 2,111 (1,562 males and 549 females). Almost one-third of the population were convicts, of whom 666 were male and 24 female. When the commonwealth assumed control of the area Canberra had a population of 1,777, many of whom were temporary residents involved in the construction of the Royal Military College. By 1926, when Canberra became the official federal capital, the number of persons had grown to 6,550. The vast majority of the Capital Territory's present population resides in Canberra proper. Since World War II the population has increased because of expanded government activities. Government employees account for more than half of the territory's work force. Other major population groups of the work force are construction workers, teachers, and persons involved in retail and wholesale trade.

THE ECONOMY

Much of the Capital Territory's economy revolves around government employment and services. A large portion of this government employment involves the Department of Housing and Construction. This governmental agency provides construction funding for homes, education facilities, roads, public transport, health and welfare facilities, and more, creating many jobs in the construction industry.

The forest authority manages some 150,000 acres of woodlands, including about 32,000 acres of land at the Capital Territory's two coniferous plantations. There is very little commercial production of hardwood from the woodlands of the territory. Several hundred thousands of dollars worth of softwood, Monterrey, Slash, and yellow pine, are produced each year. Timber is processed at the Capital Territory plantations, producing structural plywood; sawn, dressed, and kiln-dried lumber; and wood chips.

The agricultural and pastoral industries adopted by the region's early settlers are still a prominent part of the economy. Wheat is grown in the territory. Livestock, primarily sheep, cattle, and some pigs, is raised in the region, providing wool, milk, and meat for secondary industries.

Tourism has become a major contributor to the Capital Territory's economic welfare. The most popular attractions are the Australian War Memorial, the Black Mountain Telecommunications Tower, the High Court of Australia, Parliament House, the National Library, the Royal Australian Mint, and the mountain lookouts and reserves.

ADMINISTRATIVE AND SOCIAL CONDITIONS

The Department of the Capital Territory is primarily responsible for administering the Capital Territory. The functions administered by the department include housing, public transport, and municipal services. Education, public health, and justice are under the jurisdiction of the department of education, the department of health, and the attorney-general, respectively. The House of Assembly (formerly the Legislative Assembly) is the legislative body of the Capital Territory. The Assembly is composed of 18 members (nine from each of the electoral districts of Canberra and Fraser) serving on a part-time basis. The procedures of the Assembly are similar to rules and regulations used by the federal House of Representatives. Its role is to advise the minister of the Capital Territory on matters affecting the region and to act on legislation and ordinances concerning the territory.

The National Capital Development Commission

The National Capital Development Commission Act of 1957 created a commission by the same name to undertake and carry out the planning, development, and construction of the city of Canberra. Construction work has been carried on in conjunction with the Department of Housing and Construction and private consultants.

As Commonwealth or Crown territory, the Capital Territory lands cannot be sold for residential or commercial enterprises. Lands are leased for private development. In the late 20th century, one-twentieth of the Crown land was reserved for public parks and recreational reserves while about one-third was being leased for private purposes (excluding mining and forestry).

The city of Canberra is known as a garden city because of its many parks and recreational facilities. They are administered by the City Parks Administration of the Department of the Capital Territory, which also administers the National Botanic Gardens and the Horticultural Research Centre, both located in Weston.

Other municipal services, such as water supply, sewage collection and disposal, and storm drainage, are operated by the Department of Housing and Construction for the entire Capital Territory.

The Education Ordinance of 1937 calls for the compulsory school attendance of children between the ages of six and 15 years. The Schools Authority of the Capital Territory has the responsibility of administering all government schools. The Authority represents teachers, parents, and the community. Within the structure of the Authority, the Schools Accrediting Agency gives accreditation to courses and administers procedures regarding student assessment. There is a preschool system available to children less than six years of age. There are several specialized schools and learning centres that are available to children who have physical disabilities and learning handicaps. These specialized centres prepare such children in order that they may be integrated into neighbourhood schools.

Higher education

The Office of Further Education, which is a division of the Department of Education, is responsible for the Technical and Further Education Colleges. Institutions of higher education include Wooden College (1980), Canberra School of Art, and Canberra School of Music. In addition, Canberra College of Advanced Education and the Australian National University offer programs in undergraduate and postgraduate education.

Apprenticeship programs are conducted in many trades in the Capital Territory. Apprenticeship training is supplemented by classroom training in the trades at many colleges.

The Office of Further Education is also responsible for adult immigrant education in the territory. Free classes in English are available on a full-time or part-time basis for those who have become permanent Australian residents. Those attending classes on a full-time basis are eligible to receive a living allowance.

Transportation

The railway system of New South Wales connects Canberra to Queanbeyan. The rail line was opened for freight traffic in May 1914 and for passenger travel in October 1923. Service is provided to Sydney and Melbourne by direct and linking lines. Daily domestic airline service is available to Sydney, Melbourne, and other provincial centres. Bus services connect the territory to cities and towns in South Australia, Victoria, and New South Wales. The Capital Territory is served by an inner-urban and outer-urban system of highways and roads, connecting Canberra with suburban developments and the recreation and tourist attractions within the territory. The Internal Omnibus Network is a public bus service throughout the Capital Territory.

CULTURAL LIFE

As the federal capital, Canberra and the Capital Territory offer many cultural amenities not found elsewhere in the country. Both the Australian National Library and the National University are located in Canberra. Old Canberra retains much of the Australian town charm associated with less urban settings, while new Canberra, with its multistoried buildings and avenues, adds a touch of dignity and sophistication. The architecture ranges from the Mediterranean-style of old Canberra to the Neoclassical style of the National Library. Belts of parkland separate Canberra from its suburban satellites. Commuting distances, in and out of the capital city, are short. The country and mountains, covered with snow in the winter, are close to the city, and the seaside is about two hours away by automobile.

History

Charles Throsby, a naval surgeon who arrived in Australia in 1802, was probably the first white man to explore the lands of the present-day Capital Territory. In 1820 Throsby and his overseer Joseph Wild explored the region in search of the Murrumbidgee River. During the search, Throsby and Wild camped on the banks of the Molonglo, near the site of the Royal Military College at Duntroon. Wild decided to abandon the search for the Murrumbidgee, but Throsby continued on and discovered the Murrumbidgee in March 1821. Wild returned to the region in May 1823, discovering the Tuggeranong and Monaro plains and camping near Tharwa.

The early settlers of the Capital Territory were pastoralists, raising sheep and cattle on the plains. Jousha John Moore established the first settlement along the bank of the Molonglo at a site called Canberra or Canbury (a derivation of an Aboriginal term meaning "meeting place"). The homestead established by Moore survived until 1941. Other early settlers were Robert Campbell, who established settlement at Duntroon, and John MacPherson, who settled in the area near Black Mountain.

During the late 19th and early 20th centuries, life on the Limestone Plains was rough, crude, and often lawless. Outlaws and bands of convicts plagued the settlers of the region. By 1841 signs of permanent residence—a post office, a resident doctor, and a police magistrate—were in evidence, and the site of the township was gazetted.

The establishment of Canberra as the federal capital began several years before the government acquisition of land in 1911. As the demand for federation grew, the need for a federal capital became clear. The commonwealth of Australia was inaugurated in 1901 and the Commonwealth Constitution Act of 1900 provided for the establishment of a capital in the state of New South Wales, but not within 100 miles of Sydney. After two royal commissions and much public debate, the commonwealth parliament in 1908 selected the Yass-Canberra district and in the following year the site for the new city was determined. On January 1, 1911, an area of approximately 900 square miles was transferred from New South Wales to the Commonwealth thereby creating the Australian Capital Territory. A worldwide competition for a design for the capital was launched in the same year. The first prize was awarded to Walter B. Griffin (1876–1937) of Chicago. Construction was begun in 1913 but was delayed by World War I; from 1915 to 1920 Griffin took charge of the city's construction.

Early construction of the capital

After the war, work was accelerated by the Federal Capital Commission, which assumed control over all construction and administrative activities in the territory on January 1, 1925. On May 9, 1927, the Duke of York (later King George VI) opened the new parliament house and the transfer began of the central staffs of the administrative departments from Melbourne (hitherto the temporary seat of government of the commonwealth). Attractive houses, schools, and other buildings for this garden city were built in the suburbs. In 1930 the Canberra University college was opened and in 1936 a wing of the National Library.

The early administration of the Capital Territory was under the control of the minister of interior. The early law of the territory was the law of New South Wales, according to the Seat of Government (Administration) Act of 1910. Most of the state laws were soon replaced by territorial ordinances. The Capital Territory was administered by numerous different departments from 1910 to 1925. The Federal Capital Commission was the administering body from 1925 to 1930.

From its inception until 1930, the Capital Territory had no form of local or municipal government. One commissioner of the Federal Capital Commission was elected by the people in 1929, but this came to an end the following year when the commission was abolished.

In May 1930 the Australian Capital Territory Advisory Council was created to act as adviser to the ministers of the federal government on matters concerning the territory. The council was composed of three members elected by the people of the territory for three-year terms and four members selected by the federal government, one representing the departments of health and works, and two representing the Department of Interior. In 1952 the membership of the council was altered so that five members were elected by the people of the territory and four members selected by the federal government. The advisory council had no executive or legislative functions.

Post-World War II construction

The Depression and World War II curtailed construction, but after World War II a great surge in the development of Canberra took place. More than 8,000 houses and flats were built, as well as administrative offices, extensive buildings for the Australian National University (founded in 1946), shops, schools, and community facilities.

In 1958 the National Capital Development Commission (NCDC) was created. The NCDC is considered the creator of modern Canberra just as Griffin is credited as the creator of old Canberra. Since the early 1960s, the NCDC has been forced to deal with the problems of rapid urban and suburban growth of the Capital Territory.

In 1974 the advisory council was replaced by the Australian Capital Territory Legislative Assembly. The assembly consisted of 18 members (nine from each of the electoral districts in Canberra and Fraser) who served on a part-time basis. The first assembly was elected on September 28, 1974, and the first meeting of the assembly was held on October 28, 1975. In 1979 the name of the Legislative Assembly was changed to the House of Assembly. (Ed.)

NEW SOUTH WALES

The first British colony in Australia, New South Wales is the oldest, richest, and most industrialized state of the Australian Commonwealth. Originally, the name New South Wales was applied to the entire east coast of Australia when the British explorer Capt. James Cook claimed the territory for the British crown in 1770. The separate colonies of Tasmania, South Australia, Victoria, and Queensland were proclaimed in the 19th century, and in 1911 and 1915 the Australian Capital Territory around Canberra and Jervis Bay was ceded to the commonwealth. New South Wales was thus gradually reduced to its present area of 309,433 square miles (801,428 square kilometres). It is bounded by the Pacific Ocean to the east, the states of Victoria to the south, South Australia to the west, and Queensland to the north. By no means the largest Australian state, it is the most populous. Its capital, Sydney, is the nation's largest city. Lord Howe Island, a dependency of New South Wales, is administered as part of the state.

New South Wales reflects the dynamism and the growth problems of a fast-developing country. It is Australia's focal point of commercial farming, industry, and cultural development. It is also plagued by an imbalance between its urban and rural populations and often chafes under the financial restrictions of the commonwealth government.

Physical and human geography

THE LAND

The Great Dividing Range

Relief. The dominant geographical feature is the Great Dividing Range, which separates the narrow coastal strip from the great plains to the west. The coastal strip varies from 10 to 50 miles in width and is bounded along its entire length by a natural barrier of steep mountains. Beyond this barrier, however, the Great Dividing Range consists not of true mountains but of a series of high plateaus, or Tablelands, which slope gently to the west until they merge imperceptibly into the plains beyond. The average height of these Tablelands is about 2,500 feet. In some areas they rise to 5,000 feet, and they attain a height of 7,370 feet (2,228 metres) at Mt. Kosciusko—the highest mountain in Australia—in the Australian Alps in the south. The gentle western side of the Tablelands

is known as the Western Slopes. The plains cover nearly two-thirds of the state. Lying below 1,000 feet, they are interrupted only by the elevated country between Orange and Cobar in the east and by the Main Barrier and Grey ranges in the west.

Drainage. The Great Dividing Range is the state's main watershed. Numerous rivers flow eastward from the range to the Pacific Ocean. Though often beautiful, they are too short and rapid to be of much economic value. The major rivers that flow west—the Namoi, the Macquarie, the Lachlan, and the Murrumbidgee—cross some 500 miles of sunburned plains before joining the Murray and Darling rivers. These brown, muddy, inland rivers meander across the plains and lose a great deal of their water by evaporation. Over 1,600 miles of the Darling River, which rises in Queensland, flow to the southwest across the plains to join the Murray. Rising in Victoria, the Murray runs for more than 1,200 miles along the southern border of New South Wales before crossing South Australia to reach the Pacific Ocean.

Soils. A great deal of New South Wales is naturally fertile, and the red and black soil plains are extremely rich. The coastal strip, however, consists mostly of poor and sandy soils. Agricultural potential is severely limited by inadequate and uncertain rainfall and intense evaporation.

Climate. About 19 percent of the state receives less than 10 inches of rain a year, and approximately 23 percent receives only 10 to 15 inches. The coastal districts have the most annual rainfall, varying from about 30 inches in the south to about 75 inches in the north. Precipitation diminishes progressively away from the coast. The average annual rainfall in the northwest is only eight inches, and some of the land beyond the Darling River merges into desert.

ainfall

If the dry climate and brilliant sunshine present severe agricultural problems, they are yet attractive to the inhabitants of the coastal cities. Newcastle, Sydney, and Wollongong have a delightful climate. It is rarely too hot in summer or too cold in winter, and Sydney is without sunshine for an average of only 23 days a year. Inland it is both hotter in summer and colder in winter. Average temperatures range from 74° to 83° F (24° to 29° C) in the summer months and from 49° to 54° F (7° to 13° C) in winter. Temperatures of over 100° F (38° C) are frequent in summer, and frost at night is common in winter. Heavy snow falls on the southern mountains and, more rarely, on the northern and central Tablelands. On Mt. Kosciusko snowdrifts linger throughout the summer.

The seasons are fairly well defined; autumn begins in March, winter in June, spring in September, and summer in December.

Plant and animal life. The natural vegetation ranges from the dense semitropical forest of the northern coast to the sparse plant life of the western plains. Nearly one-tenth of the state is forested, and, except for the plains, a much larger area is covered with bush and scrub. The forests, concentrated mainly on the coast and Tablelands, give way to shrub eucalyptus on the Western Slopes and to salt bush and spinifex (a spiny grass) in the far west. The predominant tree is the eucalyptus, which is the state's chief source of hardwood. Smaller quantities of softwoods, such as the red cedar, the hoop pine, and the rosewood, are found on the northern coast, while the cypress pine grows on the Western Slopes. Native grasses are found everywhere but in the extreme west, and there are many wildflowers.

The rich birdlife includes many species of parrot and cockatoo, the flightless emu, the mound-building scrub-bird, and the mallee bird. Most of the species of marsupials, mammals that do not develop a placenta and that carry their young in an external pouch, are represented. These include the wombat, the koala, the common and ring-tailed opossum, the common and long-nosed bandicoot, and a variety of kangaroos and wallabies. Many of the smaller marsupials, their populations diminished by agriculture and forestry, are retreating into uninhabited regions. The platypus and spiny anteater are common.

Marsupials

Several species of poisonous snakes, including black, brown, and tiger snakes, are found throughout the state. The best known fish is the Murray cod, which is found in the western rivers and is an excellent food source. Trout have been introduced into the streams of the Great Dividing Range.

Settlement patterns. There are four regions of traditional activity. The coastal strip is mostly used for dairy farming, the Tablelands for sheep and cattle raising, and the Western Slopes for wheat cultivation. The plains are the site of the great sheep stations, for more than 100 years the basis of the state's economy. They still provide almost 40 percent of Australia's wool.

There are also four distinct political regions. The northern Tableland is known as New England. Its population, almost entirely rural, tends to resent the government's preoccupation with Sydney. There has long been an unsuccessful movement to form a new state. Similar feelings can be found in the Riverina district, located between the Murray and Murrumbidgee rivers. There, too, people tend to favour separatism; in practical matters, they look toward Melbourne, the capital of Victoria, rather than to Sydney. The Monaro sheep country comprises the windy, upland district of the southern Tableland, including what is now the Australian Capital Territory. The sheep graziers of the Western plains, living a remote and lonely life, feel a common loyalty born of common interests.

Rural settlement. Climatic conditions have also dictated the size of landholdings. The smallest are in the coastal strip, where dairy and fruit farming are the chief occupations. Holdings are considerably larger—between 500 and 5,000 acres—on the Tablelands and Western Slopes, where mixed farming is the normal practice. Further west they grow larger still; in the dry lands of the Western Division, many sheep stations cover over 100,000 acres. The exception to this general rule is in irrigated areas along the Murrumbidgee and other inland rivers, where diversified cultivation makes small holdings possible.

Land-holdings

The tenure of landholdings in New South Wales is mostly either freehold or leasehold from the crown. Tenancy, as understood in Europe, is uncommon, and, except in the Western Division, most land is occupied by the owners.

Because of the large size of the average field, or paddock, and the relatively uncultivated appearance of the land, a typical sheep station presents a characteristic appearance. The heart of each property is the homestead, with its cluster of low buildings and well-watered trees and gardens, surrounded by bare, brown paddocks. There are no villages, and the nearest country town may be 30 or 40 miles away. In spite of the severe problems faced by sheep graziers because of the unstable price of wool and the constant threat of drought, life on the larger properties is still considered a pleasant and privileged one.

Urban settlement. The largest industrial urban area is the coastal complex of Newcastle, Sydney, and Wollongong. There are several towns of 30,000 or fewer inhabitants in the interior, such as Albury and Wagga Wagga in the southeast and Orange and Tamworth in the east central region. These are essentially country towns serving the surrounding rural population. The only interior industrial town is Broken Hill, in the far west, which depends upon the rich mineral deposits in the Barrier Range.

THE PEOPLE

Population groups. *Ethnic origins.* The people of New South Wales are in no way different from those of Australia as a whole. More than three-quarters are of British origin, and more than one-fifth are of Irish descent. The small remainder is composed mainly of continental Europeans. There are also some 30,000 native tribesmen, or Aborigines, and a few thousand Chinese.

Religious groups. Almost the entire population professing a religion is Christian. The largest denomination is the Anglican Church of Australia, followed by the Roman Catholic Church. Other groups are Presbyterians, Methodists, Greek Orthodox, and Baptists. Lutherans and Congregationalists each comprise less than 1 percent of the population.

Demography. The birth rate and death rate and other vital statistics do not vary substantially from those of the rest of Australia. The most striking feature of the popu-

lation is the disparity between those living in the rural areas and those in the cities. Three-fourths of the state's people are crowded into 2 percent of its area in Newcastle, Sydney, and Wollongong. The state government has long been concerned by this trend, and various schemes have been proposed to correct it.

THE ECONOMY

Economically the most important state in Australia, New South Wales contains about one-third of the country's sheep, one-fifth of its cattle, and one-third of its pigs. It produces a large share of the nation's grain, dairy products, and wool and mines about half of its black coal and most of its silver, lead, and zinc. It is also the country's most industrialized area and produces over two-fifths of the nation's manufactured goods.

Resources. *Biological resources.* There are several million sheep, a few hundred thousand horses, and a few million cattle grazing on the state's vast grasslands. There are also a few hundred thousand pigs. The state forests provide an important natural resource of hardwood timber, although the percentage of forestland is low by international standards. The Pacific Ocean provides valuable fish.

Mineral resources. The most important mineral resource is the vast black-coal deposits of the central coastal region. The main silver, lead, and zinc deposits are located at Broken Hill. Large copper deposits have been discovered at Cobar. Other mineral resources include tin from the Ardlethan and Tallebong fields and rutile (a red or black mineral cut into gems), found in the coastal sands.

Power resources. Coal is the most developed power resource, though the Snowy River offers important hydroelectric potential.

Wheat and wool

Agriculture, forestry, and fishing. Agriculture is spread throughout the state. About three-fifths of the acreage under crops is devoted to wheat, which is grown for both domestic consumption and export. Other grains grown include oats, maize (corn), and rice; fodder, potatoes, grapes, sugarcane, and fruit are also raised. Excellent wine is produced in the Hunter Valley and cotton is grown on the Namoi River. Sheep are raised mainly for their wool, which is also exported. Both slaughter and dairy cattle are important.

New South Wales is the most important timber-producing state, accounting for about one-half of Australia's production. Hardwoods and softwoods are exploited, and there is a regular pine reforestation program.

Tuna fishing is the most important marine industry, and mullet, shark, and Australian salmon are also caught in significant numbers. The state provides about one-third of the national fish catch, as well as all of the oysters consumed domestically.

Mining and quarrying. The most important coalfields are in Hunter Valley above Newcastle, around Wollongong, and at Lithgow. Silver, lead, and zinc, as noted above, are mined at Broken Hill. Copper is mined chiefly near Cobar, and tin is mined in the central and northern Tablelands.

Industry. About two-thirds of the manufacturing industries are located in Sydney. Other important industrial centres are Newcastle, Wollongong, Lithgow, and Broken Hill. The fastest growing industry is the manufacture of iron and steel and metal goods. Other important products are textiles, food, beverages, tobacco, chemicals, paints, paper, and printed material. Factories are mainly small, and only a few employ over 1,000 persons. A very few large concerns, such as the Broken Hill Proprietary Company Ltd. (iron and steel) and the Australian Consolidated Industries Ltd. (glass), employ most of the industrial workers.

Power. Electricity is generated and distributed by the Electricity Commission of New South Wales. Power is sold to local authorities, the state railways and tramways, and large industrial users. Almost all the state's electricity is generated by thermal-power stations. The Snowy Mountains hydroelectric scheme, completed in 1974, has diverted the waters of the Snowy and other rivers westward into the Murrumbidgee.

Finance. Since 1942 the commonwealth has collected all income taxes and reimbursed the states on an agreed formula. As a result, New South Wales is almost entirely dependent upon commonwealth grants for its revenue. In 1971 the states were given the right to levy a payroll tax.

Administration of the economy. Like the rest of Australia, the state has essentially a capitalist economy, with the great majority of industry owned by public companies. The state government, however, owns and manages the railways, some coal mines, and the production of electricity. There is a vigorous trade-union movement. The Chamber of Manufacturers and other employers' organizations represent the interests of private enterprise.

Transportation. New South Wales has excellent internal air services. The state railways provide an adequate link between Sydney and larger population centres. They have suffered, however, from competition with air and road transport. Sydney has Australia's only underground rail network, and electric rail services connect the city with many of its suburbs.

Metro services in Sydney

Roads. There are hundreds of thousands of miles of public roads, including tens of thousands of miles of state highways and main roads. Most of these are paved, but many, including the main highways to Brisbane and Melbourne, are too narrow for the traffic they now bear. Most country roads are surprisingly good, though not all are yet paved.

Inland waterways. There are no commercial waterways, although before the railways were built the Murray and Darling rivers and their tributaries were used extensively for carrying freight.

Ports. The four major ports are Sydney, Newcastle, Port Kembla, and Botany Bay. Together they handle several million tons of cargo each year. All ports are administered by the Maritime Services Board of New South Wales.

Railways. The railways cover several thousand miles and centre upon Sydney. They also provide adequate facilities to the other major urban centres including the major mining centre at Broken Hill, 700 miles to the northwest. The lines run from north to south along the coast and roughly from east to west in the Tablelands and plains.

Air services. Air services, largely for passenger traffic, are provided by a number of lines. Air links are operated to all the major towns, and the airport at Sydney can accommodate jet aircraft.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. *Constitutional framework.* The state government administers internal matters, while the national government (commonwealth) is responsible for defense, foreign policy, immigration, trade, customs and excise, post and telegraph services, and air and sea transport. Within those limitations, the state is sovereign and has powers to make laws for the welfare and good government of New South Wales. It has no armed forces other than the police.

Houses of Parliament

The Parliament consists of two houses—the lower house, or Legislative Assembly, directly elected by the people, and the upper house, or Legislative Council, one-fourth of whose members are elected by both houses every three years. The Cabinet is chosen from the party that commands a majority in the Legislative Assembly; it is headed by a premier. Parliament meets for three years but can be dissolved earlier.

The state also has its own governor, who is appointed by the Queen on the recommendation of the government. The titular head of the government, he is now always an Australian, and his duties are almost entirely formal.

Local government. New South Wales is divided into more than 200 local-government areas, which are controlled by councils. These councils are elected every three years by adult residents of their areas.

Elections. All elections are conducted on the basis of universal adult suffrage, and the voting age is 18 years. Voting for the Legislative Assembly is compulsory, but voting for local councils is not.

Political parties. Political parties are usually state branches of the federal political parties and tend to have the same policies and interests. The three principal parties are the Liberal Party, the Country Party, and the Austra-

lian Labor Party. There is also a branch of the Australian Democratic Labor Party, without a seat in either house, and a small Communist Party, which still retains some influence in a few trade unions. Elections are fought on state issues, but the fortunes of the parties are often affected by the fortunes of the same parties in the commonwealth.

Justice. State law and its administration are largely based upon the British system. Legal procedure includes trial by jury in criminal cases, the right of appeal, and an independent judiciary. The highest state court is the Supreme Court, against which appeals can be made to the High Court of Australia and, in certain cases, to the Privy Council in London. Minor offenses are dealt with by magistrates in the Courts of Petty Sessions, while more serious cases are brought before a judge and jury in the Courts of Quarter Sessions.

Education. Education is compulsory for all children between the ages of six and 15. Most children are educated in free, nondenominational primary and secondary schools. A minority go to private schools, most of them administered by the Roman Catholic Church. There are also a few denominational secondary schools for the children of the wealthy. There are five universities in the state; the cost of administration is shared with the commonwealth.

Health and welfare. The state government is responsible for the supervision of public health, hospitals, and medical services. There are more than 280 public and a large number of private hospitals. The national health-insurance scheme is financed and administered by the commonwealth, as are the social services such as family allowances, child endowment, unemployment benefits, and pensions.

tandard
f living

Social conditions. New South Wales shares in the high standard of living and generous social services enjoyed by all Australians. The state has its own Industrial Commission to settle industrial disputes, though here, too, the Commonwealth Arbitration system has become predominant. The basic wage—adopted from time to time by the Commonwealth Conciliation and Arbitration Commission—is adopted for state awards and agreements. The 40-hour workweek is now standard.

CULTURAL LIFE

The state cannot claim a unique culture that distinguishes it from the rest of Australia. It is perhaps the most representative and typical of all the states, and its greater population and wealth give it a leading position over all but Victoria.

Sydney has the oldest and reputedly the best of the symphony orchestras. There are many small theatres, but no professional drama company of first-class quality. Sydney's Opera House, which opened in 1973, is a major arts centre with a concert hall, a large theatre for opera and ballet, and a small theatre.

Many of Australia's leading poets and novelists were either born in the state or live there. Sydney is the centre of a school of contemporary painting that looks toward the United States and Europe for its inspiration. The Art Gallery of New South Wales has the best collection of Australian painting in Australia. In general, the cultural climate is marked more by a healthy and democratic vitality rather than by any special distinction. This is equally true of the popular arts, where there are large audiences for and keen interest in both Australian and foreign folk singers and jazz and rock groups. (J.D.Pr.)

History

In 1768 James Cook began a voyage that took him and his crew around Cape Horn, to Tahiti and New Zealand, reaching the east coast of Australia (present-day New South Wales) in 1770. For the first time European navigators had seen a part of Australia that appeared suitable for settlement. Reaching the northern point of Queensland, after a hazardous journey, Cook took formal possession of eastern Australia on August 23, 1770. Cooks's second voyage in 1772 and his third voyage in 1776 added a great deal to European knowledge of the Pacific and showed that successful voyages could be made from Europe.

SETTLEMENT

The first suggestion for the establishment of a British colony in Australia was made before a committee of the House of Commons in 1779 by Joseph Banks, who with Cook had seen Australia for himself. Transportation overseas of persons convicted of offenses against the law in England had been practised during the 17th and 18th centuries, but the Revolutionary War then being fought in the American colonies prevented further transportation there of convicted persons. The eventual victory of the American colonies, the continued practice of judges of sentencing convicted persons to transportation, and the marked increase in offenses caused by the social upheavals of enclosure of land, obsolescence in several lines of manufacture and trade, and the sudden growth of towns in England made it certain that a new outlet for offenders had to be found. Banks believed that Australia was ideally suited for this purpose. It was so distant from any other civilized place that escape would be difficult; there was little chance of opposition from the natives; the climate was mild; the soil was capable of sustaining a large number of people; there were no beasts of prey; and there was an abundance of timber and fuel.

In addition to wanting a place to which convicts could be sent, the government thought it would have to provide a home for American loyalists in difficulties resulting from their enemy's victory. But when the Pitt government came to office (1784) it was concerned only with the practical problem of getting rid of convicts. To solve the problem an order in council dated December 6, 1786, appointed "the eastern coast of New South Wales or some of the islands adjacent" as the place to which offenders might be transported. Capt. Arthur Phillip of the Royal Navy was commissioned as the first governor. At this date Great Britain, under the belief that New South Wales might be separated from what the Dutch called New Holland, did not lay claim to all Australia, but just the eastern coast and all islands adjacent in the Pacific. The governor was to take the usual oaths of office; he was given power to pardon and reprieve offenders, to levy forces for the defense of the colony, to withstand pirates and rebels, to enforce discipline, to make land grants, and to exercise general jurisdiction.

The penal colony

The powers and duties of the governor made it clear that the British government intended the colony to be controlled as a jail and meant the governor, through his staff and "police," to employ directly most of the convicts and to keep their produce as a government stock. The possibilities of private land ownership and employment of convicts and others were always visible, but it was clear that the British government considered that for many years the government in the colony would perform most of the administrative and directive work. It was clear also that the British government intended to devote the very minimum in money and materials to the settlement. Between his appointment and the departure of the first fleet for Botany Bay nine months later on May 13, 1787, Phillip had persisted in efforts to obtain more stores and equipment for his expedition, so much so that it has been concluded that by the time it sailed the idea of founding a commercial settlement was very definitely afoot. It was, however, never much more than "in the air." The first fleet was very poorly equipped, and the convicts and their guards arrived with very little with which to contend with the forests of New South Wales. Whatever had been the intention of the government in 1787, the outbreak of war with France in 1793 made it certain that little time and money would be devoted to a convict settlement on the other side of the world.

THE EARLY YEARS

Soon after arrival Phillip decided that Botany Bay was unsuitable and moved his 11 vessels to Port Jackson. This harbour, which he described as the "finest in the world," became the scene of his settlement and of Australia's greatest city. There reached Sydney 736 convicts, of whom 188 were women. Guarded by 191 marines, under 19 officers, they reached a country accurately described as "forest-clad, unkempt, uncanny and unknown," and one

Early settlement of Sydney

on which Phillip reported: "No country offers less assistance to first settlers." Hardly had the fleet arrived when the marine guards, claiming that their duties did not extend beyond the voyage out, refused to act any longer. A special unit, the New South Wales Corps, was enlisted in England to act as guards, or a police force, in the colony.

In the meantime Phillip had to do the best he could but found his community of convicts was as well behaved as most of the towns in England from which they had come. Expecting supplies and assistance, he was soon dismayed to see the second fleet—three ships—loaded not with provisions but with more convicts. It left England with 1,017 aboard; 267 died on the voyage and 486 of those who did arrive were sick. Of these, 50 died in the first month, and those "not classed as sick were hardly able to attend themselves." It was described as a "ghastly company of sick and dying. . . . Great numbers were slung over the ship's side in the same manner as they would sling a cask." However, Phillip showed an energetic devotion to the growth of the settlement, which was in part shared by many of these poor, cruelly treated people, and he felt very soon able to report a belief that "This country will prove the most valuable acquisition Great Britain ever made." But other officers of the colony were of a different opinion, seeing at first no future in the colony for themselves and then no future in it for anyone but themselves. Some obstructed the governor in his work, as well as encouraging the British government to do nothing to change a policy of neglect.

During Phillip's time there was therefore revealed a political separation of interests—on the one side capable, energetic free men with privilege and money anxious to obtain control of convict labour on slave conditions and of all commercial activities; and on the other a government with a considerable measure of responsibility to see to the employment and rehabilitation of the convicts.

Houses and public buildings were erected of timber and, when bricklayers were discovered among the convicts, of bricks. Phillip led exploration of the colony, and settlements were established at Parramatta, on the Hawkesbury River, and at Norfolk Island. Almost immediately grants of land were made to men who had arrived free, and convict labour was provided for its working. By 1791 more land was in use under government direction than private, but by that year 150 persons were in possession of farms. Cultivation had been attempted on all farms, but crops were poor, for hardly any rain fell in the year before Phillip's departure from the colony. By the middle of 1790 only 38 convicts had been assigned to private employment, and care was being taken to see they were properly employed and treated. By 1792 the settlement was producing its requirements in several types of manufactured goods.

Land grants

Failing health compelled Phillip to relinquish his command, but by his departure in 1792 the settlement had progressed sufficiently far to allow it to be said that by that date the foundation of Australia had been achieved. Phillip was able to report: "The colony is approaching to that State in which I have so long and anxiously wished to see it." Further, he felt confident that "Time will remove all difficulties." While the achievement had been remarkable, there were great difficulties ahead, but never was there any doubt of importance that the settlement would survive.

EXPLORATION, 1796–1845

Australia was explored both by land and by sea. George Bass and Matthew Flinders in 1796 explored much of the coasts of New South Wales in small whaleboats, and in 1798 Bass made a long and successful voyage in his small whaleboat around the east and south coasts of the colony, proving the existence of a strait between the mainland and Tasmania.

Until 1813 nothing was known of New South Wales beyond a coastal strip about 150 miles long and no more than 50 miles wide. The colony was shut in much more by the Blue Mountains on the west than by the sea on the east. In 1813 Gregory Blaxland, William Lawson, and W.C. Wentworth penetrated through this canyoned plateau, almost as deep as it is high, on a journey that marked the beginning of the problems of its more extensive exploration. Soon it would be no longer any easier to confine the graziers to the boundaries of settlement than "to confine the Arabs of the desert within a circle drawn on the sands." From the bases established beyond the mountains a few small expeditions went farther and discovered rivers flowing west and southwest. The nature of the country farther to the west was not, however, to be revealed for a good many years.

In 1824 Hamilton Hume and William Hovell began what was to prove the most important journey since the Blue Mountains were first crossed. They travelled southwest to reach first the Murrumbidgee River, then Australia's greatest river—the Murray, as it was later named—and then to cross the full width of what was to become the state of Victoria. This expedition revealed not only great possibilities for the extension of settlements in New South Wales but even greater possibilities farther to the south.

Exploration of the Murray Basin

In 1831 Charles Sturt travelled down the Murrumbidgee River and into the Murray. This journey of nearly 2,000 miles proved the Murray to be the centre of a northern network of rivers, but still there were rivers farther to the north that flowed out to the west; perhaps they flowed toward some inland sea, perhaps they came to an end in dry, shingly beds.

THE NEW SOUTH WALES CORPS

When Governor Phillip departed in 1792, the senior officers of the New South Wales Corps took over. Probably no less than 16,000 acres of land were granted between Phillip's departure and the arrival of Gov. John Hunter in 1795. The small group of corps officers and their friends had a great advantage in trade—few others received income in currency acceptable by those who shipped goods to the colony. Also, they had powers to apply or not to apply the law, even if not the power to say what the law was. Acquisition of land, of advantages in trade, and of favour at the hands of "the law" ensured that they would become a wealthy and powerful group.

Hunter's main problems continued to be those of making the colony survive—the employment of convicts and emancipists (convicts who had served out their sentences) and the production of food and other necessities; but it was soon apparent that the activities of the New South Wales Corps, particularly the officers, represented a serious difficulty. The governor endeavoured to apply the policy laid down by the British government, with the aid of men whose interests were that it should not prevail. The substance of this political conflict was economic interest. The officers and their associates desired to have convicts assigned to them for employment at their own terms and to dispose of their products at the best prices obtainable. They desired to buy, or otherwise acquire, goods at prices most favourable to themselves and enter directly into the disposal of them. They desired nothing less than a monopoly of the import trade, particularly that in rum. The early governors, on the other hand, proceeded to employ many convicts on government land, to take their produce into government stores, and to dispose of it at prices determined by considerations other than making the most profit. Goods were also imported by the government and sold from its own stores. This practice had arisen because at first there had been no other way and then because of the existence of men able to exercise monopoly powers.

The acquisition and disposal of rum, in particular, became a problem. It became the customary currency, the normal means of paying wages, and its possession depended either upon having silver and gold money which shippers would accept or upon distilling it unlawfully. This "exchange economy based on tyranny and rum," which on balance was most harmful to the small community and its future, produced also the kind of initiative and ambition that gave Australia, in its very early years, the sheep industry upon which all its future prosperity was to depend. John Macarthur, the pioneer of the wool industry, was not only the personification of all that had produced so much evil and so much good but he was the man whose egotism and drive was directly responsible for so much of it.

The exchange economy

While the colony in its first decade was growing in population (only a trickle of it was free), in land under cultivation, in output and range of goods, in the number of buildings erected and the extension of settlement, difficulties with the group led by the corps officers grew also. Hunter returned to England in 1800 exhausted by his labours. Uprisings by Irish and other convicts early in the 19th century were perhaps more dramatic but far less significant than the acquisition of power by the corps. P.G. King, Hunter's successor as governor, a man of strong character and fiery temperament, believed he could do better. However, despite his orders and his indignation, the balance of political, social, and economic power continued to move in the direction of the corps officers. Conditions of life and employment of convicts and emancipists—well over 90 percent of the community—did not improve during King's term of office, but the colony made progress. The conflict of governor and corps officers came to a head in King's time with a duel between Macarthur and his own senior officer, William Paterson, who was carrying out the governor's orders. The opposition led by Macarthur was not completely successful, and Macarthur himself was sent to England to face court-martial. King, however, was left in a weakened position and was soon recalled. Macarthur, in England, took the opportunity to resign from the corps and to develop his plans for land and sheep farming in Australia.

SHARPENING OF THE CONFLICT

Gov. William Bligh

The appointment in 1805 of William Bligh (famous for the "Bounty" mutiny) as governor of the colony made a sharpening of the conflict inevitable. Bligh knew what his instructions meant and he determined to carry them out. The general lines of British government policy remained the same throughout the years 1788–1821, and Bligh proceeded to give effect to it. His defeat at the hands of the New South Wales Corps merely meant that the British government realized that its governors could not work without power independent of the dominant colonial pressure group; and, under Macquarie, the policy the corps sought to defeat triumphed. Issues that led to an insurrection by the New South Wales Corps centred in matters of trade, particularly illicit dealings in rum, and in the acquisition of land rather than in anything relating to wool growing or the affairs of the pastoralists. Bligh's policy was recognized by the "little men" to be in their interests, but the power of the corps officers in effecting Macarthur's aims was too great.

Following Bligh's arrest in Government House and his detention, the main activity of the military government was that of granting land, strengthening its own position, and clipping the wings of its competitors. The employment of convicts became little better than slavery, and the retention of a society permanently divided into free and unfree seemed certain.

MACQUARIE

The success of the New South Wales Corps and Macarthur was their undoing. Orders were given for the corps's removal to England, and Macarthur, too, left the scene of his conquests for some time. Lachlan Macquarie was appointed governor with the power to bring his own regiment to the colony. With this power to enforce his decisions, Macquarie arrived to find the select group, "pure merinos" as they were later to be called, in a dominant economic and social position. Macquarie has often been described as a despot, and no doubt a despot he was to those who desired to see a colony of great inequality between free and unfree, rich and poor. His policy increased the prospects of emancipation for convicts and their chances of gaining status and becoming small farmers in their own right. He caused public buildings and roads to be constructed, established a bank, encouraged exploration and the pastoral industry, and introduced currency to take the place of rum. He redressed the balance of social and economic power over a period of 10 years and, as it became certain that no section of the community would ever succeed in completely dominating all others, production and settlement increased and extended. There would have been more economic progress in certain fields if sectional initiative, if not ruthlessness, had been given its head; by 1817 there was room for a change in policy in certain directions. Complaints about Macquarie's administration led to the appointment that year of Commissioner J.T. Bigge to investigate. The British objected to the amount of Macquarie's public works expenditure, and some influential persons in England and Australia desired the emancipists to be given less and the big landowners more scope. This conjunction of interests resulted in the termination of Macquarie's period of office in 1821.

It could now be truly said that Australia was established on a firm economic foundation and in a manner that would not allow any great disparities to development between groups of its people. Both Macarthur and Macquarie deserve credit for this situation, the first for vigour and personal ambition and an interest that served the colony well, and the second for holding a proper balance within the colony itself and for determining to give it the public facilities essential if it was to function.

PASTORAL EXPANSION AND SELF-GOVERNMENT, 1822–55

In these years the foundation of modern New South Wales were securely laid. Self-government was attained; radicalism emerged; voluntarism was established as the basis of colonial religion; transportation of convicts ceased; trial by jury and a free press were allowed; and the rapid expansion of the pastoral industry made the colony prosperous. New South Wales changed from a prison farm into a self-governing colony with a free and expanding economy. The basis of the expansion was wool. Exploration in the 1820s and 1830s opened up the whole colony, and the demand for wool in Yorkshire enabled the squatter pastoralists to avail themselves of the new land, which provided excellent pastures for the fine-wooled Merino. Wool was a source of sterling funds and an inducement for capital imports and immigration. The consequent wealth was a solvent of autocracy. The growing body of free settlers was not prepared to suffer autocratic government and transportation, which lowered the moral tone of the colony. But the impetus for colonial reform came also from Britain.

Increasing importance of wool

Thus, acts of 1823 and 1828 gave New South Wales a nominated Legislative Council; an act of 1842 made this partly representative; and the Australian Constitutions Act, 1850, made it completely representative with the powers of writing a constitution. Nevertheless, until 1855 executive control rested entirely with the governor and his Executive Council, consisting of officials. The Legislative Council was dominated by the pastoralists, who tried to frame a constitution to thwart the democratic aspirations of the city and labour interests; but the bicameral legislature that was finally adopted avoided the autocratic ambitions of the pastoralists and was the future source of much liberal legislation.

The most important social conflict between 1822 and 1855 concerned the status of the former convicts, but, after transportation was discontinued in 1840, wealthy emancipists and exclusives were brought into an alliance to fight for self-government and against the colony's growing radical movement. In religion the privileged status of the Church of England was modified, and the various Christian denominations (including Catholicism) demanded and received legal equality. The attempt by Gov. Sir Richard Bourke to introduce public secular education foundered on the opposition of the churches. But the most important political conflict concerned the alienation of land. The squatters had settled on land beyond "the limits of location" (a defined small area, to prevent undue dispersion and make government easier) and until 1847 had the most temporary titles to their estates. Gov. Sir George Gipps tried to prevent the complete alienation of the state's pasturelands but was unable to prevent in 1847 orders-in-council which gave the squatters favourable treatment. The quarrel over land, however, continued throughout the 19th century.

COLONIAL LIBERALISM, 1856–85

In February 1851 gold had been discovered near Bathurst, but the main tide of the gold rushes soon swung to the

richer fields of Victoria. New South Wales nevertheless gained in wealth and population from gold. In 1856 the new constitution was implemented with a bicameral legislature and responsible Cabinet government. One of its early acts in 1858 introduced the ballot and universal adult male suffrage, and the new democracy soon moved against the squatters. "Radical" legislation in the next 30 years included the abolition of state aid to religion (1862), the Triennial Parliaments Act (1874), the Public Instruction (public schools) Act (1880), and public health legislation (1881). Sir John Robertson's land Act of 1861 aimed at facilitating closer settlement by allowing selection before survey; anyone might select from 40 to 320 acres (16 to 129 hectares) within the "settled" or "intermediate" districts on payment of a quarter of the price, the balance being due, with the title, after three years' residence. Some genuine closer settlement resulted, especially on the coast, but the squatters' devices of "peacocking" and dummying; *i.e.,* picking the best land and using dummy selectors, left most of the western lands in their hands. The failure to settle much of the increasing population on the land meant greater concentration in the towns, besides the rapid growth of trade unionism and radicalism among the growing body of workers. Radicalism before 1870 was reflected in the land legislation and opposition to the British government. Between 1870 and 1885 it encouraged state intervention in social and economic life and increased the political aspirations of the trade unionists. Sir Henry Parkes was the most influential personality in politics, and between 1872 and 1891 his ministries introduced free trade, established nonsectarian public schools, and sponsored railway development. He finally lost office because he favoured federation before the idea was popular in New South Wales.

The ballot and universal male suffrage

This was a period of great economic development. By 1890 New South Wales had become self-supporting in foodstuffs; valuable minerals had been discovered and mined—gold at Captain's Flat in 1861, copper at Cobar in 1869, tin at Inverell in 1871, and silver–lead–zinc at Broken Hill in 1883; 1,215 miles (1,955 kilometres) of railway were completed by 1884; unassisted immigration between the years 1873 and 1893 exceeded 230,000. These developments were greatly promoted by the capital imports that occurred during the 1870s and 1880s, many of them by the government for public works.

LABOUR, NATIONALISM, AND FEDERATION, 1886–1914

This period was dominated by growing nationalism, the rise of the political labour movement, and the federation of the Australian colonies into the Commonwealth of Australia. The period began with the collapse of export prices and the great reduction of capital imports, both of which were consequent on British financial difficulties. This led to wage reductions, industrial unrest, the great strikes of 1890–91 (in which the trade unions were defeated), and the financial crisis of 1892. Although the 1890s were a time of misfortune, culminating in the big drought of 1902–03, these years were the most significant in the history of New South Wales. The failure of direct action in the 1890 strike forced the unions into politics with immediate influence on legislation. G.H. Reid, with Labor Party support, introduced financial reforms (including income tax), removed the public service from political control, reformed the land law to allow the breakup of large estates, and passed the Factories and Shops Act (1896). In a similar manner, after 1900, liberal legislation supported by Labor introduced old-age pensions (1900), compulsory industrial arbitration (1901), women's franchise (1902), and free public education (1906). After federation Labor gradually increased its power until in 1910 J.S.T. McGowen was able to form the first Labor ministry. Without a doubt, the protection that came with federation favoured the development of New South Wales as the centre of Australian heavy industry and thus of the industrial proletariat and the Labor Party. But a similar development also occurred in agriculture, where, between 1900 and 1914, the area of cultivation doubled, which resulted in a rapid increase in the production of wheat, fruit, and dairy products. In 1912 the Riverina was opened up for closer settlement.

Labour strikes

BOOM AND DEPRESSION, THE 1920S AND 1930S

At the beginning of World War I, New South Wales had a Labor ministry under W.A. Holman, but his support of conscription led to his expulsion from the Labor Party and his formation of a Nationalist ministry in 1916. Labor was returned to office in 1920, and Labor and Nationalist ministries alternated until the Depression discredited Labor and put the Nationalists in office for a decade. The failure of Labor after its promising beginning was due mainly to its loss of both social purpose and emphasis on social experimentation, and to internal dissension. The 1920s were a period of boom, with considerable immigration and capital imports, and the expansion of public works (*e.g.,* railway building and the Sydney harbour bridge) and private industry. In the world Depression after 1929, however, New South Wales suffered badly. Recovery was slow and not complete by 1939. John T. Lang, Labor prime minister in 1925–27 and 1930–32, is one of the most controversial figures in the history of the Australian Labor movement. He introduced some important social legislation—*e.g.,* widows' pensions—but was dismissed from office by the governor in 1932 for repudiating overseas debt payments after his government had legally committed itself, by agreement with the commonwealth, to paying them. In a landslide victory the Nationalists under B.S.B. Stevens were returned in 1932 and retained office until 1941. By then, however, Lang had been expelled from the party, and Labor had regained its unity of purpose.

Nationalist election victory

WORLD WAR II AND POSTWAR INDUSTRIAL EXPANSION

Labor governments were in office continuously from 1941 to 1965, with W.J. McKell, J. McGirr, J.J. Cahill, R.J. Heffron, and J.B. Renshaw as prime ministers. The only notable legislation of this period was that for the 40-hour week (1947), compulsory voting for local government (1947), compulsory trade unionism (1953), new liquor trading hours (10 PM closing; 1955), equal pay for women (1958), and reform of secondary education (1961). In May 1965 Labor was defeated at the polls, and a Liberal and Country Party government under R.W. Askin was formed. An extensive plan to modernize the state's port facilities was announced in 1966. In 1967 a referendum in northern New South Wales for a proposed new state of New England was defeated. The history of New South Wales since 1940 has been dominated by the greatest industrial expansion in its history, much encouraged by substantial immigration and capital imports.

Industrial unrest continued to be part of life in New South Wales during this period of economic expansion. Grievances of workers in the coal industry culminated in a prolonged labour strike in 1949, which dislocated the transport and power supply segments of the economy. Additional periodic labour unrest has continued into the late 20th century primarily in public transportation, power supply services, and in shipping.

Some major capital programs began during World War II. In 1940, the production of petroleum from oil-shale commenced at Glenn Davis but was later abandoned because it was determined to be uneconomical. Dock facilities at Port Jackson were expanded in 1944 to accommodate the British Fleet during wartime. The Captain Cook Graving Dock was constructed during the port expansion, enabling this facility to accommodate the largest ships afloat at the time. Expansion of the iron and steel industry also took place during this World War II and postwar industrial activity.

One of the more monumental projects undertaken since World War II is the Snowy Mountains hydroelectric scheme. In 1949, the Snowy Mountains Hydro-electric Power Act created an authority and empowered it to generate electricity hydroelectrically in the Snowy Mountains. All electricity produced from the Snowy Mountains would be supplied to the commonwealth government for defense and other purposes, and for consumption in the Australian Capital Territory. Surpluses of electric energy would be supplied to the states of Victoria and New South Wales. The act was supported by a detailed agreement between the states of Victoria, New South Wales, and the commonwealth regarding responsibilities of each party in

Snowy Mountains hydroelectric scheme

the construction and operation of the hydroelectric system. The agreement established the Snowy Mountains Council, which consists of representatives of each party. The council directs and controls the operation and maintenance of the system. The objective of the Snowy Mountains scheme is to transfer waters, which would normally flow unharnessed to the sea, from the Snowy River and its tributaries to inland rivers and streams for irrigation and hydroelectric power.

Additional public works since World War II include massive improvements of roads, highways, and bridges; the modernization and electrification of railways; school construction; and the building of the Sydney Opera House.

An increasing amount of attention has been paid by government and citizens to the arts, conservation, and environmental protection. Irrigation areas were established as areas of Crown lands subdivided into farms to which intensive irrigation is used for livestock, agriculture, and domestic purposes. Irrigation districts were also created for privately owned lands as well as flood-control districts. Anti-pollution measures have also been instituted in New South Wales.

Commonwealth's dominant state

New South Wales remains the dominant state within the Commonwealth of Australia in the late 20th century. The state derived its prosperity from a sound agricultural base, diversified industry and manufacturing, and strong commercial and financial institutions.

(J.F.Ca./R.M.Hl./Ed.)

NORTHERN TERRITORY

The central section of northern Australia, the Northern Territory is bounded on the north by the Timor and Arafura seas, and by Western Australia to the west, Queensland and the Gulf of Carpentaria to the east, and South Australia to the south. It is approximately 1,000 miles (about 1,600 kilometres) from north to south and 600 miles (about 1,000 kilometres) from east to west. Its area is 519,800 square miles (1,346,200 square kilometres)—17.5 percent of the Australian Commonwealth. It is largely tropical.

Constitutionally, the territory was, until 1978, inferior in status to the states, and it had limited legislative powers until self-government was granted in that year. Its development since 1911, when it was transferred to the commonwealth from South Australia, has been a major item of expenditure in terms of works, services, and inducements to producers to accept the risks of an uncertain physical and economic environment. The nature of the climate, the poor soils, distance from assured markets, and problems of recruiting labour have been considerable handicaps.

Physical and human geography

THE LAND

Relief and drainage. The unspectacular coastline is flat with low headlands and is mostly fringed with mangrove swamps. There are many offshore islands, of which Melville and Bathurst islands and Groote Eylandt are the largest. Inland from the coastal belt there is a gradual rise to the town of Tennant Creek (1,229 feet, or 375 metres) on the vast Precambrian plateau (1,000–2,000 feet) that extends south and west into the neighbouring states. Farther south, Alice Springs (1,790 feet, or 545 metres) is situated on an alluvial plain in the Macdonnell Ranges, of which Mt. Zeil (4,955 feet, or 1,510 metres) is the highest point in the territory. There are some remarkable tors 200 miles southwest of Alice Springs: Mt. Olga (3,507 feet, or 1,069 metres) with 30 separate domes, and Ayers Rock (2,845 feet, or 867 metres), a red, ovoid monolith rising 1,100 feet.

A number of rivers, of which the Finke and the Todd are the largest, flow from the central ranges after rainstorms. Areas north of the plateau are drained by some substantial rivers: the Victoria, 350 miles long, and the Daly, 225 miles long, flow to the Timor Sea; the Katherine flows southwest from Arnhem Land to join the Daly; the Adelaide, Mary, and South and East Alligator rivers enter Van Diemen Gulf; and the Roper and the McArthur flow east and northeast into the Gulf of Carpentaria.

Plant and animal life. Some forests with Indo-Malaysian vegetation elements exist in Arnhem Land, but otherwise the northern vegetation is open woodland with low eucalypts and tall grasses of low nutritive value. In the main cattle areas of the Victoria River Downs and the Barkly Tableland, an open-tussock grassland on heavy, gray-brown cracking soils is dominated by Mitchell grass (a perennial Astrebla species) with subdominant Flinders grass and herbs. Between the Barkly Tableland and the ranges a wide belt of pervious sand supports only spinifex. In the Alice Springs district the rocky hills carry spinifex, but on the light-textured soils of the lower slopes and valleys an association of mulga (an acacia tree) with short grasses is a valuable fodder resource. Mixed mulga–spinifex scrub with seasonal herbs and ephemerals occupies the nearby red plains of desert loam, and farther to the west is a desert of hummock grassland composed of widely spaced clumps of spinifex and *Plechtrachne*.

Higher plants exceeding 5,000 species are represented. Species endemic to the Macdonnell Ranges include a cycad, *Macrozamia macdonnellii;* a palm, *Livistona mariae*—a surviving representative of the vegetation that once covered central Australia; and several acacias and eremophilas. A broad-leaved species of mulga, the witchety bush, harbours a grub much sought by Aborigines as food. The baobab tree, with a girth of 30 feet, occurs near the Victoria River.

Exotic animal life

Principal birds are the princess parrot of the central, rocky spinifex country, the flock pigeon of the grasslands of the Barkly Tableland, and lorikeets, parrots, and rock pigeons in rugged areas of the north. The black-banded pigeon is known only in the western escarpment of Arnhem Land. Mammals include one of the egg-laying species—the echidna—and a variety of marsupials. The kangaroo is widely distributed, but some species have restricted habitats: the rat kangaroo is adapted to the arid regions; the rock wallaby and antilopine wallaroo inhabit the rocky ridges of the northwest; and the black wallaroo is restricted to the granitic ranges of Arnhem Land. The unique rock-haunting ring-tailed opossum is an interesting evolutionary development. Formerly domestic animals now existing as large wild populations include camels, buffalos, cattle, pigs, goats, horses, and donkeys. With the exception of the buffalos, which are hunted for hides and meat, these are serious pests. The cattle tick also causes great economic problems.

Climate. There are two seasons: a wet summer, from November to April, and a dry winter. Rainfall is extremely variable and of marked summer incidence. The change from the north, where the annual rainfall is 60 inches (1,525 millimetres), to the southeast, where it is only five inches, reflects the diminishing influence of the Australian-Asian monsoon and an increasing dependence on tropical thunderstorms. Only 30 percent of the territory has an annual rainfall of between 15 and 40 inches—the effective limits of agricultural development. The climate is hot and, in the north, uncomfortably humid for eight months of the year. Mean temperatures at Darwin are 84° F (29° C) in January and 76° F (24° C) in July, and at Alice Springs 81° F (27° C) in January and 53° F (12° C) in July. The north is free from frosts.

Settlement patterns. The pastoral potential of the territory was first recognized during construction of the Overland Telegraph Line, and on its completion, in 1872, areas near Alice Springs and Darwin were stocked with cattle. The establishment of cattle stations on the Barkly Tableland during the 1880s completed the foundations of the pastoral industry. The land is rented from the government; tenure of pastoral leases is normally 50 years, and the covenants stipulate conditions of maintenance and improvement. These have been minimal, and there

are inadequate safeguards against ill-advised practices of absentee leaseholders, which have caused damage to vegetation and extensive soil erosion.

The two traditional regions

The territory is traditionally viewed as two regions, roughly delineated by latitude 20° S and commonly referred to locally as the North and the Centre. The two areas differ in topography and climate and represent the spheres of interest of Darwin and Alice Springs. As natural outlets for cattle and mineral concentrates from their respective regions, these centres have developed rapidly. Little urban growth has occurred elsewhere: Tennant Creek and Katherine have urban populations, but there are few other groupings of more than 20 dwellings.

THE PEOPLE

Demography. During the gold boom at Pine Creek in 1872, labour problems led to the engagement of Chinese from Singapore, and by 1881 the population comprised 670 Europeans and 2,781 Chinese. By 1888, when immigration restrictions were imposed, Chinese numbered about 6,000. Subsequent immigration was mostly European, and at the 1966 census the population was almost two-thirds European and one-third Aboriginal. The vast majority of the whites are of Australian birth. Age structure and other population characteristics are typical of Australia. Of the tens of thousands of persons claiming to be Christian, one-third are Catholic and two-thirds Protestant. In the middle and late 20th century more than one-third of the population was under 21 and more than three-quarters under 40 years of age. There was more than one male to every female. Whereas most of the white population is concentrated in the towns, about eight out of 10 Aborigines live in rural areas or in the Aboriginal reserves, which total more than 94,000 square miles.

In the Northern Territory the birth rate was much higher than the Australian average, though the death rate was on a par with the rest of the country. Infant mortality was more than double the national average, with greatest incidence among Aborigines.

The Aborigines. Few Aboriginal tribes are wholly nomad. Many have retained their tribal structure and their customs and religious rituals that govern their social relationships. Their religious and magical rites draw on a rich repertoire of songs and dances in which sacred objects and personal adornment play an important part. These are accompanied by a variety of musical instruments. Tribes and dialects are numerous. Languages are of the agglutinating type; *i.e.*, they combine into single words two or more elements of distinct and separate meaning. Though many of the languages have characteristics in common, the prefixing languages of the north are basically different in structure and vocabulary from the Aranda languages of the south. Many tribes have permitted in the main their languages and religious rites to be placed on permanent record. Government policy on Aboriginal welfare is one of assimilation, promoting their participation in the privileges and responsibilities of citizenship so that they may become an integral part of the Australian way of life.

Aboriginal languages

Aborigines, as Australian citizens, are entitled to equality before the law. The Department of Aboriginal Affairs administers various programs designed to benefit Aboriginal citizens. In order to better administer these programs the department, in conjunction with other commonwealth agencies and departments, established a legal definition of Aborigine as a person of Aboriginal or Torres Strait Islander descent, who identifies himself as such and as accepted by the community in which he or she lives as an Aborigine or Torres Strait Islander.

The Northern Territory is committed to governmental policies of Aboriginal self-management and self-sufficiency. The government attempts to secure equal access to services for Aborigines. Additional programs are oriented toward the social and economic betterment of the Aboriginal citizen, providing special benefits not available to other citizens. Bilingual education programs were initiated in 1973 in many Aboriginal communities. Legal services are provided by the Department of Aboriginal Affairs to ensure that all Aborigines are represented in the courts in a competent manner.

The Aboriginal Land Rights Act of 1976–78 was established for the Northern Territory, giving traditional Aborigines inalienable freehold title to former reserve land while providing a procedure for Aborigines to claim areas of unalienated Crown land. A judge of the Northern Territory Supreme Court acts as the Aboriginal Land Commissioner, ajudicating claims. Aboriginal communities are also assisted in the purchasing of land off the reserves. Money from the Aboriginal Land Fund is used for this purpose.

THE ECONOMY

Agriculture and mining. The traditional dependence of the economy on cattle raising has been substantially changed since 1966 by developments in mining and other primary industries. Agricultural production was small and related to local needs, until 1969, when the exportation of grain to Japan began. Seven companies commenced prawn fishing and processing in the same year. Pastoral production is confined to beef cattle, grazed largely under open range conditions.

Mining of iron ore at Mt. Bundey and Frances Creek (near Darwin), and of manganese ores at Groote Eylandt (an island off the east coast), commenced in 1965–66. Much of the iron ore was exported to Japan while much of the manganese ore went to Europe, Japan, and the United States. Copper and gold ores are mined chiefly at Tennant Creek. Since 1971 the Northern Territory has been among the country's most important copper- and gold-producing regions.

Manufacturing and services. Secondary industries are small service industries meeting local needs. Tourism is increasing, and many visitors are attracted by the climate of Alice Springs and by the stark, colourful scenery of the Macdonnell Ranges and the Mt. Olga-Ayers Rock National Park.

Transport. The Northern Territory has one standard gauge railway: from Alice Springs to Port Augusta in South Australia. The Stuart Highway (954 miles, or 1,538 kilometres), from Alice Springs via Tennant Creek and Katherine to Darwin, and the Barkly Highway (403 miles, or 649 kilometres), connecting Tennant Creek with Mount Isa, Queensland, are the main road links. Air services are well developed: many overseas airlines serve the international airport at Darwin, and there are services between state capitals and Darwin and intermediate towns, a substantial internal network, and charter services at Darwin and Alice Springs. There are many small airports, and most homesteads have airstrips. Shipping from Darwin has increased and necessitated a large extension of port facilities.

Development of air services

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. The Northern Territory Self-Government Act of 1978 established the Northern Territory as a self-governing entity. Under this act the commonwealth transferred most of its powers of government to the territory. The government of the Northern Territory is similar to that of the states in fields of transferred authority. There are, however, differences in office titles. For example, the Northern Territory has an administrator instead of a governor and a chief minister in lieu of a premier.

The administrator is appointed by the governor general and has the responsibility for administering the Northern Territory's government. The Executive Council, composed of all ministers in the Northern Territory, acts as adviser to the administrator. The administrator acts on all matters within the realm of the territorial government. Matters not within the realm of the government are handled in conjunction with commonwealth advice.

The Legislative Assembly serves as the Northern Territory's parliament. The Assembly is composed of members elected for four-year terms. A speaker is elected by the members of the Assembly as well as six ministers to serve on the Executive Council. A number of territorial departments and authorities operate within the realm of transferred powers. The only territory-related administrative responsibilities still retained by the commonwealth deal with uranium and other prescribed-substance mining and Aboriginal land rights.

Local government was established in the city of Darwin in 1957. Since that date local government has been extended to other towns and cities in the territory. Local municipal councils are elected by universal adult franchise. Elections are held at intervals of not more than three years.

The Northern Territory is represented in the federal government in Parliament. The territory elects one member to the House of Representatives and two members to the Senate. The legal system and the jurisdiction of the courts are similar to the other states. Darwin, as a defensive port, has extensive army, air force, and naval installations.

Health. The Department of Health provides medical and dental services and maintains hospitals at Darwin, Alice Springs, Katherine, and Tennant Creek, and a leprosarium near Darwin. Its aerial services to remote areas are based at Darwin; it also provides the medical personnel for the Royal Flying Doctor Service of Australia, which operates within 500 miles of Alice Springs. Two-way radio consultation usually suffices for minor ailments. Health inspectors visit all settlements, and medical and dental officers make periodical examinations of all schoolchildren.

The Flying Doctor Service

Education. Education is the responsibility of the minister of education, under the Northern Territory Education Act of 1979. Advisory councils were established by the act to assist the minister in special areas of education. The territory is served by several preschools, primary schools, and high schools. Educational services are also available through correspondence and private institutions. Area schools offer courses in secondary education, and three residential colleges are available for Aboriginal students. Government schools offering post-primary courses are located in many Aboriginal communities. Mission schools in some Aboriginal communities offer similar educational opportunities. Special schools for the handicapped are located in Darwin and Alice Springs.

Aboriginal education is conducted, for the most part, away from the population centres in government and mission schools close to the Aboriginal communities. Government schools at the preschool and primary levels provide tuition assistance for Aboriginal children. Bilingual education programs are widespread throughout the Aboriginal population. Courses in Aboriginal culture are also prevalent in many government and mission schools. Children wishing to continue their education beyond the primary level may attend one of the regional colleges for Aborigines. Instruction in a wide range of secondary courses is obtained at the college or in a regional urban high school.

Darwin Community College (1973) is a multipurpose institution serving the Northern Territory. It provides chiefly technical and professional courses at the university level.

The Northern Territory Industries Training Commission administers vocation and apprenticeship training programs. Members of the commission represent government, education, employers, and employees. The commission is involved in research, accreditation, promotion, financial assistance, and advice on matters pertaining to industrial training within the Northern Territory.

Technical and adult education is also offered in the territory. On-site Aboriginal adult education courses are provided by local educators who teach a variety of vocational skills. Other colleges that provide vocational training include Batchelor College, Community College of Central Australia, and Katherine Rural Education College.

CULTURAL LIFE

Cultural institutions are naturally limited in a region of small population of very low density. Because of its isolation—Darwin, for example, is nearer to Hong Kong than to Sydney—the territory is largely deprived of opportunities afforded by visiting artists. Partial destruction of Darwin during World War II led to replanning on modern lines, but even though the decade following its proclamation as a city in 1959 saw the population increase from 13,000 to 32,000, Darwin lacked museums and art galleries and a seat of higher learning. There are, however, active art, musical, and dramatic societies, and the performing and fine arts are occasionally brought to the larger towns through the sponsorship of the Arts Council of Australia.

Aboriginal arts

Indigenous arts are those of the Aborigines, which symbolize the ritual of their religion. Throughout the territory there are examples of sculpture, rock carvings, bark and rock paintings, and "X-ray" drawings (which show not only the outlines but the bone structure and internal organs of creatures of esoteric significance). The best of the decorative arts are produced in Arnhem Land and range from gravestones and ceremonial posts to personal ornaments in attractive, polychromatic designs. Aboriginal art has received wide recognition by artists and designers, and Aboriginal motifs figure prominently in the decor of many public buildings in the state capitals.

Regional national broadcasting stations are situated at Darwin, Alice Springs, Tennant Creek, and Katherine, and there is one commercial station at Darwin. The first television station came into operation at Darwin in 1971. Library services are provided from the five principal centres. Newspapers are published weekly at Alice Springs and Tennant Creek, and the *Northern Territory News* is published daily at Darwin.

(A.E.Sc./Ed.)

History

EARLY EXPLORATION AND SETTLEMENT

For some centuries before the beginnings of European exploration, the coast of the Northern Territory was visited by traders from Macassar for the purpose of obtaining sandalwood and bêche-de-mer. The earliest European explorations were those of the Dutch from Java, between 1606 and 1756. In 1623, the Dutch ship "Arnhem" explored the coastline of the Northern Territory, naming it Arnhem Land. Later, in 1644, Abel Tasman sailed along the coast, landing near the mouth of the Victoria River. Dutch explorers were followed by a period of British exploration, notably by Capt. Matthew Flinders (1803), who charted part of the coastline, and Lieut. Philip King (1817), who discovered that Melville Island was not part of the Australian mainland. The Frenchman Nicolas Baudin explored the area of Melville Island in 1803, applying French names to several physiographic features. No immediate results were derived from these explorations, and the territory remained without European settlement until 1824, when, in order to forestall possible French annexation, a settlement was founded by Capt. Gordon Bremer at Port Essington; it was removed to Melville Island, where Fort Dundas was constructed 10 years before the settlement of Melbourne, Perth, or Adelaide. A further settlement was established by Capt. James Stirling at Raffles Bay in 1827, but both this and Melville Island settlement were abandoned in 1829. A settlement was established on a new site at Port Essington in 1839 by Bremer. The settlement grew and soon had a hospital and more than 20 cottages. In July 1839 the HMS "Beagle" entered Port Essington, and three months later its first officer, Lieut. John Lort Stokes, explored Port Darwin. Prior to the arrival of the "Beagle," Bremer had been called upon to help suppress an uprising in Canton. The settlement had continued under the leadership of Capt. John McArthur. Conditions began to deteriorate at Port Essington, and many settlers died of fever. Finally, in December 1849 the settlement was abandoned.

Melville Island settlement

PERMANENT SETTLEMENT

No further settlements were attempted during the next 15 years, but the interior of the territory was extensively explored, the most outstanding expeditions being the crossing of the continent by John McDouall Stuart (in 1860 and 1862), and by Robert Burke, William Wills, and John King (in 1861). In 1863, through an issue of royal letters patent by the imperial government, the Northern Territory came under South Australian administration. In the same year a land settlement scheme was sponsored by the South Australian government, and a permanent centre of administration was established at Palmerston (now Darwin) in 1869.

The township of Palmerston was surveyed (1869–70), and Capt. Bloomfield Douglas was appointed the government resident. Between 1870 and 1872 the overland telegraph line was constructed linking Adelaide and Darwin. The

first newspaper was published in the territory in 1874, and in the same year Port Darwin grew to nearly 800 persons (three-quarters European and the remainder Chinese and Malay). The discovery of gold at Pine Creek boosted the population to more than 1,700 persons (50 females) by the end of the year. The first railroad began operation in 1889 between the goldfields in Pine Creek and Port Darwin.

19th-century cattle raising

In the late 1860s cattle were introduced from the south, and by 1888 there were 218,000 cattle, 107,000 sheep, and 5,600 horses in the territory. In 1872 gold was discovered south of Grove Hill. Further discoveries were made at Pine Creek, Union Town, Brock's Creek, and Burrundie, and within a year the population of the territory increased from 1,000 to 7,500. The introduction of Chinese labour in 1875 gave some stability to the mining industry, and by 1888 most of the gold produced was being won by Chinese. Copper was found in 1882 at Daly River and in the McArthur River area in 1891, and by 1911 several other minerals had been found in the territory.

In 1890 the Northern Territory was given parliamentary representation at Adelaide, allowing the election of two members to the House of Assembly. In 1901 the residents of the territory were given representation in the federal House of Representatives and were allowed to vote for South Australia candidates for the Senate.

COMMONWEALTH ADMINISTRATION

The territory, despite the efforts of the South Australian government, remained underdeveloped, having a population of only 3,310 (2,734 males and 576 females) in 1911. On January 1, 1911, following nearly 10 years of negotiations, it was transferred to the commonwealth under the Northern Territory Acceptance Act 1910. The Northern Territory (Administration) Act 1910 provided for the territory to be administered, subject to the instructions of the minister for external affairs, by an administrator appointed by the governor general. In the first years of commonwealth administration a number of investigations into the resources of the territory were carried out, several agricultural experimental farms were established, the mining industry was subsidized, the South Australian land laws were amended, and stock routes were improved with wells and bores. In 1917 the railway was extended from Pine Creek to Katherine. Representation in the Federal House of Representatives by a nonvoting member was granted in 1922, following local unrest.

Northern Australia Act of 1926

From 1927 to 1931 under the Northern Australia Act of 1926 the territory was administered in two parts separated by the 20th parallel of south latitude—Central Australia and North Australia—each with a government resident assisted by an advisory council. The act also provided for the establishment of the North Australia Commission with certain powers in relation to the development of North Australia, in particular in connection with transport and communications and water boring and conservation. During this period the North Australia railway was extended from Katherine to Birdum, and in the same year (1929) the extension from Oodnadatta to Alice Springs was completed. The onset of economic depression, however, brought about a serious curtailment of developmental work, and in 1931 the North Australia Act was repealed, the commission was abolished, and the administration of the territory as a whole was once again placed under an administrator at Darwin.

Electricity and water reticulations were introduced in Darwin in 1934 and 1940, respectively, and in Alice Springs in 1937 and 1942; and in 1940 a beginning was made on the Barkly and Stuart highways, which were completed in 1943.

WORLD WAR II AND LATER

Women and children were evacuated from Darwin shortly after the bombing of Pearl Harbor in December 1941. United States troops and naval units were stationed in Darwin early in 1942. On February 19, 1942, Japanese aircraft attacked Darwin, sinking and damaging several naval vessels and killing and wounding several hundred persons.

Bombing of Darwin

Following the Japanese bombing of Darwin, the northern part of the territory was placed under complete military control, and the civil administration, responsible for the remainder of the territory, was transferred to Alice Springs, where it remained until the end of the war.

Although Darwin was severely damaged by air raids and the civilian population had to be evacuated, the territory emerged from the war with greatly improved facilities for air and road communication provided by defense construction and with its main industry, the pastoral industry, in a healthy state. After the resumption of civil control the former residents returned and there was an influx of new arrivals.

Elaborate plans to redevelop a large area around Darwin were drawn following the war. These plans were abandoned in 1950 and a more feasible approach of rebuilding Darwin undertaken. A number of surveys and investigations into the territory's resources were then carried out, especially by the Commonwealth Scientific and Industrial Research Organization and the Bureau of Mineral Resources. The output of the mining industry increased steadily, due mainly to the larger copper and gold production from Tennant Creek, and to the uranium deposits discovered at Rum Jungle in 1949. Other deposits included iron ore at Mount Bundey and Frances Creek, manganese on Groote Eylandt, and bauxite at Gove Peninsula.

Legislative Council

In 1947 the Northern Territory Administration Act was amended, creating a Legislative Council composed of both appointed and elected members, with an administrator, appointed by the governor general, as president of the council. The council was charged with the responsibility of making laws for the peace, order, and good of the Northern Territory government. Laws passed by the council were forwarded to the administrator for approval. Certain laws required the approval of the governor general. The governor general could approve the laws, withhold approval or approve only a part of the law, or return the law to the council with recommended amendments. In 1959 the act was amended once again.

The Legislative Council was converted into a wholly elected body in 1974, when the Northern Territory Administration Act was again amended. The amendment called for an elected council of 19 members with a speaker elected from the membership.

The Commonwealth began a program of transferring administrative powers to the Northern Territory government in 1977. Administrative powers were transferred to the newly created Northern Territory Public Service. The positions of executive member were created, with each executive member acting as a minister in charge of certain services such as fire protection, local government, and correctional services. The Administrator's Council was replaced by the executive members, known as the Executive Council. On July 1, 1978, the Northern Territory Self-Government Act went into effect. (Ed.)

QUEENSLAND

Comprising the entire northeastern portion of Australia, the State of Queensland reaches well north of the Tropic of Capricorn, and it was the first successful settlement of European peoples within a tropical climate. The 1,000 miles (1,600 kilometres) of its eastern coastal region are separated by the northern reaches of Australia's Great Dividing Range from the vast inland plains. Extending for 1,250 miles off this coast is the Great Barrier Reef, one of the most remarkable coral formations in the world.

Queensland's 667,000 square miles (1,730,000 square kilometres) make up nearly one-quarter of all Australia and nearly one-third of the occupied part of the continent. It is bounded on the north and east by the Pacific Ocean, on the south by New South Wales, on the southwest by South Australia, and on the west by the Northern Territory. Although Brisbane, the capital, contains slightly less

than one-half of the residents of the state, smaller but sizable cities, especially along the coast, have dispersed the population across a larger area than in any other state of the commonwealth. Settled originally on the basis of the grazing potentiality of its great grasslands, Queensland has succeeded in increasing the diversification of its economy, a significant part of which derives from the allure of its tropical resorts.

Physical and human geography

THE LAND

Relief and drainage. The inland two-thirds of Queensland comprises a vast plain, broken in a few places by low ranges and hills, whereas the eastern (coastal) third is hilly, occasionally mountainous, with wide valleys and plains between the ranges. The Great Dividing Range runs the entire length of the state, separating east-flowing from west-flowing rivers. In South Queensland it lies close to the coast, and peaks reach to 4,500 feet; but it becomes a low range 250 miles inland at the Tropic of Capricorn, and again nears the coast in North Queensland. Between the Dividing Range and the coast are many other ranges, more conspicuous than the Divide in Central and North Queensland, where the state's highest peak is Bartle Frere, at 5,287 feet (1,611 metres).

Mountains, rivers, and soils

The rivers of Inland Queensland are intermittent; that is, they flow only after heavy rains, when they flood widely across the flat plains. In the arid southwest, the rivers branch into thousands of distributaries, and big floods are followed by lush growth of clover and other herbage in what is known as Channel Country. Most coastal rivers are also intermittent in flow and shallow, navigable only in the tidal reaches.

Most coastal soils have low fertility, though occasional alluvial and other richer soils occur. Large areas of rich black, gray, and gray-brown soils are found inland, forming the basis for one of the greatest natural grasslands of the world. The Great Artesian Basin underlying the plains provides water for livestock.

Climate. The rainfall of Queensland ranges from 180 inches (4,500 millimetres) a year on the wettest part of the northeastern coast to five inches (125 millimetres) in the southwest. All Queensland receives more summer rain than winter rain, but the latter is important in the southeast, in which large areas of wheat and other winter crops are grown. Rainfall decreases in quantity as one moves inland, where droughts are frequent.

Queensland's summer temperatures are warm to hot, humid on the coast but usually dry inland. Winters are mild and sunny, with frosts occasional on the southern coast and frequent inland. Average maximum summer temperatures, registered in January for the southern coast, the northern coast, and the central inland area, are about 85° F (29° C), 88° F (31° C), and 100° F (38° C), respectively; comparable winter minimums in July are 49° F (9° C), 63° F (17° C), and 45° F (7° C). Humidities are greatest in the north, lowest inland.

Plant and animal life. The wetter or more fertile parts of the east coast foster several areas of dense rain forest and its lesser variant, the softwood scrub. Otherwise, the subcoastal vegetation is more open forest of eucalyptus. Further inland, the dominant trees are mostly acacia species—brigalow, mulga, and gidyea—interspersed with large grassy plains and with some areas of desert spinifex, a spiny grass growing in clumps.

Tropical rain forests and exotic animals

Queensland has a great variety of animals—50 species of marsupials, 400 of birds, and 1,600 of fish. Both the short-nosed echidna and the platypus—egg-laying mammals—are found there. Marsupials range from the large red and gray kangaroos to koala bears, opossums, cuscusses, and marsupial mice. Birds include the flightless emu of the plains, great flocks of coloured parrots, and songbirds of the forests. Fish include the freshwater Queensland lungfish, eating and gamefish, and beautiful reef fish.

Settlement patterns. The strong regional sentiment within Queensland arises from the size and dispersion of the populated areas, some 1,000 miles from south to north, 800 miles east to west. The main regions are South Queensland, Central Queensland, North Queensland, and Inland Queensland.

South Queensland extends north to Bundaberg and some 200 miles inland, including the Darling Downs farming subregion. About three-quarters of Queensland's inhabitants live in South Queensland. Rockhampton, Central Queensland's largest city, is the outlet and commercial centre for the beef cattle and wool produced in its hinterland. This region's vast coalfields also have been developed.

North Queensland is identified with sugarcane, producing about three-quarters of Australia's crop. Subregions are Mackay and the Atherton Tableland. Townsville serves as the commercial centre for the pastoral hinterland and has a copper refinery nearby. Coalfields lie inland from Mackay and Bowen. Inland Queensland is the great pastoral area of the state. Popularly called the West, it has an identity overriding its 900-mile spread and is sharply different from the coast.

Almost all of Queensland has been occupied by pastoralists for 80 to 100 years, but large areas of the state are little changed from the original landscape. In western Queensland, the flocks of sheep and herds of cattle mainly graze the natural grasslands, the interspersed belts of trees providing only light grazing. In southern Inland Queensland the mulga is a useful drought reserve, since the leaves are edible by livestock. It is cut or rolled down for this purpose, and it regenerates.

Nearer the coast, some large areas of open eucalyptus forest have been "ringbarked," a process that kills the trees and allows grass to grow. A large belt of brigalow timber, an acacia looking much like an eucalyptus, in the 20-to-30-inch-rainfall belt of Central and South Queensland has been partially cleared for farming and grazing, since the presence of brigalow indicates good soils.

In the crop-growing and dairying region of the southeast and on the sugar-growing north coast, timber has been completely cleared from the better soils, mainly river alluviums and basalt areas. Elsewhere, much original timber remains, and there are many national parks and hardwood forests.

The outstanding feature of land settlement in Queensland is the large size of the grazing holdings and farms. Most of the western grazing country is held in leasehold from the crown, and well over a thousand pastoral holdings average more than 100,000 acres in area. On the better grassed country the holdings are 15,000 to 25,000 acres, carrying 5,000 to 10,000 sheep. In the grain-farming areas much of the land is freehold, and most farms are between 600 and 3,000 acres in size. Large holdings, with a high degree of mechanization and a small labour force, suit the rather unreliable rainfall pattern of Inland Queensland. In the coastal sugar areas, farms range from 50 to 100 acres and are highly mechanized.

Farm holdings and township patterns

The large holdings in rural Queensland have produced a sparse pattern of villages, or townships. In the far west and in the rougher rangy areas of the subcoastal belt, the grazing properties, or stations, are very large, employing six to 20 people and carrying more supplies than a village store. Hence, townships often lie as far apart as 30 to 100 miles.

Recent decades have seen a decrease of population in most of western Queensland. In the agricultural areas containing mainly single-family farms, the small towns are closer, about 10 miles apart; but with the improvement of roads and vehicles some small towns are disappearing, and towns of more than 1,000 people and lying 40 to 60 miles apart are serving the rural areas.

Queensland has a more decentralized population than any other state. Apart from Brisbane, there are fewer than a dozen cities with more than 20,000 inhabitants. The development of ports and commercial centres along the Queensland coast and the growth of the sugarcane industry are in large part responsible for this widespread settlement.

THE PEOPLE

Ethnic groups. More than four-fifths of Queensland's population is Australian born, and, as in other states, it is predominantly of English, Scottish, or Irish ancestry. Important minorities came from Germany in the 19th century and from Italy after 1920, the latter frequently

becoming cane farmers in North Queensland. After 1947, a wider range of European immigrants arrived from The Netherlands, West Germany, and southern and eastern Europe, as well as some from the United States.

The assimilation of Europeans has been rapid once some fluency in spoken English is achieved, and religion has not proven to be a barrier. The assimilation of the Australian Aborigines, on the other hand, has been slower.

Queensland's birth and death rates are close to the Australian average. Historically, Queensland's birth rate has been significantly higher than the Australian average, reflecting a more rural population. The margin has narrowed as urbanization has increased.

Scourge of tropical diseases in the 19th century

From 1860 to 1890 the death rate was substantially higher than the Australian average. During this period, Queensland's future was threatened by tropical diseases brought in by troops from India, by Chinese miners, and by South Pacific islanders. Almost every tropical disease was introduced, and Queensland seemed likely to suffer the same fate as previous European attempts to settle in the tropics. Intense and continued effort by the medical profession and the Queensland health services, however, progressively wiped out the diseases. Australia's policy of restricted immigration was strongly influenced by Queensland's experience of unrestricted immigration, and after about 1890 the state was developed almost entirely by European labour.

The number of rural workers has declined with increasing mechanization of farming and the abandonment of some small farms and dairy farms. These trends have far more than offset the increased population in those few rural areas that still are expanding, notably the brigalow lands.

Although Queensland is the most decentralized of Australia's states, the trend toward increased urbanization is strong. The development of Queensland's great mineral resources, contributing to the growth of mining towns and ports, is both a decentralizing and urbanizing force.

THE ECONOMY

Queensland's economic pattern is similar to that of the other states, but its manufacturing is less developed than that of New South Wales and Victoria in such areas as steel, chemicals, and transport equipment. It is more developed in the production of certain minerals, in tropical crops, and in extensive cattle raising.

Manufacturing, commerce and finance, construction, agriculture, and professional and personal services are the areas of greatest employment in Queensland. Seasonal unemployment is more noticeable in Queensland than in other states, mainly because of the seasonal nature of sugar harvesting and cattle slaughtering and the decline in construction work in the wet months from December to April.

Agriculture. The original attraction of Queensland is the great natural grasslands of its interior. The grasslands remain the state's largest single resource, even with the growth of manufacturing, mineral exploitation, and agriculture.

Domination of agriculture by livestock

Wool production is almost all of the fine-textured Merino variety. Beef cattle are tending to replace sheep in some areas and already have replaced many dairy cattle. Some of the best croplands in Queensland are fully developed: for sugar production on the coast and for grains on the subcoastal Darling Downs. Other crops include peanuts, tobacco, cotton, and many tropical and temperate-climate fruits and vegetables. Queensland has a greater area of land suitable for further development than any other state, especially brigalow and similar lands suitable for beef grazing and summer grain crops.

Manufacturing. Queensland's manufacturing and processing industries now exceed the output of the rural industries in their contribution to the state's income. Brisbane, which employs almost two-thirds of the factory workers, has by far the greatest range of manufacturers. Elsewhere in the state, most manufacture comprises the processing of such primary products as sugarcane, meat, timber, and alumina and various base metals, as well as in industry supplying local needs—printing, baking, vehicle repair, and the like.

Mining. The most spectacular development in Queensland in the middle and late 20th century was in minerals, including alumina and coal. The great bauxite field at Weipa on Cape York Peninsula exports bauxite overseas and supplies the big alumina refinery at Gladstone. The Mt. Isa mines in the northwest greatly expanded their production of copper and of silver, lead, and zinc. Several large coal mines for the export market have been opened up in the hinterland of the central coast. Brisbane is supplied natural gas and oil from the Roma fields and oil from those at Moonie.

Tourism. A major Queensland industry, the tourist facilities of the state are serving a rapidly increasing number of Australian and overseas visitors attracted by the mild, sunny winters and moderate summers. Prime attractions include the surfing beaches and the Great Barrier Reef islands, as well as the rain-forested national parks and tours of the eastern coast. The surfing beaches are in South Queensland. Gold Coast, 20 miles of beaches near the southern border, supports a booming tourist and holiday industry.

Administration of the economy. The state government in Queensland regulates those parts of the economy not under federal control and directly provides some services, especially railways, main roads, education, health services, police and law, some forestry and irrigation, and some housing. Operating under state legislation, local authorities provide minor roads, some bus services, water supply, drainage and sanitary services, and town planning. Statutory bodies provide electricity, harbours, slaughterhouses, and marketing of some primary produce.

Federal and local services

State industrial awards (wages and hours fixed by the state-appointed arbitration authority) cover some 65 percent of the employees in Queensland, a larger percentage than other states. Notable among employee unions is the large Australian Workers Union, covering shearing, grazing, canefarm, and mill employees and construction workers.

Transportation. Queensland developed as a series of ports, with railways tapping the inland, but now coastal shipping is employed exclusively for heavy cargoes such as steel and sugar. Brisbane is the largest receiving port, while Gladstone (alumina and coal) and Weipa (bauxite) are the largest shipping ports. Several thousand miles of railway operate throughout the state of Queensland. Closure of some branch lines in agricultural areas has occurred; but two railways have been constructed for coal exports, and other lines have been improved. Air services are important in Queensland, especially in getting about the large area of the inland.

A steadily improving road network links all parts of the state, but maintenance of unpaved roads is costly and difficult with heavy summer rainfall. A paved road reaches Cairns and is partly constructed to the main inland towns. Paved beef roads have been built to get fat cattle to railheads from the southwestern Channel Country and the northwest.

Brisbane is the only city with serious traffic congestion, and a 25-year program of freeway construction is under way. Most provincial cities also have planned similar but less extensive systems.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. The state government follows the usual British pattern of a legislature, an executive, and a judiciary. Queensland is the only state with a unicameral parliament, the upper house having voted itself out of existence in 1922. Local authorities are established under the Local Government Acts; they are elected through adult franchise, and voting is compulsory. Unlike the situation in other state capitals, most of the metropolitan area of Brisbane is controlled by a single city council. Public justice is vested in the Supreme Court and district courts and, for civil jurisdiction, in lower courts as well. The Supreme Court holds periodical sittings in centres throughout the state.

The Australian Labour Party controlled the state for two long periods, 1915–29 and 1932–57. Since 1957 a coalition of the Country and Liberal parties has governed.

Social welfare. Social and economic divisions are even less marked in Queensland than in the rest of Australia, which itself makes up the world's largest area of uniform language, social customs, and standards of living.

Education. The vast majority of primary and secondary school children attend state-government schools, and the rest are in schools run by religious and other bodies. Education is compulsory between ages six and 15.

Private schools receive governmental subsidies, as well as grants for libraries and science laboratories. Correspondence schools always have been important to the remote parts of the state, and thousands of children, including apprentices, are educated in this way. Regular school assessments of pupils are made, and university-admission examinations are held.

Universities are located in Brisbane and Townsville and institutes of technology in Brisbane, Toowoomba, and Rockhampton. An agricultural college, a conservatory of music, and many technical colleges complete the state's offerings in higher education.

Health and housing. Queensland is the only state with a public hospital system that provides free wards as well as the usual subsidised private wards that charge fees. Among the medical-research institutes is the Radium Institute, which successfully deals with skin cancers, a high-incidence affliction in Queensland. The Flying Doctor Service, which commenced in Queensland in 1928, now makes hundreds of flights a year to remote farms or settlements, especially in the inland region.

Prevalence of single-family homes

Several thousand dwelling units a year are built in Queensland, of which the vast majority are separate houses. With a warm climate and ample hardwoods, relatively cheap timber houses have been the most common type in Queensland. Older houses often were erected on timber piles to give room below the house for laundry, automobiles, etc., and to keep houses airy and free from termites. The trend in recent years is to build low-set houses, as in other states, and brick or brick veneer is now very common.

CULTURAL LIFE

A feature of recent cultural development in Queensland is the greater opportunity now enjoyed by people in the nonmetropolitan areas. A network of radio stations, both governmental and commercial, extends over the whole state, except in the most remote areas, which must depend on shortwave transmissions of national programs. Television also covers most of the state. Several companies sponsored by the Arts Council make continuous tours of music, ballet, and theatre into the provincial cities and inland country centres and schools, covering a far greater rural area than is done in any other state. Provincial newspapers are strong in Queensland, and the larger daily papers carry international news.

Local participation in press, radio, television, theatre, and vocal, orchestral, and band music is growing in provincial and rural Queensland, as is the time spent on the arts in school courses. At a higher level, the new James Cook University at Townsville offers arts courses at both undergraduate and graduate levels.

Thus, the earlier isolation and lack of cultural opportunities of rural dwellers in Queensland is, to an extent, being overcome. The state government has established a Cultural Activities section in the Department of Education to advise and coordinate cultural work and to help remote areas.

Brisbane, with a population 10 times that of any provincial city, is naturally the strongest cultural centre. It has a history of good performance in orchestral music, and the Queensland Symphony Orchestra, though small, is accorded high rank. There is an excellent junior orchestra as well. Vocal music also has been strong, especially in the city of Ipswich, where many Welsh coal miners settled. In theatre, Brisbane is notable for its number of little theatres, run for many years by competent amateurs and now receiving financial aid; some groups have become professional companies. Several new theatres have been built recently, and playwriting has shown strength in Queensland. Brisbane also has many privately owned art galleries, in addition to the state art gallery and museum, and interest in the visual arts has been increased by leading Australian painters working in Queensland at various times. On the more popular level, annual competitions of fence painting are held in Brisbane and elsewhere, which attract many entries, and there are competitions for works of sculpture. The state Public Library, with its associated Oxley Memorial Library of specifically Queensland items, is in Brisbane. Libraries are maintained by the majority of Queensland's local governments, some having several branches.

Popular culture shows little that is distinctively Queensland in origin. One widely enjoyed form of popular culture, however, is the appreciation of the many miles of unspoiled landscapes and shorelines within the state. This is reflected back in the popularity of separate houses that offer outdoor living amid trees and gardens. (H.W.H.)

History

EARLY EXPLORATION AND SETTLEMENT

During the period of initial European exploration of Australia and the region of present-day Queensland, it has been estimated that more than 200 Aboriginal tribes inhabited the area, totalling about 94,000 persons. The Aboriginal tribes were either fishing people, living along the coast where food was plentiful, or mountain people, occupying the central and western areas where survival was more difficult.

The Talgai skull, discovered in 1884 and estimated to be about 10,000 to 25,000 years old, exists to prove the immemorial stirrings of human life on Queensland soil. But although by 1606 both Dutch explorers and the Spanish explorer Luis de Torres had found Cape York Peninsula, it was 1770 before Capt. James Cook discovered the east coast of Australia and noted signs that a great river might empty into Moreton Bay. Cook named and charted many capes, bays, and islands along the coast, landing on the shore of what is now Queensland nine times. Matthew Flinders explored and charted Moreton Bay, refuting Cook's claim that a great river might enter into the bay. In 1823 John Oxley, aided by castaways, discovered the Brisbane River and chose its vicinity for a new and stricter penal settlement remote from Sydney. The following year, Lieut. Henry Miller, accompanied by Allan Cunningham, set out with 30 convicts and their guards to establish a penal settlement on the site recommended by Oxley. After six months at the site, the settlement was abandoned and reestablished at present-day Brisbane in February 1825. In the next few years exploration of the region continued as Capt. Patrick Logan and Edmund Lockyer explored the hinterland of the penal settlement, discovering coal and limestone deposits in the process. In 1827 Cunningham discovered the Darling Downs.

Cook's explorations

THE PENAL SETTLEMENT

Following the establishment of the penal settlement at Brisbane, more settlements were founded at Ipswich and Stradbroke Island. Accounts of life in the penal settlements report harsh treatment of the convicts, particularly those confined to chain-gang duty. Colonization of Moreton Bay region was strictly forbidden because the more dangerous convicts were housed in this region. The number of convicts varied from the initial 30 to more than 1,100 (including 30 females) in 1833. In 1840 the penal settlement was abolished, at which time the convict population numbered about 100.

FREE SETTLEMENT AND SEPARATION FROM NEW SOUTH WALES

Allan Cunningham's discovery of the Darling Downs pointed the way to more flourishing settlement, which had already begun overland from the south when in 1840 the abolition of the penal colony facilitated healthy development. The early squatters were followed in 1842 by the first free settlers, and sales of land took place. The main hindrances then became the remoteness of Moreton Bay district, the lack of understanding of the region in Sydney, and the consequent small number of settlers—no more

than 2,000 in the mid-1840s. It was 1840 before Patrick Leslie ventured on the downs at Warwick with sheep, and the first crop farmers, apart from the Moravian missionaries at Nundah in the penal days, were brought by J.D. Lang in the "Fortitude" in 1849. It was therefore mid-century before emigrant ships from Britain sailed directly to Brisbane. Nevertheless, political separation from New South Wales was achieved in 1859 and the colony of Queensland proclaimed, when the population numbered only 23,520 and before any industry had established itself, though gold had been discovered in 1858.

Queensland gold rush

Coal was found at Ipswich as early as 1827 and the first mine opened in 1846, but it was the gold rush that really inaugurated Queensland's mining industry. From 1858 to 1873 the east and north of the state were invaded and opened up by diggers at Canoona, Peak Downs, Gympie, Ravenswood, Charters Towers, and Palmer River. Within a few months isolated spots in the bush became townships of 10,000 people. There some of the beginnings of the "White Australia" policy (1877) may be seen in the discrimination by act of Parliament against Chinese and other Asian speculators. By 1867 the population of the state had grown to 100,000. Even where the gold failed, as at Canoona, a town such as Rockhampton could rise from the ruins. In 1882 came the discovery of a mountain of gold and copper, Mt. Morgan, near Rockhampton.

In the 1860s westward migration was very rapid wherever there was water, and the movement was encouraged in 1869 by an act of Parliament which granted 21-year leases to those who had 25 sheep or five cattle to the square mile. Many of the early pastoralists failed. Wool had to be transported in drays by long trains of bullocks and markets were far away and uncertain. But by 1873 Victorian prosperity (in gold) began to be invested in Queensland. The first railways, from Ipswich to Dalby and Warwick, were operating by 1870. The population of Queensland was more than 200,000 in 1880, with the largest cities being Brisbane, Townsville, and Rockhampton. Pastoral industry spread across the Darling Downs in the 1860s and 1870s. By 1880 about 3,000,000 cattle and 7,000,000 sheep were in the colony. Sugar and cotton production, established in the 1860s, increased. In the 1880s attempts were made, not always successfully, to end the bitter struggle between grazier (livestock rancher) and squatter by a succession of acts of Parliament. Artesian boring was introduced in 1881 and was energetically developed after the bad years of drought and depression between 1890 and 1902, which wiped out flocks and herds. In addition,

The cattle tick

after 1894, cattle suffered the onslaught of the cattle tick from northern Queensland, and an industry that had been stimulated by the advent of refrigeration and that had made its mark on Australian life in the tradition of droving over huge distances saw its cattle population halved by the 20th century.

There was similar strife between the early crop farmer and the grazier who had come before him. Hewing out his farm by clearing the bush, attempting crops where none had ever been cultivated, the farmer won the contemptuous name of "cockatoo farmer." But, supporting himself, he advanced from maize (corn) and pumpkins to lucerne and sorghum; his livestock increased; and the plow, reaper, and farmhouse replaced the hoe, scythe and sickle, and bark hut. By 1900 the government had recovered much pastoral land for the arable farmer, and by the mid-20th century land that had originally belonged to graziers had become renowned for wheat, sugarcane, and bacon.

Dairying did not flourish until the 20th century, when there were sufficiently populous towns to give it encouragement. Until 1888 Queensland imported much of its butter from the south, but by 1895 it had become self-sufficient in dairy products.

Between 1860 and 1904 Queensland was involved in the dispute over the employment of South Sea islanders (Kanakas) as cheap labour. The recruiting of Kanakas (often against their will) began with the introduction of cotton cultivation during the American Civil War. After cotton failed at the end of the war, recruiting continued as the sugarcane industry grew. The replacement of the hoe by the plow increased production and decreased the need for Kanaka labour; by a 1904 act the new federal government ended the importing of labour and agreed to support sugar financially, when necessary, in the interests of the "White Australia" policy.

The Kanaka problem influenced the separatist movement in northern Queensland (where both sugarcane and the goldfields were), but whereas the planters wanted separation the miners did not, fearing that the planters would impose a policy of continued importation of labour.

Toward the end of the 19th century the increase in population, the advance of social legislation in Europe, the socialist idealism of William Lane, and the depression of the 1890s encouraged the growth of trade unionism and led to the emergence of a Labor Party with well-defined policies. The most notable event in Queensland at this period was the shearers' strike in 1891. It was broken, but subsequent legislation providing for shorter working hours, improved conditions of work, and the encouragement of the smaller settler showed clearly the trend of the times. In 1899 Queensland had Australia's first Labor government, though a minority one, but Labor's position rapidly became so strong that after World War I it was almost continuously in office.

Emergence of the Labor Party

FEDERATION AND THE STATE OF QUEENSLAND

On January 1, 1901, the Commonwealth of Australia was proclaimed, creating the state of Queensland. The census of the same year recorded 498,129 inhabitants, excluding Aborigines. In 1904 women gained the right to vote, and in 1914 compulsory voting was enacted first in Queensland, followed by the other states.

In 1922, at the instigation of the ruling Labor government, the Legislative Council (upper house of the bicameral parliament) was abolished, leaving the Legislative Assembly. Three years later Greater Brisbane was established as the largest municipal council in Australia. From the beginning, the Brisbane council was elected by a complete adult electorate.

The Labor government was replaced by the Country Party as the ruling government in 1929. The new government came to power amid difficult times of rising employment, falling incomes, and the social distress of the Depression years. During its tenure of government, the Country Party abolished state trading and established the Bureau of Economics. The first woman was elected to the Queensland Parliament during this period of Country rule. The Country Party was unable to stem the tide of the Depression and was replaced by the Labor Party, who attempted to stimulate the economy through large capital improvement projects. Several substantial projects were undertaken, such as the Story Bridge, Stanley River Bridge, and construction of the University of Queensland at St. Lucia. The worst of the Depression was ending by 1934, and many social services, suspended during the bad economic times, were reinstituted. In 1946 free hospital service was introduced and large-scale irrigation projects were begun by the government, which included the Burdekin and Tully hydroelectric scheme. In 1957 the Labor government was ousted by a Country–Liberal (now called National–Liberal) coalition.

The Country–Liberal coalition

In the 20th century improved farming methods, irrigation, insecticides, communications, and new markets at home and in Japan greatly strengthened primary production. In 1923 vast silver–lead–zinc deposits were found at Mt. Isa, and in 1969 further vast deposits were found. Uranium was discovered and mined at Mary Kathleen from 1950 to 1963, and bauxite was found in great quantity at Weipa. In the 1960s the Mooni oil field, the natural-gas field at Roma (piped to Brisbane), and the huge mining port of Gladstone were developed.

In 1901, Queensland was represented by six senators in the national Parliament. This number was increased to 10 in 1948. The state's representation in the House of Representatives remains proportional to Queensland's population.

In the 1980 elections held in Queensland, the National–Liberal coalition won control of the state Parliament, as it has done consistently since 1959.

(R.H.G./Ed.)

SOUTH AUSTRALIA

One of the six federated states of the Commonwealth of Australia, South Australia lies on the south central coast of the nation. Western Australia lies to the west, the Northern Territory to the north, Queensland to the north and east, and New South Wales and Victoria to the east. The great majority of its people cling to the seacoasts, most of them living in Adelaide, the capital. The rainfall of two-thirds of the vast interior is insufficient to support significant human or animal populations. In the remainder there are scattered towns, mostly small, linked with the coasts by rail, road, or air. The aridity of the interior is only slightly compensated for by the presence, in the northeast, of a portion of the Great Artesian Basin, the world's largest region of natural springs. In two reserves in the northwest and southwest live remnants of the Aboriginal peoples of Australia.

Physical and human geography

THE LAND

Most of South Australia is flat, with large tracts of sand and of the stony plains known as gibber desert. Over 80 percent of the land is less than 1,000 feet (300 metres) above sea level.

Relief. The state is divided into five major regions. The western shield, a vast barren region that also takes in much of Western Australia, is underlain primarily by Precambrian rock, over 570,000,000 years old. It swoops down from the north and west to engulf the entire Eyre Peninsula and much of the Yorke Peninsula on the coast. Bordering it in the northeast and reaching nearly to the coast, great layers of sandstone, lying 4,000 to 5,000 feet underground atop the Precambrian Shield, act as the water bed for the Great Artesian Basin. The several ranges of the Precambrian highland chain stretch mainly north from the Adelaide region and east into New South Wales.

The Eucla and Murray basins

In the extreme southwest and southeast, the Eucla and Murray basins reach into Western Australia and Victoria, respectively. Most of the land in these areas is of Mesozoic origin, between 65,000,000 and 225,000,000 years old. Near the town of Mount Gambier, close to the border of Victoria, a few lake-filled craters have become tourist attractions, but the state is geologically inactive in terms of volcanic activity or surface glaciation.

The coastline is indented by two large, navigable gulfs separated by Yorke Peninsula, which is about 30 miles wide. Gulf St. Vincent, the more easterly of the two, is about 100 miles in length; Adelaide lies on its eastern shore. Spencer Gulf, twice as long, has near its northern limits the industrial towns of Port Pirie, Port Augusta, and Whyalla. The only large stream is the Murray River, which enters South Australia after forming the New South Wales–Victoria boundary. The rivers shown on maps as lying in the north rarely contain any water. To the south and east of Lake Eyre is a striking group of "mound springs," mineral deposits looking much like miniature volcanic cones and rising as much as 130 feet in the air. They have been formed by subterranean artesian action, which forces the water to the surface. The highest point in the state, Mt. Woodroffe, rises to 4,723 feet in the far northwest.

Climate. More than 80 percent of the state receives less than 10 inches (250 millimetres) of rain annually, all of it sometimes falling within a few months to be followed by months of almost complete drought. Only 0.3 percent gets 30 inches or more. The driest known area on the continent occurs around Lake Eyre. A few areas in the southeast receive more than 35 inches, but the average is between 20 and 30 inches. During the winter months of June, July, and August, most of the state has mean temperatures between 50° and 60° F (10° and 16° C), whereas summer figures stand at 65° F (18° C) in the south and between 80° and 85° F (27° and 29° C) in the north.

Land usage. Land suitable for farming other than extensive grazing is confined to the south, excluding the far west. For the analysis of rural statistics, the commonwealth statistician divides the state into nine divisions. Seven of these represent about one-eighth of the state's area. About two-thirds of the state was thus unused for either agriculture or pasture. Some of this area is set aside for Aboriginal reserves.

Plant and animal life. No vegetation grows at all in the stretches of sand and gibber desert, and only scrub grasses and saltbush are hardy enough to survive in the dry regions of the north and west. Eucalyptus and native pines are scattered in the Flinders Ranges; the Mt. Lofty Ranges, near Adelaide, are more heavily wooded, mainly with eucalyptus. In the southeast, more than 170,000 acres of man-made forest, 90 percent of it in softwood, have been created since the late 19th century to assure forest preserves. These have softened considerably the landscape of the entire region.

Man-made forests

Most Australian species are represented, and some species are unique to the state. However, in comparison with the eastern states, South Australia has a sparse population of native fauna, partly because of the climate and soil but also because of the use of better land for farming. Some species have become extinct. Kangaroos and wallabies are common, as are wombats and bush rats. There are many kinds of birds, lizards, and snakes. The coastal sea has a wide variety of fish, but few fish are to be found in inland waters except in the Murray River.

Drainage. Maintaining and transporting supplies of fresh water for human, animal, and agricultural use is a constant concern in nearly all of Australia, the world's most arid continent. A few small streams rising in the Mt. Lofty Ranges near Adelaide have been dammed, but supplementary supplies must be pumped over these mountains from the Murray River. Another pipeline to the industrial town of Whyalla stretches for 223 miles from the Murray, whose water is also used for irrigation. The need to ensure a regular flow of high-quality water in the Murray has led to disputes between South Australia and its partners in the River Murray Agreement—the commonwealth, New South Wales, and Victoria—on the location of additional dams. In the interior, supplies are even scarcer, and private water catchment devices are still widely used.

Settlement patterns. The first surveyor general of the South Australia colony, Col. William Light, delimited the colony into nine counties in 1842. In 1846 the lands of counties were divided into hundreds, based on the system used in many English counties. The boundaries for counties and hundreds were based on natural features, but as more counties and hundreds were surveyed natural features became more difficult to use. In most cases, boundaries were based on parallels of latitude and longitude. The last of the 49 counties of South Australia was delimited in 1933. The counties of South Australia average 293 square miles in size.

Adelaide was surveyed and lands were allotted or sold in March 1837. The colony had grown to about 18,000 by 1844, with about 10,000 living in or near Adelaide. By that time the colony was producing an excess of wheat, and copper had been discovered at Kapunda and Burra. The colony began to prosper and heavy immigration followed the copper discoveries, continuing until the discovery of gold in Victoria in 1851. The concentration of people in Adelaide created a demand for community services. Water was laid in 1861 and gas in 1863. Adelaide became more attractive to settlers because of the added amenities and greater employment opportunities.

Much of the colony had not been exploited. Very few settlers lived in the Murray Valley or in the northern district. After 1961 the pattern of settlement in South Australia began to change. The opening of the northern wheat lands, the drainage of the southeastern swamps, the increase of farmers on the two peninsulas and in the Murray Mallee, and irrigation of the Murray Valley, altered the distribution of settlement. Port Lincoln and Mount Gambier be-

came more important distribution centres, and improved roads and railways made the movement of persons and goods easier. The settlement continued to concentrate in Adelaide and the surrounding cities and towns.

THE PEOPLE

Slightly more than three-fourths of South Australia's population was born in Australia, and virtually all others were born in the British Isles or continental Europe. About 10,000 persons report having 50 percent or more Aboriginal blood, and few of these had been assimilated into the processes of modern Western society prevalent throughout the state. The Anglican Church has the largest number of adherents, followed by the Methodist and Roman Catholic churches, with approximately equal numbers.

Between 1945 and 1965 the state's population grew at a faster rate than that of Australia as a whole, mainly because of a disproportionately large influx of immigrants. After 1965, however, the rate of growth fell sharply and the immigration rate fell below the Australian average because of a deteriorating employment picture. The birth and death rates have declined since World War II.

Population distribution

South Australia's population distribution is extremely skewed, plunging from Adelaide's concentration of nearly 1,000,000 inhabitants to the less than 50,000 in Whyalla, the next largest urban centre. The only other centres with 10,000 or more are Mount Gambier, Port Pirie, and Port Augusta. The proportion of rural population, as in the entire country, has declined since World War II.

THE ECONOMY

South Australia's rate of economic growth exceeded that of the nation as a whole during the mid-20th century, and the labour market was strong, though a lower rate of growth in demand for motor vehicles and consumer durables, in later years, slowed the pace. Although the mean income is below the national average, so are living costs, putting the standard of living on a par with the rest of Australia. There were more automobiles and television sets per capita than in other states. In Adelaide the cost of land and building is below that of other Australian capitals.

Resources. More than one-quarter of the state's work force is engaged in primary production, including mining and quarrying. The state is not rich in minerals, but the Middleback Ranges produce the bulk of Australia's iron ore. Some of this is processed at the Whyalla blast furnaces, but most is carried by water to Newcastle and Wollongong in New South Wales. The state is a major world source of opals. Most of the nation's salt and gypsum come from South Australia, but the open-pit coal mines in the Flinders Ranges are not extensive. A pipeline to Adelaide from the large natural gas fields discovered in the north was completed in 1969.

Manufacturing. Motor-vehicle manufacture is a large component of secondary industry, which employs about one-tenth of the state's manufacturing labour force. General Motors-Holden Pty. Ltd., one of the nation's largest manufacturers, divides its operations between Melbourne and Adelaide. Consumer durables, metal pipes and tubes, chemicals, and textiles are produced in or near Adelaide. A soda-ash plant at Osborne, near Port Adelaide, is the major producer in the Australian alkali industry. Whyalla, in addition to its iron and steel industry, has Australia's largest shipyards. Sawmills and factories producing particle board and paper are located near the softwood plantations in the southeast. Port Augusta has a large power station using the low-grade coal transported by rail from the Flinders Ranges. Smelters at Port Pirie treat ores sent by rail from Broken Hill in New South Wales.

Agriculture. South Australia is a major producer of wheat and barley for export abroad, but it excels in its vineyards. Growing about a third of Australia's grapes, it produces about two-thirds of the wine and most of the brandy for the tables of the commonwealth. Tuna and crayfish are pulled from the coastal waters for export to other states and abroad, and its millions of sheep produce wool, meat, and hides. Dairy production is largely for local consumption, but a considerable quantity of vegetables is sent to other states.

Role of the vineyards

Transportation. Transport services within the state centre upon Adelaide, and there has been little planning to coordinate the transportation systems as a whole with the state's economic development in terms of geography. The railways are almost entirely owned by the state and commonwealth governments, most of the commonwealth operations being related to the transcontinental line linking Sydney and Perth. A direct service operates between Adelaide and Melbourne, the Victorian capital, and a line of five-foot three-inch gauge from Adelaide meets the commonwealth railway at Port Pirie, the latter a standard-gauge line. Operating losses have caused the closure of many rural lines and a diversion of traffic to road transport. Many of the roads are hard-surfaced or bitumin-sealed, but most are unsealed or of crushed stone. Port Adelaide and Whyalla are major harbours for trade with other states and foreign nations; Port Stanvac is an oil-discharging port near Adelaide. Direct air services operate from Adelaide to Sydney, Melbourne, and Perth and to several towns within the state.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. The division of power between commonwealth and state parliaments results in commonwealth predominance in defense, foreign affairs, economic policy, welfare payments, and shipping and aviation. The main matters under state authority are education, hospitals, housing, police and prisons, and railways and roads. South Australia is represented in the House of Representatives and the Senate in the Commonwealth Parliament. The state parliament comprises a House of Assembly elected by universal and compulsory suffrage, and a Legislative Council elected by a restricted and voluntary franchise. Legislation must be passed by both houses.

The governor, the official representative of the crown, accepts the advice of ministers who, by constitutional convention, are collectively responsible to the House of Assembly. The principal minister, the premier, is usually the leader of the majority party in that house. Local councils are elected by property owners and tenants in local-government areas.

Political parties

The two main political parties are the Australian Labor Party (ALP) and the Liberal–National Country Party (LCP). The ALP usually receives a majority of the votes, but because the distribution of representatives favours rural areas the party is not always assured of a majority in the House.

The governor appoints the members of the state's Supreme Court, from which appeals lie to the High Court of Australia and the Privy Council. Among the lower courts are those dealing with such specific matters as licenses for the sale of liquor. The Industrial Commission is responsible for labour arbitration, but most workers are covered by decisions of the Commonwealth Conciliation and Arbitration Commission.

Education. Although education is compulsory from six through 15 years of age, most children enter at five, and the rates of retention in secondary education are rising. All state schools are tuition-free and administered by the Department of Education with a cabinet-level minister. The secondary system comprises high schools offering general academic training, vocationally oriented schools, and the "area schools" that serve rural populations in primary and secondary grades. Private schools enroll a small percent of primary pupils and secondary pupils. Apprenticeships are controlled by a state commission.

The institutions of higher learning in the state include the University of Adelaide, founded in 1876; the Flinders University of South Australia, which opened on the outskirts of the capital in 1966; and the South Australian Institute of Technology, dating from 1889. There are, in addition, an agricultural college, a school of art, and several teacher-training colleges.

Health and welfare. South Australia's very high health standards are reflected in the figures for infant mortality, which are among the lowest in the world (although the Aboriginal infant mortality rate is high). Hundreds of public and private hospitals are in service throughout the state. There are few slums, and a large proportion of housing is built by the South Australian Housing Trust.

Department of Aboriginal Affairs

The Aborigines and the state. In 1973 the Commonwealth assumed responsibility for Aboriginal affairs. The Department of Aboriginal Affairs administers a variety of educational and social welfare programs throughout the state, and the Aboriginal Land Fund Commission assists Aboriginal communities in the purchase of land and homes.

CULTURAL LIFE

The arts. South Australia's contributions to the arts are few, but it provides facilities for its citizens to participate in them. The Art Gallery of South Australia has an interesting collection of Australian art. A professional symphony orchestra is maintained by the Australian Broadcasting Commission and several theatres provide amateur and professional drama. Visiting artists present frequent concerts and recitals, and every second year a Festival of Arts is held, modelled on the Edinburgh International Festival of Music and Drama in Scotland. In addition to the art school, there is a conservatorium of music at the University of Adelaide, and Flinders University offers courses in theatre, film, and television.

Sports. The main spectator sport is Australian rules football, played during the winter from April to September. Cricket takes over during the summer. Year-round horse racing is popular, and in the summer the Adelaide showgrounds are given over to night trotting races.

History

EXPLORATION

The South Australia coast was first discovered and explored in 1627, when the Dutch ship "Gulden Zeepaard" sailed the coastline from Cape Leeuwin to the islands of St. Francis, under the command of Francois Thyssen. Since South Australia did not look promising for trade, which was the prime interest of the Dutch, the region remained unexplored until the late 18th century.

The Frenchman Antoine Bruni d'Entrecasteaux, sailing along the coastline in search of another French explorer, sighted land south of Cape Leeuwin in 1792. He sailed from this point to the head of the Great Australian Bight and then south to Tasmania.

The first Englishman to sail and explore the coast of South Australia was Lieut. James Grant, who sighted the extreme easterly shores of the region in about 1800. During his voyages around the Australian continent, Matthew Flinders explored the coast of South Australia between January and April of 1802. Flinders named many places along the coast after places in his home county of Lincolnshire. While exploring the area of Encounter Bay, Flinders met a French explorer, Capt. Nicholas Baudin, in his ship the "Le Geographe." Baudin was in the process of charting the coastline of South Australia.

From 1804 to the first settlement in 1836, exploration continued in South Australia by several persons, such as captains Dillon (1815–16), Goold (1827–28), Hart (1831–33), and Jones (1833–34). The most important of these explorations were journeys of Capt. Charles Sturt, who explored the Murray River as it flowed from its source to the mouth in South Australia during 1830. Sturt's glowing reports of the region were influential in the decision to establish a colony. In fact, he recommended the site of present-day Adelaide as the best place for the capital of the colony.

Murray River explorations

THE FIRST SETTLEMENT

South Australia was officially settled as a new British province on December 28, 1836. Proposals for settlement had not been made until 1830, when plans made by the National Colonization Society were placed before the Colonial Office. Later the South Australian Land Company and the South Australian Association also put forward plans. Each proposed to apply the Wakefieldian theory of systematic colonization in a new territory where settlers might enjoy civil and religious liberties, but each in turn was rejected by the government as "too republican." These frustrating negotiations ended in 1834 when an appeal to Parliament brought the South Australian Act, which guaranteed a fixed price for land and ensured that no convicts would be sent to the colony. To make certain that no cost would be borne by the mother country, the Colonial Office was to have charge of all government affairs except land sales, emigration, and fund-raising, which were to be controlled by an independent board of colonization commissioners.

When settlement began, this division of authority led to bitter factional strife, exacerbated by the ill-considered rules of the commissioners in London. A site for the capital, Adelaide, was chosen and soon divided into quickly sold lots, but the survey of the country sections was unduly delayed, and very little food was produced until 1840. Some settlers thrived on speculation in town land and imported supplies, while thousands of poor immigrant families, heedlessly sent out by the commissioners, remained idle. As the commission had ordained a free market for labour, the first governor, Capt. John Hindmarsh, was powerless; the second, Col. George Gawler, exceeded his instructions by employing immigrants on costly public works. Before his unauthorized bills reached London, the commission was already bankrupt, its funds frittered away in "puffing" the new province. However, a parliamentary committee that examined South Australian affairs in 1841 blamed Gawler for the province's disastrous financial state. During the next year, Parliament paid most of the debts, stopped emigration, removed the colonization commissioners, and placed the province wholly under Colonial Office control.

PROGRESS TOWARD SELF-GOVERNMENT

The third governor, Capt. George Grey, was pledged to economize. He arrived to find land surveyed and settlers at work on their country sections. By 1844 the colony was paying its way. Although wool was the chief export, farmers were growing more wheat than the population of 17,000 could consume. In 1845 rich copper discoveries brought a spectacular mining boom that made many settlers independent of the absentee investors who had hitherto financed and directed them from England. Local politics thus gained new interest and became more controversial. The Colonial Office was defied over mining royalties and road taxes, and when it insisted that state aid be offered to all churches, only four denominations accepted it. The vigorous protests of Nonconformists brought an end to government grants in 1851, making South Australia the first part of the British Empire completely to separate church and state. At the same time, four years of heavy immigration increased the population to 67,000 and qualified South Australia for the grant of a partially elected legislative council with the right of drafting a constitution of self-government.

Discovery of copper

The gold rush to Victoria had drawn thousands of South Australians when the first constitution was prepared in 1853. To returning diggers and irate citizens alike the constitution was "a caricature of self-government." Their petitions led to a second constitution, which provided two elective chambers: a House of Assembly with triennial elections, adult male suffrage, secret ballot, and no property qualifications; and a Legislative Council with a modest property franchise to protect landed interests. To the Colonial Office this was "the only thorough Benthamite constitution in the empire," but royal assent was given, and South Australia's first Parliament with responsible government met in 1857.

Political independence seemed to exhaust the colonists' ideas but not their powers of resistance. During the first 30 years of self-government there were 34 changes of ministry and very little experimental legislation.

One important early exception was the Real Property Act (1858), subsequently copied by more than 50 countries and sometimes called the Torrens Title System after its sponsor, Sir Robert Torrens. To make conveyancing simple, quick, and cheap, the act replaced the unwieldy system of title deeds by one of certificates guaranteed by the state. In the courts the act was persistently challenged by Judge Benjamin Boothby, who claimed that it and other colonial enactments, including the constitution, were repugnant to English law. Boothby's stubborn stand soon

led to his removal from the bench. To meet his objections the Imperial Parliament passed the Colonial Laws Validity Act (1865), which, by defining "repugnancy," became the legal keystone of the empire until the Statute of Westminster of 1931.

ECONOMIC EXPANSION

By making titles secure the Real Property Act also simplified mortgaging, especially for wheat growers, whose small freeholds were beginning to force livestock owners farther afield in search of leases. Because pastoral expansion seemed to be checked by a barrier of salt lakes, exploration was stimulated. Slow-moving government parties found gaps between the lakes, and more mobile private explorers passed through them to find vast new pastures. The most notable of these pioneers was John McDouall Stuart, who finally crossed the continent in 1862, paving the way for South Australia's acquisition of the Northern Territory (1863) and for the overland telegraph, which in 1872 linked Adelaide with the ocean cable terminus at Darwin. Other explorers found traces of minerals. In 1860 the discovery of rich copper lodes near Moonta aroused hopes of general prosperity and encouraged many pastoralists to move their stock beyond the salt lakes. Disaster followed, for the country was poorly watered; in the drought of 1864–65, thousands of sheep and cattle perished. As the drought did not extend very far to the south, Parliament was easily persuaded that all the southern areas were safe for agriculture.

1864 drought

During the gold rushes South Australian grain had fed the diggers in Victoria and followed them into New South Wales and Queensland. From 1853 steamboats carried flour far up the Murray and Darling rivers and returned with cargoes valuable enough to justify a railway and new port at Encounter Bay. In the mid-1860s an even greater market for grain was found in England. To the Parliament in Adelaide the prospect seemed brighter for wheat than for wool. In 1869 the Strangways Act introduced "credit land sales," by which the land hungry might acquire freeholds on expired pastoral leases on easy terms. A decade of prosperity followed. Immigration, heavily subsidized by the state, provided agricultural recruits and labour for the government's new railways. Each year brought new records in cultivation; yet South Australia, with one family in three on its farms, depended too much on agriculture for its economic well-being.

Hope and inexperience carried the farms into unsafe districts, and old overworked districts became "wheat-sick." Though prosperity lasted until 1884, two droughts heralded collapse. Bankruptcies mounted as prices fell, banks failed, and copper mines showed signs of exhaustion. Average yields of 15 bushels per acre dropped to less than two bushels. Long before the economic depression ended, South Australia lost its lead in wheat growing to Victoria and New South Wales and fell behind Queensland in population. Numerous families migrated to eastern states, and many more were attracted to the towns even though urban industry had been neglected and employment was insecure. Demand for liberal reform stirred Parliament into action. Land in safe districts was offered on easy terms to homesteaders and workingmen. Promises of compensation encouraged pastoralists to improve their ranges and multiply their flocks. Water conservation projects were started; southeastern swamplands were drained; and irrigation and village settlements were begun on the Murray River. The opening of Roseworthy Agricultural College introduced farmers to the use of superphosphates, while scientific techniques began to produce better strains of wheat, freedom from disease, systematic fallowing, and more varied crops. Assisted immigration stopped, but railway building continued. To avoid further borrowing in London—the public debt was already close to £50 per head—in 1884 the government introduced for the first time in Australia direct taxation on incomes and land. When this proved insufficient, tariffs were sharply increased to curtail imports and foster urban industry. The opening of Broken Hill in New South Wales helped South Australia by providing employment for its miners, freight for its railways, and smelting works at Port Pirie, but these gains were at first offset by heavy migration to Western Australian goldfields. The high levels of production in 1884 were not regained again until 1906. Although the population had passed 300,000 by the mid-1880s, it did not reach 400,000 until 1910.

Roseworthy Agricultural College

POLITICAL PARTIES

The most marked advances of the depression years were in politics. Growing discontent brought the eight-hour working day (1884), payment of members of Parliament (1887), workmen's compensation (1889), industrial arbitration and votes for women (1894), and the first Australian use of a referendum (1895). Primary education, which had become compulsory and secular in 1875, was made free in 1891. The depression years also hastened South Australia's progress toward federation. The tentative beginnings of a Labor Party during the 1890s forced its opponents into closer alliances and more stable ministries. Leading politicians, perplexed by inland tariff barriers, problems at Murray River irrigation, and annual deficits in the Northern Territory, were eager for intercolonial cooperation. In the federal conventions South Australians played a leading part. Later, when the ablest leaders were drawn into the federal Parliament, local politics became more subdued. The Labor Party grew in strength and in 1905 took office in a coalition government. Its main concern was the reform of unequal electoral constituencies: Adelaide, with half the population, had only one-third of the seats in Parliament. Reform was resisted by the Legislative Council, whose abolition, though advocated by Labor, was not popular with electors. Nevertheless, the Labor Party did form occasional governments, most of them ending in dissension.

The years following World War I brought the organization of the Farmers and Settlers' League, the Progressive Country Party, the Nationalists, and the Liberal Union. From these emerged the Liberal Federation and Country Party Alliance, which by 1933 forced Labor into opposition except in 1965–68.

ECONOMIC DEPRESSION

During the first decade of federation South Australia seemed to prosper. Its share of federal customs revenue paid the annual interest on the public debt, while bumper harvests and rising prices renewed enthusiasm for agriculture. Aided by new railways and superphosphates, farmers opened fresh wheat belts on Eyre Peninsula and in the southeast. Assisted immigration was resumed. Valuable iron-ore deposits at Iron Knob were linked by rail with the new port of Whyalla. Port Adelaide was enlarged and an outer harbour added for mail steamers. Electric trams and suburban railways revived land speculation, while government high schools and free secondary education attracted families to the city.

The tide turned in 1910. Although the costly Northern Territory passed under commonwealth control, a new agreement for distributing federal revenue lowered South Australia's income. From 1914 to 1926 the government had to budget for eight deficits. State taxation quadrupled and government borrowing increased the public debt to £A136 per head (compared with Victoria's £A88). Large numbers of workers and some entire industries migrated each year to the eastern states where bigger markets, cheaper power, and lower taxes offered better opportunities. After 1928, four dry years coincided with worldwide depression to reduce the state to a worse plight than any of its neighbours. In the winter of 1931 more than 70,000 unemployed out of a population of 575,000 were dependent on government relief. Thousands of the unemployed sought work in the country, enabling a record crop of 8,000,000 acres (3,237,600 hectares) to be sown, although depressed prices gave farmers an average of less than 20 shillings per acre for their harvest.

Public debt

Appeals for federal aid led to the establishment of a Commonwealth Grants Commission and brought substantial assistance earmarked for developmental works. However, most politicians still looked to the land for salvation. To the auditor-general, W. Wainwright, this dependence on rural output seemed disastrous. He advocated more sec-

ondary industry; by judicious government guarantees to suitable enterprises the state would attract overseas investment and unlock its own private capital tied up in land. The threatened departure of a large motor-body-building industry forced the government to support Wainwright's plan. Certain wharf dues were abolished, and company tax was halved. The first large project was the planting of pine forests in the southeast, for the state had always depended on imported building timber. Guarantees were made to the cement and chemical industries at Port Adelaide. Elsewhere, industries were encouraged to make equipment for the expansion of roads, water supply, sewerage, and building.

To supplement private efforts the government built large reservoirs for Adelaide, expanded technical education, and created a trust for housing industrial workers.

WORLD WAR II AND AFTER

In 1938 Thomas Playford began his record term of 26 years as premier, and his accession infused new life into industrial policy. Some of his plans had strategic importance and were implemented during World War II. The Broken Hill Proprietary's new blast furnace and shipbuilding yard led to great expansion at Whyalla which had to be supplied with water by pipeline from the distant Murray River. Near Adelaide large munition works built by the commonwealth government were taken after World War II by overseas firms, some for new industries and others for the development of long-range weapons. The need for an isolated testing site for the weapons brought the town of Woomera into existence, its water piped from the Murray. In 1946 Playford's government took over the private Adelaide Electric Supply Company, turning it into an electricity trust that cut prices and greatly expanded consumption. To make the state less dependent on imported fuels, the government opened a brown coal mine at Leigh Creek, and a large supplementary power station soon followed at Port Augusta. The postwar years also brought great rural expansion. Scientific testing of inferior soils revealed the absence of trace elements, which, when restored, gave fertility to much unused scrubland. High returns for wool and barley freed farmers from the vagaries of wheat markets, while road transport, diesel rail engines, and bulk handling of grain helped to produce new records in cultivation, pasture improvement, and sheep numbers.

Postwar rural expansion

The most spectacular expansion, however, was in Adelaide. Its new and growing factories attracted a great influx of labour, which in turn demanded new homes and services. The city itself became independent on water from the Murray. As the Adelaide Plain rapidly filled with buildings, a new satellite town was created nearby at Elizabeth and other new southern suburbs.

In 1973 the South Australian Parliament underwent a fundamental reform as the special voting franchise was abolished and replaced by an 18-years-of-age adult requirement for all voters. Also under this reform, proportional representation was introduced for parliamentary elections. The first election held under these reforms occurred in 1975.

The South Australian Land Commission was established in 1973 to stabilize the price of urban land and stimulate urban development through land acquisition and management. Financial assistance for land acquisition was provided through the Urban and Regional Development Act of 1974. In 1980 the name of the commission was changed to the South Australian Urban Land Trust and its role was altered, transforming it to an urban land bank.

(D.H.Pe./Ed.)

TASMANIA

Location and general character of the state

The island state of the Commonwealth of Australia, Tasmania, lies about 150 miles (240 kilometres) south of the State of Victoria, from which it is separated by the relatively shallow Bass Strait. Physically, Tasmania forms part of the Great Dividing Range; culturally, it is part of Melbourne's metropolitan sphere of influence. The state comprises a main island called Tasmania; Bruny Island, nestling close to the southeast coast near Hobart, the capital; King and Flinders islands in Bass Strait; numerous smaller islands off the coast of the main island; and sub-Antarctic Macquarie Island, some 1,000 miles to the southeast. The main island is roughly heart-shaped, and its latitude and climate are broadly comparable to those of northern California and northwestern Spain. Its 26,383 square miles (68,332 square kilometres), although slightly larger than the area of Sri Lanka, comprise less than 1 percent of Australia.

The state owes its name to the Dutch navigator-explorer Abel Tasman, the first European to discover the island, in 1642, though until 1856 it was known as Van Diemen's Land, after the governor of the East Indies who had sent Tasman on his voyage of exploration. The island of Tasmania contains some of the most spectacular mountain, lake, and coastal scenery in the continent, has much of the country's hydroelectric-power potentiality, and displays a great diversity of natural resources. Throughout much of its history, Tasmania has experienced a net out-migration that has deprived the state of a wealth of talent but has contributed, perhaps disproportionately, to the leadership of the nation. Although insularity renders much of the political, economic, and social life distinctive, proximity to Melbourne and modern air travel make the island less isolated and more progressive than is often assumed in other states.

Physical and human geography

THE LAND

Relief. Tasmania is essentially a mountainous island. In the west, where the highest peak on the island, Mt. Ossa, reaches 5,305 feet (1,617 metres), the landscape comprises several parallel northwest–southeast ridges and valleys; eastward lies a series of plateaus at various altitudes, the highest point being Ben Lomond at 5,160 feet (1,573 metres) in the northeast. But the dominant feature of Tasmanian geography is the glaciated, lake-studded Central Plateau, bounded on the north and east by a 2,000-foot fault scarp and sloping gently southeastward from 3,500 to 2,000 feet (1,100 to 600 metres). Much of the east is made up of a low, dissected plateau averaging about 1,200 feet (365 metres). Extensive plains are confined to the far northwest, the lower South Esk River Valley, and the northeast. The Bass Strait islands represent outliers of the northern coastal platforms. In the southeast, postglacial submergence has produced one of the finest drowned coastlines in the world.

Major river systems

Drainage. There are two major river systems—the Derwent in the southeast and the South Esk in the northeast—many small systems, especially westward flowing to the west coast, and innumerable lakes. The Central Plateau is studded with more than 4,000 lakes in a landscape similar to northern Canada and Finland; almost all, including Great Lake, are shallow. Lake St. Clair, the deepest lake in Australia (over 700 feet [215 metres]), is a piedmont lake similar to the lakes of northern Italy. Several lakes, notably Lake King William, have been created by hydroelectric-power development.

Soils. Most Tasmanian soils are leached, acidic, poorly drained, high in humus, and low in fertility. Least fertile and most extensive are the soils, especially the moor peats, of the west and northeast. Fertile areas occur extensively in the northwest and locally elsewhere, notably in the northeast. Brown earths occupy the drier areas east of the Central Plateau; black earths, the southeast; and alluvial soils, the narrow valley floors to the east. Other fertile soils are those of former swamps in the far northwest and the Bass Strait islands.

Climate. Tasmania, located in the mid-latitude westerly wind belt and dominated by southern maritime air masses, enjoys a moist, equable climate, with mild to warm

summers, mild winters in most settled areas, and rain during all seasons. Yet the occasional incursion, in summer, of tropical continental air masses and, in spring and autumn, of tropical Tasman air masses along the east coast, together with the mountainous surface, results in greater annual rainfall variability, seasonal moisture deficiencies, and temperature changes than are the norm in similar climates elsewhere. Climatic averages thus mask considerable variations. The average annual precipitation exceeds 100 inches (2,500 millimetres) on the western ranges and declines eastward to under 20 inches in some places; along the north coast it exceeds 30 inches in all locations. The seasonal incidence in the north and west is greatest in winter, and in the south and east it is greatest in spring. Summer rainfall may vary markedly from year to year, especially in the drier east. Mean January temperatures are higher in the north and east than elsewhere, reaching 64° F (18° C) at Launceston; mean July temperatures are 46° to 49° F (8° to 9° C) in all coastal stations, declining sharply with altitude. Almost everywhere, the mean daily range of temperature exceeds the mean annual range.

Rainfall and temperature ranges

Plant and animal life. In general, the wettest areas have temperate rain forest, especially the beech or myrtle; areas having 30 to 60 inches of rain annually carry good-quality eucalypt forest; and the drier areas carry poor-quality eucalypt forest or savanna woodland. In certain areas, particularly in the forest of the south and southwest, an almost impenetrable thicket known as horizontal scrub develops. This is caused by the growth of a remarkable small tree called the horizontal (*Anodopetalum biglandulosum*). The slender trunk of the tree falls over under its own weight, and from it branches arise that behave in the same way. On the mountain plateaus are found many plants having subantarctic affinities. These include Tasmania's only deciduous tree or shrub, myrtle beech, and certain cushion plants. Rain forest would be more widespread in the absence of fires. Other vegetation includes the sedgeland along the west coast, the high moorlands, and the coastal heaths of the far northwest, the far northeast, and the Bass Strait islands.

Animal life is virtually absent from the true rain forest but abounds in the extensive eucalypt forest. The avian fauna includes the honey eaters, the black jay, black magpie, the black cockatoo, and various parrots. Among the mammals are the wallaby, brush and ringtail possum, and the marsupial carnivores—the native cat, the tiger cat, the Tasmanian devil, and the rare thylacine. The sedgeland and moorland are distinctive for the wombat, and the coastal heath for the green rosella, the platypus, and the short-nosed echidna.

Mammals

Settlement patterns. The inhospitable terrain of much of Tasmania naturally has had much influence on settlement patterns. The nomadic original Tasmanians have left a few archaeological traces, including geometric designs on exposed rock surfaces and evidence of cremations and corroborees, or ceremonial gatherings. The European settler has left his imprint according to economic activity, whether it be in the mining settlements of the west; the intensive cropping or dairying of the northern coastal belt, or of the southeast lowlands; the intensive beef fattening of the northwestern tip; or the dryland sheep farming of most of the eastern sector. The southwestern segment of the island is scarcely utilized by humans.

Traditional regions. A widely recognized regionalism bears witness to the diversity of the Tasmanian landscape. In the north the distinctive regions are the far northwest around Smithton; the northwest coast extending along the north coast west of Port Sorell; the Tamar Valley; the northeast around Scottsdale and Lilydale; and the far northeast from Ringarooma eastward. In central Tasmania the regions are the west coast, usually comprising only the Queenstown and Rosebery area; the Central Plateau and the Derwent Valley; the midlands, comprising the area east of the Central Plateau between Hobart and Launceston; and the east coast. Southern regions are the southwest, the Huon Valley, and the southeast. Numerous subdivisions, such as the north midlands comprising the South Esk plains around Launceston and the lower midlands around Tunnack, are also recognized.

Rural and urban settlement. While the pattern of rural settlement differs strikingly by region, the basic contrasts stem from farm size and the length of settlement. In general, the older settled areas, including the midlands, the central north, the east coast, and the southeast, have larger properties, dispersed homesteads, buildings often of stone or brick, architecture that typically is early Georgian, and nucleated villages laid out on a grid. Higher rainfall areas settled since 1850, chiefly the northwest, the northeast, and the Huon Valley, have generally small farms, buildings mainly of weatherboard, and houses and villages mainly aligned along roads. In all areas, villages normally contain a post office and store, but most villages also have a primary school, public hall, church, service station, and transport services.

Rural building and town patterns

Tasmania is less urbanized than other Australian states and exhibits a dispersed pattern of peripheral growth that falls into three urban regions. Hobart, located at the foot of Mt. Wellington on the Derwent estuary, is not only the capital city, the premier port, and leading industrial centre but the metropolitan focus for the southeast, the upper Derwent, the Central Plateau, the midlands south of Woodbury, and the east coast south of Swansea. Launceston, at the head of the Tamar Valley, is a secondary administrative centre and hub of the state's transport network, with important textile and engineering industries. Its sphere of influence extends westward to Elizabeth Town and incorporates the entire north and northeast. The third region centres on both Burnie and Devonport; it includes the northwest and the west coast. Significantly, the Hobart region contains only one full-fledged town; the Launceston region, three; and the Burnie–Devonport region, five. Each, however, has six or seven minor towns.

THE PEOPLE

Ethnic and religious groups. The original Tasmanians were an anthropologically interesting Negritoid people, with the widest nasal index ever recorded and shorter and broader heads than the Aboriginal peoples of the continental mainland. They may originally have drifted across from the mainland or arrived from as far as the New Hebrides, several thousand miles to the northeast. Estimates of their numbers at the onset of European settlement vary considerably, some investigators claim a population of about 1,200, but most estimates range from 3,000 to 5,000 among several tribes.

The Aboriginal Tasmanians

The last full-blooded Tasmanian on the island died in 1876. As a consequence of the "black war" and attacks from white outlaws, they were removed in the interim to Flinders Island, off the northeast tip of Tasmania, where the survivors languished and died. Within Australia as a whole, the population of Tasmania has a distinctive composition both by birthplace and by nationality. Of all the Australian states Tasmania has the highest proportion born in Australia, the lowest proportion born in the British Isles, the lowest proportion born in continental Europe, and the lowest proportion born elsewhere in the world. Nationality is thus overwhelmingly British by descent, the proportion being higher than that of any other state.

The origins and nationality of the population are reflected in its religious affiliations. Of the four major denominations, Tasmania has, relative to its population, more Anglicans and Methodists but fewer Roman Catholics and Presbyterians than Australia as a whole. In the postwar years, the only major denomination to show a relative increase has been Roman Catholicism, partly because of immigration from Catholic countries and partly because of stringent religious beliefs regarding the use of modern birth-control methods.

Contemporary demography. Tasmania continues to display a higher birth rate than most other states, but, as in Australia generally, crude birth rates have tended to fall, average birth rates declining in the decades of the middle and late 20th century. Birth rates are lower in the cities than in the smaller towns and rural areas. Death rates remain fairly constant; partly because the ratio of children to adults in the population is high, death rates tend to be among the lowest in Australia. Infant mortality rates are also among the lowest.

Birth and death rates and migratory patterns

After World War II Tasmania experienced a net in-migration of population from other states and overseas, but since 1959 there has been, in most years, a resumption of net out-migration to the mainland, particularly of young persons, chiefly men, entering the work force. This out-migration has been accompanied by a pronounced internal rural-to-urban migration, largely through the increasing scale of farming and the substitution of capital for labour in the farming sector. As a result, Tasmania differs from the mainland in having the smallest proportion of population in the labour force and the lowest growth rate of any state.

Since more than two-fifths of the island—comprising areas in the west and the south—is too rugged and too wet for agriculture, the population is largely confined to the north and the southeast, with the sparsely settled midlands region connecting them with an isolated cluster on the west coast. Hobart has one-third of the state's population in its metropolitan area and nearly one-half within its sphere of influence; the rest of the people are distributed more or less equally between the respective spheres of influence of Launceston and the Burnie–Devonport area. No other Australian state has so equitable a balance of population among the capital city, other urban centres, and the rural areas, the nearest equivalent being Queensland. One-quarter of the population live in centres of less than 1,000 inhabitants and on farms.

THE ECONOMY

The Tasmanian economy enjoys many comparative advantages, notably in its mineral, water, and tourist resources, in the diversity of the economic activity, and in fairly stable labour relations. It suffers markedly, however, from the small scale of much of its resource base, from restricted local markets, and from problems of transport to external markets. About one-eighth of the work force is in the primary sector (the production of raw agricultural and mineral resources), one-quarter in the secondary (manufacturing and processing), and the remainder in the tertiary (services).

Resources and primary industries. Resources are highly diversified. Important mineral deposits include iron at Savage River, zinc, lead, and copper at Rosebery, copper at Queenstown, and tin and tungsten in the northeast; poor-quality coal abounds in the Fingal Valley but is of declining importance. The heavy, well-distributed rainfall and the rugged terrain in the centre and the west facilitate hydroelectric-power development. The western forests furnish not only excellent hardwoods but also the raw material for pulp-and-paper industries, while the drier eastern forests yield wood chips. Dairying and mixed farming characterize the wetter north; extensive sheep grazing, the drier midlands and the east coast; and specialized horticulture, notably for apples and hops, the southeast. Apples and pears are also locally important in the Tamar and Mersey valleys, potatoes and canning peas in the northwest, and vegetables in the northeast. Fisheries occur in all coastal waters, the catch mainly comprising crayfish, abalone, shark, barracouta, and scallops. A tourist potential lies in variety of landscape.

Agriculture and fishing

The high degree of diversification in resource development is reflected in the relative contribution of each primary industry to the net value of primary production: mining generally contributes about one-quarter, dairying one-fifth, wool growing one-sixth, fruit growing one-seventh, and forestry one-eighth. Iron ore mined by the opencut method at Savage River is converted to slurry, piped to Port Latta near Stanley, pelletized, and exported to Japan. Copper ore mined underground at Queenstown and Rosebery is shipped directly to Japan, Tasmania accounting for nearly one-sixth of the total Australian copper output. Tin production fluctuates with market conditions. Butter, wool, and fruit are exported mainly to Great Britain. Tasmanian hops meet almost all of Australia's requirements. In timber production, Tasmania furnishes about one-sixth of the Australian total; wood chips are exported to Japan. The fishing industry depends largely on exports, which are fairly evenly distributed between mainland and overseas markets.

Manufacturing. Secondary industries are twice as important in net value of production as are the primary industries. Foremost among them are the electrometallurgical and electrochemical specialties dependent on cheap, bulk power provided by the Hydro-Electric Commission. The resultant industries include the electrolytic refinery in Risdon, which treats zinc concentrates from Broken Hill (New South Wales) and Rosebery, the aluminum and ferro-manganese plants at Bell Bay, near George Town, pulp-and-paper mills in Burnie and Boyer near New Norfolk, a pulp mill in Port Huon, and a cement plant in Railton. Other important industries include the manufacture of chocolate near Hobart, titanium pigments (Burnie), textiles (Launceston and Devonport), carpets (Devonport), and alginate from sea kelp (Orford).

Administration of the economy. Government intervention in economic matters takes place largely at the federal level in the primary industries and at the state level in the secondary industries. The Directorate of Industrial Development seeks to foster manufacturing growth by the provision of financial and other assistance. The state government also is active in promoting tourism and trade. Tourist development is favoured by Tasmania's highly diversified and spectacular scenery, its equable climate, its coastal, lake, and mountain recreation areas, and its colonial heritage of Georgian architecture. As a result, Tasmania is visited by more than 100,000 tourists each year. The private sector supports well-established chambers of commerce, a chamber of manufacturers, a tourist council, and more than 100 trade unions.

Transportation. Given its island setting and dispersed pattern of development, transportation, both internal and external, is especially important to Tasmania. The Transport Commission regulates and, where necessary, provides internal transport. Tasmania has the highest density of roads per square mile of any Australian state. The government railways comprise more than 500 miles (800 kilometres) of line. Of the intrastate freight movement, the majority is by road, about one-third by rail, and about one-tenth by sea; virtually all passenger movement is by road. Almost all interstate and overseas freight moves by sea and almost all passengers by air. Of the major seaports, Hobart has about one-third of the trade and Launceston, Burnie, and Devonport each about one-fifth; port administration is decentralized. Minor ports are Stanley, Currie, and Strahan. Of the airports, Hobart handles the most passengers (with Launceston close behind) and Launceston the most freight. Regularly scheduled air services also operate from Devonport, Wynyard, King Island, and Flinders Island.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government and politics. The state parliament comprises a House of Assembly and a Legislative Council, the latter by tradition a largely nonparty house. The system of elections for the House of Assembly is proportional representation by the single transferable vote; the system for the Legislative Council is the preferential system, with an obligation to record preferences, used for the federal House of Representatives. The main political parties active in Tasmania are the Australian Labor Party and The Liberal Party of Australia; the Australian Centre Party affiliated with The Australian Country Party dates from 1966. The Labor Party was in power from 1934 to 1969, when it was replaced by a Liberal–Centre party coalition; in May 1972 the Labor Party once more regained office. Executive government is by the Cabinet system, the governor representing the British monarch and the Executive Council of Ministers of State giving Cabinet decisions where necessary to legal form. Local government is exercised through cities and municipalities, which comprise the 49 divisions of the state.

Legislative, executive, and judicial institutions

Although the state now administers some of the lower courts, most are still administered by municipal authorities, a feature unique to Tasmania; in other states the administration is vested in a state department. Courts of petty session have jurisdiction over all summary offenses and certain indictable offenses at the option of the defendant. Minor civil proceedings are dealt with by courts of

request in the cities and some municipalities or by courts of general sessions. The Supreme Court of Tasmania sits regularly in Hobart, Launceston, and Burnie; it has jurisdiction over all causes save those reserved to the high court of Australia under the commonwealth constitution. The high court normally sits in Hobart each year, but Tasmanian cases are also heard in Melbourne and Sydney. Children's courts have jurisdiction over persons under the age of 17.

Social welfare. Wages and working conditions of Tasmanian employees are regulated either by awards of the Commonwealth Conciliation and Arbitration Commission or by state wages boards. Tasmania tends to have the lowest average weekly earnings per employed male of all the states except Queensland and, usually, South Australia. That weekly earnings are not the lowest is in line with the cost of living, which is relatively high, partly because of freight charges on imported goods. Although the standard of public health is good, there is a high incidence of hydatids in some rural areas, and goiter is endemic locally. Social status, as in Australia generally, derives primarily from occupation, but Tasmanians accord a lower ranking to professionals and a higher ranking to businessmen than do Australians as a whole. The standing and numerical importance of small and medium property owners is reflected in the relatively conservative tendency of the two main political parties. There are no great extremes of wealth or poverty.

The general standards of living

Social-service benefits provided by the Commonwealth include maternity allowances; child-care payments; unemployment, sickness, and special benefits; age, invalid, and widows' pensions; and funeral benefits. The commonwealth also provides paid employment for the disabled, a rehabilitation service, and subsidies for aged persons' homes. The state Department of Social Welfare provides assistance to deserted wives or husbands with children, wives with husbands in prison, and neglected or deserted children. It also maintains homes for maladjusted and delinquent children and wards of the state.

Education. School attendance is compulsory for all children between the ages of six and 16. Government-supported schools include infant, primary (some with preschool facilities), area, district, and high schools (nonselective, comprehensive, mostly coeducational), together with matriculation colleges (a Tasmanian innovation) and special schools. Independent (nongovernment) schools, which enroll about one-sixth of the school population, are mostly controlled by religious denominations, the great majority being Roman Catholic; since 1967 independent schools have received state aid. Institutions of higher learning include technical colleges, teachers colleges at Hobart and Launceston, the University of Tasmania (founded 1890) at Hobart, and the College of Advanced Education (opened 1972), providing technical, education, liberal arts, and professional courses.

Health. The state government controls directly or through hospital boards the general hospitals at Hobart, Launceston, Latrobe, and Burnie–Wynyard; numerous district and district nursing hospitals; a mental hospital at New Norfolk; maternity hospitals at Hobart and Launceston; a chest hospital at New Town; and hospitals for the aged at Hobart, Launceston, and Wynyard. It also provides district medical officers for the more remote areas, a district nursing service, a school medical service, a school dental-health service for which it trains dental nurses, and a child-health service. Private institutions include seven hospitals and numerous nursing homes. Annual X-ray examinations for adults are compulsory by law. Public water supplies are fluoridated at Hobart, Launceston, and Beaconsfield.

Housing. Three-quarters of all Tasmanian houses are owner occupied, and two-thirds are built of weatherboard; apartments make up less than one-tenth of all dwellings. The Commonwealth Housing Commission administers the homes-savings-grant plan, which makes a gift to young persons with certain minimum savings for a first home, a housing-loans-insurance plan, and assistance to certain former members of the armed forces. The State Housing Commission caters to the lower income groups, providing mainly three-bedroom timber units for families to rent or buy and apartments for elderly persons to rent. Rental rebates are allowed as necessary. Advances for home building are made available by the Agricultural Bank of Tasmania and cooperative building societies.

Public aid for housing

CULTURAL LIFE

The arts. For the smallness and dispersion of its population, Tasmania has a remarkably vigorous cultural life. At the amateur level, there are numerous musical groups, ranging from the full orchestra to the ensemble, as well as several choral societies and repertory companies. The College of Advanced Education incorporates a conservatorium of music and a school of art. The Australian Broadcasting Commission, with financial support from the Hobart and Launceston city councils, maintains the Tasmanian Symphony Orchestra, which gives regular concerts in the main centres, often with visiting artists from the mainland or overseas. The National Theatre and Fine Arts Society of Tasmania, in association with the Elizabethan Theatre Trust, is responsible for bringing drama and opera from the mainland to the Theatre Royal in Hobart, Australia's oldest theatre (1834), and the National Theatre in Launceston. Both cities have museums and art galleries that exhibit paintings, pottery, and sculpture. Tasmania has well-established film festivals and eisteddfods (Welsh poetry festivals); in 1972 it also held its first arts festival. At Hobart's Battery Point, Narryna, a Georgian town house dating from 1839, has been preserved as the Van Diemen's Land Folk Museum, with furniture and furnishings of the early 19th century. Other Georgian houses that have been restored for public benefit include Franklin House and Entally House, both near Launceston, and Runnymede, at New Town, Hobart.

Library services. The state provides lending-library services to adults and children, including a central service with film and recorded music in Hobart, regional services in Launceston and Burnie, and country services in almost all municipalities. Bookmobiles operating from Hobart, Launceston, and Burnie serve schools and other institutions as well as rural areas that lack library facilities. A state reference library and the state archives are located in Hobart.

The communications media. Tasmania has daily newspapers published in Hobart, Launceston, and Burnie and receives national dailies from Sydney and Melbourne. Each of the smaller centres also publishes a weekend paper, and weeklies of regional interest are published in Queenstown, Smithton, George Town, Scottsdale, New Norfolk, and Huonville.

In Tasmania, as throughout Australia, broadcasting and television services are produced by both the Australian Broadcasting Commission and by commercial transmitters. National radio stations operate from Hobart, Launceston, and Queenstown, while commercial radio stations relay from Hobart, Launceston, Devonport, Burnie, Queenstown, and Scottsdale. There are both national and commercial television stations in Hobart and Launceston. Tasmania's rugged relief necessitates the provision of an elaborate network of translator stations to ensure adequate reception in all districts. The Australian Broadcasting Control Board exercises control in certain matters over the commercial private-enterprise services. The island is connected with the mainland by a broad-band radio link that makes it possible for television programs to be relayed directly from other states.

(P.Sc.)

History

EARLY EXPLORATION AND SETTLEMENT

The Aborigines of Tasmania, like the Aborigines of the Australian mainland, were hunter-gatherers when first contacted by Europeans during the late 18th century. They grew no crops, raised no domesticated animals, had no metal tools, and possessed no system of writing. They had adapted for many years to the Tasmanian environment, prior to their confrontation with 19th-century Europeans and the metal-gunpowder technology. Radiocarbon dating from two sites in northwest Tasmania has shown that

Aboriginal people occupied the region about 8,000 years ago.

Origin of the Aborigines

Two main theories of their origin are held: (1) They formed the original population of eastern coastal Australia; then, yielding to Australoid immigrants, they crossed into Tasmania. (This view implies a land corridor or shorter stretches of ocean and also winds and currents in the opposite direction to those now prevailing.) (2) They drifted to Tasmania in canoes or rafts from the New Hebrides region where there are similar Negritoid types; winds and currents favour such voyages as well as possible landings on the Queensland coast.

The most reliable assessment of Tasmanian population before European settlement in 1803 is 2,000 or less; the last full blood is recorded as having died in 1876. This peaceful people became fearful and resentful when faced with dispossession and with cruelty on the part of some European convicts and settlers. By 1826 the clash of cultures was officially recognized; by 1831 the remaining Aborigines were removed first to Gun Carriage Island and then to Flinders Island, where, in spite of care, they languished and died out.

The Tasmanians were organized as five tribes, each of which spoke its own dialect or language. They usually travelled in small groups, gathering food and hunting with sticks and clubs; unlike mainland people, they had neither spear-thrower nor boomerang. They held corroborees, cremated the dead, scarred and red-ochred their bodies, and engraved lines and circles on rocks.

After the initial exploration undertaken by Abel Tasman, Tasmania (then Van Diemen's Land) was explored by the French and British navigators Marion Dufresne (1772), Tobias Furneaux (1773), James Cook (1777), William Bligh (1788 and 1792), Bruni d'Entrecasteaux (1792–93), John Hayes (1793), George Bass (1798), Nicolas Baudin (1800 and 1802), and Matthew Flinders (1798 and 1802). In 1803, a party of 49 persons, led by John Bowen, settled at Risdon Cove. The settlement was abandoned and relocated at the new settlement of Hobart in 1804. The British settlement at Hobart was followed by another that was to become Launceston (1806); most of the first settlers, both free and convict, were transferred from Norfolk Island. The settlement, under resident lieutenant governors, was governed from New South Wales. Free immigrants were attracted by land grants and by the development of the sheep and whaling industries.

INDEPENDENT SETTLEMENT

Van Diemen's Land was made a colony by order in council in 1825, and henceforward its government was practically separated from that of New South Wales and until 1850 was exercised through nominated executive and legislative councils. Law and order and a sound administration were introduced by Lieutenant Governor William Sorell (1817–24) and were developed by Lieutenant Governor George Arthur (1824–36), with wider powers, into a detailed and efficient control.

"Black war"

In this period, despite the depredations of the outlaw bushrangers and the "black war," which virtually extinguished the Aboriginal people, great material progress was made. In 1828 the total white population was 17,000, of whom 7,500 were convicts under restraint, though a majority were assigned as servants to free settlers. Grain was exported regularly to New South Wales, while rising wool prices brought general prosperity and stimulated much speculation in land. The adoption of the probation system for convicts in 1840 marked a change in British policy on transportation, depriving free settlers of assigned servants and transforming the colony into a penal settlement. The influx of population was rapid until 1847, growing to 70,000, but the ratio of free to unfree was reversed. In the late 1840s the boom gave way to an economic depression, and the colonial government faced a deficit, which local opinion attributed to the cost of police and jails. Belatedly, the home authorities offered some relief but not before public opinion was roused to demand representative institutions and the cessation of transportation of British convicts. Representatives were first elected to the Legislative Council in 1851, and the transportation policy ceased in 1853.

The constitution was settled more definitely in 1856 with the election of a two-chamber Parliament and with the appointment of the first responsible ministry. From 1856, the colony was known as Tasmania.

The gold discoveries in Victoria in 1851 caused inflation and labour shortage in Tasmania, and the economy was unable to support the strain. The whaling industry declined and with it shipbuilding. The adoption of a protectionist policy by Victoria further injured Tasmanian manufactures. After 1857 a prolonged depression, lasting 25 years, was marked by deficits, reduction in services, opposition to all forms of taxation, political feuds, and frequent changes in ministries. Under pressure of competition from continental Australia, wheat production declined to its present insignificance.

After 1880 economic conditions improved, largely because mining industries were opened up in the west and northeast. The hardwood forests were exploited, and fruit growing in the south became the basis of small manufacturing and export industries. Railways, roads, and harbour facilities were developed, while relative political stability was achieved, particularly during the Fysh ministry (1887–92). After the recession following on the failure of the Bank of Van Diemen's Land in 1891, there was from 1894 to 1899 a slow recovery during Sir Edward Braddon's ministry. In the 1890s a majority of Tasmanians supported the movement that ended in 1901 with Australian federation. Economic development slowed down after 1910 as the mining boom passed, and during the next 25 years Tasmania was relatively depressed, the worst years being 1922–26 and 1931–35. Population grew slowly, the birth rate fell, and the exodus of the young and more vigorous people was resumed.

Labor Party

State politics entered a new phase with the founding of the Labor Party in 1903. Labor first took office in 1909 and was again returned to power in 1914. From that time both the Labor and the Liberal (Nationalist) parties sponsored social and industrial legislation. All the administrations faced financial difficulties, which were not resolved until in 1933 the commonwealth government set up the Grants Commission, through which special financial assistance is given to the state. This enabled Tasmania to bring the level of its social services up to the national average. After 1942 uniform taxation throughout the commonwealth and virtual commonwealth control of the main sources of revenue, together with the provision of reimbursement grants to the states, favoured Tasmania, which received more per capita in such grants than any other state. With increasing revenue, supported by loan funds backed by the commonwealth, Tasmania has invested since 1950 in a large capital works program, especially in the development of hydroelectric power, which in turn has stimulated the growth of much secondary industry.

A Labor government was formed in 1934 and won eight successive elections, continuing without a break to govern the state until the 1969 election when it was replaced by a Liberal–Centre Party coalition. Liberal–Centre Party rule ceased in 1972, following Cabinet resignations, and the Labor Party returned to power in the elections of that year. The Labor Party has remained in power since 1972, winning majorities in the House of Assembly in 1976 and 1979.

During the mid-20th century the Tasmanian economy went through a transformation. Secondary industry expanded because of increases in hydroelectric energy. Some of the major industrial operations established since 1945 include the production of aluminum at Bell Bay in 1955, the discovery of uranium at Mt. Balfour and Royal George the same year, the Savage River mining operations along the west coast and the associated iron-ore pelletizing plant at Point Latta, and acid production for the processing of pyrites at Burnie in 1970.

In February 1980, the state government approved a new system of government by consensus in which the opposition and the Legislative Council would be allowed a voice in the governmental decision-making process.

(A.P.E./W.A.T./Ed.)

VICTORIA

Among the Australian states, Victoria is second to New South Wales in terms of population, production, and party strengths in federal politics, but, since 1945, as the traditional financial hub of Australia, has sustained the faster rate of economic advancement. Thousands of immigrants have arrived, and manufacturing industry has expanded to the point at which the economy is now broadly and soundly based. Two recent developments—the exploitation of the gas and oil fields of Bass Strait, which will provide both cheap fuel and state revenues, and an integrated steel plant—were, in the late 20th century, further narrowing the economic gap between Victoria and New South Wales.

Victoria, which lies at the southeastern tip of the continent, was politically separated from New South Wales in 1851, and responsible government was conferred in 1855, with power vested in a bicameral legislature. On January 1, 1901, Victoria and the five other Australian colonies became states and formed the Commonwealth of Australia. Only Tasmania is smaller than Victoria's 87,884 square miles (227,620 square kilometres), but only New South Wales has a population greater than that of Victoria. Victoria is separated from New South Wales to the north by the River Murray (for a length of 1,065 miles) and also by a straight boundary (110 miles long), linking Cape Howe and the nearest source of the Murray. The meridian marking 140°58′ E forms the western boundary with South Australia for a distance of 280 miles. The coastline, which completes the land boundaries, stretches for 980 miles. It includes the 164-mile shoreline of Port Phillip Bay, at whose head lies Melbourne, the capital and major city. The maritime boundary with Tasmania is latitude 39°08′ S.

Physical and human geography

THE LAND

The rich variety of landscapes in Victoria includes both alpine plateaus in the northeast, around Bright, and sandy deserts in the west, near Lake Hindmarsh. This wide range results from a complex geological history and from variations in the weather as it is experienced in particular areas. These dominant factors have created distinct regions, which create different opportunities and problems. The main upland areas are a continuation of the Dividing Range of eastern Australia. Starting with a width of 190 miles on the New South Wales border, these uplands arc westward across the state, becoming narrower and lower for 400 miles before terminating in the Grampians and Dundas Highlands, 25 miles east of the South Australian boundary. Plains surround this upland core on the north, west, and south. The southern plains are divided into smaller areas by the Otway Range, the South Gippsland Highlands (north of Wilsons Promontory), and Port Phillip Bay, which was formed by the invasion of the sea after a downward movement of the earth's crust.

Climate. The easterly passage of anticyclones (high-pressure areas) and depressions is the main determinant of weather for most of Victoria. Their track lies overland during winter (generally the wettest season), and during summer a more southerly oceanic course reduces the frequency of rain days. East Gippsland is an exception, since most of its rain results from intense depressions centred east of Bass Strait in the summer. There is a close correlation between annual rainfall and elevation, and there is a clear decline in annual rainfall toward the northwest.

Relief. *The central uplands.* The upland core of Victoria is divided by the low, wide Kilmore Gap into two distinct sections. The Eastern Cordillera are more extensive and higher, with several peaks over 5,000 feet, culminating in Mt. Bogong (6,516 feet [1,986 metres]). There are also some high plateaus. The varied geological structure has been heavily cut into by perennial streams, fed in spring by melting snow and ice. The steeper slopes and longer winter of the Eastern Cordillera have discouraged cultivation except in sheltered valleys, where some hops and tobacco are grown. Beef-cattle breeding and fattening, the raising of prime lambs, and the production of crossbred wool are the main rural activities. This area also contains the most extensive forest in Victoria, the main species being snow gum, Alpine ash, and mountain ash. Its beautiful scenery makes it a popular year-round attraction for tourists.

The highest of the peaks in the Western Highlands is Mt. William (3,829 feet [1,166 metres]), in the Grampians. The low relief, gentler slopes, and milder winter makes the area suitable for farming, and much of the forest has been cleared. Most farmers rear sheep and beef cattle.

The northern plains. The plains north of the uplands can be divided into three distinct areas. Apart from a distinctive narrow strip adjoining the River Murray, where conditions for farming are more reliable, the entire northwest area, bounded by 36° latitude and the Avoca River, is known as the Mallee. This name is derived from a type of eucalypt that sends up a number of slender trunks from a single large, underground source; the trunks rarely exceed 30 feet in height. The region has unreliable annual rainfall, generally less than 15 inches. The undulating surface of broad, low ridges and depressions reflects the faulting and folding of the underlying sedimentary rocks, which in turn have been overlain by windblown deposits that, except in the region known as the Big Desert, have been fixed by drought-resisting vegetation. No streams rise in the Mallee, and those that enter from the south fail to reach the Murray, terminating instead in such salt lakes as Lake Tyrrell. Apart from the extreme northwest and the Big Desert, where lack of water and wind-erosion hazards make conditions too difficult for farming, the area has been only lightly settled. The light soils are easily cultivated, and the development of suitable fertilizers has allowed better crop rotation and the production of improved pasture. Wheat and fodder are the main crops, supplementing the production of prime lambs and wool.

Erosion hazards

The plains that lie between the Mallee and the uplands have a uniform rainfall, which varies from 15 inches (381 millimetres) on the northern edge to 24 inches near the foothills. In the area west of the Loddon River, known as the Wimmera, the soils are mainly gray clays that swell when wet and crack open when dry. Wheat growing and the raising of prime lambs and Merino sheep form the basis of rural industries there, except in the Little Desert, where deep sands, deficient in zinc and copper, make the land unsuitable for settlement.

The plains east of the Loddon River, which narrow toward Albury, are irrigated and support a wider range of farming activities. In recent geological periods the forerunners of present rivers laid down the alluvial deposits, which reveal considerable diversity in sand and clay content. When irrigated, the differing soils allow the rearing of sheep and dairy cattle and the cultivation of wheat and fruit.

The southern plains. Port Phillip Bay divides the southern plains into two distinct regions. To the west, most of the surface is formed from ancient basaltic flows, above which stand some of the original volcanic cones. The flows covered 7,000 square miles and stretch 190 miles west of Melbourne. The uniform origin of this plain has not provided identical soils, as there are local differences in the colour, texture, and stone content of the soils. These variations were, however, masked by the grasslands that originally covered the area, and today there is a uniform land use. Livestock are preeminent here: fine-wool-sheep breeding and beef-cattle breeding and fattening are general, with dairying around the towns of Colac, Camperdown, and Koroit.

The Gippsland Plains are located east of Port Phillip Bay. The larger East Gippsland Plain experiences maximum rainfall during the summer. It has fairly mild winters. These conditions are excellent for dairy farming, which is the main rural activity, although the production of veal and pork supplements the yields of milk and cheese. Inten-

sive settlement of this area has resulted in the destruction of most of the original forest cover.

THE PEOPLE

Before 1939 the majority of Victoria's population had been born in Australia, and in 1947 only 8.7 percent of the population was foreign-born, most of it British. Since 1945, however, Australia in general and Victoria in particular have encouraged large-scale immigration from Europe in order to make the country stronger strategically, to assist many European refugees made homeless by the war, and to reduce the economic problems caused by the low Australian birth rate during the interwar depression. By the latter decades of the 20th century more than one-fifth of the Victorian population was foreign born. The main national groups, apart from Australians and British, were Italian, Greek, Dutch, and German. In some sections of Melbourne, Greek or Italian communities predominate, but the "new Australians" mix easily with the rest of the population, and national friction is at a minimum. The benefit of these groups to the state's economy is incalculable. European migrants have also made a distinctive contribution to the cultural life of Victoria—in architectural style and house decoration, in sport, with soccer growing in popularity, and in culinary variety. Estimates indicate that there are about 6,000 Aborigines in Victoria. By the Aborigine Land Act of 1970, title to a few thousand acres was transferred to a Trust of Aborigines. Some Aborigines face problems of adjustment to a white society, and government policies are designed to reduce difficulties associated with housing, employment, and education.

The role of immigration

The diverse origins of the population are reflected in the variety of religious faiths found in the state. These include, most importantly, the Anglican Church, followed by Roman Catholic, Presbyterian, Methodist, Greek Orthodox, Baptist, Churches of Christ, Lutheran, and Jewish groups.

Almost three-quarters of the population live in the Melbourne metropolitan area, about one-tenth live in six other urban areas (Geelong, Ballarat, Bendigo, Albury-Wadonga, Morwell, Shepparton-Mooroopna), and the rest of the population resides in towns of less than 20,000 and in rural areas. Population distribution outside the metropolitan area reflects the qualities of the landscape. Geelong is the second port of Victoria; Ballarat and Bendigo originally grew up around goldfields, now largely worked out, and Moe-Yallourn stands on brown-coal beds, used for electricity production. The densest rural settlements are in fertile sections of the irrigated Murray Valley and the dairying areas of Gippsland, and the lowest are in the Alpine sections of the Eastern Cordillera and the dry Mallee.

THE ECONOMY

Victoria has a broadly based economy with well-developed primary, manufacturing, and service sectors. The lack of major mineral deposits was balanced by the discovery of huge natural-gas fields in East Gippsland waters in 1965 and of major oil fields in eastern Bass Strait in 1967.

Most of the main farming areas are used for improved or natural pastures or cultivation, which involves mainly wheat and fodder crops. The main categories of productive holdings are dairy farms, sheep stations, mixed sheep and cereal farms, cereal farms, and beef cattle.

Resources and manufacturing. Prior to the discovery of oil and natural gas, the brown-coal deposits near Moe-Yallourn were the mineral deposits of greatest value to the state. The focus of attention has shifted to Barracouta, a gas and oil field in 150 feet of water, 14 miles offshore; Marlin, a gas field in 195 feet of water 32 miles offshore; and the Halibut and Kingfish oil fields in 250 feet of water 40 and 48 miles offshore, respectively. All these fields have been linked by pipelines to the Longford gas-processing and crude-stabilization plant in Gippsland and the Long Island Point fractionation and crude-storage plant on Western Port Bay.

Oil and gas discoveries

Victoria's factories employ several hundred thousand workers: the vast majority of the factories and workers are employed in Melbourne, and Geelong and the coalfield centres of the Latrobe Valley. The original industrial suburbs of Melbourne had a central location, but many new factories are now being constructed in peripheral areas, such as Altona, Dandenong, Broadmeadows, and Moorabbin, where larger areas of cheaper land are available. Geelong, like Melbourne, produces a wide range of products, but other centres tend to be specialized. The Latrobe Valley is noted for the generation of power, and other centres are concerned mainly with food and clothing manufacture, using local materials. Although only about one-tenth of the factories employ more than 50 workers, such factories employ two-thirds of the total work force. In terms of numbers employed and value of wages, the most important industries produce metals, machines, vehicles, clothing, foodstuffs, and paper.

Transportation. The major port and the focus of the rail, air, and road systems of Victoria is Melbourne. Melbourne and Geelong ports between them handle almost all of the cargo entering and leaving the state, and Melbourne is the dominant passenger terminal, as well. Victorian Railways serve all productive areas through the several thousands of miles of mainly single-track lines. Since 1962, narrow gauge tracks have linked Melbourne with the standard system of New South Wales at Albury. The capital's electrified metropolitan system carries thousands of passengers each working day. Melbourne Airport was opened to international flights in 1970 and to domestic flights in 1971. It stands on several thousand acres, 13 miles from the city, and includes an industrial estate served by taxiways. Through highways, with many divided sections, link all the major centres of the state.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. The Parliament of Victoria consists of two houses: the Legislative Assembly and the Legislative Council. The leader of whichever party or alliance of parties forms a majority in the Legislative Assembly is requested to form a government by the governor, the titular representative of the English monarch. The premier-elect submits names of proposed ministers to the governor for appointment. These ministers become members of the Executive Council, which advises the governor. His position places him above party politics, and he is regarded as the trustee of the constitution. The governor summons and prorogues Parliament, outlines the government's legislative program at the beginning of each session, and gives assent to bills that do not have to be referred to the monarch.

The role of the governor

The Victorian Parliament legislates for those subjects not exclusively granted to the commonwealth Parliament by the commonwealth constitution. If there is any inconsistency between state and federal laws, the federal laws prevail, and the subjects granted to the commonwealth may be varied by an appropriate commonwealth act. The public service of Victoria is based on the departments of chief secretary, premier, and treasury, which serve a variety of purposes, and a number of other departments and ministries dealing with a single subject. There are also several public corporations, of which the most important are the Country Roads Board, the Gas and Fuel Corporation, State Electricity Commission, and State Rivers and Water Supply Commission.

The political process. The members of the Legislative Assembly are elected by universal adult suffrage in single-member electorates for a period of three years. Members of the Legislative Council are elected from two-member electoral provinces by universal adult suffrage for a six-year term. Elections to the council are arranged so that half the members, one from each province, retire every three years. Voting for both houses is compulsory.

In the late 20th century there were three major political parties in Victoria—the Liberal Party, the National Party, and the Australian Labor Party. The Liberal Party, predominant in recent decades, supports free enterprise and draws most of its support from middle- and upper-class voters in urban and some rural areas. The National Party represents rural interests and wins no urban seats. The Australian Labor Party finds its strongest support among the working classes and forms the official opposition when not in office.

Local government and the judicial system. Apart from

some lakes and small islands, the total area of Victoria is incorporated into more than 200 municipal districts for local government. There are, in addition, shires, boroughs, towns, and cities, which are distinguished by population and the annual revenue derived from rates (taxes). The towns contain at least 5,000 citizens each. The cities in Victoria have at least 10,000 residents each. Councils are elected each August by ratepayers and derive their revenue from rates, government grants, and certain license fees. Some councils levy rates on net annual value, while the remainder employ unimproved capital value.

Before 1973 local governments received no financial assistance from the commonwealth government. Financial assistance did exist, but it was filtered through the state governments. Procedures have been established whereby local governments can apply to the commonwealth for general purpose grants. Victoria local governments received several million dollars in grants from the commonwealth during the initial years. Victoria and its local governments also receive personal income tax funds that are redistributed by the commonwealth under the Local Government Personal Income Tax Sharing Act of 1976. The monies are distributed by the state of Victoria to the local governments based on a fixed percentage of income taxes collected within the municipality the previous year.

The courts of justice in Victoria are graduated in status according to the gravity of cases that they consider. Petty sessions courts, found in metropolitan suburbs and about 200 other towns, deal with less serious criminal offenses, hold initial inquiries into indictable criminal offenses, and adjudicate civil matters not involving more than A$1,000. A county court sits continuously in Melbourne, and visits 18 other circuit towns. It deals with civil matters in which the amount does not exceed A$4,000, and all criminal offenses except murder, treason, and other statutory exceptions. It may also act as an appeals court for petty sessions courts. The Supreme Court sits in Melbourne and visits ten other cities. It may deal with all matters not excluded by statute and act as appeal court for the county court.

Social welfare and education. Wages and working conditions in Victoria are supervised by the Commonwealth Conciliation and Arbitration Commission, for industries that extend beyond the state, and by the Victorian Conciliation and Arbitration Boards, for industries entirely within the state. In 1981 the national basic minimum wage, based on fluctuations in the Consumer Price Index, was abolished. Basic wages are now established according to specific industry or trade requirements. In 1982 a 38-hour workweek was implemented by numerous conciliation and arbitration boards.

The basic wage

Since 1872 every child in Victoria has been entitled to secular, compulsory, and free education to the age of 15 years. Both state and private schools operate. Primary schools offer seven years' education and teach general academic skills. Secondary schools offer six years' education and should fit the student for any tertiary course. Technical schools operate on a five-year course and qualify students for training in technical colleges. In addition, there are certain special schools for handicapped children. There are three universities in Victoria. The Victoria Institute of Colleges is an association of many technical colleges, which now awards degrees, as well as diplomas, in certain fields.

CULTURAL LIFE

The most important recent cultural development in Victoria has been the creation of the Victorian Arts Centre, on land near the centre of the city of Melbourne. The entire project includes art galleries, courtyards for theatrical productions and displays of sculpture, underground theatres, a convention and concert hall, a display centre, and a hall for state receptions. There are several other art galleries at such centres as Ballarat, Bendigo, Geelong, Warrnambool, Hamilton, and Shepparton, and many of them award annual prizes to be won in competition. A folk museum of buildings, machinery, and paddle steamers has been built on a large site at Swan Hill. The Library Council of Victoria, created in 1966, manages the important State Library of Victoria and advises the government on the promotion of library services throughout the state. During the last century the State Library built up strong collections in a variety of fields, but more recently a shortage of funds and rising costs have limited the areas where collections are made in depth. Fields of current interest include historical bibliography, fine arts, biography, military history, and British typography. The collection of Victoriana in the library and the state archives are valuable historical sources.

The Victorian Arts Centre

Melbourne's orchestra has made successful overseas tours, and the city has many cinemas, theatres, and restaurants. The National Trust of Australia (Victoria) plays an important part in stimulating the public's interest in old buildings and places of scenic beauty and with rare flora and fauna. A number of old buildings have been acquired and restored, and a schedule of other existing buildings has been prepared to avoid major cultural loss through demolition. Melbourne's daily papers have a combined daily circulation exceeding 1,300,000. Most of the other urban centres throughout Victoria have their own local papers, and other daily papers circulate in the state. The Australian Broadcasting Commission, financed by the government, provides a comprehensive radio and television service to the entire state. There are also many commercial radio stations and several commercial television stations. Victoria has numerous national parks with a total area of several hundred thousand acres. (J.R.V.P.)

History

EXPLORATION AND SETTLEMENT

Victoria was founded by groups of pastoral pioneers who crossed Bass Strait from Launceston in the 1830s in search of fertile grazing land. The occupation of the area was made in defiance of a British government edict forbidding settlement in the territory, which was then part of the colony of New South Wales.

In November 1834 Edward Henty and his father and brothers landed stock and stores at Portland, on the south coast, and established the first settlement. In 1835 John Batman, backed by a Launceston syndicate, landed at Port Phillip. Batman's venture led the way to the pastoral occupation of Victoria. In the same year John Pascoe Fawkner established a small colony of settlers on the banks of the Yarra River. From Batman's colony grew Victoria's capital city, Melbourne.

Early settlement of Melbourne

Exploration by sea and land had preceded settlement. George Bass, Matthew Flinders, and John Murray had established the coastline and the main harbours by the beginning of the 19th century. In the 1820s and 1830s a series of overland expeditions from New South Wales had opened up the hinterland. Hamilton Hume and W.H. Hovell struck south and reached the coast of Port Phillip in 1824; Charles Sturt plotted the full reach of the Murray in 1829; Maj. Thomas L. Mitchell crossed the central and western plains in 1836; and several parties had penetrated the mountainous Gippsland district to the east by 1840. Early attempts to establish convict settlements on the south coast (near Sorrento in 1803 and on Western Port in 1826) failed. But the Port Phillip settlement developed rapidly. In 1836 the British government authorized the settlers but gave no title to their land. In December of that year Capt. William Lonsdale was appointed first resident magistrate.

During the 1840s and 1850s Victoria became a prosperous pastoral community. The squatters extended their grazing runs to the boundaries of the territory. The population rose rapidly as British migrants arrived and more settlers crossed from Van Diemen's Land (renamed Tasmania in 1856) or drove their flocks and herds south from New South Wales. By 1850 Victoria had 76,000 people and 6,000,000 sheep. Melbourne (pop. 23,000), Geelong, and Portland were its main urban centres.

INDEPENDENT SETTLEMENT AND DISCOVERY OF GOLD

Dissatisfied with their limited representation on the Legislative Council of New South Wales, the Port Phillip pastoralists agitated for separation. In 1851 Victoria became a separate colony, with an Executive Council appointed

by the crown and a Legislative Council, partly elected and partly nominated, effectively dominated by conservative landed interests.

Victoria's establishment as a separate colony coincided with the discovery of gold. An early find at Warrandyte, 16 miles from Melbourne, led to a dramatic rush. By the end of 1851 half the men of the colony were working on the goldfields. In 10 years, more than £105,000,000 worth of gold was won from fields of which Ballarat and Bendigo were the most important. More than 200,000 migrants arrived there from Britain and 25,000 from China. By 1860 the population of Victoria had passed the 500,000 mark and was 46 percent of the Australian total.

Gold transformed Victoria from a pastoral backwater into the most celebrated colony of the empire. The comparatively well-educated and skilled artisans lured by gold produced a society renowned for its attachment to 19th-century middle-class values and institutions. Although actual opportunities soon contracted and a Melbourne proletariat rapidly emerged, Victoria was noted for its economic individualism and opportunism, its material progress and financial speculation, as well as its imperial loyalty and political pragmatism.

The gold rushes produced a spectacular, but short-lived, boom. By 1854 Melbourne was suffering from a severe depression. Financial stringency aggravated discontent on the goldfields. The miners strongly resented the fee demanded for a mining license and the brutal fashion in which it was collected by the goldfields' police. This discontent culminated in a minor rebellion at Eureka, near Ballarat. Mining licenses were burned and a republican flag was hoisted. On December 3, 1854, police and troopers stormed the rebels' stockade. Thirty miners and four soldiers were killed. But the incident hastened the redress of the miners' grievances and gave colonial radicals symbols and martyrs.

Miner's revolt

Victoria attained self-government in 1855. The new constitution set up two Houses of Parliament—a Legislative Council of 34 members, elected on a limited property franchise, and a Legislative Assembly, elected on a wider property and income franchise.

The Legislative Council remained the stronghold of the rich conservative landowners and the main obstacle to land reform. But in the 1860s a series of land acts, designed to encourage small freeholders and "unlock" the large grazing leases of the pastoralists, helped establish small wheat farmers in the Mallee and Wimmera. Victoria, previously an importer of flour, became Australia's largest wheat producer by the end of the century.

In other districts, however, the wealthy pastoralists managed by guile and financial manipulation to evade the land acts, and very many of them acquired freeholds to large estates at low prices, especially in the fertile Western District.

In 1871 the property qualification for the Council was reduced and the tenure of Council members shortened. In 1888 additional electoral reforms for both houses were passed. With a few exceptions, single-member constituencies became the rule for the Assembly. In 1899 plural voting for the Assembly was abolished and in 1900 postal voting introduced. A free, compulsory, and secular educational system was established in 1872. The introduction of an eight-hour working day in 1856 began a series of social and industrial reforms, which produced a minimum wage and standard hours and conditions of employment in the 1890s.

By the end of the 1880s the state's growing prosperity had expanded into a speculative boom. The crash came in 1891 and was considerably aggravated by a sharp fall in the prices of Victoria's main exports, wool and wheat. In 1891–92, 21 finance societies and land banks collapsed and in 1893 all but three of the trading banks closed their doors. The depression that followed was marked by high unemployment and considerable industrial unrest; it did not completely end for almost 20 years. These disasters transformed Victorian politics and socioeconomic attitudes and behaviour. The confidence of the bourgeoisie was completely destroyed. Men of property rallied, but without intellectual or even spiritual convictions, to defend the old order against those who proposed change. In this they were overwhelmingly successful. From Australia's most radical and progressive colony, Victoria, almost overnight, became the bulwark of conservatism. In consequence, although all parties were forced in some measure to recognize the peculiar problems of the environment by introducing a form of state Socialism, Victorian politics in the 20th century were generally characterized by greater ideological cleavages than usually appeared in the other states and by the monopoly of effective political power by interests committed to the preservation of 19th-century notions of property and social conformity.

FEDERATION AND THE STATE OF VICTORIA

In 1891 the first Australian National Convention met in Sydney to consider proposals for the creation of an Australian federation. On May 9, 1901, the first federal Parliament was opened in Melbourne. It was moved to Canberra in 1927.

First Australian National Convention

Following federation, Victoria's final legacy to the Australian colonies, there was a need to rationalize the constitutional structure of the states. In Victoria, the number of members was reduced in 1903, the Council franchise and property qualifications for membership were liberalized, and adult suffrage was introduced in 1908. In 1923 women candidates were admitted for election to both houses. Preferential voting was introduced for the Assembly in 1923 and for the Council 10 years later, while voting was made compulsory for the Assembly in 1926, and for the Council in 1935. Full adult suffrage was not introduced for Council voting until 1950.

Political developments after federation were marked by the rise of the Labor and Country parties, leading, in the 1920s, to the creation of a three-party pattern in place of the former Liberal–Conservative two-party system. The existence of three parties partly accounts for the apparent instability of Victorian government. Between 1901 and 1955 there were 31, mostly composite, ministries. Labor first won office, as a minority government, in 1913 and formed coalition governments on five subsequent occasions. It succeeded in winning political power only in 1952, when it gained a majority under John Cain. In 1914 the Victorian Farmers' Union was founded, sending four of its members to Parliament in 1917. In 1926 it changed its name to the United Country Party, and from 1935, led by Albert Dunstan, governed for eight years with the support of the Labor Party.

The Country Party's influential role in Victorian politics was partly explained by the unequal size of rural and urban electoral districts. Between 1924 and 1945 the unequal size of electorates made each rural vote equal to more than two urban votes. In 1953–54 an electoral redistribution, planned by a section of the Liberal Party and carried through by a Labor government, restored comparative parity between rural and urban electorates. This destroyed the crucial influence of the Country Party in the Assembly. The rebel Liberal Party was annihilated at the 1955 election. But a breakaway Labor Party, known eventually as the Democratic Labor Party, while losing Parliamentary representation, survived with Roman Catholic lay support and backing by the hierarchy. However, the Legislative Council, which retained its gerrymandered electorate despite the introduction of adult suffrage, continued to provide opportunities for political intrigue and remained the main divisive force in the Victorian political system, often vetoing bills originating in the Assembly.

Labor Party government

From 1955 to 1981 Victoria was governed by the Liberal Party under Sir Henry Bolte, a shrewd, earthy, and assertive leader, and the state's most successful 20th-century politician. His administration coincided with a lengthy period of general Australian prosperity. In the 1982 elections, the Labor Party won the majority, ending more than one-quarter of a century of Liberal government.

The major concerns of the state government are the administration of the police force and of justice, education, health services, agriculture (including marketing boards), transport, and the utility and development services associated with electricity, irrigation, water supply, ports and harbours, sewerage, forestry, and country roads. Govern-

ment departments or agencies are also vested with responsibility for the regulation of primary production, industry and commerce, labour, professional and occupational standards, education, social welfare, and public health.

The development of Victoria during the 1950s and 1960s was marked by two main trends. First, an increasing proportion of the population became urbanized. At the beginning of the century 58 percent of the people lived in urban areas. By the mid-1960s the proportion had risen to more than 85 percent. After the mid-1950s, however, "development" and private economic opportunism, fostered by liberal concessions to business and industrial enterprises, produced both crisis and expansion in Victorian affairs.

The discovery of natural gas and oil on the Gippsland Shelf in Bass Strait in February 1965, the increasing industrialization of the state, the high rate and proportion of migration which resulted in 20 percent of all Victorians having been born overseas (many in Italy and Greece), and the creation of two new universities, Monash and La Trobe, have given Victoria the basic resources, people, and skills it requires to overcome the lengthy inertia following the depression of the 1890s. The opening of the Victorian Arts Centre in August 1968 partly remedied 50 years of official cultural indifference and neglect.

Nevertheless, although the electorate's public devotion to mid-19th-century individualism and provincialism remained unshaken, the problem of commonwealth–state financial relationships, the social demands of a predominantly urban community, and the general array of problems that afflict federalism in Australia suggested that Victoria's individuality would become increasingly submerged beneath the general Australian suburban patterns of life, attitudes, culture, and thought.

In 1972 the Ministry of Conservation was created by an act of Parliament as an umbrella organization to bring together other government agencies and departments responsible for conservation and environmental protection. The ministry is responsible for achieving the aims of the Ministry of Conservation Act, the protection and preservation of the environment, and the proper management of Victoria's land and water resources.

Victoria Constitution Act

In 1975 the Victorian Parliament adopted the Constitution Act, defining the basic laws governing the state, outlining the state's relationship to the commonwealth, enumerating the powers of the state Parliament, the Supreme Court, and the executive. Prior to this, the Constitution was contained within an act passed by the United Kingdom Parliament in 1855. This document served as Victoria's constitution for some 120 years, although the state did have the power to adopt its own constitution during this period.

The National Parks Act of 1979 increased the acreage of national parks in Victoria to almost three times the previous area. Four new national parks were created under the act in 1979, and two existing parks were brought under state control. In 1980 seven additional parks were declared under the jurisdiction of the National Parks Service, bringing the total amount of park land under government control to about 3 percent of the entire state's area.

(D.B.Wa./Ed.)

WESTERN AUSTRALIA

Western Australia, by far the largest state of the Commonwealth of Australia, comprising that part of the continent lying west of longitude 129° E, covers an area of 975,920 square miles (2,527,621 square kilometres), or one-third of the total area of Australia, and about eight times the size of the British Isles. Most of the inhabitants are clustered around Perth, the capital, which has been called the most isolated city in the world. Most of Western Australia is a low tableland called the Great Western Plateau and is bounded on the east by the Northern Territory and South Australia. It has a maximum northeast-to-southwest length of 1,480 miles (2,382 kilometres) and a long, sometimes jagged, coastline of 4,350 miles, which provides few good harbours except Albany. Broome, for instance—sometimes called the Port of Pearls—is the busiest port in the northern part of the state, but tides sometimes leave ships stranded beside the jetties. More serious is the almost complete lack of any large rivers that flow all year round. There are no large lakes, and the rainfall is insufficient everywhere except in the southwest corner, the warm, sunny climate of which is considered by some the best in Australia. Western Australia is correctly said to be separated by an "ocean of sand" from the more thickly populated eastern coastal belt, but the isolation has been diminished by rapidly improving communications. The continental shelf is very narrow in the south and very broad, sloping, and deeper than usual in the north. Subsidence is evidenced by numerous coral and limestone reefs in the north and west and by granite islands in the south.

Water problems

Physical and human geography

THE LAND

Relief. The Kimberley Block (70,000 square miles) is the northernmost region, bounded by King Sound and the King Leopold Range (Mt. Broome, 3,040 feet [927 metres]). It is a plateau incised by deep valleys and with a rugged coastline cut by drowned valleys. Tides are extreme (Hanover Bay, 38 feet [12 metres]).

The Canning Basin (150,000 square miles), immediately south of the Kimberley Block, has a low-lying and uniform coast known as the Eighty Mile Beach. There is artesian water; and most of the interior is covered with sand dunes.

Southward, the Nullagine Platform (200,000 square miles) is a plateau (1,000–1,400 feet) with hills, often flat-topped, giving way to dunes in the northeast. In the north is the Pilbara Block, with flat-topped hills. The Hamersley Plateau has been uplifted and dissected, residual mountains rising to more than 3,000 feet (Mt. Bruce, 4,024 feet [1,227 metres] is one of the highest peaks in Western Australia). Rocky headlands and coral islets line the shore.

The Carnarvon Basin (50,000 square miles) has artesian water and rises gradually to 1,000 feet from the hills near Exmouth Gulf and the lowlands around Shark Bay.

Southward, the Yilgarn Block (300,000 square miles) has very poor soils, and southwestward are small basins with coal deposits. To the south is the Stirling Range (Bluff Knoll, 3,640 feet). The southwestern edge of the plateau forms the Darling Range (Mt. Cooke, 1,910 feet), which rises above the great Darling Fault (600 miles north to south).

The Swan coastal belt covers about 16,000 square miles west of the Darling fault scarp. It is mainly lowland, forming an artesian basin.

Part of the Eucla Basin, which is artesian and underlies the enormous Nullarbor Plain, is in Western Australia; it slopes to the south from about 1,000 feet, ending in cliffs 200–400 feet high.

Climate. An anticyclone approaches Western Australia from the Indian Ocean with cool, humid, southwesterly air, usually polar maritime in winter, modified in summer. Inland the air becomes drier, and the southwesterly wind is gradually replaced by a northeasterly, with all the characteristics of tropical continental air.

Temperature ranges

In summer (December–February) the anticyclones travel along their southernmost path and bring an alternation of cool southwesterlies (70°–75° F, 21°–24° C) and hot, dry northeasterlies (80°–100° F, 27°–38° C) to the southern parts of the state. Occasional high temperatures reach 110° F (43° C). Humidity is very low, and there is no rain except rare local thunderstorms. The heat over the northwest allows equatorial air to flow in, bringing heavy rains to the north and sultry days to large areas. Temperatures in the northwest vary from 75° F at night to 110° F in the afternoon. Summer rains vary from one to three inches (25 to 76 millimetres) in the south to 20–30 inches in the north, with large dry areas in the interior.

In February and March, disastrous hurricanes ("willy-willies") sometimes hit the coast between Broome and Onslow and proceed southeastward, bringing torrential rains, perhaps two to three inches in one hour. Occasional hurricanes in the northwest occur during autumn (March–May), with the last rains in the north and the gradual northward migration of the anticyclones. Humidity varies at this time, and the far southwest receives its first frontal rains (six to nine inches for the season). In winter (June–August), cool, dry air (trade winds) blows offshore in the north, whereas there are heavy frontal rains in the south, ranging from 15–20 inches on the coast to eight to 10 inches in the interior. Temperatures are 30°–60° F (−1°–16° C) at night and 60°–75° F in the afternoon in the south and about 10 degrees warmer in the north. Spring (September–November) brings the last frontal rains to the south (four to eight inches) and the highest temperatures to the parched north, before the first monsoonal rains fall in November.

The rainfall is very reliable in the far south and the far north, but in between it is variable and scarce, 58 percent of the state receiving less than 10 inches per year. Reliable rains of 30 inches or more a year fall over only 5.4 percent of the state, mostly in the southwest.

Drainage. The rivers of the Kimberley Block flow only after the summer rains but have large permanent pools. The Ord (300 miles) has a large estuary, and the Fitzroy (325 miles) crosses the King Leopold Range. The northwestern rivers flow occasionally but may be dry for several years. They include the De Grey-Oakover (370 miles), the Fortescue (340 miles), the Ashburton (400 miles), the Gascoyne (475 miles), and the Murchison (440 miles). A very large inland area has sporadic drainage at best.

The rivers that rise on the Yilgarn Block and flow west through the Swan coastal plain are short, such as the Swan-Avon (240 miles), which is dry in summer, the Murray (70 miles), and the Collie (60 miles). Farther south the flow is nearly perennial with a strong winter–spring maximum: the Blackwood (190 miles) and the Frankland (80 miles); these rivers are more or less brackish. The rivers that flow to the south are short and intermittent and run mostly in winter.

Plant and animal life. Botanically, Western Australia may be divided into three provinces, each with its own distinctive vegetation. In the northern province, the flora is rich in Malayan (Palaeotropical) forms, whereas the native element is strongly represented in the Eremean (desert) and in the southwestern provinces; in the latter there are also distinct Antarctic affinities. Long isolation without interference has resulted in the evolution of many forms and a high degree of endemism (confinement to a particular area).

There are approximately 6,800 species of plants, the carnivorous pitcher plant, the kangaroo paws, the feather flower, and the Christmas tree being of special interest. The northern province is characterized by monsoonal woodland and by rich grassland in the Kimberleys, whereas south of the Fitzroy River harsh grassland is dominant. By contrast, the southwestern province has relatively little grassland, whereas the trees and shrubs have developed strongly. There the sand-plain vegetation shows exceptional diversity and floral brilliance. The Eremean, or desert province, covers a very large area of the state.

The main woodland is in the southwestern province. Jarrah, a type of eucalyptus, grows on the sandy coastal plain, and another eucalyptus, karri, occurs in the deep southwest. Of two other eucalyptuses, the tuart is restricted to the coastal plain, whereas the wandoo grows throughout the jarrah forest area. Yet another eucalyptus, the marri, is found with the jarrah. Drought-resistant woodlands of mixed *Eucalyptus* species occur farther inland, being succeeded in drier areas by mallee shrubs (a low-growing eucalyptus).

Eucalyptus types

Fauna are also grouped in three regions. Unique forms are the burrowing frog, found where there are termites, and a member of the butterfly and moth family, often found in the nests of the ant. The numbat (banded anteater) is now restricted to the wandoo forests. The northern province has a fauna related to that of Queensland and northern Australia. In the desert areas, among other animals, is found a grotesque lizard.

THE PEOPLE

Although Western Australia comprises almost one-third of the total area of Australia, it contains less than 8 percent of the population. When the colony was founded in 1829, the population was 1,003. Growth was slow until the latter part of the 19th century; at the census of 1881, the population was 29,708, but, by 1901, it had increased sixfold to 184,124. In the 20th century, the state's average annual rate of increase was higher than that of any other Australian state. The population of 332,732 in 1921 more than quadrupled by the late 20th century. Immigration in Western Australia comes largely from other parts of Australia. Of immigrants from abroad, by far the majority were of British origin. There is no state church, but there are several hundred thousand members of the Anglican Church and the Roman Catholic Church; other major religious denominations include Methodists and Presbyterians. Western Australia is a comparatively young state; in the late 20th century about one-third of the population was under 15 years of age.

The vast majority of the population of Western Australia is urban. Much of the interior of the state is sparsely populated by white Europeans, despite its considerable pastoral capacity and the phenomenal northwest iron-ore and other mineral developments of the 1960s. Most of the increase in population occurs on and near the coasts, chiefly in the temperate southwestern corner. In this zone of settlement, Perth and its port, Fremantle, hold a key position, strengthened by major industrial development in the neighbouring Kwinana–Cockburn Sound area from the mid-1950s onward. Other settlements of the southwest are mainly small agricultural and railway centres, with the beginnings also of some industries processing primary products.

Major cities and towns are Perth Statistical Division, including Fremantle, Rockingham, and Kwinana; Kalgoorlie–Boulder; Bunbury; Geraldton; and Albany.

THE ECONOMY

Agriculture, pastoral activities, and land settlement. The boom prices after World War II transformed Western Australia's economic outlook.

Agriculture is specialized and commercial in character. The farmer expects to produce sufficient supplies for sale to enable him to enjoy a standard of living comparable to that of the town worker. Farm labour is scarce and expensive, and full advantage is taken of mechanization, particularly for the growing of grain.

The three climatic economic zones

On the basis of rainfall distribution, the state falls into three well-defined zones: (1) the Kimberley division in the extreme north; (2) an area in the southwestern corner where the rainfall ranges from 50 inches on parts of the coastline down to 11 inches on its inland boundary; and (3) the large area lying between these two, where the annual rainfall is sparse (10 inches or less) and uncertain in its incidence.

In the southern part of the northern region, sheep are raised, and sugarcane, safflower (a yellow herb), and rice have emerged as potential commercial crops. The cattle industry also benefitted greatly from "beef roads" constructed in the 1960s with commonwealth and state funds. Pearling and the production of cultured pearls are other economic activities of note in this northern region.

The vast arid zone is bad for agriculture or grazing. A few hundred million acres, however, are occupied as pastoral leaseholds, and wool is produced under conditions of extensive grazing. In places, even pastoral activities are impossible, and the only agricultural settlement in the central and northwest region is at Carnarvon, on the coast, where bananas and vegetables are grown. Farther north, in the eastern Kimberleys, cotton growing was stimulated in the mid-1960s by plans for the construction of the Ord River Dam, which was completed in 1972.

In the southwest, agriculture extends over nearly 100,000 square miles. Most of the region has little value for grazing before it is cleared of timber and scrub and fertilized with

phosphates. By the late 20th century millions of acres had been cleared with government support.

Wool is the most widespread of the state's rural industries. The sheep population of Western Australia is several tens of millions, mostly Merinos. Nearly three-quarters of the sheep are in the agricultural districts in the southwest, where grain and sheep can be raised well together. In the northwest, fewer sheep per acre can be raised, and, despite pastoral properties of between 100,000 and 1,000,000 acres, the carrying capacity averages one sheep to 20–30 acres.

Farms in the wheat and sheep districts vary considerably in size. Although when judged by European standards the grain yields of Western Australian farms are low, a favourable combination of circumstances permits high output per person, and a large wheat and sheep property is usually a highly mechanized and efficient concern.

Meat production ranks second to wool in value. The only area in which it is a single specialized enterprise on a large scale is in the northern part of the state, where cattle raising is almost the sole occupation. Uncertain prospects handicap the production of high-quality beef. In most agricultural areas, meat production is mainly a sideline to wool production, wheat growing, and dairying.

Dairying is an important occupation in the more heavily timbered country of the extreme southwest. Irrigation and drainage projects on the coastal plain south of Perth have considerably increased the productivity of the area. Several thousand acres are irrigated each year as pasture for dairy cows, but physical conditions hinder expansion.

Forest products

Almost two-thirds of the prime-forest belt has been designated as state forest for the production of timber in perpetuity. Managed under the principle of sustained yield, these forests provide 80 percent of the state's total timber output. The remainder comes from private property.

A stable and thriving sawmilling industry produces sawed timber, mainly jarrah and karri. Jarrah has a worldwide reputation for durability and general utility, and karri is equally renowned for strength and size.

The dry country savannah forests to the east of the southwestern province are slowly giving way to agriculture in the more favourable situations but still cover several million acres. Tens of thousands of acres of pines had been established by the late 20th century. In a region that suffers from a long summer drought, protection from fire is essential for the preservation of the forest.

Orchards and vineyards occupy several thousand acres. The poultry industry produces a surplus of eggs, which are exported chiefly to the United Kingdom. Cereals are widespread, and flax is grown on a small scale.

Industry and trade. The state's predominantly agricultural and pastoral economy has twice been revolutionized by mineral discoveries—gold toward the end of the 19th century (chiefly on the eastern fields of Coolgardie and Kalgoorlie) and, since the late 1950s, by the rapidly expanding exploitation of one of the world's greatest iron ore deposits in the Ashburton and Pilbara districts in the northwest. Other minerals produced include manganese, ilmenite, monazite, rutile, leucoxene, and zircon. A large bauxite deposit has been developed in the hills south of Perth, and polar salt is produced in the northwestern area of the state.

In 1967, at Barrow Island, near Onslow, one of Australia's largest commercial oil fields began operations, and natural gas was discovered at Yardarino near Geraldton. Meanwhile, after 1971, a 225-mile pipeline carried natural gas from Yardarino to the Pinjarra alumina refinery in the southwest. One of Australia's largest nickel mines is at Kambalda near Kalgoorlie.

Manufacturing is confined mainly to the Perth metropolitan area. Until mid-century, most industries were related to primary production: sawmilling, bacon curing, dairy products processing, superphosphates manufacture, and railway engineering. Thereafter, substantial industrial development in the Perth–Fremantle–Cockburn Sound (Kwinana) area included a large oil refinery and a steel mill, and these became the nucleus of an industrial complex of allied industries. These were facilitated by new public works and services, including a deepwater supplement to Fremantle harbour for oil tankers; freeways; an additional power station; and standard-gauge railway communication (opened 1968) with iron ore deposits at Koolyanobbing near Southern Cross en route to Kwinana on the coast south of Fremantle. The standard-gauge railroad was eventually extended through Kalgoorlie to link with Sydney and Brisbane in eastern Australia.

Apart from its iron ore and other mineral exports to overseas countries, chiefly Japan, a large portion of the state's trade is still with other Australian states.

The main sources of state revenue are grants from the Commonwealth government. Other income comes from land, probate, betting, and payroll taxes; license fees and stamp duties; mining royalties; and departmental and utility charges including railways. State expenditure is chiefly on public utilities, law and order, education, health (including hospitals), and other social services, supplementing those of the Commonwealth government.

Transportation. Railways were first developed in the late 19th century. Apart from certain privately owned mineral lines of standard-gauge, all railways are state-owned and most are narrow gauge (3 feet 6 inches [107 centimetres]) except for the standard-gauge transcontinental line mentioned above, which is partially owned by the commonwealth government. Road transportation, now widespread, competes with the state government railways, and, in the northern pastoral and mineral areas, airplanes are used extensively. A network of flight schedules links Perth with these areas and with highly developed ports for mineral exports such as Dampier and Port Hedland. Of particular importance is the Royal Flying Doctor Service begun in 1935 to assure the isolated stations of the northwest of regular medical attention. Perth is on international air routes.

Air services

Shipping services include: (1) the main overseas lines, which make Fremantle their first and last port of call and help to make it the largest oil-bunkering port in Australia; (2) services to other states; and (3) Western Australian coastal services, mainly northward, extending also to Java and Singapore, where a trade in fat sheep and fruit has been developed.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. The state Parliament of Western Australia, representing each province, consists of two members per province who serve terms of six years. One-third of the Legislative Council is elected every two years, whereas the Legislative Assembly members are elected for three years. Since 1963 a property qualification no longer restricts voting for the Council, but seat distribution ensures an anti-Labor majority there. Local government is conducted through city, town, and shire councils.

Education. Two systems of primary and secondary education exist side-by-side. The state schools are under centralized administration; the private, or independent, schools, serving between one-quarter and one-fifth of the children, are controlled for the most part by church organizations, among which the Roman Catholic teaching orders predominate. Education is compulsory for children between the ages of six and 15 years who live within three miles of an established school or within two miles of a school-bus route. In rural areas children attending schools at central points are taken there daily by bus at government expense. This system is supplemented by correspondence classes for more isolated children and by the use of itinerant teachers in the remote northwest.

The University of Western Australia (founded 1911) has several thousand students in the faculties of arts, law, education, economics and commerce, science, engineering, agriculture, architecture, dental science, and medicine. The state also possessed an autonomous institute of technology, established in 1967, and several technical colleges within the technical division of the state education department, as well as technical schools and centres scattered through the state. It has secondary and primary teacher-training colleges, one agricultural college, and four residential agricultural schools. A second metropolitan university, Murdoch, was opened in 1974.

Health and welfare. Old-age, invalid, and widows' pen-

sions are generally provided by the federal government, which is also responsible for unemployment and sickness benefits, as well as maternity, child endowment, tuberculosis, repatriation, and rehabilitation allowances. The state's social services include those of municipalities and state government departments, such as education, public health, police, mental health, child welfare, and native welfare. The Western Australian Workers' Compensation Act provides for compulsory insurance by employers to compensate for losses by industrial accident, including industrial diseases.

CULTURAL LIFE

Despite Western Australia's isolation from the more sophisticated east, Perth, the capital, has an annual five-week summer festival of the arts—drama, music, ballet, films, and art. Perth boasts theatres, concert halls, "art" cinemas, and many commercial cinemas.

The Australian Broadcasting Commission invites international orchestras, soloists, and singers to Perth for celebrity concerts and youth concerts. It also sponsors the West Australian Symphony Orchestra, which also enjoys state-government assistance. Australian composers are included in the repertoire.

The University of Western Australia is also concerned with music, offering degree courses for which the Wigmore Music Library is indispensable. University music societies of various sorts flourish. Another service the university renders is the study of Aboriginal musical forms. Other musical organizations include a youth orchestra, music clubs, and choral groups. The professional Western Australia Opera Company receives both federal and state subsidies.

The state has its own Ballet Company and the Western Australian Ballet Workshop. Regular tours of country areas take place, and international troupes visit Western Australia.

Perth has an art gallery and museum, which displays works from abroad as well as contemporary native art and Aboriginal bark paintings. There is a state library, and over half the population uses the Library Board of Western Australia's services, through a steadily increasing number of local public libraries. (F.A.)

History

EXPLORATION AND SETTLEMENT

Prior to European exploration, Western Australia was inhabited by Aboriginal peoples, who migrated to this part of the continent from southern Asia some 25,000 to 30,000 years ago. These peoples were nomadic hunters and gatherers, holding undisputed possession to the region for several thousand years. Occasional Asian visitors may have reached the coast of Western Australia, but the impact of such visitors was slight and was confined to the coastal regions.

The date of the first sighting by Europeans of the western shores of Australia is uncertain. It has been suggested that both the western and northern coasts of the state may be identified with the "Java le Grande" of maps said to date from around 1550. It is possible that Portuguese navigators sighted the northwestern coast on the way to the Spice Islands, as early as 1527. The first landing of which definite records exist is that of the Dutch captain Dirck Hartog in October 1616. To commemorate his discovery, Hartog left a pewter dinner plate, with an inscription scratched into it, on the island now bearing his name. Subsequent Dutch navigators, including Abel Janszoon Tasman, charted the coast as far east as Nuyts Land, between 1618 and 1644. Later comers included William Dampier (1688 and 1699) who visited the northwest coast but reported unenthusiastically on colonization and trade. Other early adventurers and explorers were William de Vlamingh (1697–99), George Vancouver (1791), and Antoine Bruni d'Entrecasteaux (1792). None of these early explorers ventured beyond the waterless and barren coastal hills, as the insects and heat discouraged excursions inland and prospects for trade looked slim.

Dutch exploration

The colony of New South Wales, established by the English in 1788, included only the eastern half of Australia. The remainder of the continent continued to be known as New Holland, the name given to the region by Abel Tasman in 1644. The western boundary of New South Wales was extended to longitude 129° E, leaving the area of Western Australian unclaimed.

The earliest settlement was made from Sydney, then a British possession, in December 1826. Because of suspicions that the French might establish a base on the west coast of Australia, Maj. Edmund Lockyer was dispatched to take formal possession of King George Sound with a party of convicts and soldiers. This establishment remained under the control of the government in Sydney until 1831. Meanwhile, in March 1827 Capt. James Stirling had made a survey of the Swan River and offered to lead an expedition to establish a settlement on the coast. His offer was at first rejected, but in 1828 the British government, uncertain of French intentions in the area and encouraged by the interest of a number of potential investors and colonists, sent Capt. C.H. Fremantle to take possession of the unoccupied part of Australia west of 129° E. In June 1829 Stirling arrived, as lieutenant governor, and shortly afterward founded the towns of Perth and Fremantle on the Swan. Several parties of migrants followed, including those brought out by Thomas Peel, the largest single investor. They were ill-prepared for pioneering; the coastal land was poor and labour to work the large and scattered land grants was unobtainable. Many left for the eastern colonies, but the discovery of better land beyond the Darling Range led to the extension and consolidation of settlement by 1835.

Western Australian Company

Despite Peel's failure, a second syndicate, the Western Australian Company, was formed in 1840 to acquire the Lautour estate, 90 miles south of Perth, and to establish a settlement there. Between 1841 and 1843, several parties were sent out to this new settlement, Australind, but loss of confidence among those financing the scheme contributed to its failure. The explorations of George Grey (1838) and the Gregory brothers (1845–46 and 1848) led to the settlement of the Champion Bay district, north of Perth, centred on the town of Geraldton.

The continued labour shortage in the colony led to a demand that convicts be imported from the United Kingdom for employment on public works and private farms. Consequently, an order-in-council authorizing the transportation of convicts to the colony was issued in 1849. The cheap convict labour, combined with grants-in-aid from the United Kingdom, gave an impetus to expansion before convict transportation ceased in 1868. The northwestern pastoral country was opened in 1863 after further explorations by the Gregory brothers. After the abolition of transportation, a partly elective Legislative Council was appointed in 1870, during the administration of Gov. F.A. Weld. Between 1870 and 1890 valuable work in opening up more land for pastoral and agricultural settlement was performed by the officers of the Survey Department, under Malcolm Fraser and John Forrest. The brothers John and Alexander Forrest crossed the continent between Esperance and Adelaide in 1870 and between Geraldton and the overland telegraph line in 1874. Other transcontinental crossings were made by P.E. Warburton in 1873 and E. Giles in 1875. Such explorations enlarged the area of pastoral settlement but demonstrated the desert nature of much of the interior.

Alexander Forrest opened up the Kimberley district in 1879 and there, in 1885, the government geologist reported indications of the presence of gold. A gold rush to Hall's Creek followed (1885–87), but this field had been largely abandoned by the time of the proclamation of goldfields in the Pilbara district in the north in 1888, and in the Yilgarin, 200 miles to the east of Perth, in 1887. Within five years, richer finds followed at Murchison (1891), Coolgardie (1892), and Kalgoorlie (1892–94).

Progress in other directions included the construction of a railway from Perth to Albany, completed in 1889, and the beginning of another to Geraldton. The improving prospects of the colony induced a demand for responsible government. A bill enabling Queen Victoria to grant a constitution to Western Australia received the royal as-

Representative government

sent on August 15, 1890. This provided for a governor, a nominated Legislative Council, and an elected Legislative Assembly. The Legislative Council was to become elective when the population reached 60,000—a change effected in 1893.

FEDERATION AND THE STATE OF WESTERN AUSTRALIA

Sir John (later Lord) Forrest, prime minister from 1890 until his entry into federal politics on the establishment of the Commonwealth of Australia in 1901, led a legislature at first dominated by primary producing interests. The advent of thousands of gold miners accelerated the progress of Western Australia and led to the provision of such public works as the Fremantle harbour and the Perth–Kalgoorlie railway. Forrest also sponsored the construction of a pipeline through which water was pumped more than 300 miles from Mundaring (new Perth) to the arid Coolgardie goldfields. During Forrest's later years of office, however, an opposition party arose among the goldfields men—many of them from Victoria and New South Wales—who strongly supported the movement to have Western Australia join in an Australian federation.

The agricultural interests hesitated to join the new Commonwealth of Australia without receiving a pledge for the retention of their own customs dues for five years, but after Forrest had made an unsuccessful attempt early in 1900 to secure this concession from the other colonies, a referendum in July of that year showed that a majority of more than 25,000 in Western Australia favoured federation. The Constitution Act ultimately provided that Western Australia should have the right to enact its own tariff as against the sister states for five years, decreasing annually at the rate of one-fifth of the amount of the original duty until it disappeared. A gentlemen's agreement among the prime ministers also provided for the construction of a transcontinental railway.

With the decline of alluvial mining, a policy of agricultural expansion was pursued and, between 1906 and 1914, the wheat lands were extended into the 10-inch rainfall area. The growth of the new wheat belt was the greatest achievement of the first 30 years of the 20th century. The federal government's policy of protecting secondary industries tended to react unfavourably on Western Australia, which emphasized primary production, so that during the Depression at the end of the 1920s a movement arose for secession from the federation. A referendum held in 1933 favoured secession, by 138,653 votes to 70,706, but in 1935 a joint committee of the British Houses of Parliament declared itself incompetent to consider the state's petition to give effect to this move. With the revival of prosperity and the coming of World War II, during which Western Australia faced a threat of invasion by Japan, the secession movement lost force. Good wheat and wool prices and a rapidly rising population, mainly the result of federally aided immigration from the United Kingdom and other European countries, ensured postwar prosperity. The potentialities of the northern part of the state were emphasized in the 1960s by iron-ore sales to Japan and by cotton growing, which was made possible by the damming of the Ord River.

Western Australia thus entered the second half of the 20th century with an awareness of impending economic and social changes. The material progress of the 1950s and 1960s in fact proved comparable with that which had followed the gold discoveries.

Liberal–Country coalition

In 1959 a Labor administration (1953–59) was succeeded by a Liberal–Country coalition government under the leadership of David Brand. Both governments were active in promoting housing programs and industrial development with overseas capital, but the Brand administration and its minister for industrial development and for the northwest, Charles Court, were particularly identified with the Northwest mineral and Ord River schemes noted below. Confirmed in office in 1962 and 1965, the Brand administration faced a strong challenge from a Labor Party led by John Tonkin on the retirement of A.R.G. Hawke in 1968, but was returned to power, with a reduced majority, in elections in March of that year. The Liberal–Country party remained the dominant political force in the later 20th century.

Technological advances, further agricultural mechanization, and irrigation from the Ord River have opened new areas for agricultural development in the southeast.

Since the end of World War II, Western Australia has attempted to attract outside capital for industrial development. These efforts created increased volume in manufacturing beginning in the 1950s. The opening of an oil refinery and steel mill in Kwinana (1955–56) was one of the early rewards. Emphasis shifted to mineral exploitation during the 1960s with the discovery of a commercial oil field on Barrow Island, vast iron-ore deposits, and extraction of bauxite and nickel. (F.A./Ed.)

AUSTRALIAN EXTERNAL TERRITORIES

Apart from claims in Antarctica, the external territories of the Commonwealth of Australia are made up entirely of islands. They comprise innumerable small reefs, cays, and atolls between the Great Barrier Reef of Queensland and longitude 157°10′ E, and several remote and diverse islands in the Pacific and Indian oceans. These latter oceanic outposts represent the tips of submerged mountain ranges, many of volcanic origin. Those in the tropics often support fringing coral reefs, or atolls, where the sea level has risen sufficiently relative to the basic rock. Each of the Australian external territories was uninhabited when it was first annexed by Great Britain.

The composition of the Australian external territories is as follows: Norfolk Island, in latitude 29°02′ S, longitude 167°57′ E, a fertile and beautiful island famous for its indigenous pine (*Araucaria excelsa*). Also in the Pacific is the Coral Sea Islands Territory (created by act of the commonwealth on September 30, 1969), scattered over 400,000 square miles (1,000,000 square kilometres) of tropical waters and uninhabited except by observers at the commonwealth meteorological station on Willis Island (established 1921) at latitude 16° S, longitude 150° E.

The Cocos (Keeling) Islands, consisting of two atolls totalling 27 islands, are located in the Indian Ocean in latitude 12°10′ S, longitude 96°55′ E. By their transfer from Britain to the Commonwealth of Australia under the Cocos (Keeling) Act (1955), they ceased to be part of the then British colony of Singapore.

Christmas Island, in latitude 10°30′ S and longitude 105°40′ E, is a source of high-grade rock phosphate. It was transferred to Australia by Britain, under the Christmas Island Act (1958). The minute, uninhabited Ashmore and Cartier Islands, also in the Indian Ocean, are defined by the Ashmore and Cartier Islands Acceptance Act, 1933. Cartier is in latitude 12°32′ S, longitude 123°32′ E, and the Ashmore group of three small exposures lie about 30 miles (48 kilometres) northwest of Cartier.

The claim comprising Australian Antarctic Territory consists of all islands and territories, other than Adélie Land, situated south of the 60th parallel of south latitude and between the 45th and 160th eastern meridians. This territory, over which the British government formerly asserted the crown's sovereign rights, was transferred to Australia under the Australian Antarctic Territory Acceptance Act (1933). Heard Island, in latitude 53°06′ S, longitude 73°30′ E, is perpetually ice-capped; with the nearby McDonald Islands, it was transferred from Britain to Australia in 1947. The Heard and McDonald Islands Act (1953) defines Australia's claim.

A radio network provides channels for administrative and commercial interests and for an extensive exchange of meteorological and other scientific information. Physical contact between the commonwealth and its territories varies from periodic air services from the appropriate Australian capitals to the annual relief of Antarctic stations by vessels strengthened for ice.

Administrative responsibilities

The commonwealth Department of Home Affairs provides administrative services for Norfolk Island, the Cocos (Keeling) Islands, Christmas Island, the Coral Sea Islands, and the Ashmore and Cartier group, except in matters of defense and civil aviation, for which other departments are responsible. The Department of Administrative Services provides policy advice with regard to the phosphate enterprise of Christmas Island, and, in general, the Department of Primary Industry is concerned with fishing rights in the Australian 200-mile zones surrounding the territories, which effectively increase their areas of economic interest very considerably. For the inhabited territories, an administrator or official representative is appointed by the governor general of Australia to assist the government of the territory on behalf of the commonwealth. By act of self-determination the Cocos (Keeling) Islands voted for integration with Australia in 1984. In 1968 and 1975, respectively, the independence of the former external territories of Nauru and Papua (as Papua New Guinea) was attained.

The commonwealth Department of Science and the Environment is responsible for the administration of Australia's Antarctic interests and the enactments defined by the Antarctic Treaty Act (1959), the Australian Antarctic Treaty Acceptance Act (1933), and the acts relating to Heard and the McDonald Islands. The Department of Science and the Environment, through its Antarctic Division, oversees the logistics of the annual relief operations of Australia's scientific bases in Antarctica (for which such departments as that of national development supply certain scientific and technical personnel) and for their general function and administration.

Norfolk Island

PHYSICAL AND HUMAN GEOGRAPHY

Norfolk Island, with a total area of about 13.3 square miles (34.5 square kilometres), is volcanic in origin and rises precipitously from an extensive submarine ridge connecting the North Island of New Zealand with New Caledonia and thence, in general, with Melanesia and New Guinea. It has a mean altitude of 360 feet (110 metres), with two high points, Mt. Pitt and Mt. Bates, just exceeding 1,000 feet (300 metres). To the south, and close inshore, are two small, uninhabited islands—Nepean, of limestone, and Phillip, which is volcanic, eroded, and almost denuded of vegetation by introduced animals. Norfolk Island is 1,041 miles (1,676 kilometres) east-northeast of Sydney and 660 miles (1,063 kilometres) north of Auckland, N.Z., in latitude 29°02′ S and longitude 167°57′ E. The climate is pleasant and equable, with a mean rainfall of 53 inches (1,350 millimetres), and temperatures ranging between 81° F (26.7° C) and 50° F (10.3° C). Although most of the island has been cleared for cropping and pasture, the once dominant Norfolk Island pines (*Araucaria excelsa,* or *heterophylla*) are still a notable feature of the landscape. Kingston, in the south, is the main settlement and administrative centre. Norfolk Island possesses a considerable flora and fauna. To 173 species of native vascular plants have been added some 250 introduced species. Fifty plants are endemic to the island. Apart from 55 indigenous species of birds (14 endemic) the fauna includes one species each of gecko, bat, and turtle; plentiful fishes; and numerous invertebrates. For some decades whaling was a hazardous island industry.

Tourism is the dominant economic activity on Norfolk Island. A large segment of the population derives its income from various aspects of the tourist industry, such as hotels and duty-free goods. Sea and air services are available on a regular basis. The soil is fertile and allows a variety of tropical and semitropical cultivation. There are, however, only a few crops exported from the island, and most foodstuffs must be imported from the mainland. Fish are plentiful, but the lack of a sheltered harbour has prevented any exploitation of this resource.

Imports to Norfolk Island have risen since World War II. The majority of the imports come from Australia, New Zealand, and the Pacific Islands. Goods manufactured and produced on Norfolk Island can be exported to Australia duty free. Passenger service and airfreight are available between Sydney and Norfolk Island while oceangoing shipping services operate at monthly intervals between the island, the mainland, and New Zealand.

Local government

Norfolk Island has a Legislative Assembly and Executive Council, which have ministerial duties and run many of the affairs of the island. The Supreme Court is the island's highest judicial authority and the original jurisdiction for criminal and many civil cases. The Court of Petty Sessions is the lower court for criminal and civil jurisdiction.

Like the other states and territories of the commonwealth, education is free and compulsory for children between six and 15 years of age. Island schools cover the kindergarten years through grade 10. Higher education must be sought at mainland colleges and universities. A limited number of vocational apprenticeships are also available.

HISTORY

Following his discovery of the island, which he found uninhabited, Capt. James Cook, in 1774, wrote enthusiastically on the indigenous "spruce pines," which he believed to be of great potential value as ships' masts, and on the local flax (*Phormium tenax*). Within a few weeks of the settlement of New South Wales by Gov. Arthur Phillip, in February 1788, Norfolk Island was also settled by a small party, including 15 convicts, under the command of Lieut. Philip Gidley King. Its purpose was to forestall any possible French occupation, to propagate the native flax, and to exploit the timber. After 26 years as a British convict colony, with a maximum of 1,100 convicts and free settlers, the island was abandoned. The population was withdrawn, mainly to Van Diemen's Land, renamed Tasmania in 1856.

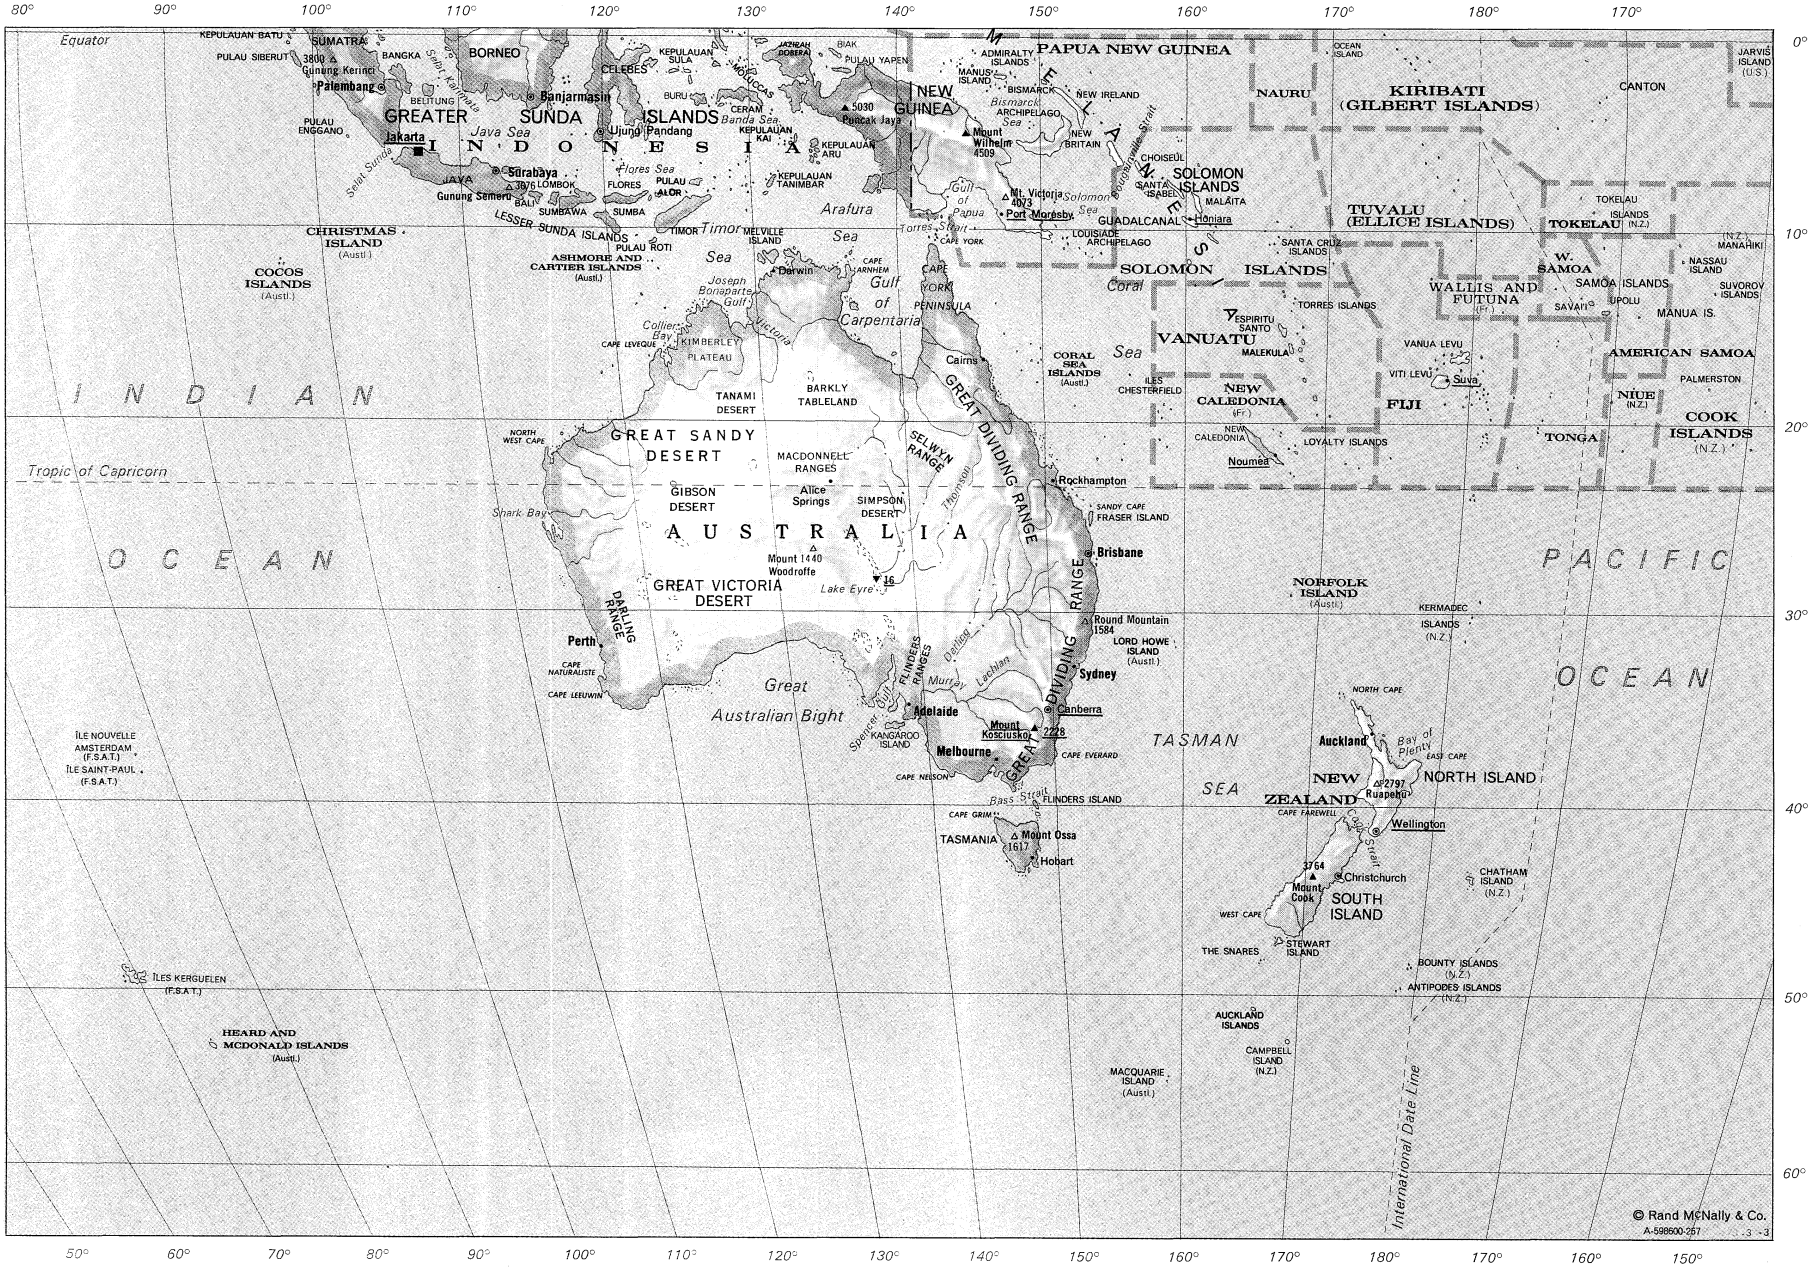
The next phase of Norfolk Island history lasted from June 1825 to June 1856. Reestablished as a penitentiary for the reception of the most desperate criminals from the British convict settlements in Australia, it became a place of merciless discipline and punishment. Fear possessed both prisoners and jailers, and in the three decades of convict occupation and human misery there were few redeeming aspects of settlement or administration. A number of substantial ruins and a few colonial buildings intact in stone remain, giving a poignant and picturesque note to the gentle landscapes.

Although the reasons for again evacuating all convicts to Tasmania resulted from difficulties of supervising the administration as much as that of the convicts, the contemporary need for better accommodation of the Pitcairn islanders contributed reasons for the change. Norfolk Island seemed a most suitable place for resettling the descendants of the mutineers of the "Bounty."

In April 1789, when Capt. William Bligh of HMS "Bounty" and a number of loyal officers had been set adrift, ultimately to reach Timor, the Pitcairners' history began. While most of the mutineers stayed on Tahiti, nine, with a number of Tahitians, both men and women, sailed on, by way of Tonga and Fiji, and eventually reached Pitcairn Island, latitude 25°04′ S, longitude 130°06′ W, a desert island discovered by Philip Carteret in 1767. In the early years violence, bloodshed, and illness ultimately left one European male, Alexander Smith, with a number of Tahitian women and half-caste children surviving in a strangely tranquil and pious community. Smith had changed his name to John Adams. The descendants of the mutineers, with a few adventurous newcomers, comprised 194 persons when, after 67 years and many vicissitudes, they were transported to Norfolk Island, arriving there in the "Morayshire" on June 8, 1856.

Not all of the islanders settled happily on Norfolk; two small parties returned to Pitcairn. Strong Polynesian characteristics and residual traits and customs persisted and are considered to be an influence among some island people to this day. A distinctive society developed, based on neighbourliness, self-help, barter, and respect for authority. Specific ethnic and religious festivals continue to be celebrated. Of the total population, perhaps one-third may claim lineal descent from the Pitcairners. Immigration is now strictly controlled.

Norfolk Island was originally made "a distinct and sep-



AUSTRALIAN EXTERNAL TERRITORIES

Size of symbol indicates relative size of town • ⊙ ■

Elevations in metres

arate settlement" from the mainland colonies on June 24, 1856. Rapidly the islanders established their own systems of land tenure and society generally. In 1897 Britain conferred administrative status on the governor of New South Wales, though the island still remained a separate British colony.

Norfolk Island Act

In 1913, under the Norfolk Island Act (effective 1914), the colony became a territory of the commonwealth, but the precise constitutional relationship with Australia was never the subject of complete agreement. The independent nature of the original Pitcairners has often seemed dominant in island aspirations. An airfield constructed on the island during World War II gave Norfolk a close, reliable link with the outside world and the means to support steady growth of facilities to match its potential attraction for tourists. There was inevitable trading in ideas: Norfolk became aware of modern amenities. Australian enterprise rapidly moved into tax-free Norfolk Island, and many hundreds of new companies were registered there. Australia also discovered that its Norfolk territory required the fuller application of certain conventions of the International Labour Organisation.

With such emphases and with visitors to this beautiful tax-free island reaching 20,000 or more annually (a third of them from New Zealand), a royal commission was appointed in 1975, under Sir John Nimmo, to report on the future status of Norfolk Island. His report (1976), concerned with the territory's constitution, its relationship to Australia, and the most appropriate forms of administration, was exhaustive. It revealed two opposing views: that Norfolk Island should be virtually absorbed into the mainland social and political system as a detached piece of Australia, a new electorate with all the privileges and duties of such; and that it should move at least some distance toward self-government. After long negotiations, a government of the second type for Norfolk Island, becoming operative in August 1979, was established by Australian commonwealth legislation. The Norfolk Island Act, 1979, provided for a nine-member Legislative Assembly elected triennially, an administrator, and an executive council holding ministerial portfolios. The duly elected assembly has the formal right to legislate on the raising of revenue and on other island functions, such as supply, commerce, immigration, and tourism; it may not act in matters of defense, coinage, or certain property transactions. The bill also reserves commonwealth powers of veto and of delaying the implementation of Norfolk Island acts. The recommendations for absorption were set aside, and the course of the territory headed toward internal self-government as a territory under the authority of the commonwealth.

The elections of 1979 were held under a proportional representation system. The legal system includes a Supreme Court, held on the mainland or with visiting mainland judges, and a Court of Petty Sessions under the jurisdiction of local magistrates.

Various Australian government departments are concerned with Norfolk Island as a commonwealth territory. In general, the responsible authority is vested in the Department of Home Affairs. The Department of Primary Industry controls the Australian Fisheries Council, being the advisory body on all aspects of administration and management of Australian fisheries, including those of Norfolk Island. The declaration of Norfolk's 200-mile economic zone, extending its fishing grounds to 124,000 square miles (320,000 square kilometres), is of considerable commercial interest not only to Australia but to its Pacific neighbours.

From the mid-1960s the economy of Norfolk Island changed from one based on subsistence farming, seed production, grazing, and local fishing, with a small tourist industry, to one principally dependent upon and catering to an annual influx of upwards of 20,000 visitors. Island agricultural produce cannot sustain demand, and most food must therefore be imported. There is considerable island revenue from liquor sales (a government monopoly), from sales of postage stamps to collectors around the world, and from customs duty and company fees. Australian currency is legal tender.

Christmas Island

PHYSICAL AND HUMAN GEOGRAPHY

At several points exceeding 1,100 feet (335 metres) in altitude, Christmas Island, with an area of 52 square miles (135 square kilometres), is situated in the Indian Ocean, the summit of an oceanic mountain surrounded by depths of 6,000 feet (1,800 metres). The abyssal Java Trench (24,440 feet, or 7,450 metres, at its deepest) is to the northeast. Abrupt cliffs comprise much of the coastline, but there are sand and coral beaches. The rock is mainly limestone stratified with old volcanic flows, with valuable deposits of lime near the chief port at Flying Fish Cove, below the northern Headridge Hill, and on the Southern Plateau. The island is 815 miles (1,312 kilometres) from Singapore, 220 miles (360 kilometres) from Java Head, and 1,630 miles (2,623 kilometres) from Fremantle, Western Australia. Its climate is salubrious and warm (64°–86° F, or 18°–30° C), with little seasonal variation but with a tropical rainy season between November and April. Rich forest clothes the island, and both flora and fauna are varied and numerous. The latter includes birds, small reptiles, crustaceans, insects, spiders, scorpions, and centipedes. The birdlife, with several endemic species, includes a large number of seabirds nesting on the island. About one-seventh of the flora, numbering 200 species of flowering plants, is endemic. Freshwater is available from springs and wells. Subsistence cropping and fishing are undertaken on a small scale, but virtually all food is imported. Charter flights link Christmas Island with several cities. Radioteletype and the usual overseas radiotelephone services are available. There are several major roads on the island, which has about 800 privately owned vehicles. A 20-kilometre railway transports phosphate from the southern plateau to the port and settlement on Flying Fish Cove. A spur line serves the western part of the island. The economy of the island is based entirely on phosphate mining.

Java Trench

An administrator of Christmas Island is appointed by the Australian governor general, with a staff for secretariat, education, police, radio, and harbour duties. There is also a full-time conservation officer. The judiciary consists of a Supreme Court, District Court, Magistrate's Court, and Children's Court. The Christmas Island Area School provides preschool, primary, and secondary education while trade instruction is available in the Island Technical School.

HISTORY

First sighted in 1615, the island was named on Christmas Day 1643 by Capt. William Mynors of the British East India Company. The British "Challenger" Expedition (1872–76) collected phosphate specimens from Javanese islands, and the expedition naturalist, John Murray, predicted massive deposits of guano on nearby Christmas Island. It was annexed by Great Britain on June 6, 1888. A 99-year lease, granted in 1891 to George Clunies-Ross of Cocos and John Murray, to mine phosphate and cut timber, was transferred six years later to the Christmas Island Phosphate Company Ltd., largely owned by the former lessees. Christmas Island was incorporated in the British crown colony of the Straits Settlements (capital, Singapore) in 1900. In 1942 many residents were evacuated, and the island was subsequently occupied by the Japanese, though phosphate was not mined by them. After the war (1948) the interests of the Christmas Island Phosphate Company were acquired by the governments of Australia and New Zealand. In 1958, when the island became an Australian territory, a new agreement ratified the existing legislature, and it was arranged that the Christmas Island Phosphate Commission (established 1949), on behalf of both governments, should quarry and ship the valuable deposits. Reserves of phosphate of various grades have been estimated at a few hundred million metric tons, but first-grade material is much less plentiful.

The population is mainly Chinese and Malay labourers recruited from Malaysia, Singapore, and the Cocos (Keeling) Islands, working for the commission, with Australian and British management personnel, and the island admin-

Migration of workers

istration. About one-third of the population arrives or departs each year. For long-term Asian residents, legislation has provided opportunities of resettlement in countries as chosen, provided the emigrants conform to immigration requirements. Most have chosen resettlement in Western Australia. Between December 1976 and June 1978, 578 Christmas islanders were permanently resettled under the scheme.

Cocos (Keeling) Islands

PHYSICAL AND HUMAN GEOGRAPHY

The two low coral atolls known together as the Territory of Cocos (Keeling) Islands, lie in the Indian Ocean in latitude 12°10′ S and longitude 96°55′ E, approximately 1,720 miles (2,768 kilometres) northwest of Perth and 2,290 miles (3,685 kilometres) almost due west of Darwin. They comprise 27 small coral islands totalling about 5½ square miles (14 square kilometres) in area. One atoll, North Keeling, is a single island standing about 15 miles (24 kilometres) north of the main lagoon, which is surrounded by the numerous exposures of the South Keeling Islands. Of these, West Island is the largest, measuring 6¼ miles (10 kilometres) long and one-third of a mile (0.5 kilometre) wide. The other principal islands of the South Keelings are South, Home, Direction, and Horsburgh. Coral sand or clinker raises the larger islands to heights of 10 to 20 feet (three to six metres). They shelve steeply to the surrounding sea and to the reef that protects and, from its debris, nourishes them.

Vegetation is extensive on all islands, with valuable coconut palms predominating over scrubby jungle along the outer, seaward margins. On North Keeling and Horsburgh islands there are areas of coarse grass. Large numbers of seabirds—terns, gannets, and petrels—thrive on the islands. Some land birds, white-eyes, Java sparrows, and thrushes, have reached Cocos (Keeling) from Indonesia.

Climate

The climate is equable, the range of temperatures throughout the year varying between 72° and 90° F (22° and 32° C). Rainfall, over five years, averaged 91 inches (2,312 millimetres) a year; relative humidity averages about 75 percent. In 1968 severe damage was caused by a tropical cyclone. No streams or surface water occur, but on the larger islands ample water may be obtained from wells sunk to depths of three to five metres.

The Cocos Islands Council is responsible for a wide range of functions in the Home Island village area. It also advises the administrator on matters concerning the islands and comments upon proposed legislation. The islands operate their own postal service with the revenues used for the benefit of the citizens.

HISTORY

Capt. William Keeling is credited with the discovery of the northern island in 1609, but the group remained uninhabited until 1826 when the Englishman Alexander Hare settled. A year later he was joined by John Clunies-Ross, who brought a number of Malays to assist in harvesting the coconuts for copra. Hare departed in 1831, and Clunies-Ross increased his holding and his labour force and commenced a powerful association which, in changing circumstances, has since been maintained. Descendants of the original workers, who, though often called Cocos Malays, included natives of several Asian countries and some East Africans, are still living in the islands. In the years 1948–51 more than 1,600 of the population, which had grown beyond the capacity of the islands to sustain, were assisted to migrate. The majority were resettled on estates in what is now Sabah, Malaysia. Some went to Singapore or Christmas Island.

Urged by Clunies-Ross, Britain annexed the islands in 1857, when John George Clunies-Ross had succeeded his father. A formal declaration to this effect was made by Capt. Stephen Fremantle of HMS "Juno." Subsequently, supervisory roles were bestowed successively on Ceylon (1878) and the Straits Settlements (1886). In 1886 also, Queen Victoria made her historic grant in perpetuity to George Clunies-Ross of all land above high-water mark, subject to a formal right of repossession by the crown. So began the benign but authoritarian rule, lasting more than 90 years, of the "kings of the Cocos."

The islands, as a site of a vital cable station and as a military base, proved to be of strategic importance and saw enemy action in both world wars. In 1945, during the allied military occupation, an airstrip was constructed on West Island. In 1951 the purchase of land on West Island by the Australian commonwealth was negotiated, the airstrip was reconstructed for civilian use, and until 1967 Cocos (Keeling) was used as a staging point on flights between Australia and Africa.

Australian sovereignty

From the then British colony of Singapore, Australia accepted territorial rights over Cocos (Keeling) on November 23, 1955, effected by an order in council made by Queen Elizabeth II and under reciprocal rights of the United Kingdom and Australia. With the Cocos (Keeling) Islands Act, 1955–75, of Australia, all Cocos Malays born after November 23, 1955, are Australian citizens and entitled to residence on the mainland; former British subjects also had the option of Australian citizenship. Numbers of Cocos islanders have accordingly settled in Australia, mainly in Western Australia. The Cocos Malay group live on Home Island; the remainder of the population are mainland-recruited employees of the territory administration, and their families, living on West Island.

Clunies-Ross interests purchased by the commonwealth

Until 1984 the Territory of Cocos (Keeling) Islands was a non-self-governing territory to which Chapter XI of the United Nations Charter applied. In September 1978, after considerable negotiation, the Australian commonwealth purchased all of the Clunies-Ross commercial plantation and island enterprises; it first leased the property to the Cocos Islands Co-operative Society Limited at a nominal rental and subsequently transferred the ownership of most of the land to the Cocos Islands Council. A high security animal quarantine station has been established to safeguard Australian herds while allowing the entry of genetically superior animals. With plantation palms numbering some 350,000, copra is the sole cash crop and thus the territory's mainstay. The Local Government Ordinance of 1979 established the Cocos (Keeling) Islands Council, which provides local government. In 1984, following an act of self-determination by the Cocos Malay people witnessed by a UN Mission, the Cocos (Keeling) Islands became integrated with Australia.

Coral Sea Islands Territory

Australia's Coral Sea Islands include the Flinders Reefs, Herald Cays, Holmes Reefs, Moore Reefs, Bougainville Reef, Osprey Reef, Willis Group, and others in the northwest of the Coral Sea, and a southeasterly group embracing Frederick Reefs, Saumarez Reefs, and Cato Island. All except Willis Group are uninhabited, but they are occasionally visited by scientists, fishermen, and prospectors for oil or minerals.

British naval vessels—HMS "Cato" (1803), "Frederick" (1812), and "Herald" (1854–60)—discovered and surveyed these low coral islands, all of which are either the tops of volcanic foundations or the dissected remnants of submarine plateaus. Spread over 400,000 square miles (1,000,000 square kilometres) between the Great Barrier Reef and longitude 157°10′ E, and south of latitude 12° S, the islands were declared a Territory of Australia by the Coral Sea Islands Act, 1969, with amendments, 1973.

Coral Sea Islands Act

The territory is administered by the Department of Home Affairs. Several automatic weather stations supplement information from the manned Australian Bureau of Meteorology station (1921) on Willis Group, some 300 miles (500 kilometres) east of Cairns, Queensland.

Ashmore and Cartier Islands

Similarly administered by the Department of Home Affairs are the remote, uninhabited Ashmore and Cartier Islands, the Australian territory nearest to Indonesia. Cartier Island was discovered by Captain Nash, and named after his vessel, in 1799 or 1800. It is about four feet (one metre) above sea level and little more than an acre (0.4 hectare) in extent. On Ashmore Reef there are three small

coral islands—West, Middle, and East—totalling about 230 acres (93 hectares). Turtles are plentiful, and at one time guano was dug, though supplies were soon exhausted. Ashmore Reef, rising from the broad, shallow sea covering the Sahul Shelf, was annexed by Britain in 1878, Cartier in 1909. Australia officially agreed to accept sovereignty in 1933 and an amendment of 1938 annexed the islands to the Northern Territory. There is an automatic weather station on West Island.

Heard and McDonald Islands

Heard Island was occupied continuously from 1947 to 1955 by the Australian National Antarctic Research Expeditions (ANARE), the scientific program then being transferred to stations on the Antarctic mainland. The deserted station on Heard, latitude 53°06′ S, longitude 73°30′ E, is visited occasionally by relief expeditions bound for the more southerly bases and has been used by U.S. scientists and technicians concerned with satellite tracking and other space programs. The island was first sighted in 1833 but was lost and rediscovered once or twice before being named, in 1855, after an American captain. After 1855 many teams exploited the island's elephant seals and penguins for their oil. The island is about 180 square miles (466 square kilometres) in area, and its dormant volcano, Big Ben, rises to 9,005 feet (2,745 metres). The island has been extensively explored by Australian expeditions. The nearby McDonald Islands have not been occupied. Like the lower parts of Heard Island, they are sparsely covered with cushion plants, rough tussock grass, mosses, and lichens, and they are visited by large numbers of elephant seals, leopard seals, and penguins. Several kinds of petrels, albatrosses, and skuas that breed on Heard Island probably also inhabit the McDonalds.

Australian Antarctic Territory

Under the terms of the Antarctic Treaty (1959), until virtually the end of the 20th century, territorial claims and ambitions in the Antarctic were to be held in abeyance. The concept of a United Nations or other international control of the whole continent in perpetuity has been advanced from time to time. Scientific cooperation between the treaty nations has proved successful, and the BIOMASS (Biological Investigation of Marine Antarctic Systems and Stocks) program has engaged the research of the Antarctic Treaty signatory nations. Any real or potential exploitation of Antarctic resources, or of exclusive economic zones, however, has revived consideration of national territorial claims and fishing rights. The focus of world interest on the possible exploitation of hydrocarbon deposits and (though whaling has declined) on the marine wealth of the Antarctic seas in krill trawling and fisheries also has retarded activities pertaining to international control.

Australian Antarctic research

Australia has maintained continuous Antarctic scientific research and an extensive program of physical exploration by sea, land, and air since 1954. Before that Australian explorers had been associated with most of the major British expeditions and played a leading role in some. Apart from the long-established sub-Antarctic base on Macquarie Island (administratively part of the state of Tasmania), in latitude 54°28′ S, longitude 158°57′ E, Australia maintains three continental bases: Mawson station (1954) on MacRobertson Land in latitude 67°36′ S, longitude 62°53′ E; Davis station (1957) on Ingrid Christensen Coast in latitude 68°35′ S, longitude 77°58′ E; and Casey station (1969) in Wilkes Land in latitude 66°17′ S, longitude 110°32′ E. Casey replaced the U.S. base at Wilkes station, built for the International Geophysical Year in 1957 and occupied by Australia during 1959–69.

History: The best general accounts of traditional Aboriginal life are A.P. ELKIN, *The Australian Aborigines* (1964); R.M. and C.H. BERNDT, *The World of the First Australians,* 3rd ed. (1969); F.D. MCCARTHY, *Australia's Aborigines: Their Life and Culture* (1957); R.M. and C.H. BERNDT (eds.), *Aboriginal Man in Australia* (1965); and R.M. BERNDT (ed.), *Australian Aboriginal Anthropology* (1970). H. SHEILS (ed.), *Australian Aboriginal Studies* (1963), also gives a general coverage focussed on research problems. Most of these volumes include sections on change; but see especially M. REAY (ed.), *Aborigines Now* (1964); I.G. SHARP and C.M. TATZ (eds.), *Aborigines in the Economy* (1966); W.E.H. STANNER, *After the Dreaming* (1969); D.E. HUTCHINSON (ed.), *Aboriginal Progress: A New Era?* (1969); G. BLAINEY, *Triumph of the Nomads: A History of Aboriginal Australia* (1976); and, related to Aboriginal policy and practice, C.D. ROWLEY, *The Destruction of Aboriginal Society* (1970), *Outcasts in White Australia* (1971), and *The Remote Aborigines* (1971). A large series of monographs on various aspects of Aboriginal life has been produced by the Australian Institute of Aboriginal Studies.

Separate and detailed studies of Aboriginal societies are by W.L. WARNER, *A Black Civilization* (1937); C.W.M. HART and A.R. PILLING, *The Tiwi of North Australia* (1960); M.J. MEGGITT, *Desert People: A Study of the Walbiri Aborigines of Central Australia* (1962); L.R. HIATT, *Kinship and Conflict: A Study of an Aboriginal Community in Northern Arnhem Land* (1965); and R.M. and C.H. BERNDT, *Man, Land and Myth in North Australia: The Gunwinggu People* (1970).

Among the classic studies of the pre-anthropological era are those by R.B. SMYTH, *The Aborigines of Victoria,* 2 vol. (1878); J.D. WOODS (ed.), *The Native Tribes of South Australia, Comprising the Narrinyeri* (1879); E.M. CURR, *The Australian Race,* 4 vol. (1886–87); W.B. SPENCER and F.J. GILLEN, *The Native Tribes of Central Australia* (1899, reprinted 1938); A.W. HOWITT, *The Native Tribes of South-East Australia* (1904); W.B. SPENCER, *The Native Tribes of the Northern Territory of Australia* (1914); B. MALINOWSKI, *The Family Among the Australian Aborigines* (1913); and H. BASEDOW, *The Australian Aboriginal* (1925).

The basis of professional anthropological work was established by A.R. RADCLIFFE-BROWN—see his *Social Organization of Australian Tribes* (1931) and *Structure and Function in Primitive Society* (1952); and A.P. ELKIN, *Studies in Australian Totemism* (1933) and *Aboriginal Men of High Degree* (1946); in the contact sphere, A.P. ELKIN's article on "Reaction and Interaction: A Food Gathering People and European Settlement in Australia," *Am. Anthrop.,* 53:164–186 (1951), is significant. In regard to studies on Aboriginal women, see P.M. KABERRY, *Aboriginal Woman, Sacred and Profane* (1939); and C.H. BERNDT, *Women's Changing Ceremonies in Northern Australia* (1950); also F. GALE (ed.), *Women's Role in Aboriginal Society* (1971). On Aboriginal art, see F.D. MCCARTHY, *Australian Aboriginal Decorative Art,* 5th ed. (1958) and *Australian Aboriginal Rock Art* (1958); C.P. MOUNTFORD, *The Tiwi: Their Art, Myth, and Ceremony* (1958), and (ed.), *Art, Myth and Symbolism* (1956); and R.M. BERNDT (ed.), *Australian Aboriginal Art* (1964).

Controversies have stimulated discussion on certain aspects of traditional Aboriginal life. One arose from W.L. WARNER's and A.R. RADCLIFFE-BROWN's interpretation of the so-called "Murngin" kinship system. See also J.A. BARNES, *Inquest on the Murngin* (1967); and R.M. BERNDT in F.L.K. HSU (ed.), *Kinship and Culture* (1971). The concept of the local group vis-à-vis the horde, also arising from Radcliffe-Brown's earlier contentions, has been discussed by R.M. BERNDT in *Oceania,* 30:81–107 (1959–60); W.E.H. STANNER, *Oceania,* 37:1–26 (1965); and L.R. HIATT, *Oceania,* 32:267–286 (1962), and 37:81–92 (1966); as well as by J.B. BIRDSELL, with a commentary by students of Aboriginal affairs, in *Cur. Anthrop.,* 11:115–131, 138–142 (1970). The issues of law and order in the absence of clearly defined political authority, the relevance of kinship in this respect, and the place of tribal elders are the subject of conflicting views. R.L. SHARP in *Systems of Political Control and Bureaucracy in Human Societies,* ed. by V.F. RAY (1958); M.J. MEGGITT, *Indigenous Forms of Government Among the Australian Aborigines* (1962); and L. HIATT, "Social Control in Central Arnhem Land," *South Pacific,* 10:182–192 (1959), have taken one approach against A.P. ELKIN and R.M. BERNDT in *Aboriginal Man in Australia* (1965); and T.G.H. STREHLOW in *Australian Aboriginal Anthropology* (1970). However, the most long-standing controversy, deriving from Durkheim, has centred on totemism and has recently been revived by C. LEVI-STRAUSS in *Le Totémisme aujourd'hui* (1962; Eng. trans., 1963).

New South Wales: The best source for up-to-date facts and statistics on New South Wales is the *Official Year Book,* issued annually by the government of New South Wales in conjunction with the Commonwealth Bureau of Census and Statistics. Historical, as well as other, information on New South Wales may be found in books on Australia, such as G. GREENWOOD (ed.), *Australia: A Social and Political History* (1955 and 1966); and A.G.L. SHAW, *The Story of Australia* (1955).

Northern Territory: Accounts of investigations of dry-land and irrigation farming, establishment of pastures, and husbandry are published in the COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION (CSIRO), *Division of Land Research and Regional Survey* (annual). Other references are CSIRO, *Katherine Research Station Report 1946–56* (1959); the DEPARTMENT OF TERRITORIES, *Prospects of Agriculture in the Northern Territory* (1960); B.R. DAVIDSON, *The Northern Myth: A Study of the Physical and Economic Limits to Agricultural and Pastoral Development in Tropical Australia* (1965); J.H. KELLY, *Struggle for the North* (1966); and the annual *Official Year Book of the Commonwealth of Australia and Northern Territory Statistical Summary.*

Queensland: GOVERNMENT STATISTICIAN, *Queensland Yearbook* (annual) and current bulletins; PREMIER'S DEPARTMENT, *The Queensland Scene* (1971), a pictorial account, with brief text; DEPARTMENT OF INDUSTRIAL DEVELOPMENT, *Investment Queensland, Australia* (1969); R.H. GREENWOOD, *Regions of Queensland* (1971); R.W. CILENTO (ed.), *Triumph in the Tropics* (1959), a historical study; STANLEY and KAY BREEDEN, *Tropical Queensland* (1970), on the flora, fauna, and landscape; GEORGE FARWELL, *The Sun Country* (1970).

South Australia: The best general sources of information are the annual *South Australian Year Book* and the *Official Year Book of the Commonwealth of Australia,* both published by the Commonwealth Bureau of Census and Statistics. More detailed statistical information is contained in the *Statistical Register of South Australia* (South Australian Parliamentary Paper, annual). For geographical aspects, see R.J. BEST (ed.), *Introducing South Australia,* pt. 2 (1958); and M. WILLIAMS (ed.), *South Australia from the Air* (1969). A popular survey of the economy is *Business Guide to South Australia,* published by the Premier's Department (1969).

For a comprehensive study of education see *Education in South Australia* (1971), the report of an official enquiry published by the Government of South Australia.

Tasmania: J.L. DAVIES (ed.), *Atlas of Tasmania* (1965), comprehensive topical and topographical map coverage with detailed commentary; HOBART, COMMONWEALTH BUREAU OF CENSUS AND STATISTICS, *Tasmanian Year Book* (published annually since 1967), the most comprehensive and important single reference on Tasmania; WINIFRED M. CURTIS, *The Endemic Flora of Tasmania,* 3 pt. (1967–71), a definitive study, beautifully illustrated; MICHAEL SHARLAND, *Tasmanian Birds,* 3rd ed.

rev. (1958), a field guide; E.R. GUILER, *Marsupials of Tasmania* (1960), an illustrated handbook of diagnostic features; HUNTER VALLEY RESEARCH FOUNDATION, *Tasmania in the Seventies* (1970), an analysis of economic growth and growth potential; P.G. PAK POY AND ASSOCIATES, *Study of the Transport of Goods for Tasmania,* 5 reports (1971), an economic evaluation of Tasmanian transportation commissioned by the state government, including (no. 4) an economic growth study; R.L. WETTENHALL, *A Guide to Tasmanian Government Administration* (1968), a descriptive classification.

Victoria: The MELBOURNE, COMMONWEALTH BUREAU OF CENSUS AND STATISTICS, *Victorian Year Book* (annual), is the outstanding reference on all aspects of Victoria, including articles on a wide range of topics, well illustrated by maps and photographs, and bibliography.

Western Australia: MICHAEL K. MORCOMBE and OSMAR WHITE, *Western Australia in Colour* (1971), has excellent illustrations. Other illustrated books with general texts are OSMAR WHITE, *Under the Iron Rainbow: Northwest Australia Today* (1969); T.A.G. HUNGERFORD and RICHARD WOLDENDORP, *A Million Square: Western Australia* (1969); and IVAN O'RILEY, *Giant in the Sun* (1968). JAMES S. BATTYE, *Western Australia* (1924), was the first substantial historical work, now largely supplanted by FRANK K. CROWLEY, *Australia's Western Third* (1960); and FRANK K. CROWLEY and BRIAN DE GARIS, *A Short History of Western Australia,* 2nd ed. (1969). See also FREDERICK ALEXANDER, FRANK K. CROWLEY, and J.D. LEGGE, *The Origins of the Eastern Goldfields Water Scheme in Western Australia* (1954); and ALEXANDER M. KERR, *Australia's Northwest* (1967) and *The South-west Region of Western Australia,* 2nd ed. (1965), for regional economic studies. CAROLINE GYE, *The Cockney and the Crocodile* (1962); and CYNTHIA NOLAN, *Outback* (1962), are personal accounts dealing with the Aborigines. *The Official Year Book of Western Australia* contains political, social, and economic explanatory and summary data in addition to statistical information.

Australian External Territories: AUSTRALIAN BUREAU OF STATISTICS, *Year Book Australia* (annual); AUSTRALIAN GOVERNMENT PUBLISHING SERVICE, *Commonwealth Government Directory* (annual); R. ROSE, *Australia's Island Territories* (1967); DEPARTMENT OF EXTERNAL AFFAIRS, COMMONWEALTH OF AUSTRALIA, *External Territories* (1970). See also the annual reports of the Australian Commonwealth Departments of Home Affairs, Administrative Services, Science and the Environment, and National Development. Current events are recorded in the Commonwealth Parliamentary Debates (*Hansard*) and the Australian national newspapers.

Norfolk Island: AUSTRALIAN GOVERNMENT PUBLISHING SERVICE, *Norfolk Island* (annual reports); J.J. SPRUSON, *Norfolk Island: Outline of Its History from 1788 to 1884* (1885); A.S.C. ROSS *et al., The Pitcairnese Language* (1964); J.S. TURNER, C.N. SMITHERS, and R.D. HOOGLAND, *The Conservation of Norfolk Island* (1968, for the Australian Conservation Foundation); AUSTRALIAN GOVERNMENT PUBLISHING SERVICE, *Report of the Royal Commission into Matters Relating to Norfolk Island* (1976); PHILIP GRUNDY and ROGER WETTENHALL, "Norfolk Island Versus The Nimmo Report," *Current Affairs Bulletin* (Oct. 1977); STUART INDER, "Islanders or Australians?", *Pacific Islands Monthly* (Feb. 1979); MERVAL HOARE, *Norfolk Island, An Outline of Its History, 1774–1977* (1979); *Norfolk Island, a History Through Illustration, 1774–1974* (1979). Hoare's volumes contain an extensive bibliography of primary and secondary sources.

Cocos (Keeling) Islands: AUSTRALIAN GOVERNMENT PUBLISHING SERVICE, *Territory of Cocos (Keeling) Islands* (annual reports); J.S. HUGHES, *Kings of the Cocos* (1950); CHARLES DARWIN, *The Structure and Distribution of Coral Reefs* (1842); HUGH CLIFFORD, *Heroes of Exile* (1906); N. TARLING, "The Annexation of the Cocos-Keeling Islands," *Historical Studies,* vol. 8 (May 1959); and T.E. SMITH, "The Cocos-Keeling Islands: A Demographic Laboratory," *Population Studies,* vol. 14 (Nov. 1960).

Christmas Island: AUSTRALIAN GOVERNMENT PUBLISHING SERVICE, *Territory of Christmas Island* (annual reports); C.W. ANDREWS, *A Monograph of Christmas Island* (1900); A.C. GIBSON-HILL, "The Early History of Christmas Island," *Australian Territories,* vol. 3 (May 1963); PETER HASTINGS, "A Tale of Two Islands: The Cocos/Christmas Story," *NG & Aust., Pacific & S.E. Asia,* vol. 9 (Sept.–Oct. 1974).

Coral Sea Islands: GOVERNMENT PRINTING OFFICE (Canberra), *External Territories of Australia* (March 1970); AUSTRALIAN BUREAU OF STATISTICS, *Year Book Australia* (annual).

Ashmore and Cartier Islands: AUSTRALIAN BUREAU OF STATISTICS, *Year Book Australia* (annual); ROBERT LANGDON, "Our Far Flung Empire," *NG & Aust., Pacific & S.E. Asia,* vol. 1 (June–July 1966).

Heard Island and the McDonald Islands: P.G. LAW and T. BURSTALL, *Heard Island* (1953); M.C. DOWNES *et al., The Birds of Heard Island* (1959); G.M. BUDD, "The Anare 1963 Expedition to Heard Island," *ANARE Reports,* series A, vol. 1 (1964); P. TEMPLE, *The Sea and the Snow: The South Indian Ocean Expedition to Heard Island* (1966).

Australian Antarctic Territory: D. MAWSON, *The Home of the Blizzard: Being the Story of the Australasian Antarctic Expedition, 1911–1914* (1915); P.G. LAW and J.M. BECHERVAISE, *Anare: Australia's Antarctic Outposts* (1957); R.A. SWAN, *Australia in the Antarctic* (1961); A.G. PRICE, *The Winning of Australian Antarctica* (1962); J.K. DAVIS, *High Latitude* (1962), and *With the "Aurora" in the Antarctic, 1911–1914* (1919); DEPARTMENT OF FOREIGN AFFAIRS, "Antarctica and the Question of the Exploitation of Its Resources," *Australian Foreign Affairs Record,* vol. 48, no 12 (Dec. 1977); DEPARTMENT OF SCIENCE AND THE ENVIRONMENT (Report by the Minister, Hon. J.J. WEBSTER), *Antarctica, an Information Paper* (1977); LENNARD BICKEL, *This Accursed Land* (1977). Current affairs in Antarctica are recorded in the quarterly journals *Aurora, ANARE Club Journal,* and *Antarctic* (New Zealand Antarctic Society). Other works of a more general nature published in Australia include: J.F. LOVERING and J.R.V. PRESCOTT, *Last of Lands, Antarctica* (1979); and J.M. BECHERVAISE, *Men on Ice in Antarctica* (1978), and *Antarctica, the Last Horizon* (1979).

Literatures of Australia and New Zealand

Although derived in part from the English literary heritage and influenced by its traditions, the literatures of Australia and New Zealand developed, from beginnings in the late 18th and early 19th centuries, their own characteristic themes, styles, and idioms. Moreover, they are quite distinct from one another, since they evolved at different rates and were affected by different historical and environmental circumstances; for example, the first settlers in Australia included many convicts transported from Britain, whereas in New Zealand they were largely traders and organized colonizers. Differences in geography, strength of indigenous opposition, pace of settlement, and degree of contact with Great Britain and other countries also contributed to divergences in literary expression. (Ed.)

This article is divided into the following sections:

AUSTRALIAN LITERATURE

Three main periods may be distinguished in the history of Australian literature. In the first (1788–1880) descriptive and documentary writings predominated. The second (1880–1940) was a time in Australia of expansion and consolidation and growing national feeling, and the diversification of Australian society was mirrored in a greater variety in its literature. In the third (from 1940) an increase in literary activity matched and reflected the country's increase in immigration, expansion of industrialization, and growth of large suburban areas. During this period the "cultural cringe," a feeling of many Australian writers that they worked under the shadow of English literature, was largely replaced by a growing confidence in Australia's nationhood and separate cultural identity.

The first hundred years. The life of the convicts, administrators, and soldiers who arrived in New South Wales in 1788 and of the free settlers who followed them was a constant struggle, allowing little time for the arts. Most of those with literary talent employed it in describing their new world. Memoirs and eyewitness accounts of convict life and, later, of conditions in the goldfields abounded and provided inspiration and material for later writers.

Novels of life in the colonies

The first Australian novel is generally agreed to be Henry Savery's *Quintus Servinton* (1830–31), the prototype of the convict novel through which Australians have continued to examine their relationship with Britain and the terms on which they came into existence as a nation. The most famous novel of convict life is Marcus Clarke's *For the Term of His Natural Life* (1874); a less documentary work than Savery's, it angrily indicted the transportation of prisoners and the brutal conditions of penal servitude in Tasmania. An outstanding early novelist was James Tucker, the probable author of *Ralph Rashleigh; or, The Life of an Exile* (written in 1844; published in 1952), who brought together the four cornerstones of Australian preoccupation: Britain, the convicts, the bushrangers, and the Aborigines. Rolf Boldrewood (pseudonym of Thomas Alexander Browne) enjoyed a huge popular following with his adventure novels, of which only *Robbery Under Arms* (1888) achieved classic status. The prolific English novelist Henry Kingsley (the brother of Charles Kingsley) is now chiefly remembered for his two Australian novels, *The Recollections of Geoffry Hamlyn* (1859) and *The Hillyars and the Burtons* (1865), both concerning the successful immigration of a British family; in the former novel the family returns to Britain, while in the latter the family achieves a social status in Australia that it could never have attained back home. Catherine Helen Spence's *Clara Morison* (1854) offered an ironic view of Adelaide in the period, and Mrs. Campbell Praed's *Policy and Passion* (1881) examined the personal life of an Australian politician.

Poetry in the first hundred years developed less steadily than did prose, with poets struggling to adapt the English Romantic tradition of landscape and reflective poetry to Australian subjects. Adam Lindsay Gordon, however, composed his *Bush Ballads and Galloping Rhymes* (1870) in a distinctly Australian idiom.

Nationalism and expansion. The last 20 years of the 19th century saw a growth of nationalism and movement toward federation of the separate states. National pride, the values of country life, and sympathy for the struggles of small landholders were common literary themes, particularly in stories by Henry Lawson and Steele Rudd (pseudonym of Arthur Hoey Davis). Another theme was that of early convict days; four volumes of tales by Price Warung (William Astley) exemplified this concern. Joseph Furphy's large novel *Such Is Life* (1903), describing the rural world of the 1880s, was full of details of station life, conversations of bullock drivers, nationalistic sentiments, and philosophizings about chance and determinism. A tradition of ballad verse that had long flourished was kept alive by Lawson and A.B. "Banjo" Paterson.

Federation (1901) was greeted with patriotic fervour in prose and in verse. In the early 1900s generally, however, nationalistic themes diminished in a growing awareness of the complexity of Australian life, and attention was drawn to the plight of ordinary people and the need for social reform. There was a new emphasis on realism in fiction. Its masterpiece was probably the trilogy of Henry Handel Richardson (Ethel Florence Lindesay Robertson), *The Fortunes of Richard Mahony* (1917–29), a study of fluctuating fortunes among the immigrants who were establishing the new urban Australia in the late 19th century. The last volume, *Ultima Thule,* graphically described conditions in the goldfields and brought its character studies of the temperamentally opposite Richard and Mary to a profoundly moving climax.

New realism

Richardson's skill in evoking the birth of Australia's urban society was matched by writers such as Louis Stone and Edward Dyson with their stories of inner-city life. Katherine Susannah Prichard was to take up their themes in a more radical vein in her novels, notably in *The Roaring Nineties* (1946); Kylie Tennant also made statements on behalf of the underdog in her fiction of the 1930s. Some of the most memorable works of the early part of the century emphasized the heroic nature of the pioneer instinct at the root of Australian society; one greatly popular example was Miles Franklin's fictitious autobiography *My Brilliant Career* (1901). Mrs. Aeneas Gunn's *We of the Never-Never* (1908) examined the relationship of the white inhabitants to the Aborigines, a theme taken up by Prichard in *Coonardoo* (1929) and by Xavier Herbert in *Capricornia* (1938). Vance Palmer, a prolific writer, made a particular contribution to the public discussion of an Australian cultural identity.

The success of poets was slighter but showed diversity of aims and interests. John Shaw Neilson wrote fine, delicate lyrics; Victor Daley produced romantic poems and some sharp satires; C.J. Dennis continued the ballad tradition with popular verse; Christopher Brennan, in his Symbolist poems, owed much to European tradition; and Kenneth Slessor created powerful, dramatic lyrics.

The modern period. During and after World War II, literary magazines proliferated, and the reading public grew. Though factual and descriptive writing remained prominent, from the 1950s onward Australian writers became increasingly speculative and searching. The most influential of mid-20th-century novelists was Patrick White, whose major novels were distinctively Australian but whose treatment had a largeness of vision surpassing nationalistic limitations. The Australia depicted in *The Tree of Man* (1955), *Voss* (1957), *Riders in the Chariot* (1961), *The Solid Mandala* (1966), and *A Fringe of Leaves* (1976), as well as in White's short stories, gave evidence of a critical, poetic imagination. White was awarded the Nobel Prize for Literature in 1973. He was drawn particularly to the underlying formative elements in Australian history.

The novels of Patrick White

The other dominant novelist of the mid-20th century was Christina Stead, with her interest in disrupted lives and financial pressures. Her most widely admired novels are *House of All Nations* (1938) and *The Man Who Loved Children* (1940); but only one, *Seven Poor Men of Sydney* (1934), was set entirely in Australia. Other novelists included Martin Boyd, Randolph Stow, and Thomas Keneally, who was drawn to a variety of historical subjects, including Joan of Arc, the Holocaust, the convict settlements, and World War I. Among novelists of importance in the 1970s and '80s were Thea Astley, Shirley Hazzard, Roger McDonald, and C.J. Koch, whose *Year of Living Dangerously* (1978) helped open up for Australian literature the subject of the Far East.

Aboriginal writing in English was uncommon, but Colin Johnson made a mark with *Wild Cat Falling* (1965). Literature on Australian themes began to be written in European languages other than English, particularly by members of Greek, Italian, and Maltese minorities during the 1960s. Also of interest were the autobiographical short stories of Hal Porter, which revealed the changes in Australian society from the 1930s to the 1960s.

Postwar poetry

A tradition of descriptive poetry remained, but mid-century poets ranged more widely than their predecessors. Robert D. FitzGerald was noted for strenuously argued poems; A.D. Hope for searching, allusive, witty verse; Douglas Stewart for forthright, vigorous works; Judith Wright for sensitive lyrics; and James McAuley for meditative lyrical poetry. Bruce Dawe evinced the Australian voice in his contemporary, journalistic poetry. Among the leading poets of the 1980s were Les Murray, allusive and humane, and Chris Wallace-Crabbe, with his precisely depicted states of mental and physical being. Kath Walker was the first Aboriginal poet who wrote in English.

Australian literature was long deficient in drama; not until the late 1950s and '60s did any plays achieve real success. Best known were Douglas Stewart's *Ned Kelly* (published 1943) and *Fire on the Snow* (performed 1941); Ray Lawler's *Summer of the Seventeenth Doll* (1955); Alan Seymour's *One Day of the Year* (1961); and Patrick White's *Four Plays* (published 1965). Several playwrights came into prominence during the next two decades, among them David Williamson, Jack Hibberd, Alexander Buzo, Jim McNeil, and Peter Kenna. (L.J.K./A.N.R.N.)

NEW ZEALAND LITERATURE

In organized settlement New Zealand was 50 years behind Australia, and for most of the century from 1840 to 1940 a similar gap in national consciousness seemed to prevail. Yet from about 1930 there was a flowering of literature.

Early writings. Up to the 1920s most writers aimed at British readers and often exploited and distorted exotic and indigenous elements of their surroundings. There did emerge some worthwhile chronicles and autobiographical narratives, such as *A First Year in Canterbury Settlement* (1863) by Samuel Butler (author of *Erewhon*), Frederick Maning's *Old New Zealand* (1863), and Lady (Mary Anne) Barker's *Station Life in New Zealand* (1870). Among colonial versifiers the most notable were Alfred Domett and the Scots dialect poet John Barr.

Katherine Mansfield

Katherine Mansfield was one of the great names in short-story writing. She did not expect to find a readership in her own country and emigrated to England to establish her career. But her debt to New Zealand pioneer society was clearly evident in her most admired stories, such as "At the Bay," "The Voyage," and "The Stranger" (in *The Garden Party, and Other Stories,* 1922). Two other writers achieved works of distinction during this period: William Satchell, in *The Land of the Lost* (1902); and Jane Mander, in *The Story of a New Zealand River* (1920).

Outstanding in the 1920s and '30s were the short-story writer Frank Sargeson (pseudonym of Norris Frank Davey) and the poets A.R.D. Fairburn, R.A.K. Mason, Allen Curnow, and Denis Glover; what distinguished their work was that they assumed a readership of fellow countrymen. The yarn spinner had always been characteristic of New World writing, and Sargeson used this to great effect in tales of the Depression years. Two novelists to emerge during this time were John Mulgan, whose *Man Alone* (1939) attained the status of a New Zealand classic, and John A. Lee, with his harrowing *Children of the Poor* (1934). Robin Hyde (pseudonym of Iris Wilkinson) wrote in *The Godwits Fly* (1938) a perceptive study of a Wellington family in the early part of the century.

World War II and after. In the years from 1940 most literary genres flourished, especially the short story, whose best writers included Roderick Finlayson, Maurice Duggan, O.E. Middleton, and Phillip Wilson. The poet James K. Baxter was perhaps the most considerable figure of the postwar period. Among the best known prose writers were Sylvia Ashton-Warner (*Spinster* [1958], *Greenstone* [1966]); Janet Frame (*Faces in the Water* [1961], *A State of Siege* [1966], *The Rainbirds* [1968]); Ian Cross (*The God Boy* [1957], *After Anzac Day* [1961]); Maurice Shadbolt (*Among the Cinders* [1965], *Strangers and Journeys* [1972]); Maurice Gee (*A Special Flower* [1965], *In My Father's Den* [1972]); Dan Davin (*No Remittance* [1959]); and David Ballantyne (*The Cunninghams* [1949]).

Modern prose

The growth of New Zealand writing and a rapid expansion of theme reflected an accelerating national consciousness. The international recognition of Keri Hulme's partly Maori-based novel *The Bone People* (1984) finally disposed of the image of New Zealand as exclusively genteel and concerned only with farming and a sentimental view of Britain. Janet Frame's three-volume autobiography also helped to show a more socially troubled and psychologically stressful side of New Zealand. New poets with a distinctive national voice emerged, among them Fleur Adcock, Lauris Edmond, Michael Jackson, C.K. Stead, and Ian Wedde. Maori writers included Hone Tuwhare, Witi Ihimaera, and Patricia Grace. (M.F.R.S./A.N.R.N.)

Austria

Located in the centre of Europe, Austria is a federal republic with a scenic and largely mountainous terrain of 32,375 square miles (83,850 square kilometres). In the decades following the collapse, in 1918, of the multinational Austro-Hungarian Empire of which it had been the heart, this small landlocked country experienced more than a quarter-century of social and economic turbulence and a Nazi dictatorship. Yet the establishment of permanent neutrality in 1955, associated with the withdrawal of the four-power troops that had occupied the country for a decade, enabled Austria to develop into a stable and socially progressive nation, with a flourishing cultural life that was reminiscent of its earlier days of international musical glory. Its social and economic institutions, too, have been characterized by new forms and a spirit of cooperation, and, although political and social problems remain, they have not erupted with the intensity evidenced in other countries of the Continent.

A great part of Austria's status in the late 20th century can be attributed to its geographical position: it is at the centre of European traffic between east and west along the great Danubian trade route and between north and south through the magnificent Alpine passes. Austria is bordered on the west by Switzerland, and together these countries form what has been characterized as the neutral core of Europe. The tiny principality of Liechtenstein also forms a small enclave on the west. Hungary on the east, Germany and Czechoslovakia on the north, and Italy and Yugoslavia on the south illustrate the variety of political and economic systems within which Austria is embedded (see EUROPEAN HISTORY AND CULTURE and VIENNA).

This article is divided into the following sections:

Physical and human geography

THE LAND

Relief. Mountains and forests give the Austrian landscape its character, although in the northeastern part of the country the Danube winds between the eastern edge of the Alps and the hills of Bohemia and Moravia, in its journey toward the Hungarian Plain. Vienna, the capital of Austria and long one of the great cities of Europe, lies in the area where the Danube emerges from between the mountains into the drier plains.

The landscape of the eastern Alps offers a complex geological and topographical pattern, with the highest elevation—the Grossglockner (12,457 feet [3,797 metres])—rising toward the west. The Austrian Alps may be subdivided into a northern and a southern limestone range, each of which is composed of rugged mountains. These two ranges are separated by a central range that is softer in form and outline and composed of crystalline rocks. North of this massive Alpine spur, which forms the physical backbone of the country, lies a hilly subalpine region, stretching between the northern Alps and the Danube, while to the north of that river lies a richly wooded foothill area. The lowland area east of Vienna may be regarded as a western extension of the great Hungarian Plain.

Drainage. Austria is a land of lakes, many of them a legacy of Ice Age erosion, which scooped out mountain lakes in the central Alpine district, notably around Salzkammergut. The largest lakes—lying partly in the territory of neighbouring countries—are the Bodensee (Lake

Elevations in metres

of Constance) in the west and the marshy Neusiedlersee (Neusiedler Lake) to the east.

Ninety-six percent of Austrian territory drains to the Danube River system. The main watershed between the Black Sea and the North Sea runs across northern Austria, in some places lying only 22 miles (35 kilometres) from the Danube, while to the west the watershed between the Danube and the river systems emptying into the Atlantic and the Mediterranean coincides with the western political boundary of Austria. In the south the Julian and Karnische Alps, and, farther to the west, the main Alpine range, mark the watershed of the region draining into the Po River of northern Italy.

Climate. The wooded slopes of the Alps and the small portion of the plains of southeastern Europe are characterized by differing climatic zones: the wetter western regions of Austria have an Atlantic climate with a yearly rainfall of about 40 inches (1,000 millimetres), whereas the eastern regions, in particular those under the influence of the drier, more continental type of climate, have less precipitation.

In the lowlands and the hilly eastern regions, the median temperature ranges from 30.4° F (−0.9° C) in January to 68.6° F (20.3° C) in July. In those regions above 10,000 feet, by contrast, the temperature range is between 11.8° F (−11.3° C), with a snow cover of about 10 feet in January, and 35.8° F (2.1° C) in July, with about five feet of snow cover.

The prevailing wind is from the west, and the humidity, therefore, is highest in the west, diminishing toward the east.

Plant and animal life. Two-thirds of the total area of Austria is covered by woods and meadows, and the country is the most densely forested nation in central Europe. Spruce dominates the forests, with larch, beech, and oak also making a significant contribution. In the Alpine and foothill regions coniferous trees predominate, while leaf-bearing deciduous trees are more frequent in the warmer zones.

Wild animals, now protected by conservation laws, include the brown bear, the eagle, and all buzzard species, as well as falcons, owls, cranes, swans, and storks. Game hunting is restricted to certain periods of the year, with deer and rabbits the most frequent quarry. Austrian rivers nurture river and rainbow trout, grayling, hake, pike, perch, and carp.

Traditional regions. Western Austria, comprising the *Bundesländer* (states) of Vorarlberg, Tirol, and Salzburg, is characterized by high Alpine regions with majestic mountains and magnificent scenery. This high Alpine character also extends to the western part of Kärnten (Carinthia), the Salzkammergut of central Austria, to the Alpine blocks of Steiermark (Styria), and to the eastern rim of the Alps.

Alpine scenery

The outer fringes of the Alps dominate the northern portion of Oberösterreich (Upper Austria) with their subalpine characteristics, while the richly wooded Bohemian massif extends across the Czechoslovak border. This part of Austria is furrowed by many valleys that, for centuries, served as passageways leading to the east and southeast of Europe and even, in the case of medieval pilgrims and crusaders, to the Holy Land.

A hilly vineyard district extends into the *Bundesland* of Burgenland. This region, together with the eastern part of the state of Steiermark, lies at the gateway to the Hungarian Plain. Burgenland, Steiermark, Kärnten, and Niederösterreich (Lower Austria) form a region, throughout which agriculture abounds. The city of Vienna and its peripheral suburbs and industrial settlements border both Alpine and lowland regions.

Settlement patterns. The pattern of rural settlement in Austria was shaped centuries ago by the exigencies of the Alpine environment, and new rural building is still influenced by these ancient traditions, especially in the west and in the centre of the country. By contrast, rural housing in the eastern parts of the nation, especially in the lowlands, is dominated more by agricultural needs than by harsh weather conditions.

Austria is not only a mountainous but also a highly urbanized country. In the late 20th century, roughly half of the Austrian population lived in cities and towns with more than 10,000 residents, and about one-fifth of the total Austrian population lived in Vienna. The state capitals have, as a consequence of national economic and social development, grown somewhat in population since the end of World War II. Graz, Austria's second largest city, is the gateway to the Balkans; Innsbruck is the rail and road centre through which the north–south traffic of western Austria passes; Salzburg is one of the best known European centres of musical culture and Baroque architecture; Linz is an important industrial centre; and Klagenfurt lies astride routes that provide access to both Italy and Yugoslavia.

Major Austrian cities

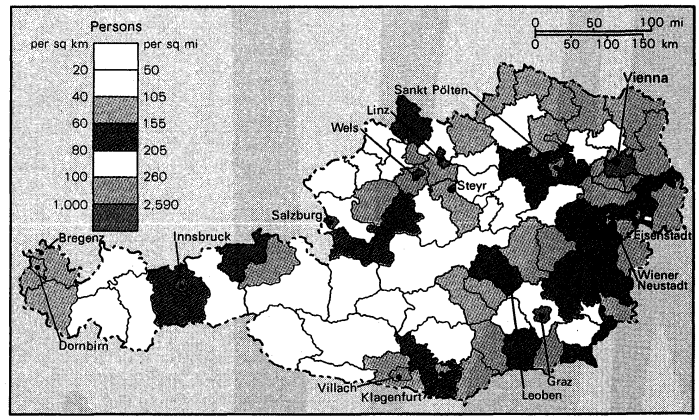
THE PEOPLE

Ethnic and linguistic heritage. Virtually all Austrians are German-speaking. The tiny minority belonging to other nationalities consists of Croats and Magyars living in Burgenland; Slovenes living in the southern part of Kärnten; and Czechs living in Vienna. The population is predominantly Roman Catholic, with Protestant churches, the so-called Old Catholic church, and Judaism constituting the largest remaining affiliations.

The westernmost states, and Vorarlberg in particular, are inhabited by Alemannic groups whose dialect is similar to the Swiss-German dialect, while the dialect of the people in Salzburg and Oberösterreich and the eastern states resembles that which is spoken in Bavaria. People in Steiermark and Kärnten speak a dialect that is clearly distinguishable from that of the people in the west. In general, the German spoken in Austria has a softer, more drawling, and melodious sound than that which is spoken in Germany.

Demography. Throughout the second half of the 20th century, the birth rate and life expectancy in Austria rose steadily; concurrently, the expanding population became increasingly urban as, particularly in the western states, agriculture gave way to industry. Birth rates varied from state to state, being generally highest in the strongly Roman Catholic western states and rural areas and lowest in the urban centres. The almost complete destruction of Vienna's Jewish population (about 200,000 in 1938) during the Nazi era was only partly compensated by an influx from rural areas and by refugees after World War II.

Population shifts



Population density of Austria.

Emigration resulted in some losses in national population during the disastrous post-World War II years, although a stream of refugees from eastern European countries helped to make up some of the deficit. Most of these refugees were soon integrated into Austrian society. As a result of the turmoil in Hungary in 1956, some 180,000 Hungarians crossed the frontiers into Austria, creating a new refugee problem. By the end of the following decade, however, most had migrated to other countries.

THE ECONOMY

The Austrian economy has been shaped by two factors: first, the nation occupies a mountainous area, only half of which is even potentially usable for the production of food; second, and as a result, the success of industrial

production, exports, and trade is basic to the economy. The natural resources available within the country for industrial exploitations are, therefore, of considerable significance.

Resources. Austria is the world's leading producer of natural magnesite, a magnesium carbonate that is used extensively in the chemical and other industries, with Kärnten being the main centre of magnesite production. In the late 20th century, new methods of smelting and processing magnesite fostered a significant increase in production.

Iron-ore deposits are found in the Erzberg in Steiermark—which accounts for the major portion of Austria's total iron production—and in the Hüttenberg region in Kärnten. The large oil refinery at Schwechat provides roughly three-fourths of the nation's consumption of oil and oil products, the balance in crude and refined oils being met by imports. Reserves of oil and natural gas are a steadily diminishing asset. Austria has made several agreements with the Soviet Union to ensure the delivery of increasing quantities of natural gas. Deposits have been explored in the Vienna and Graz basins and in Oberösterreich near Linz and Wels. Coal, which is found only in small quantities and is mostly of the soft variety, is mined chiefly in Upper Austria and in Styria.

Developing oil production

Since World War II, Austria has become one of Europe's foremost producers of hydroelectric power. The issue of nuclear power met with public controversy in the late 20th century.

Agriculture and forestry. Since barely half of Austria's territory can be used for food production, an intense program of agricultural modernization was introduced after World War II. The number of tractors, for example, rose from 1,800 in 1939 to 300,000 40 years later. The rural economy is dominated by small holdings, although some large forest estates still remain. As a result of the modernization program, the yield of the most important agricultural products has risen considerably.

In the lowland regions of the country, the abundance of pasture land and the production of animal feed has promoted cattle breeding. Dairy products are plentiful, resulting in a surplus. With the exception of horses, Austria's livestock has grown in numbers during the modernization period.

Timber from Austria's vast national forests is only partly processed in the country, and untreated lumber makes up a large percentage of the nation's exports. More than half of the forests are part of small holdings; the rest are on large, old estates or are government-owned.

Industry. Industry and trade form the most important sources of national income. Iron and steel production, in particular, increased greatly after World War II: both pig iron and raw steel production, for example, rose more than threefold during the first three decades after mid-century. Despite an abundance of domestic iron ore, scrap iron and iron ore must be imported, due to increased steel production. An oxygen blast furnace, based on the so-called L.D.-process (named after the cities of Linz and Donawitz [now Leoben], where it was developed), reduced the need for imported scrap iron and is now used in many countries under license agreements.

The iron and steel industry

Aluminum became one of the more important Austrian manufacturing industries during the 1960s and '70s. Other manufacturing includes paper production, based on the nation's extensive forest reserves, and the chemicals and plastics industries.

Trade. Austria's main trading partners are its neighbours, Germany and Switzerland, who together account for almost half of Austria's imports and more than one-third of its exports. Trade with the European Economic Community (EEC, or Common Market) as a whole is also important. Significantly lesser proportions of Austria's trade are conducted with countries of the European Free Trade Association (EFTA) and with eastern European countries. Although manufactured goods accounted for about two-thirds of Austria's exports in the late 20th century, timber, iron, and steel continued to be very important export items.

The EEC's important role in Austria's foreign trade has prompted the government to establish a free-trade agreement with the organization (full membership would not be compatible with Austria's policy of neutrality). Since July 1977 trade in industrial goods, with the exclusion of certain products, such as paper and steel, has been duty free.

The tourist trade is Austria's outstanding invisible export. The number of nights spent by foreign tourists in Austria rose almost 20-fold in the first three decades after mid-century. Expenditures by tourists at the end of that period largely met Austria's balance-of-payments deficits.

Finance. Monetary policy is jointly determined by the Ministry of Finance and the Austrian National Bank. The bank operates under a law passed in 1955 and amended in 1969 that states that in its policy decisions the bank must pay "due regard to the economic policy of the government." Half of the shares of the bank are held by the government, and the other half are held by various economic institutions. A majority of the members of the board of governors, including the president and two vice presidents, are appointed by the government. The bank is also charged with the administration of foreign-exchange controls. There is virtually complete freedom for current account transactions and a very liberal regime governing capital account transactions with foreign countries.

Financial services are handled by a wide range of other institutions, including joint-stock commercial banks, private commercial banks, savings banks, provincial mortgage organizations, agricultural credit cooperatives, industrial credit cooperatives, building societies, and specialized banks. Vienna's geographic location has made it an important financial centre for East–West trade.

Administration of the economy. The private sector, comprising roughly three-quarters of Austria's mixed economy, is concentrated in agriculture and food processing, forestry and timber, paper mills, textile and clothing, food and beverages, and retail and wholesale trade. Private enterprise has a relatively low degree of monopolistic concentration, although ties among the guildlike cooperatives (Berufsgenossenschaften und Innungen) are not without influence.

Nationalization of industry

In 1946 the Austrian parliament nationalized a large segment of Austrian industry, which, at that time, was being held under Soviet control as alleged former German property. After the State Treaty of 1955 established Austrian neutrality and brought the end of Soviet authority, these enterprises passed into exclusive Austrian control. The 1946 nationalization covered the three biggest banks and some 70 larger industrial enterprises, chiefly in the fields of iron and steel, aluminum, and machinery. Subsequent reorganization reduced the number of nationalized enterprises to 19. By the fourth quarter of the century, the net value of the output of nationalized concerns amounted to about one-fifth of the total industrial production.

Most of the nationalized industries are organized as joint-stock corporations, and their central direction by the government has undergone several changes, for both political and managerial reasons. Until 1966, for example, a Cabinet member supervised the nationalized industries, but after that date they were handed over to the government-owned Austrian Industrial Administration (Österreichische Industrie–Aktien–Gesellschaft [OIAG]). The Administration's board of directors, although representing the government, is independent as far as managerial decisions are concerned.

The most important source of federal tax revenue is the income tax. In 1973 the sales tax was replaced by a value-added tax on all sales and transactions, with necessities and luxury items assigned special lower and higher rates, respectively.

Transportation. Austria's location in the centre of Europe determines its role in European road, rail, air, and river traffic, whether the flow is from north to south or from east to west. Austria consequently is not only a tourist country but in many aspects is also a freight clearinghouse, servicing the great trade routes running across the Alps and along the Danube River.

Roads. The road system, which sustained heavy damage during World War II, was subsequently adapted to vastly increased traffic requirements. Much of the Austrian road network leads over spectacular Alpine passes.

A federally built east–west highway was in operation between Vienna and Salzburg by the early 1960s. It also connects Salzburg with Munich, Germany. The Trans-European North–South Motorway project will eventually connect Austria with nine other countries. The total number of motor vehicles rose more than 10-fold during the first three decades after mid-century.

Railroads. Forty-one percent of the Austrian railroad network and 381 bridges were destroyed during World War II and had to be repaired as well as modernized in subsequent years. More than half of the federal rail network, carrying two-thirds of the traffic, has been converted to electric traction. Passenger and freight traffic have shown a proportionate increase. The Austrian railroads are state-owned; by a law of 1969, however, the railroad administration—formerly part of the Transportation Ministry—became an independent commercial enterprise.

Importance of the Danube

Water transport. The Danube is the most important river connection between Germany and the Black Sea, and the federally owned Danube Steamship Company plays an important role in both freight and passenger traffic along this waterway. Although Austria is landlocked, its federally owned shipyards build vessels not only for Austria but also for the Soviet Union and for other countries.

Air transport. Austrian Airlines, which began operations in March 1958, has since established service throughout Europe and to several countries abroad. Austria's main airport is at Wien-Schwechat, southeast of Vienna.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. *Constitutional framework.* Under the constitution of 1920—with minor changes made in 1929—Austria is a "democratic republic: its power derives from the people." A federal state, Austria consists of nine self-governing states: Burgenland, Kärnten, Niederösterreich, Oberösterreich, Salzburg, Steiermark, Tirol, Vorarlberg, and Wien (Vienna).

In 1934 the Austrian constitution was replaced by an authoritarian regime under chancellors Engelbert Dollfuss and Kurt von Schuschnigg. This, in turn, was eliminated by Hitler after Nazi Germany annexed Austria in 1938. With the liberation of Austria in 1945, the constitution of 1929 was revived and subsequently became the foundation stone of constitutional and political life in the "Second Republic."

The federal president and the Cabinet share the executive authority. The president is elected by popular vote for a term of six years. He acts as head of state, appoints the Cabinet, and calls Parliament into session. He can dissolve Parliament during the four-year legislative period, unless it dissolves itself by law, and can order new elections. He also acts as commander-in-chief of the armed forces.

The president appoints the federal chancellor and, at his suggestion, the other Cabinet members. The Cabinet cannot remain in office if it and its members do not enjoy the confidence of the majority of the National Council.

The Austrian parliament

The Parliament consists of two houses: the National Council (Nationalrat), wielding the primary legislative power; and the Federal Council (Bundesrat), representing the states. The National Council, which had had 165 members since 1920, was expanded to 183 members under a law passed in 1970 that took effect at a national election in 1971. The National Council is elected by all citizens over the age of 19, and every citizen over the age of 26 is eligible to run for office. The distribution of parliamentary seats is based on a system of proportional representation.

The members of the Federal Council represent the states, and the state assemblies, or diets, elect the members by a proportional system based on the population of the state.

The legislative process originates in the National Council. Each bill—except for the budget, which is the sole prerogative of the National Council—must be approved by the Federal Council. The National Council, however, can override a Federal Council veto by a simple majority vote.

Each of the nine states is administered by a government headed by a governor; the governor is elected by the legislative diet, which in turn is elected by general and equal ballot.

The local municipalities each elect a mayor and a city council. Vienna is a unique case: as both municipality and state, its mayor also functions as the governor.

The political process. The first popular election of a president, although provided for by the 1929 amendment to the constitution, did not take place until after the death of the first post-World War II president, Karl Renner (1870–1950), who had been unanimously elected by the National Assembly after the liberation of 1945 and the ensuing unsettled political circumstances. A succession of presidents, belonging to, or nominated by, the Socialist Party have occupied the post since then.

The major parties

In the eight elections held from the immediate post-World War II period to the early 1970s, the stability of the two main Austrian political parties—the People's Party and the Socialist Party—is shown by their respective shares of the vote, which has been in each case, approximately 45 percent of the total votes cast. The Liberal Party has polled an average of only 5 percent of the votes, and the Communist Party has polled an even smaller share. From 1945 to 1966 the two principal parties maintained coalition governments with the chancellorships held by the People's Party. In 1966 the People's Party, with a slim majority of parliamentary seats, formed the government alone, but after the 1970 elections, in which it lost its majority, the Socialists, as the strongest party, formed a minority government. Its first budget was passed with the help of the votes of the Freedom Party. In the parliamentary election that was held in October 1971 the Socialist Party won more than 50 percent of the popular vote, the first party to do so in Austrian history, and it retained this position until the election of 1983, when it won a plurality of the votes and formed a coalition government with the Freedom Party.

The People's Party is the successor of the Christian Social Party, founded in the 1890s. It represents a combination of conservative forces and various social and economic groups forming semi-independent federations within the overall party. The divergencies of economic and social interests of these groups—farmers, businessmen, and blue- and white-collar workers—necessitate policy compromises, which are not always easy to implement.

The Socialist Party, which followed a democratic Marxist program during the 1918–34 period, has adopted a more pragmatic approach since 1945. The party program, in its 1958 and 1978 versions, stressed these new tendencies. Emphasis is placed on social problems, on government influence on an expanding and socially oriented economy, on full employment, and on a rising standard of living, with a more equal distribution of wealth. The Austrian Socialists are no longer an exclusive party of the working class: by the 1970s they had a much wider appeal.

The Liberal Party has undergone several changes in emphasis since it was admitted into politics by the occupying powers in 1949, at which point it was a third party with nationalistic tendencies. The initially prominent influence of former Nazis has diminished.

The Communist Party, always negligible in Austrian politics, reached its high point during the Soviet occupation of the eastern zone of the country, when it attained 5 percent of the popular vote. By 1959 it had lost representation in Parliament, and by 1970 in all of the provincial diets and in most municipal councils.

The participation of the citizens. The Austrian constitution provides for two kinds of popular initiatives: one is the so-called popular demand (*Volksbegehren*), by which 400,000 vote-eligible citizens can petition Parliament for approval of any bill; it can also be initiated, in the case of any bill or proposal, by a majority of the National Council. A total revision of the constitution must be approved by plebiscite.

Justice. The administration of justice is independent of Austrian legislative and administrative authorities. Judges are not subject to any government influence: they are appointed by the Cabinet upon nomination by judicial panels and can neither be dismissed nor transferred without their agreement.

Austria has three high courts: one sitting as the highest body of appeal in civil and criminal matters; a top ad-

ministrative court to which citizens aggrieved by administrative decisions can appeal; and a constitutional court that decides on all constitutional matters, civil rights, and election disputes.

Armed forces. Under the State Treaty of 1955 Austria is permitted armed forces of 50,000 men for the defense of its territory. The armaments permitted Austria specifically exclude nuclear or other major offensive weapons. Only the four signatory powers—the United States, Great Britain, the Soviet Union, and France—can permit such armaments, and they must do so by a unanimous decision.

All male citizens between the ages of 18 and 50 are liable to military service, and conscripts are called up for six months, followed by 60 days of reserve training, with an additional 30 to 90 days of training for reservists in special functions. Austria's armed forces total 38,000; in addition there are some 70,000 reservists called up for short training periods each year. The total mobilizable strength is 155,000.

Education. Austria's educational system is based on obligatory school attendance between the ages of six and 15. A major reform of the school administrative structure, providing for a unitary school system with access to higher education and experimentation with various types of schools, has been in progress since 1970.

Austrian universities

Intermediate schools include those preparing students for university and other higher studies, for teachers' and commercial colleges, and for other specialized institutions.

Austrian universities are among the oldest German-speaking universities of Europe: the University of Vienna, for example, was founded in 1365. Austria has more than 15 universities, including two technical universities, a university specializing in economics and another in agriculture, as well as academies for fine arts, music, drama, and design. Austria also has an extensive adult-education system.

Health and welfare. *Public health.* Public health in Austria is the responsibility of the Ministry of Health and Environment. It supervises 14 subsidiary institutes responsible for the prevention of infectious diseases and inspection of drugs and food. The provincial governments also have public-health centres, and each municipality and rural district must employ a public-health physician.

National health insurance covers expenses of medical and hospital treatment: blue- and white-collar workers and salaried employees are protected in cases of sickness, disability, unemployment, and maternity and in their old age. There are also survivors' pensions. Pension systems for self-employed persons and farmers have also been established.

Cooperative wage–price policy

Wages and cost of living. Government, management, and labour follow a wage–price policy that attempts to avoid social cleavages and strikes through cooperative participation in a joint wage–price commission. The representatives of the various segments of the economy, together with the chambers of commerce, agriculture, and labour and the federation of trade unions, have tried, with the active cooperation of the government, to coordinate wage and price movements. It is within this framework that collective bargaining takes place, and agricultural prices are also negotiated by the wage–price commission without infringement of the market economy.

Social and economic divisions. The three important economic groups in Austria—labour, management, and farmers—have similar structures: each has its own independent organization: the trade unions, the management association, and the farmers' federation. At the same time, laws provide for semi-official "chambers" for each group. This type of guild organization promotes cooperation in the governmental wage–price commission. Despite the divergent interests of the various groups, their cooperation has resulted in relative economic stability, and labour–management relations have remained unmarked by major crises.

CULTURAL LIFE

The cultural milieu. The cultural milieu of Austria has a rich heritage: in architecture and poetry it dates to the Middle Ages, and in medicine and science it can be traced to the 18th and 19th centuries. Similarly, Vienna's art galleries are among the most highly esteemed in Europe because of their wealth of old Dutch masters. Austria's most highly recognized cultural contribution has been in the field of music, and this tradition still dominates its present cultural achievements. Austrian cultural life has exerted attraction beyond its borders. Such great musicians as Beethoven (a native of Bonn), Brahms (from Hamburg), Mahler (from Bohemia) and, to a certain extent, Richard Strauss (from Munich) are considered as much a part of Austria's musical life as the celebrated native Austrians Haydn, Mozart, and Schubert. The Vienna waltzes emanating from the Johann Strauss dynasty, as well as the Vienna operetta, whose presiding genius was Franz Lêhar, round out the rich traditions of Viennese musical life. Austria has also been the birthplace of modern, especially 12-tone, music, centred in the work of Arnold Schoenberg and known as the Second Viennese School.

Musical tradition

Although in literature Austria has often been considered a segment of German culture, writers such as Franz Grillparzer, Johann Nestroy, and Ferdinand Raimund in the postclassic era, and Hugo von Hofmannsthal and Arthur Schnitzler in the 20th century, all developed special Austrian traits. Austrian culture was also strongly influenced by the various cultural elements of the multinational Austro-Hungarian Empire, with its Slavic and Magyar traces. They still exist, making Austria a bridge between various parts of Europe and attracting performing artists from East and West.

Austrian cultural and scientific life had to recover from the severe wounds inflicted by Nazi domination and the loss of intellectuals and artists through emigration and persecution after 1938. A 10-year occupation by four world powers promoted recovery of an independent cultural life only to a small degree. Austria has, nevertheless, managed—particularly since the late 1950s—to regain something of its past cultural posture.

The state of the various arts. Austrian expressionism in literature has gained world renown through the visionary novelist Franz Kafka, a native of Prague who died near Vienna in 1924. As part of a general Kafka revival, one of his haunting novels, *Der Prozess* (*The Trial*), was made into an opera by Austria's best known contemporary composer, Gottfried von Einem.

Georg Trakl, a promising Expressionist who was killed in World War I; Franz Werfel, an Expressionist novelist and playwright; Karl Kraus, a critical lyricist and essayist; and Robert Musil, who wrote along Expressionist lines, have all played a considerable role in contemporary Austria. Hermann Broch, a novelist with symbolic tendencies, is recognized beyond Austria. Heimito von Doderer is considered the most remarkable post-World War II novelist. Modern playwrights who are well known include Alexander Lernet-Holenia and Fritz Hochwälder, who has created historical dramas that have been produced throughout the world.

Austrian theatre and opera

The Austrian theatre and opera recovered quickly after the war. The Vienna Burgtheater, considered to be the best German-speaking theatre in the 19th century, may again be counted among the foremost German stages. It presents the classics, as well as modern English, American, and occasionally Russian and Czech plays. A new trend in the Vienna theatre has developed in so-called cellar-theatres ("off-Broadway" stages), which favour the theatre of the grotesque.

The Vienna Staatsoper (State Opera), which was completely rebuilt after World War II, ranks today with La Scala in Milan and the Hamburg and Munich operas, while the Vienna Philharmonic Orchestra has played in almost all the musical capitals of the world. Austrian theatre life is intense, with large and enthusiastic audiences and a bewildering succession of shows. The theatre has spread to small stages in the Vienna suburbs, while the various state capitals have also become theatre and light-opera centres, developing their own identities. Special performances for students aid an early participation in cultural life.

Modern music was born in Vienna, and Arnold Schoenberg, Alban Berg, and Anton von Webern are considered among its major creative founders.

Clemens Holzmeister, the best known modern Austrian architect, was responsible for the two festival theatres in Salzburg, which combine classical and modern theatre styles. Artur Perotto, of Linz, designed several striking skyscrapers in western Austria, while in Vienna public apartment building has had a strong overall influence on architecture.

In sculpture Fritz Wotruba became internationally recognized. His style has often been compared with that of the modern English sculptor Henry Moore.

Austria's most famous modern painter is Oskar Kokoschka, truly a world figure: he and Alfred Kubin are regarded as two of the foremost creators of modern painting in Austria. In addition, a young group of Surrealists has shown its works in international exhibitions.

Folk art and folk traditions, supported by provincial governments, have survived in western Austria, especially in Tirol.

The oldest Austrian academic research institution is the Academy of Science, whose traditions date to the end of the Middle Ages. More modern scientific foundations, notably the Körner Foundation and the Renner Foundation, support scientific research and other cultural endeavours: their main support comes from government sources. A federal Ministry of Science and Research was established in 1970; it is responsible for university institutions and for the advancement of scientific activities. For statistical data, see the "Britannica World Data" section in the current *Britannica Book of the Year.*

History

PREHISTORY AND ROMAN TIMES

In the territories of the Austrian Republic the first traces of human settlement date back to the Early Paleolithic Period. The archaeological material becomes richer and more varied for subsequent periods, giving evidence of several distinct cultures succeeding one another or coexisting. The Austrian site of Hallstatt gave its name to the principal culture of the Early Iron Age (*c.* 800–450 BC). Celtic tribes invaded the eastern Alps around 400 BC and eventually founded the kingdom of Noricum, the first "state" on Austrian territory known by name. In the west, however, the ancient race of Raetians was able to maintain its seat. Then, attracted by the rich iron resources and the strategic importance of the region, the Romans began to assert themselves. After an initially peaceful penetration during the last two centuries BC, Roman troops finally occupied the country *c.* 15 BC, and the lands as far as the Danube became part of the Roman Empire, being allotted to the Roman provinces of Raetia, Noricum, and Pannonia.

Occupation by Roman forces

The Romans opened up the country by an extensive system of roads. Among the Roman towns along the Danube, Carnuntum (near Hainburg) took precedence over Vindobona (Vienna), while Lauriacum (Lorch, near the confluence of the Enns and the Danube) belonged to a later period. Roman municipalities (*municipia*) also grew up at Brigantium (Bregenz), Juvavum (Salzburg), Ovilava (Wels), Virunum (near Klagenfurt), Teurnia (near Spittal an der Drau), and Flavia Solva (near Leibnitz). North of the Danube the Germanic tribes of the Naristi, Marcomanni, and Quadi settled. Their invasions in AD 166–180 arrested the peaceful development of the provinces, and even after their repulse by the emperor Marcus Aurelius the country could not regain its former prosperity. In the 3rd century the Roman frontier defenses began to be hard pressed by invasions from the Alemanni. Finally, in the 5th century, heavy attacks by the Huns and eastern Germans put an end to the Roman provincial defense system on the Danube.

There is archaeological evidence of a Christian cult in this area from the 4th century, and the biography of St. Severinus by Eugippius constitutes a unique literary source for the dramatic events of the second half of the 5th century. At that time several Germanic tribes (Rugii, Goths, Heruli, and later Langobardi) settled on Austrian territory. In 488 part of the harassed Norican population withdrew to Italy.

EARLY MIDDLE AGES

Germanic and Slavic settlement. Following the departure of the Langobardi to Italy (568), further development was determined by the Bavarians in a struggle with the Slavs, who were invading from the east, and by the Alemanni, who settled in what is now Vorarlberg. The Bavarians were under the political influence of the Franks, whereas the Slavs had Avar rulers. At the time of their greatest expansion the Slavs had penetrated as far as Styria, Carinthia, and eastern Tirol. After 624 the western Slavs rose against the Avars under the leadership of the Frankish merchant Samo, whose short-lived rule may also have extended over the territories of the eastern Alps. Around 700 the Bavarian lands again bordered on Avar territory, with the lower course of the Enns forming the approximate frontier. On the death of the Frankish king Dagobert I (639) the Bavarian dukes from the house of Agilolfing became virtually independent.

Christianity had survived only here and there among the remnants of the Roman population, when around 600 and then again around 700 Christian missionaries from the west became active, with the support of the Bavarian dukes. At the end of the 7th century St. Rupert, who came from the Rhine, founded the church of Salzburg. When they were threatened once more by the Avars, the Alpine Slavs (Karantaner) placed themselves (before 750) under the protection of the Bavarians, whose mission was extended to them. At the same time, Bavarian settlers penetrated into the valleys of Carinthia and Styria. Charlemagne, emperor of the neighbouring Franks, however, defeated the Bavarian duke Tassilo III, wiping out the Bavarian dukedom for a century. During the following years (791–796) Charlemagne also led a number of attacks against the Avars and destroyed their dominion. Surviving Avars were made to settle in the eastern part of Lower Austria between the rivers of Fischa and Leitha, where they soon disappeared from history, most probably mixing with the native population.

Frankish domination in the 8th and 9th centuries

As was the usual Frankish practice, border provinces (Marken, or marches) were instituted in the newly won southeastern territories. The Avar March on the Danube and Lower and Upper Pannonia and Karantania were to form a border fortification; but this arrangement soon became less effective because of frequent disagreements among the nobility. To that unrest was added a threat from the Bulgarians and from the rulers of "Great Moravia." Nevertheless, the process of Germanization and Christianization continued, during the course of which the churches of Salzburg and Passau came into conflict with the eastern mission which was led by the Slav apostles Cyril and Methodius. The Frankish kingdom richly endowed the church and nobility with new lands, which came to be settled by Bavarian and Frankish farmers.

In 881 the beginning of incursions by the Magyars led to a first clash near Vienna. By 906, they had destroyed greater Moravia, and, in 907, near Pressburg (Bratislava), the Magyars defeated a large Bavarian army that had tried to win back lost territory. Liutpold of Bavaria and Theotmar, the archbishop of Salzburg, were killed in battle. The Lower Austrian territories as far as the Enns River and Styria as far as the Koralpe fell under Magyar domination. Nevertheless, a certain continuity of German-Slav settlement was maintained, so that, after the victory of the German king Otto I (955) and the further repulse of the Magyars in the 960s, a fresh start could be made.

The Babenberg period. The first mention of a ruler in the regained territories east of the Enns is of Burchard, who probably was count (burgrave) of Regensburg. It appears that he lost his office as a result of his championship of Henry II the Quarrelsome, duke of Bavaria. In 976 his successor, Leopold I of the House of Babenberg, was installed in office. Under Leopold's rule the eastern frontier was extended to the Vienna Woods after a war with the Magyars. Under his successor, Henry I, the country around Vienna itself must have come into German hands. New marches were also created in what was later known as Carniola and Styria. Wars against Hungarians and Moravians took up the reign (1018–55) of Margrave (a count who ruled over a march) Adalbert. Parts of Lower

Austria on both sides of the Danube were lost temporarily; after they were retaken, they became the so-called Neumark (New March), which for some time enjoyed independence—as did the Bohemian march to the north of the Babenberg territories. The position of the Babenbergs was at that time still a modest one; their territorial rights were no greater than those of other leading noble families. Their power within their own official sphere was further diminished by ecclesiastical immunities (Passau in particular, but also Salzburg, Regensburg, and Freising), with numerous monasteries owning large territories as well.

Involvement in the papal-investiture controversy

Austria was repeatedly drawn into the disputes of the investiture controversy in which the Pope and the Holy Roman Emperor fought for control of the church in Germany. In 1075 Margrave Ernest, who had regained the Neumark and the Bohemian March for his family, was killed in the Battle of the Unstrut, fighting on the side of the king (later emperor) Henry IV against the rebellious Saxons. Altmann, bishop of Passau, a leader of church reform and a champion of Pope Gregory VII, influenced the next Babenberg margrave, Leopold II, to abandon the cause of Henry IV. As a result, Henry roused the Bohemian duke Vratislav II against him, and in 1082 Leopold II was defeated near Mailberg and his territories north of the Danube devastated. The Babenbergs, however, managed to survive these setbacks. Meanwhile, the cause of church reform gained ground, with its centres in the newly founded monasteries of Göttweig, Lambach, and, in Styria, Admont.

Under Leopold III (1095–1136) the history of the Babenbergs reached its first culmination point. In the struggle between emperor and pope, Leopold avoided taking sides until a consensus had built up among the German princes that it was Emperor Henry IV who stood in the way of a final settlement. Then Leopold did not hesitate to side with Henry's rebellious son, Henry V (1106). For this he was rewarded with the hand of Henry V's sister Agnes, who had formerly been married to the Hohenstaufen Frederick I of Swabia. The intermarriage with the reigning dynasty not only increased Leopold's reputation but no doubt also brought him additional power. Leopold was even proposed as a candidate to the royal throne, but he declined. It was apparently his intention to concentrate on consolidating his position in Austria. He was the first Austrian margrave to describe himself as the holder of territorial principality (*principatus terrae*), and during his time Austrian common law is mentioned for the first time, another proof of the developing national consciousness.

Leopold's reputation with the clergy was high, and he was eventually canonized (1485). He gave generous endowments to religious communities, establishing the Cistercians at Heiligenkreuz, and he founded, or at least restored, the monastery of Klosterneuburg, which he gave to Augustinian canons. It was in Klosterneuburg as well that he built a residence in which he stayed even after he had acquired Vienna.

Conflict of the Hohenstaufen, Welfs, and Babenbergs

On the death of Leopold III, the Babenbergs were drawn into a conflict between the two leading dynasties of Germany, the Hohenstaufen and the Welfs—on the side of the Hohenstaufen because of their family ties. In 1139 the German king Conrad III bestowed Bavaria, which he had wrested from the Welfs, on his half-brother, Leopold IV. After the latter's untimely death, Henry II Jasomirgott succeeded to the rule of Austria and Bavaria.

Emperor Frederick I Barbarossa tried to put an end to the quarrel between the Welfs and the Hohenstaufen, and in the autumn of 1156 at Regensburg he arranged a compromise. Bavaria was restored to the Welf, Henry the Lion, duke of Saxony, while the Babenbergs were confirmed in their rule of Austria, which was made a duchy, and were given the "three countships," the actual location of which is disputed. Also, the obligations of the dukes of Austria toward the empire were reduced. Their attendence at royal court days was only called for when court was held in Bavaria, and they were compelled to participate only in campaigns of the empire that were directed against Austria's neighbour; that is, Hungary. Henry II Jasomirgott and his wife, Theodora, a Byzantine princess, were granted succession through the female line and the right, in the event of the premature death of their children, to appoint a candidate for the succession. The Babenbergs also were given the right of approving the exercise of jurisdiction by other powers within the new duchy, permitting Henry to exert pressure against such rival internal powers, secular as well as ecclesiastical. The rights of the duke were laid down by imperial charter (*Privilegium Minus*). For centuries, however, Austria continued to contain territorial dominions not subject to the duke. Henry moved his residence to Vienna, where he also founded the monastery of the "Scottish" (actually Irish) monks.

Acquisition of Styria by the Babenbergs

In 1192 the Babenbergs' territory was greatly extended when they won the duchy of Styria. In Styria the margraves of the family of the Otakars of Steyr had gradually asserted themselves—under conditions similar to those of the Babenbergs—over their rivals, the noble families of the Eppensteiner, Formbacher, and Aribonen. The most successful among the Styrian margraves had been Otakar III (reigned 1130–63). Then, in 1180, Emperor Frederick I, in the course of a renewed anti-Welf policy, raised Styria to the status of a duchy and granted it complete independence from Bavaria. A few years later, a treaty of inheritance (Georgenberg; 1186) was concluded between the dukes Leopold V of Austria (reigned 1177–94), a son of Henry Jasomirgott, and Otakar IV of Styria, the ailing last Otakar ruler. When Otakar died in 1192, Leopold succeeded him, and thus the Babenbergs came into the inheritance.

With the exception of a short intermission (1194–98), the reigning Babenberg henceforth ruled both duchies, Austria and Styria. Styria then included parts of the Traungau, which eventually was to become part of Upper Austria, and the province of Pitten, north of the Semmering, afterward assigned to Lower Austria. In logical continuation of the Babenberg policy, Leopold VI the Glorious and his successor, Frederick II the Warlike, the last representative of the dynasty, extended their domains farther south, gaining fiefs in Carniola.

Before he had inherited the duchy of Styria, Leopold V had taken part in the Third Crusade, during which, on the ramparts of Acre, he had become involved in a quarrel with the English king, Richard I the Lion-Heart. Later, on his return journey to England, Richard tried to make his way through Austria in disguise but was recognized near Vienna, taken prisoner, and later handed over to Emperor Henry VI. England had to pay a heavy ransom, a share of which Leopold obtained and invested in the foundation, extension, and fortification of towns as well as in the stamping of a new coin, the so-called Wiener Pfennig. The road connecting Vienna and Styria was improved, and the new town of Wiener Neustadt was established on its course to protect the newly opened route across the Semmering Pass.

On Leopold V's death the Babenberg domains were divided between his sons for four years, until the death of one of them, Frederick I, in 1198. His brother Leopold VI, the most outstanding member of the family, then took over as sole ruler (1198–1230). This was a time of great prosperity for the Babenberg countries. In imperial politics Leopold VI again took sides with the Hohenstaufen, backing Philip of Swabia. In church matters the Duke was a great supporter of the monasteries, founding a Cistercian monastery at Lilienfeld (*c.* 1206). He tried to concentrate patronage rights over ecclesiastical property in his own hands and took rigorous action against the heretics (Cathari and Waldenses). He participated in several crusades in Palestine, Egypt, southern France (against the Albigenses), and Spain (against the Saracens). Leopold VI's efforts to emancipate Austria ecclesiastically by creating a separate Austrian bishopric in Vienna came to naught because of the opposition of the church in Passau and especially Salzburg; nor did his son Frederick II succeed in the same matter. Leopold VI played some role in imperial politics, bringing about the peace Treaty of San Germano between Emperor Frederick II and Pope Gregory IX (1230). He met his death in San Germano, and his body was transported to Lilienfeld to be buried there.

The rule of Leopold VI

A change came about under the last representative of the dynasty, Frederick II the Warlike, Leopold's son. His harsh

internal policy and military excursions against neighbouring lands, together with his opposition to the emperor Frederick II, led in 1237 to the temporary loss of both Austria and Styria. The crisis, however, was overcome, and fresh opportunities were about to open for the Duke when, on June 15, 1246, he was killed in battle against the Hungarians on the Leitha River. With him the male line of the family came to an end.

The political history of Austria from the end of the 10th to the middle of the 13th century is marked by the establishment and consolidation of territories. This process was most advanced in the Babenberg domains but was not confined to them. Dukes Herman (1144–61) and Bernhard (1202–56) of Carinthia achieved a comparable status, and Count Albert of Tirol (died 1253) moved in the same direction. The archbishops of Salzburg strove to eliminate all secular powers and patrons of their see, but in the other territories, secular princes strengthened their rule.

Another milestone of this period was the completion of the colonization of the Austrian territories. New settlements were now established by clearing the woods and advancing to more remote mountain areas. Several old and new settlements grew into market centres and towns and were eventually granted charters. The colonization movement also affected the ratio of German to non-German population. Except for some places in the Alpine regions, the Slavs were gradually assimilated, and the same holds true of the remnants of the Roman population in Salzburg and northern Tirol.

The intellectual life of the period deserves mention, too. The Babenberg court was famous enough to attract some of the leading German poets. At the beginning of the 13th century the Nibelung saga was written down by an unknown Austrian. Historical writing flourished in the monasteries. The era also produced first-rate Romanesque and early Gothic architecture.

LATE MIDDLE AGES

The contest for the Babenberg heritage. Upon the death of Frederick II the Warlike, the Babenberg domains became the political objects of aspiring neighbours. The Emperor and the Pope also tried to intervene. Two female descendants of the Babenbergs, Frederick's niece Gertrude and his sister Margaret, were considered to embody the claims to the heritage. Gertrude married first the Bohemian prince Vladislav and afterward the Margrave Hermann of Baden, who died in 1250. After Hermann's death, Otakar II (Přemysl Otakar II), prince of Bohemia (from 1253 king), married the widowed Margaret. Thereupon Hungarian forces intervened. Under the Treaty of Ofen (1254) Otakar was to rule Austria, while King Béla IV of Hungary received Styria. Troubles in Salzburg, stemming from a conflict between Bohemia and Hungary, inspired a rising among the Styrian nobles. Otakar intervened and in the Treaty of Vienna (1260) took over Styria as well. The state of anarchy that prevailed in Germany during this period proved advantageous to Otakar, who was granted both Austria and Styria in fief from Richard, earl of Cornwall, the titular German king. The grant, however, was only by writ and was invalid according to German law. During the following years Otakar's energetic rule met with growing opposition among the Austrian nobility. He introduced foreigners into important official positions, broke fortresses that had been erected without his consent, and dissolved his childless marriage with Margaret. Otakar had two of the opposition leaders, Otto of Meissau and Seifried of Mahrenberg, executed. The inhabitants of the cities, on the other hand, and the gentry, as well, generally favoured Otakar, who supported the churches and the monasteries. To complete his success, Ulrich of Spanheim, duke of Carinthia, willed Carinthia and Carniola to Otakar in 1269.

Rise of Přemysl Otakar of Bohemia

Reverses came only when Count Rudolf IV of Habsburg was elected German king as Rudolf I on September 29, 1273. Cautiously but nevertheless energetically, Rudolf set about to undermine the powerful position Otakar had created for himself. He challenged the legitimacy of Otakar's acquisitions and finally placed the Bohemian king under the ban of the empire. In 1276 Rudolf and his allies invaded Austria, forcing Otakar to do homage and to renounce his claims to Austria. Two years later, while trying to recover what he had lost, Otakar was defeated by the united forces of Rudolf and the Hungarians and was killed on the battlefield near Dürnkrut (August 26, 1278).

The accession of the Habsburgs. As the German princes had not cared to give Rudolf adequate support against Otakar, he did not feel bound to them and set about to acquire the former Babenberg lands for his own house. In 1281 he made his eldest son, Albert (later Albert I, king of Germany), governor of Austria and Styria; on Christmas, 1282, he invested his two sons, Albert and Rudolf II, with Austria, Styria, and Carniola, which they were to rule jointly and undivided. As the Austrians were not used to being governed by two sovereigns at the same time, the Treaty of Rheinfelden (June 1, 1283) provided that Duke Albert should be the sole ruler. In 1282 Carniola had already been pawned to Meinhard II of Tirol (of the counts of Gorizia), one of the most reliable allies of Rudolf who, in 1286, was also invested with Carinthia.

At first the Habsburg rulers were far from popular in Austria. Albert's energetic and relentless rule roused bad feeling, and the Swabian entourage that had arrived with the new dynasty to occupy key positions was despised by native nobles. There were conflicts with Bavaria, Salzburg, and Hungarian nobles who violated the Austrian frontier. After the death of King Rudolf (1291), all the neighbours and rivals of the Habsburgs and the counts of Gorizia united. Albert, however, succeeded in negotiating a peace with his most dangerous foes, the Hungarians and the Bohemians, and he broke the fortresses of the rebel nobility. Meanwhile, Meinhard II had stifled the uprising in Carinthia.

Rule of Albert of Habsburg

In 1292 Albert had been passed over in the German election, and Adolf of Nassau was called to the throne. When Adolf fell out with the electoral princes, however, they went over to Albert, who had just subdued another rebellion in Austria. After Adolf was defeated and killed near Göllheim (1298), Albert had himself elected a second time. In his Austrian lands Albert's main concern was to provide for an effective administration, in which he was assisted by his privy councillors, most of whom were foreign. Records were set up to codify the prerogatives and returns of the ducal property. Eventually Albert did not spare the church, either. When the Přemysl family died out in 1306, Albert aspired to the Bohemian throne. He had his eldest son, Rudolf III, elected Bohemian king, but Rudolf died the following year. Albert was preparing for a new campaign when he was murdered by his nephew, John, and some accomplices (1308).

On Albert's death the anti-Habsburg movement flared up again in Austria, but his sons, Frederick I the Fair and Leopold I, managed to maintain control. Frederick stood for election as German king (as Frederick III), and for the next years the Habsburg countries had to support the cost of the war with his rival, Louis IV of Bavaria, until 1322, when Frederick was defeated near Mühldorf. Earlier, another more decisive battle had been lost by the Habsburgs to the Swiss at Morgarten in 1315. From that time on, the Habsburg domains in the territory south of the Rhine and the Bodensee (Lake Constance) began to crumble away. Frederick the Fair spent his last years in Austria and was buried in the Carthusian monastery of Mauerbach (1330). He seems to have been the first of the Habsburgs for whom Austria meant home. From his time on, Habsburg rule and Habsburg territories were known as the Austrian domains (*dominium Austriae*), a term that was replaced, in the course of the 14th and 15th centuries, by the new concept of the House of Austria.

After Frederick's death the Habsburgs were for some time ruled out as possible candidates for the German throne; but, under the brothers Albert II and Otto, Habsburg Austria received its first important accession of territory. In 1335 Carinthia and Carniola were acquired after the death of Henry of Gorizia; while, with the help of Luxembourg troops, Henry's daughter Margaret (surnamed Maultasch) managed to retain the Tirol. Albert and his brother Otto had not gotten on too well, but when Albert came to rule on his own, he proved to be of sound judgment and

Acquisition of Carinthia, Carniola, and Tirol

keen on preserving the peace. It was a time of severe catastrophes: bad harvests, floods, and earthquakes, and in 1348–49 the plague, which brought a persecution of the Jews that was suppressed, however, by the Duke. Albert arranged several tours around his domains to establish contacts with the populace and improve jurisdiction. Two campaigns against the Swiss failed to yield any spectacular results, but they helped once more to consolidate the weakened Habsburg position. At his death in 1358, Albert left four sons. Though in 1355 a family ordinance had decreed that all the male members of the family were to rule jointly over the undivided domains, only the eldest among them, Rudolf, was then fit to rule. Throughout his short reign (1358–65), Rudolf IV showed himself extremely energetic and ambitious. He started to rebuild St. Stephen's Cathedral in the Gothic style, and he founded the University of Vienna (1365). With these two projects he imitated and rivalled his father-in-law, the emperor Charles IV, at Prague.

In 1359 Rudolf's forged charter, the Privilegium Majus, by which he claimed immense privileges for Austria and its dynasty, as well as the title of archduke, caused a breach between him and the emperor Charles IV. Charles was not prepared to accept the Privilegium Majus to its full extent (although it later was sanctioned by the Habsburg emperor Frederick III in 1442 and again in 1453). Upon news of the death of Duke Meinhard in 1363, Rudolf prevailed upon the Duke's mother, Margaret, to make over the Tirol to him. On this occasion the Emperor backed the Habsburgs against the Wittelbachs, and the Tirol thus passed to the House of Austria.

The division of the Habsburg lands. Rudolf was succeeded in 1365 by his two brothers, Albert III and Leopold III. After some years of joint rule, however, they quarrelled and in 1379, by the Treaty of Neuberg, partitioned the family lands. Albert, as the elder brother, received the more prosperous countries on the Danube (Upper and Lower Austria). The rest of the widespread domains fell to Leopold (including Styria, Carinthia, Tirol, the old Habsburg countries in the west, and central Istria). The treaty also contained several points on mutual wardship, preemption rights, and common titles, by which some connection between the two lines was to be preserved.

Treaty of Neuberg of 1379

In 1381 the resourceful Duke Leopold took advantage of the weak position of Venice in its war with Genoa and seized Trieste, which had broken away from Venice. His efforts to expand his rule in the west, however, were less successful, though he seemed lucky enough at first. Envisaging a connection between the original Habsburg territories in the west and the new domains in the Tirol, the Habsburgs looked for a foothold in the region west of the Arlberg (modern Vorarlberg). Neuberg on the Rhine was won in 1363 and Feldkirch in 1375. Another important acquisition was the city of Freiburg in the Breisgau. But then Leopold came into conflict with the Swiss, which led to defeat and his death at Sempach in 1386. An army of his brother, Albert III, was likewise defeated near Näfels in 1388, and the Habsburgs suffered heavy territorial losses. Leopold's sons recognized the wardship of Albert, who acquired Bludenz and the Mantafon Valley west of the Arlberg in 1394. In his own domains Albert was forced to check the dynasty of the Schaunbergs (in Upper Austria), who tried to create an independent domain around Wilhering and Eferding. Albert III especially favoured the city of Vienna as his capital, and it was because of his reorganization that the university Rudolf IV had founded there was able to survive.

After Albert's death in 1395, new Habsburg family troubles arose, differences that the treaties of Hollenburg (1395) and Vienna (1396) tried to settle. Under the Vienna treaty, the line of Leopold III split into Styrian and Tirolian branches, resulting in three complexes of Austrian territories—a state of affairs that was to reappear in the 16th century. The individual parts came to be known by the names of Niederösterreich (comprising modern Lower and Upper Austria), Innerösterreich (comprising Styria, Carinthia, Carniola, and the Adriatic possessions), and Oberösterreich (comprising the Tirol and the western domains, known as the Vorlande, or Vorderösterreich).

In 1396 the Austrian estates, or diets, were first assembled to consider the Turkish threat and henceforth were to play an important political role in Austria. In them the nobility usually took the lead, but they also included representatives of the monasteries, the towns, and the marketplaces. In the Tirol, in Vorarlberg, and, at times, in Salzburg, the peasants also sent their representatives to attend the diets. Because of the Habsburg partitions and frequent regencies, the estates were able to gain in importance. They did not obtain the right to pass laws, but they obstinately insisted on the privilege to grant taxes and duties.

The early diets of the nobility, church, and towns

After the short rule of Albert IV (1395–1404) and a troublesome tutelary regime (1404–11), Albert V came into his own, and with him the Danube countries again enjoyed a strong and energetic rule (1411–39). Albert, however, had married the daughter of the emperor Sigismund and was thus drawn into the Hussite religious wars, in the course of which the Austrian lands north of the Danube were ravaged. In the Austrian west, Duke Frederick IV of the Tirolian branch lost the Aargau to the Swiss but was able to assert himself in Tirol against a rebellion of his nobles.

When Sigismund died, Albert inherited his positions. In 1438 he was first elected Hungarian king, with the German (as Albert II) and the Bohemian crowns to follow later. Albert no doubt had many of the qualities of a born ruler, but he died prematurely in 1439 on an unsuccessful campaign against the Turks. Soon thereafter, his widow gave birth to a son and heir, Ladislas Posthumus, to whom Frederick V of Styria, as the senior member of the house, became guardian. Frederick also had Sigismund, the son of Frederick IV of Tirol, under his tutelage.

Thus began the long reign of Frederick V (as Roman emperor he was to become Frederick III). His reign was marked by almost ceaseless strife with the estates, with his neighbours, and with his jealous family. When he tried unsuccessfully to take advantage of a conflict among the Swiss Confederates, the Tirolians made Frederick release Duke Sigismund from tutelage (1446). A few years later, on his return from Rome, where he had been crowned emperor, his enemies at home and abroad in 1452 forced him also to give up Ladislas, who was then the recognized king of Hungary and Bohemia. The boy king's policies were made by Count Ulrich of Cilli. Ulrich was murdered at Belgrade in 1456, however, and a year later King Ladislas died. In Bohemia and Hungary national kings came to power. Frederick now won himself a foothold in the Austrian domains on the Danube and succeeded in acquiring the rich estates and fiefs of Ulrich.

The Burgundian and Spanish marriages. Maximilian I, the son of the emperor Frederick III, was married to the Burgundian heiress, Mary, at Ghent (1477). By that tie to Burgundy the Habsburgs became involved in long struggles with France. After Mary's death (1482), Maximilian, moreover, met with increasing difficulties in the Burgundian countries themselves. In the meantime, another crisis had arisen in the eastern Habsburg domains. Disagreement about the Bohemian succession and a political error of Frederick III, who tried to install the former archbishop of Gran (Esztergom) at Salzburg, led King Matthias I Corvinus of Hungary to march against Austria. Vienna was besieged and finally taken by the Hungarians (1485), as was Wiener Neustadt (1487). The harried Maximilian came into even greater distress in the Low Countries, where the rebellious citizens of Bruges put him under arrest (1488). Sigismund, the Habsburg ruler of the Tirol, who was heavily encumbered by debts, planned to sell his country to the Bavarians. A complete breakdown of the House of Habsburg threatened, but Maximilian was ultimately released. He prevailed upon Sigismund to abdicate in his favour. In 1490 the Habsburgs were able to take over Lower Austria. Maximilian even attacked Hungary but in the Treaty of Pressburg (1491) renounced claims to Hungary, though reserving the succession rights of his family.

Near collapse of House of Habsburg

After the death of his father, Emperor Frederick III, Maximilian came into a heritage that surpassed the endowments of all his predecessors. Furthermore, his son, Philip I the Handsome, who governed the Low Countries, was betrothed to the Spanish infanta, Juana (later Joan

the Mad), and through the unexpected death of male members of the Spanish dynasty this marriage was to raise the Habsburgs to the throne of Spain. In the German Empire as well as in Austria, Maximilian introduced sweeping administrative reforms that were the first steps toward a centralized administration. In 1508 Maximilian assumed the title of elected emperor as he was unable to pass through hostile Venetian territory to go to Rome for his coronation, and henceforth Rome and the pope had no more say in the creation of new emperors.

During Maximilian's last years, Eastern politics again came to the fore. The great crusade he planned against the Turks, however, never materialized. In 1515 Maximilian arranged a double marriage between his family and the Jagiellon line that ruled Bohemia and Hungary, thus reviving earlier Habsburg claims to these countries. Maximilian's energetic reign added greatly to the prestige of the Habsburgs. Thus, his grandson Charles (V) was able to prevail against French intrigue to inherit the imperial crown. Charles's younger brother, Ferdinand I, took over the rule of the Austrian countries but encountered the opposition of the estates, which he cruelly suppressed. In the agreements of Worms (1521) and Brussels (1522) Charles V formally handed over the Austrian lands to his brother. The subsequent years of Ferdinand's reign were troubled by peasant risings in the Tirol and Salzburg and were followed by similar upheavals in Innerösterreich.

Summary of developments in the late Middle Ages

In the late medieval period the Alpine lands were assembled by the Habsburgs into a monarchical union comprising about the extent of the present Austrian state. The process of union was at times intercepted and hindered by the partitions among the dynasty. When the process was finished, however, the territories still preserved their individuality and their own legal codes. During this period the towns developed and prospered, but in the rural settlements a backward tendency had set in. Many settlements were abandoned, especially in Lower Austria. The leading classes lost their interest in rural colonization as they found other and more lucrative sources of income. Mining developed, but trade was impaired by political instability. Until about 1450 the University of Vienna enjoyed some fame in the fields of theology and science. The literary culture of Austria was characterized by remarkable works, among them the rhyming chronicle of the Styrian Otakar aus der Geul, the work of the Carinthian abbot John of Viktring, the poetry of Oswald of Wolkenstein, and the works of the theologian and historian Thomas Ebendorfer. From the middle of the 15th century onward Austria came under the influence of Italian Humanism.

REFORMATION AND COUNTER-REFORMATION

The acquisition of Bohemia. The year 1526 saw the defeat and death of the Jagiellon king of Hungary and Bohemia, Louis II, who fell in the Battle of Mohács against the Turks. In view of the treaties of 1491 and 1515, Ferdinand I and the Vienna court envisaged Hungary and Bohemia plus the adjoining countries falling to the Habsburgs. Thus, the union of Austria, Bohemia, and Hungary became the leading concept of Habsburg politics. After clever diplomatic overtures, Ferdinand was elected king of Bohemia (October 23, 1526). In Hungary, however, there was a split election; János (John) Zápolya, *voivode* (governor) of Transylvania, was chosen by an opposition party, whereupon war broke out between the two candidates.

Ferdinand's troops in Hungary would have been in a stronger position had Zápolya not been assisted by the Turks under Süleyman I. In 1529 the Turks advanced as far as Vienna, which they besieged in vain. Another Turkish offensive came to a halt at Güns in western Hungary in 1532. Ferdinand, on the other hand, failed in his attempt to take Ofen (Hungarian Buda), where the Turks had entrenched themselves. By around the middle of the century the frontiers had become fixed. Hungary happened to be divided into three parts: the west and the north remained with the Habsburgs, the central part came under Turkish rule, and Transylvania and adjoining territory were kept by Zápolya and his successors. This situation was anticipated in the truce of 1547 and became formalized in the Peace of Constantinople (1562).

Ferdinand I's administrative reforms

During a short truce in the fighting against Zápolya and the Turks, Ferdinand started to reorganize Austrian administration. In 1527 he created new central organs: the Privy Council (Geheimer Rat) for foreign affairs and dynastic matters; the Court Council (Hofrat) as the supreme legal authority; the Court Chancery (Hofkanzlei), which served as the central office and only later on was to deal with internal affairs; and the Court Treasury (Hofkammer) for finance and budgeting. As the Court Treasury proved inefficient in the financing of the Turkish war, the Court Council of War (Hofkriegsrat) was established in 1556 to take care of the pay, equipment, and supplies of the troops, acquiring some influence on military operations as well.

The advance of Protestantism. The Protestant movement gained ground in Austria very fast. The nobility especially turned toward the Lutheran creed. For generations eminent families provided the protagonists of Protestantism in the Lower and Inner Austrian territories. The sons of the nobility were often sent to the north German universities to expose them more fully to Protestant influence. From 1521 Protestant pamphlets were produced by Austrian printers. Bans on them, issued from 1523 onward, remained ineffective, however.

Among the peasant population the Anabaptists had a stronger appeal than the Lutherans. As they had no support from the estates and because of their radicalism, however, the Anabaptists were persecuted from the start. In 1528 Balthasar Hubmaier, their leader in the Danube countries and southern Moravia, was burned at the stake in Vienna, and in 1536 another Anabaptist, the Tirolian Jakob Hutter, was put to death in the same way in Innsbruck after he had led many of his followers into Moravia. Ferdinand, for his part, advocated religious reconciliation and looked for means to achieve it; but the dogmatic viewpoints proved irreconcilable. The Peace of Augsburg (1555) finally brought some respite in the religious struggles.

When Charles V abdicated, Ferdinand I became emperor (1558), and thus the leadership of the empire was taken over by the Austrian (German) line of the Habsburgs. Maximilian II, the eldest son, followed his father in Bohemia, Hungary, and the Austrian Danube territories (1564). The next son, Ferdinand, was endowed with Tirol and the Vorlande; Charles, the youngest of the brothers, received the Inner Austrian lands and took up residence in Graz. Maximilian was known for his Protestant leanings but was bound by a promise he had given his father to remain true to the Catholic religion. The Protestants were therefore granted fewer concessions from him than they might have expected.

Catholic reaction and the Counter-Reformation

Meanwhile, Catholic counteractivity began, with the Jesuits particularly prominent in Vienna, Graz, and Innsbruck. A new generation of energetic bishops took part and proved a great asset to the cause. It was also of some importance that the monasteries, though they had been deserted by many of their members and were struggling for existence, had not been secularized. On the Protestant side, it proved impossible to reconcile the various reforming movements. Social differences between them, especially between the nobility and the peasants, also stood in the way of a united Protestant front. The Counter-Reformation scored its first successes in Gorizia and Carniola, where Protestantism had remained insignificant. And in other parts, official religious commissions started to replace the Protestant preachers with Catholic clergymen.

Rudolf II and Matthias. Maximilian's successor, Rudolf II (reigned 1576–1612), had been educated in Spain strictly in the Catholic faith. He had all Protestants dismissed from court service. The conversion of the cities and market centres of Lower Austria to Catholicism was conducted by Melchior Klesl, at that time administrator of the Vienna see but later to become bishop and cardinal. In Upper Austria, where the Protestants had their strongest hold, the situation remained undecided, with the Catholic governor, Hans Jakob Löbl of Greinburg, and the Calvinist Georg Erasmus of Tschernembl leading the opposing religious parties. When Charles's son, Ferdinand II, took over in Styria, he proved to be the most reso-

lute advocate of the Counter-Reformation. It was he who eventually succeeded in uprooting Protestantism, first in Inner Austria and then in the other Habsburg countries, with the exception of Hungary and Silesia.

From local skirmishes along the frontier, a long, drawn-out war with the Turks developed (1592–1606). In 1598 Raab (Hungarian Győr), which served as a bastion of Vienna, was temporarily lost; Gran, Veszprém, and Stuhlweissenburg (Hungarian Székes-fehérvár) passed several times from one side to the other. The introduction of the Counter-Reformation in Hungary, moreover, resulted in a rising of Protestant elements under István Bocskay. But in 1606 at Vienna a peace was concluded between Austria and the Hungarian estates. At Zsitvatorok another peace was negotiated with the Turks, who for the first time recognized Austria and the emperor as an equal partner.

Conflict between Rudolf and Matthias

Political disagreements between Emperor Rudolf, who to an increasing degree showed signs of mental derangement, and the rest of the family led to the "Habsburg Brothers Conflict." Cardinal Klesl in 1607 brought about an agreement among the younger relatives of the Emperor to recognize the Emperor's brother Matthias as the head of the family. As the conflicts with Rudolf persisted, Matthias strove also to come to an understanding with the estates, which were mainly Protestant. The formation of opposing religious leagues in Germany, the Protestant Union and the Catholic League, also added to the general confusion.

Matthias advanced into Bohemia, and, in the Treaty of Lieben (1608), Rudolf conceded to him the rule of Hungary, the Austrian Danube countries, and Moravia, while Matthias had to give up the Tirol and the Vorlande to the Emperor. In 1609 the estates received a confirmation of the concessions Maximilian II had made to them. The cities were guaranteed only in general terms that their old privileges should not be interfered with. At the same time, Rudolf II was forced to grant to Bohemia the so-called Letter of Majesty, which contained far-reaching concessions to the Protestants. After a final defeat of Rudolf in Bohemia in 1611, Matthias was crowned king of Bohemia. Rudolf's death in 1612 finally ended the conflict.

After Matthias had been elected emperor, his principal councillor, Cardinal Klesl, tried in vain to arrange an agreement with the Protestants in Germany. The ensuing years were filled with wars in Transylvania, where Gábor Bethlen came to power. In the Peace of Tyrnau (1615) the Emperor had to recognize Bethlen as prince of Transylvania, and in the same year he extended the truce with the Turks for another 25 years. In the meantime, war had broken out with Venice (1615–17) because of the pirating activities of the Serb refugees (Uskoken) established on the Croatian coast. A settlement was reached in the Peace of Madrid. The situation in Bohemia then reached a critical point, the religious tensions in the country finding a vent in the "Defenestration of Prague" (May 23, 1618), in which two of the Emperor's regents were thrown from the windows of the Hradčany Palace.

The Bohemian rising and the victory of the Counter-Reformation. War became inevitable when Emperor Matthias died in 1619. Not that he had been master of the situation, but his death brought Ferdinand II, the most uncompromising Counter-Reformer, to the head of the House of Habsburg. Ferdinand was hard pressed at first, as Bohemian and Moravian troops invaded Austria. A deputation of the estates of Lower Austria tried to make him renounce Bohemia in a peace treaty and demanded religious concessions for themselves, unsuccessfully, however. The Bohemians were forced to retreat, and imperial troops advanced into their country. The Bohemians deposed Ferdinand from the throne of Bohemia and elected Frederick V in his stead. But two days later Ferdinand II was elected German emperor at Frankfurt (August 28, 1619).

War over the Bohemian crown

War was the only means of resolving the issue. The conflict for the Bohemian crown developed into a European war when Spain, the Bavarian duke Maximilian I, and the Protestant elector of Saxony entered the struggle on the side of the Emperor. The Upper Austrian estates rashly joined Frederick, with the result that their country was occupied by the army of the Catholic League and afterward pledged to Bavaria. At the Battle of the White Mountain, Ferdinand became master of Bohemia, Moravia, and Silesia, while Lusatia was pledged to Saxony. King Frederick fled to the Netherlands. The leaders of the Bohemian rising were executed, and other nobles who had compromised themselves lost their property. Many Protestants left the country. In the new constitution of 1627 Bohemia and its associated lands became a hereditary kingdom. The diets were not dissolved entirely, as the government wanted to make use of their administration, but their influence was restricted to financial matters.

After the death of Matthias, Ferdinand had also inherited the Danubian territories. Tirol, however, retained a special status under a new Habsburg secundogeniture (inheritance by a second branch of the house). Upper Austria, pledged to Bavaria, was disturbed by a great peasant rising. The Protestant peasants were defeated after heavy fighting, and in 1628 the country passed into the hands of the Emperor again.

The Counter-Reformation was vigorously enforced in the Austrian domains. This led to the mass emigration of Protestants, including many members of the nobility. Most went to the Protestant states and to the imperial cities of southern Germany. After the Bohemian victory the war went favourably for the Emperor, and the Peace of Lübeck (1629) seemed to secure the hegemony in Germany for the Habsburgs. But in 1629 Ferdinand's attempt in the Edict of Restitution (Restitutionsedikt) to establish religious unity by force throughout the empire provoked the violent opposition of the Protestants.

The struggle with Sweden and France. July 1630 saw intervention in Germany's religious strife from a different quarter—Sweden. In that month the Protestant Swedish king, Gustavus II Adolphus, landed on the Baltic coast of Pomerania. His purpose was to defend the Protestants against further oppression, to restore the dukes of Mecklenburg, his relatives, who had been driven from their lands by Ferdinand's forces, and perhaps to strengthen Sweden's strategic position in the Baltic. In the ensuing conflict the city of Magdeburg was destroyed by fire after it had been taken by the troops of the Emperor under Gen. Johann Tserclaes, Graf von Tilly (1631). The north German Protestants, who had so far remained undecided, consequently went over to the Swedes. After victories near Breitenfeld and on the Lech, the Swedish troops entered Bavaria.

During the subsequent period of the Thirty Years' War, Ferdinand adopted a rigorous and often unrelenting attitude, though he yielded a little when the Peace of Prague was being negotiated (1635). His successor, Ferdinand III (1637–57), was as loyal to Catholicism as the father had been but showed himself more of a realist. He was not able, however, to prevent the war from again dragging into Habsburg territory, so that in 1645 even Vienna was threatened. The extremist party that had rejected all concessions lost its influence at the Vienna court, and two able diplomats, Maximilian, Graf von Trauttmansdorf, and Isaac Volmar, were entrusted with the representation of a weakened Austria at Münster and Osnabrück, where extended negotiations were conducted until acceptable terms could be settled for Austria. In the Peace of Westphalia (1648) Austria lost its possessions in Alsace, and Lusatia had to be ceded for good to Saxony. The peace in many respects marked the beginning of a new epoch. The Holy Roman Empire from then on was reduced to a loose union of otherwise independent states, and Habsburg politics shifted its emphasis, falling back entirely on the political, military, and financial resources of the hereditary Habsburg lands, now including also Bohemia. The new central organs and the administrative bodies of the territories took on much greater importance than the remaining institutions of the Holy Roman Empire. The Emperor came to rely on a standing army rather than upon troops provided by the German princes.

Economic and cultural consequences of the religious struggle

The heavy drain the religious wars had made on the population of the Austrian territories was compensated for by immigrants from the Catholic parts of the empire and by Croatian refugees from the southeast. The economic position of the peasants on the whole deteriorated. Many members of the nobility, as well as the church, acquired

new property. In mining, boom and depression followed quickly upon each other. The loss of many experienced miners during the Counter-Reformation resulted in difficulties, but the government took several steps toward improving and extending the salt mines. In 1625 it founded the Innerberg Union, under which the Styrian iron industry was reorganized. The Emperor also tried to interfere with the trade organizations of the towns, though without much success. Trade and finance in the Austrian territories was dominated by foreign capital.

The cultural life of the period was also dominated by the religious struggle. In the field of education the schools of the denominational parties rivalled each other. In 1585 a Jesuit university was founded at Graz, while at Salzburg a Benedictine university was established (1623). Austrian humanists produced some outstanding works of poetry and historical writings, and the sovereigns were great patrons of the arts, but on the whole this was an epoch dominated by Italian and Western influences.

AUSTRIA AS A GREAT POWER

After the Thirty Years' War, Austrian politicians were understandably reluctant to enter into another military conflict. In 1654 Ferdinand IV, the eldest son of the Emperor, died. His brother Leopold, who had been destined for a church career, then was considered as heir to the throne and was recognized as such by Austria, Bohemia, and Hungary. In Germany, however, difficulties arose when France declared itself against Leopold. Nevertheless, after the death of Emperor Ferdinand, Leopold was finally elected (1658), after having conceded constitutional limitations that restricted his liberty of action in foreign politics. West German princes under Johann Philipp von Schönborn, archbishop of Mainz, formed the French-oriented League of the Rhine. At the same time, Austria was engaged in the northeast, when it intervened in the war between Sweden and Poland (1658) in order to prevent the collapse of Poland. There were some military successes, but the Treaty of Oliva (1660) brought no territorial gains for Austria, though it stopped the advance of the Swedes in Germany.

During the Thirty Years' War the Turkish front had been quiet, but in the 1660s a new war broke out with the Turks (1663–64) because of a conflict over Transylvania, where a successor had to be appointed for György II Rákóczi, who had been killed fighting against the Turks. The Turks conquered the fortress of Neuhäusel in Slovakia, but the imperial troops succeeded in throwing them back. The Austrian military success was not, however, reflected in the terms of the Treaty of Vasvár: Transylvania was given to Mihály Apafi, a ruler of pro-Turkish sympathies. A minor territorial concession was also made to the Turks. The year after the Turkish peace, Tirol and the Vorlande reverted to Leopold I (1665), and the second period of the Habsburg partition (1564–1665) came to an end.

In Hungary dissatisfaction with the results of the Turkish war spread. Not only the Protestants, who were threatened by the Counter-Reformation, but also many Catholic nobles were alarmed by Habsburg absolutism. A group of Hungarian nobles and the Styrian count Hans Erasmus of Tattenbach entered into a conspiracy. The Austrian government, informed of their activities, had four of the ringleaders executed—an action that led to a rising by rebels known as Kuruzen (Crusaders).

In the meantime, the position of the Habsburgs in the west had again deteriorated. At first Leopold I's leading statesmen, Johann Weikhard, Fürst Auersperg (dismissed in 1669), and the president of the Court Council of War, Wenzel Eusebius, Fürst von Lobkowitz, remained rather passive in view of the expansionist policies of Louis XIV of France. They also stayed outside the Triple Alliance of Holland, England, and Sweden that was concluded in order to ward off the attacks of Louis against the Spanish Netherlands. When Louis actually invaded Holland, the Emperor finally entered the war, but in the ensuing Treaty of Nijmegen (1679) he had to cede Freiburg im Breisgau to France.

The threat to Vienna by the Turks

Another and still more menacing danger appeared in the southeast. After some deliberation, the leader of the Hungarian rebels, Imre Thököli, had asked the Turks for help, whereupon the grand vizier Kara Mustafa organized a large Turkish army and marched it toward Vienna. Habsburg diplomats succeeded in concluding an alliance between Austria and Poland. Meanwhile, imperial troops under Duke Charles of Lorraine tried to hold the enemy but had to retreat. From July 17 to September 12, 1683, Vienna was besieged by the Turks. Deciding against a direct assault, the Turks began to drill tunnels underneath the bastions of the city, when relief columns arrived from Bavaria, Saxony, Franconia, and Poland. King John III of Poland took over the command of the relieving army, which descended upon the Turks and dispersed them. The Emperor concluded a pact with Poland and the Venetian republic—the Holy League. In 1685 Neuhäusel was won back, and in September of 1686 Ofen was captured, despite fierce Turkish resistance.

In 1687 the Hungarian diet recognized the hereditary rights of the male line of the Habsburgs to the Hungarian throne. In 1688 Belgrade was conquered and Transylvania was secured by imperial troops. In the meantime, Louis XIV had begun an offensive against the German Palatinate. This meant that no further troops could be spared for the Turkish war, and in 1690 all recent conquests in the south, including Belgrade, were lost again. A victory of the imperial and the allied German troops under Margrave Louis of Baden near Slankamen (1691) prevented the Turks from advancing farther, but then the Margrave was ordered to the Rhine front. Eventually Prince Eugene of Savoy took over the command and gained a decisive victory over the Turks near Zenta (1697). After another offensive against Bosnia, the Turks finally decided to negotiate a peace. In the Treaty of Carlowitz (1699), Hungary, Transylvania, and large parts of Slavonia fell to the Habsburg emperor. In the meantime, the war in the west had come to an end (Treaty of Rijswijk, 1697), overshadowed already by the question of the Spanish succession.

The War of the Spanish Succession. From 1701 to 1714 Austria was involved in hostilities with France over the issue of the Spanish succession. The childless King Charles II of Spain, a Habsburg, had willed his entire possessions to a Bourbon prince—a grandson of Louis XIV of France. All those who disliked the idea of a French hegemony in Europe consequently united against the French. The Emperor declared war (1701) and was immediately supported by Brandenburg-Prussia and Hanover. In the spring of 1702 England and Holland entered the war in the Grand Alliance against France. Louis XIV, on the other hand, was able to win the electoral princes of Bavaria and Cologne as his allies. At this critical juncture another Hungarian rising, led by Ferenc II Rákóczi, occurred. The rebels were prepared to join forces with the enemies of Austria and for years engaged Austrian troops. The rebels even threatened Vienna, whose suburbs had to be fortified.

Scale of the Spanish war

In the war with France, imperial troops fought on four fronts: in Italy, on the Rhine, in the Spanish Netherlands, and in Spain. Much larger forces were mobilized than had been customary during the 17th century, with the result that the financial drain on the imperial treasury was so heavy that the Emperor had to resort to Dutch and English loans. When Bavaria entered the war on the side of the French, Austria was in further danger, until the Battle of Blenheim (1704), in which a joint English and Austrian army under the Duke of Marlborough and Prince Eugene defeated the French and Bavarian forces.

After a reign of 48 years filled with almost endless troubles, Emperor Leopold died in 1705. He was succeeded by his son, Joseph I (1705–11). In the religious quarrels the new emperor, an ally of Protestant states, showed great restraint and allowed himself to be guided mainly by political motives.

In 1703 the Duke of Savoy, who had left the French to go over to the Habsburgs, found himself in a critical situation; his capital, Turin, had come under French siege. An imperial army under Prince Eugene and reinforced by a Prussian contingent was sent to his aid and succeeded in uniting with the Savoyan forces and relieving Turin after a victorious battle (1706). At the beginning of the next year an agreement was reached under which the French eva-

cuated northern Italy. The same year a smaller imperial army under Wirich, Graf von Daun, conquered Spanish-ruled southern Italy; but an invasion of southern France, which the sea powers had instigated, failed. A quick success, however, fell to the Austrians in a campaign against the Vatican state over a conflict between the Emperor and the Curia concerning mutual feudal rights and because of Pope Clement XI's rather pro-French leanings.

The allies were victorious in the Netherlands, winning the Battle of Oudenaarde and conquering Lille (1708). Paris seemed within easy reach. The Battle of Malplaquet (1709) was another victory for the allies, but they had to pay dearly for it. In the meantime, peace negotiations had foundered. After reverses in Spain and a political change in England, the alliance itself was in danger of falling apart. The situation was further aggravated by the death (1711) of Emperor Joseph I, who left daughters only.

At this juncture, liquidation of the Hungarian rising became possible. Rákóczi, who in 1707 had declared the deposition of the Habsburgs, began to meet with growing opposition among his followers. Imperial troops forced Rákóczi to flee to Poland; and the rebels, who had been promised an amnesty and who were guaranteed religious liberty, made their peace in 1711. From then on the Vienna government tried to be more considerate of Hungary and its aristocracy.

The Peace of Utrecht

The election of Charles VI as emperor was effected without any difficulties. The English left the coalition, and after a military reverse most of the Habsburgs' allies joined the Treaty of Utrecht (1713). In the peace negotiations between Austria and France that were begun at Rastatt, Prince Eugene showed himself an unyielding and successful agent of Habsburg interests. Austria gained the Spanish Netherlands, a territory corresponding approximately to modern Belgium and Luxembourg. These gains were somewhat impaired, however, by the Dutch privilege of stationing garrisons in a number of fortresses. In Italy, Austria received Milan, Mantua, Mirandola, the continental part of the kingdom of Naples, and the isle of Sardinia. The Wittelsbachs of Bavaria regained their country, but the treaty contained an appendix that provided for the eventuality of Bavaria's being exchanged for the Spanish Netherlands. Of its gains, the north Italian territories were of the greatest value to Austria; the possession of Naples and the Netherlands, on the other hand, posed considerable military and political risks.

The problem of the Austrian succession. The extinction of the Spanish line of the Habsburgs and the fact that the emperor Charles VI was the last male member of that house posed serious problems for the Habsburg territories, which at the beginning of the 18th century were held together mainly by the person of the sovereign, notwithstanding the fact that there were some institutions of central administration. A settlement was made in the form of a family ordinance. On April 19, 1713, Charles VI issued a decree according to which the Habsburg lands should remain an integral, undivided whole. In the event of the Habsburgs' becoming extinct in the male line, the daughters of Charles or their descendants and, in default of any descendants of Charles, the daughters of Joseph I and their descendants and, after them, all other female members of the house should be eligible for the succession. As the son that was born to the Emperor in 1716 died after a few months, and only daughters were born to him after that (Maria Theresa, 1717; Maria Anna, 1718; Maria Amalia, 1724), this Pragmatic Sanction (a term used to characterize a pronouncement by a sovereign on a matter of prime importance) became of great significance. Austrian diplomacy in the last decades of Charles's reign was directed toward securing acceptance of the Pragmatic Sanction from all the European powers. It was published in 1720 and by 1722 had been recognized by the estates of all the Habsburg countries. Even the unanimous consent of the Hungarian diet was eventually obtained.

The Pragmatic Sanction of Charles VI

New conflicts with Turkey and the Bourbons. During the War of the Spanish Succession, Turkey had remained neutral toward Austria. But the Turks had attacked the possessions of the Venetians on the Pelopónnisos and the Ionian Isles. Austria tried to intervene and finally declared war. Prince Eugene defeated the Turks near the fortress of Peterwardein and conquered the strong bastion of Temesvár (1716). In the summer campaign of 1717 Belgrade again came into the hands of the imperial troops after a battle had been won against a Turkish relief army. In the Treaty of Passarowitz (1718) a frontier line was agreed upon that corresponded to the de facto situation. The Turks had to cede to the Austrians the Banat, the Turkish part of Syrmia, Walachia Minor as far as the Aluta, northern Serbia, Belgrade, and a strip of land along the frontier in northern Bosnia. A favourable trade agreement was also concluded.

During the Turkish war another crisis emerged. The Spanish minister Giulio Alberoni tried to initiate a policy of expansion in Italy. When Spanish troops landed in Sardinia and Sicily, the Emperor formed an alliance with Great Britain and France, later joined by the Netherlands (the Quadruple Alliance). After the English defeated the Spanish fleet, Madrid recalled its troops from the disputed territories. Austria received the more prosperous Sicily in exchange for Sardinia, which fell to Savoy. Charles then agreed to recognize the Spanish Bourbons. The gains from the Quadruple Alliance plus those of the Treaty of Passarowitz gave the Habsburgs the largest territory they were ever to rule. Their domains were far from unified, however, with the individual provinces showing a wide national, economic, cultural, and constitutional diversity.

Trading interests soon interfered with the alliance with the maritime powers. At first the attempts of the Ostend Company, which was backed by Charles VI, to enter into trade with India were quite successful. Because of the antipathy of the maritime powers, however, it seemed advisable to find an alternative to trade with Dutch and English colonial markets in the vast transatlantic empire of Spain. In 1725 Charles entered into an alliance with Spain, whereupon France, Great Britain, and Prussia formed a rival alliance. But soon after Russia was won over to the Habsburg cause, Prussia changed sides. As the outbreak of a European war seemed imminent, attempts were made at the Congress of Soissons to relax political tensions. Spain abruptly changed its alliances and concluded a treaty (1729) with England and France, the Netherlands joining in later. When Russia also began to waver, Prince Eugene tried to fall back on the traditional alliance with the maritime powers. After prolonged and difficult negotiations, England in 1731 accepted the Pragmatic Sanction, the Emperor in return giving a promise not to marry off his daughter Maria Theresa, the Habsburg heiress, to a prince who was himself heir to important domains. Austria finally dissolved the Ostend Company, having already suspended its charter in 1727. Charles VI then invested a great deal of energy in his endeavours to secure the recognition and the guarantee of the Pragmatic Sanction in the German diet. In this he was opposed by Bavaria and the elector of Saxony, but Austria finally obtained the guarantee of the Pragmatic Sanction at the Regensburg Diet (1732).

The question of the Polish succession

The question of the Polish succession led to a revival of the Austrian conflict with the Bourbon countries. Austria, with Prussia and Russia, favoured Augustus III of Saxony, the son of the deceased king, whereas France backed Stanisław I (Stanisław Leszczyński). On the military intervention of Russia in Poland, the Bourbons attacked Austria. The issue came to be mixed up with the problem of Lorraine, France dreading that on the impending marriage of Maria Theresa to Francis Stephen, duke of Lorraine, the latter's domains would be united with Austria's, so that French plans for the acquisition of Lorraine would be thwarted. France, Sardinia, and Spain simultaneously opened the war against Austria (1733). Prince Eugene, who was now aged, was able only to prevent a major success of the enemy on the Rhine. On the Italian front the Habsburgs fared even worse. The Battle of Parma ended undecided, but the Austrians were finally beaten near Guastalla. The small Austrian force that was stationed in southern Italy was unable to resist the Spanish attack, and Sicily and Naples were occupied by the Spaniards. In 1735 a Russian relieving corps reinforced the Habsburg front on the Rhine, and in northern Italy also there were a few successful operations of some local importance.

Direct contacts between Austria and France eventually led to the preliminary Peace of Vienna (October 3, 1735). Austria lost Naples and Sicily, which fell to a secondary branch of the Bourbons, and had to cede a tract of Lombard territory to Sardinia. As some compensation, Austria received Parma and Piacenza. Francis Stephen of Lorraine was promised Tuscany but had to renounce his hereditary duchy. On these conditions, France agreed to recognize the Pragmatic Sanction. The final peace was then concluded at Vienna in 1738.

Prince Eugene had died during the War of the Polish Succession. It soon proved disastrous that a successor of similar capacity of the prince was not found. During the second Turkish war of Charles VI (1737–39), Austria had joined in the Turkish-Russian conflict but without coordination of military operations. The Austrians, furthermore, underrated the Turkish forces and were themselves reduced by epidemics. The fortress of Niš was taken but was lost again soon thereafter. Peace negotiations conducted at Nemirov were broken off, and the war went on. The Austrians lost another battle at Grocka. Again peace negotiations were launched, in the course of which the larger part of the gains of the Peace of Passarowitz were lost. More disquieting even than the territorial losses was the loss in prestige. The epoch that had been the rise of Austria to a great power thus ended with reverses.

Social, economic, and cultural trends in the Baroque age. The Thirty Years' War and the Turkish wars had resulted in the devastation of large parts of the country and in great losses among the population, which suffered further reduction during the plague years of 1679 and 1713. The territories that had been wrested from the Turks had to be resettled systematically by German and other immigrants. The initiative for resettlement projects came from the official bureaucracy, the settlements being concentrated mainly in the south of Hungary. During the period of religious conflicts many Protestants had been exiled, but in the 18th century transportation to the various underpopulated parts of the empire was often resorted to.

Mercantilist policies after the 1660s

In the industrial and commercial field, mercantilist ideas, encouraged by the government, were prominent from the 1660s. The situation of the peasantry was thoroughly unfavourable. Tentative measures in the reigns of Leopold I and Charles VI to protect the peasants had little effect. Certain "model industries" (mostly textile factories) were established but were only partly successful. The economic policy of the absolutist state also resulted in strong interference with trade organizations. The guilds were suppressed or at least debarred from the new manufactures.

Trade was encouraged but yielded only small gains for the state. Industrial and commercial undertakings were managed in part directly by the state but largely through privileged corporations or private persons. Of some importance were the first (1667) and the second (1719) Oriental trading companies and the Ostend Company (1722). Trade in the Mediterranean was also intensified. Promising colonial ventures in India were discontinued for political reasons, however, in the middle of the 18th century. Under Charles VI new roads came to be planned and built on a large scale.

The state was in permanent want of money. This was a period of perpetual war as well as great economic investments, both entailing an excessive strain on state finances. At first the government resorted to the rich bankers such as Samuel Oppenheimer and his successor Samson Wertheimer for funds. Soon, however, it attempted to establish banking firms that were state controlled. The Banco del Giro, founded in Vienna in 1703, quickly failed, but the Vienna Stadtbanco of 1705 managed to survive; the Universalbancalität of 1715 was liquidated after a short period of operation.

After the victory of the Counter-Reformation, education was almost exclusively in the hands of the Catholic Church. The grammar schools of the religious orders, especially of the Jesuits and the Benedictines, set a very high standard for the most part. In 1677 another university was established at Innsbruck, the theological school of which was to acquire some fame. Historical writing flourished, the most outstanding works being those of two Benedictine brothers, Bernard and Hieronymus Pez; Gottfried Bessel, abbot of Göttweig; and Leopold I's official historiographer, the Jesuit Franz Wagner. The Austrian Jesuits were famous for their scientific and geographic researches, most notably the exploration of China.

Baroque poetry, theatre, and music

Among the achievements of Baroque poetry, mention should be made of Wolf Helmhart of Hohberg, whose works offer interesting insights into the life of the nobility, and of Katharina of Greiffenberg. The theatre of the Baroque was of great appeal, being remarkable for the splendour of its decorations and the ingenuity of stage machinery. The plays produced ranked from the elaborate Italian opera to the blunt humour of the popular play. Music attained an especially high standard, encouraged by three emperors who were composers themselves (Ferdinand III, Leopold I, and Joseph I). Charles VI was also a skillful musician, and he engaged the services of Johann Joseph Fux, who came from eastern Styria and developed into an important composer and teacher.

Austrian Baroque culture is, however, most clearly revealed by the splendours of its architecture. At first the field was dominated by the Italians, but soon native architects stepped forth. Preeminent was Johann Bernhard Fischer von Erlach (first plan of Schönbrunn Palace, Karlskirche in Vienna, Kollegienkirche in Salzburg) and his son Josef Emanuel (Hofbibliothek). They were rivalled by Jakob Prandtauer (Herzogenburg, Melk, and part of Sankt Florian monasteries) and especially by Johann Lucas von Hildebrandt (Schwarzenberg Palace, Belvedere, Peterskirche in Vienna, monastery of Göttweig). Among native sculptors Georg Raphael Donner was the first in rank and quality of work. Fresco painting was represented by Johann Michael Rottmayr from Salzburg, Daniel Gran from Vienna, and Paul Troger from the Tirolian Pustertal.

(E.Zö.)

FROM THE ACCESSION OF MARIA THERESA TO THE CONGRESS OF VIENNA

The war period, 1740–63. In October 1740 the Holy Roman emperor Charles VI, the last male Habsburg ruler, died and was succeeded by his daughter Maria Theresa, the wife of the grand duke of Tuscany, Francis Stephen of Lorraine. Until the election of her husband as emperor in 1745, Maria Theresa was referred to only as queen of Hungary and Bohemia. Her descendants represented the House of Habsburg-Lorraine.

Charles VI had established a reasonably unified order of succession for all the lands under the Habsburg sceptre (the so-called Pragmatic Sanction). By making broad concessions to foreign powers, he had secured their recognition of this act, and he died expecting a smooth succession for Maria Theresa. It was her misfortune that the poor state of Austria's military defenses during the last years of Charles's reign had vitiated his careful diplomatic manoeuvres, and it was of particular importance that four months prior to the Emperor's death another young ruler, Frederick II the Great, had succeeded to the throne of Prussia, which he wanted to raise to great power status. Thus it was that a major German state, which previously had been consistently loyal to the Austrian and imperial cause, became throughout Maria Theresa's entire reign the most determined foe of the Habsburg Empire. The specific issue in the conflict over supremacy in the German orbit was Frederick's intent to wrest the rich province of Silesia from the Habsburgs. The kings of Spain and of Piedmont-Sardinia and the electors of Bavaria and Saxony in full or in part challenged Maria Theresa's claims to succession, despite the fact that they had previously all acknowledged the Austrian heiress' right to rule. Frederick, on the other hand, cared less about the succession than about Silesia.

Conflict with Prussia over Silesia

By October of 1741 Frederick's army, then the best trained in Europe, had occupied Lower Silesia, and Maria Theresa in that month concluded a treaty in which she ceded this major and richest part of the province to Prussia under threats from other quarters. France, the hereditary foe of Austria and main inspiration of the anti-Habsburg coalition, had, in an alliance of Nymphenburg (May 1741), pledged to support Spanish and Bavarian claims on Maria Theresa's inheritance. Charles Albert, the

elector of Bavaria, was promised part of the Alpine Hereditary Lands and Bohemia, and, with French support, was elected emperor as Charles VII. On the day of his coronation, Austrian forces occupied his own capital, Munich.

Maria Theresa was helped by the fact that two major European powers, Great Britain and Russia, did not wish to see the Habsburg Empire dismembered. The British and the Dutch soon gave Austria active support, and Saxony and Sardinia dropped out of the anti-Habsburg coalition to support Maria Theresa, whose chances of consolidating herself on the throne thus became more promising.

But the situation remained serious. Habsburg forces still had to face Spanish troops in northern Italy, and in the spring of 1744 France declared war on Austria. One year later, in May, French troops defeated British and Dutch forces at Fontenoy in the Austrian Netherlands (the major part of present-day Belgium).

Frederick II of Prussia, who had watched developments closely after the definitive peace with Austria (Treaty of Berlin, July 1742), was afraid that the Austro–British–Dutch coalition might eventually be victorious and that Maria Theresa might be able to turn her main forces against him and regain Silesia. Stealing a march on the Habsburgs, he invaded Bohemia in August 1744. This time Austrian resistance was more determined, and though Frederick failed in his designs on Bohemian territory, he succeeded in confirming the victory of his first campaign by a new peace treaty, the Treaty of Dresden, December 1745. Having thus secured his Silesian spoils, he could afford to support the election of Francis Stephen of Lorraine as Holy Roman emperor in succession to Charles VII (died January 1745).

Francis Stephen becomes Holy Roman emperor

The war over the Austrian succession continued. As far as the Habsburg power was concerned, the results of the fighting in Italy, Belgium, and Holland were on the whole indecisive. A defensive alliance with Russia (1746) protected Austria from the danger of a new Prussian attack.

During these latter stages of the conflict, the question of the preservation of the Habsburg Empire was no longer an issue. The problem was merely the price that had to be paid for survival. In the long, drawn-out peace negotiations of Aix-la-Chapelle, Wenzel Anton, Graf von Kaunitz (subsequently Prince von Kaunitz-Rietberg, from 1753 to 1792 Austria's state chancellor) showed for the first time his mettle as a diplomat of consummate skill. Austria had to return some minor principalities in Italy to Spanish Bourbons until such time as the Bourbon lines there became extinct. A small frontier rectification in favour of Piedmont-Sardinia also had to be made, but neither of these adjustments was of great consequence. Far more important and painful was, of course, the loss of the major part of Silesia to Prussia, which opened the way to the rise of a new European great power as the most serious rival of the Habsburgs in Germany. It also meant a considerable drop in the number of Germans living within Habsburg lands, with important consequences in the rise of the national problem in the following century. On the other hand, Maria Theresa, a determined woman of courage, moderation, and charm, had managed to establish good relations with the frequently rebellious Magyars and had secured at least their nominal support at the height of the succession crisis.

The Habsburg Empire was not dismembered. Nor did it become a satellite state under the tutelage of other great powers. The outcome of the War of the Austrian Succession, except for the loss of Silesia, was a genuine defensive victory and proved to the world that Austria represented more than an agglomeration of lands under the same rule, acquired by wars and marriage contracts. In the two centuries since Ferdinand I, regent in the so-called Hereditary Lands, had become king in Bohemia, Hungary, and Croatia, a certain cohesion between the major historic units of the empire had clearly, after all, been established.

As far as the worldwide colonial aspects of the struggle were concerned, the results of the war were indecisive; certainly they were not to the advantage of Austria's traditional ally, Great Britain. A more permanent settlement of the conflict was reached only at the Treaty of Paris between Britain, France, Spain, and Portugal in February 1763—by and large to the disadvantage of the French, by then Austria's nominal ally.

During the brief era of peace—the eight years (1748–56) between the end of the War of the Austrian Succession and the Seven Years' War—Austrian military organization was revamped, and a state-wide system of conscription was introduced. The artillery in particular was greatly improved, and at the end of the period the Empress was ready once more to take up the struggle with Prussia. The new state chancellor, Kaunitz, had set an entirely new diplomatic stage for this difficult enterprise. The diplomatic actions taken at that time are generally referred to as the "reversal of alliances," actually a treaty system intended to isolate Prussia. It was in the interests of both Austria and France, hereditary enemies for two centuries, to become allies, since both were concerned about the rapid rise of an aggressive and unpredictable Prussia in the north. In the event of an Austrian reconquest of Silesia, the Austrian Netherlands were to be ceded to France. Russia, worried about Prussia's future designs in the east in regard to Poland, joined the coalition in January 1757, as did Sweden.

Cooperation with France against Prussia

Prussia forestalled the Austrian diplomatic and military preparations by means of a surprise preventive attack in 1756. But it was able to counterbalance the weight of the formidable coalition rallied against it only by a subsidy treaty agreement with Britain, the former traditional ally of the Habsburg Empire. The tremendous superiority of the great coalition in territory and population figures was, however, in part offset by divisions among its members, in whose success Austria had by far the major stake. In a purely military sense, Frederick II had the full advantage of an inner line of defense. His brilliance as a military leader compared to that of the careful but too cautious Austrian commander in chief, Leopold Joseph, Graf von Daun, also counted heavily in his favour. The French army was in full decline, and the forces from the Holy Roman Empire outside of Austria, convoked by the emperor Francis of Lorraine against the Prussian aggressor, failed lamentably.

Though Austrian and Russian victories were sparse compared to a string of Prussian successes, the superior power of the coalition would have inevitably resulted in victory if the new tsar, Peter III, a great admirer of the Prussian King, had not withdrawn in 1762 from the war. Further designs to reverse Russia's position and to side openly with Frederick were foiled by Peter's overthrow a few weeks later. The initiator of the plot, his former consort and now ruling empress, Catherine II, did, however, sign a separate peace with Prussia on the basis of the status quo. Only a few weeks later the French withdrew from the war as well, since the obvious inability of the Austrian troops to regain Silesia killed France's hope for the acquisition of Belgium. In consequence of this, Maria Theresa, in the hardest decision of her reign, was forced to give in. Thus it was that the Treaty of Hubertusberg, concluded with Prussia in February of 1763, merely confirmed the outcome of the two previous Silesian wars. The only minor concession made by Frederick was a pledge to cast the electoral vote of Brandenburg (Prussia) in the next imperial election in favour of Maria Theresa's oldest son, Joseph.

The most decisive result of the Austro-Prussian Seven Years' War was the rise of Prussia to great power status. Austria, though weakened, remained a great power, and compensatory acquisitions for the loss of Silesia were impending. But, taking a long-range view, the Prussian victory represented a decision in the first round of the struggle for supremacy in Germany between the Habsburg Empire and Prussia, a conflict that the Habsburg Empire was to lose decisively within a century.

Foreign policy, 1763–92. In 1772 Austria participated in the first partition of Poland and acquired Galicia. The initiative for the partition came from Frederick II. Catherine II the Great of Russia would have preferred to have an undivided satellite Poland as her neighbour, but Maria Theresa, anxious to prevent a further shift of the balance of power to Austria's disadvantage, participated in the partition, though she regretted the breach of all traditions of international order. In 1774 the Habsburg Empire was given the Bukovina to the southeast of Galicia from the

Ottoman Empire as reward for Austrian mediation in a Russo-Turkish conflict. These enterprises were due in part to the influence of the young Joseph II, who, after the death of his father, Francis, in 1765, succeeded as shadow emperor of the Holy Roman Empire and became co-regent with his mother in the Habsburg lands.

Joseph's ambitions went much further. In 1778, after the older line of the House of Wittelsbach had expired, he came to an understanding with the head of the younger Palatine line, according to which the Habsburgs would become heirs to the rule of Bavaria. Frederick II quite naturally opposed this agreement, which would much more than offset the loss of Silesia and would have given the Habsburgs renewed predominance in Germany. Joseph refused to yield, even though he was only lamely supported by his mother, and a new confrontation became inevitable. Military operations initiated in Bohemia in the summer of 1778 remained indecisive, however, and in May 1779 the Treaty of Teschen was negotiated between Maria Theresa and Frederick, both then in their old age and reluctant to fight another major war. Thus, Joseph had to put off his ambitious scheme, and the cession of the Innviertel by Bavaria, now incorporated into Upper Austria, had to serve as meagre consolation. Though Joseph's original plan would, in fact, never have been tolerated by the European great powers, in 1785, five years after the death of the great Empress, her intemperate son and successor reverted to his old scheme, this time proposing the exchange of Bavaria against the Austrian Netherlands. Again Frederick thwarted the plan, and Joseph's designs to undo the balance established by the Silesian wars were put to rest.

Joseph's foreign policy lacked success in other respects, too. His eagerness to barter the noncontiguous Austrian Netherlands for Bavaria resulted in part from the fact that he was frustrated in his understandable designs to undo the restrictions imposed on the Austrian rule there by the peace treaties of Utrecht and Rastatt of 1713 and 1714. These restrictions included the closing of the Scheldt River by the Dutch and Dutch rights to garrison the Austrian border fortresses against France at Austrian expense. But Dutch and French objections blocked Joseph's plan.

Failing thus in the west, Joseph hoped, as Russia's ally, to make at least some gains in a new Austrian war against the Turks. This struggle, started in 1788, ended the year after Joseph's death (1791), again in a meagre compromise. Thus the Emperor, whose great gifts included skill neither in diplomacy nor in military strategy, was in his conduct of foreign affairs far more unfortunate than most of his predecessors, who were not in other respects his intellectual peers.

Accession of Leopold II, 1790

His brother and immediate successor, Leopold II, heretofore Grand Duke of Tuscany, certainly was Joseph's intellectual peer, particularly in his ability as diplomat. He inherited from his brother a domestic situation in which Hungary and Belgium were in full revolt. In international relations he had to carry the mortgage of the sterile Turkish War begun by his brother, and he was faced as well by the possibility of a new partition of Poland, which might exclude Austria as beneficiary. But above all he had to deal with the spectre of an ever more serious revolutionary situation in France, which might well involve Austria in a long war of unpredictable outcome.

In domestic matters, Leopold, an enlightened ruler in Tuscany, had to retreat cautiously and regretfully from some of the reform legislation in the Habsburg Empire. In foreign affairs he had to end the Turkish War by the best possible compromise. As to the Polish question, encouraged by the spirit of reform in truncated Poland, he wanted to avoid a new partition altogether, but at the same time he wished to keep relations with Russia and Prussia on an even keel. This included, of course, an understanding in regard to the foremost international problem of his reign—the relationship to revolutionary France. Though naturally opposed to the revolutionary spirit, Leopold's course was remarkably free from considerations arising from close family ties, specifically the fate of his brother-in-law, King Louis XVI, and sister, Queen Marie-Antoinette. Leopold approved of the concept of a French constitutional monarchy, but to be prepared for all contingencies, in July 1790, he secured an understanding with Frederick William II, the new king of Prussia, concerning common interests of both countries in the east. At this time relations with France were aggravated further by the French seizure of the estates of great nobles in the Alsace, since they could be considered subjects of the Holy Roman Empire as well. The establishment of the headquarters of anti-revolutionary French political refugees in

the German Rhineland created additional tension. In a second meeting with Frederick William II at Pillnitz in Saxony in August 1791, the two rulers publicly expressed their concern with the French situation. But joint intervention would depend on British and Russian support. In February 1792 the Emperor considered it opportune to go one step further and concluded a defensive alliance with Prussia. Whether he would eventually have taken the final step and gone to war with France is conjectural; on March 1, 1792, he died unexpectedly. Less than two months later Austria did find itself at war, and while the declaration to that effect was made by France, the new emperor, Francis II, Leopold's son, a young man of modest abilities, had done little to prevent it.

The struggle with France, 1792–1815. In the ensuing era of almost continuous warfare that lasted for nearly a quarter of a century, the Habsburg Empire was involved more heavily than any other continental European power. This was partly because of its geographic location in the centre of Europe, partly because of Francis' position as Holy Roman emperor until 1806. The gradual transition from enlightened regimes of Joseph II and Leopold II to an increasingly conservative spirit under his rule was of additional significance. At the beginning of the war period Austria fought the spirit of the French Revolution. Supported by Spain, Portugal, and, above all, Prussia, it was engaged in the War of the First Coalition from beginning to end (1792–97). Yet Prussia dropped out of the war in 1795 to prepare for the third partition of Poland, after Prussia and Russia had jointly excluded Austria from the second partition. The Austrians fought against the French revolutionary armies in Belgium, Holland, and the Rhinelands with indifferent success. While the emperor Francis' far abler younger brother Archduke Charles checked the French in southern Germany, the young Bonaparte routed the Austrians in Italy, crossed the Alps, and invaded Carinthia and Styria. In April 1797 Austria had to agree to the armistice and Preliminary Peace of Leoben and in October of the same year to the permanent one of Campo Formio. The Habsburg Empire was let off relatively lightly. While the Austrian Netherlands (an indefensible province anyway) and Lombardy had to be ceded, territories of the Republic of Venice to the east of the Adige were gained. This forced participation in the destruction of the ancient Venetian republic put Austria in no better light than Prussia and Russia in the second partition of Poland. On behalf of the Holy Roman Empire, Francis also had to cede the left bank of the Rhine to France and accept a scheme by which the German ecclesiastical princes were deprived of their secular powers (Congress of Rastatt, 1797–99). This action further weakened Francis as Holy Roman emperor, although his position as ruler of the Austrian lands was strengthened somewhat by the third and final partition of Poland in 1795, in which Austria gained West Galicia as far as the Bug River.

Gains and losses at the Peace of Campo Formio, 1797

In the War of the Second Coalition (1798–1802), three major European powers—Prussia, England, and Austria—supported by Portugal, Naples, and the Ottoman Empire, represented the anti-French alliance. The theatres of war were again southern Germany and Italy, and, this time, Switzerland. When, in 1800, the Russian armies withdrew, the Austrian position became precarious. French advances in northern Italy and southern Germany were followed by the Armistice of Steyr in December 1800 and by the Treaty of Lunéville in February 1801. According to the terms of the latter, the provisions of the Treaty of Campo Formio of 1797 and the cession of the left bank of the Rhine to France were confirmed. The system of French satellite republics in Holland and Italy had to be recognized. Thus the main Habsburg territories were left intact, but Austria's position in Germany was further weakened.

Austria's chances in the War of the Third Coalition (1805–07) at first seemed promising. There was genuine military cooperation with Russia, and the coalition was able to count on the naval and financial support of Britain. Prussia, however, delayed a decision concerning its participation. The Austrians were defeated in Germany and the critical situation thus created forced their retreat from Italy as well. In November 1805 French troops occupied Vienna for the first time. On December 2 the Austrians and Russians were badly defeated by Napoleon at Austerlitz in Moravia, and the harsh Treaty of Pressburg was imposed on Austria hardly three weeks later. According to its principal provisions the Venetian territories gained in 1797 had to be ceded together with Tirol, Vorarlberg, Brixen, and the Trentino. The confirmation of Austria's incorporation of Salzburg and Berchtesgaden (1803) could not serve as adequate compensation for these severe losses. The Habsburg Empire had ceased to be a great power, and the Holy Roman Empire, in the face of French advances toward the east, was doomed.

Battle of Austerlitz, 1805

It had not been difficult to foresee these developments when Bonaparte proclaimed himself emperor of the French in 1804. To maintain Austria's position as best he could, and anxious to preserve the imperial title for his house, Emperor Francis proclaimed himself emperor of Austria on August 14, 1804. This purely declaratory manifesto, never submitted for the consent of the Estates of his lands as the Pragmatic Sanction had been a century before, pertained to all the Habsburg realms and might well therefore have been challenged, above all by Hungary. Yet this was not a major issue in the turmoil of the times. A month after Napoleon established the Confederation of the Rhine, Francis accordingly abdicated the empty title of Holy Roman emperor (August 1806). Invested only with an imperial title devoid of a great historical tradition, he ruled henceforward as Emperor Francis I of Austria.

The period from 1805 to 1809, when Austria was compelled to join the French continental blockade system, was one that saw the rise of feelings that were truly national, even though they were largely confined to the Austro-German orbit. A new, energetic, and idealistic foreign minister—Johann Philipp, Graf von Stadion—attempted to prepare the diplomatic ground for a renewed struggle against French expansion, and the archduke Charles organized a national militia. Encouraged by continued British resistance and by the guerrilla warfare of the Spanish people against the French occupation, Austria, on April 9, 1809, declared war on France. In contrast to a prostrate Prussia and to the German princes who catered to the whims of the foreign conqueror, the Habsburg Empire—bravely and vainly—tried to redress the balance in Europe. By mid-May 1809 Vienna was in French hands, though this time only after an artillery bombardment. The Austrians fought on, and a week later, at Aspern, on the left bank of the Danube opposite Vienna, Archduke Charles administered the first defeat to a French army commanded personally by Napoleon. He failed, however, to take advantage of this victory, and six weeks later the Austrians were decisively defeated at Wagram. Peace was dictated by the victors at the imperial castle of Schönbrunn in October 1809. This time Salzburg, a part of Upper Austria, and northern Tirol became parts of Bavaria; southern Tirol became part of the satellite kingdom of Italy, and West Galicia part of a new puppet Grand Duchy of Warsaw. The western parts of the Austrian southern Slav territories were ceded to France, and a heavy indemnity had to be paid.

A by-product of the defeat was the crushing of the heroic rising of the Tirolean peasants and the execution of their brave leader, Andreas Hofer. A far-reaching economic consequence of the war period was the state bankruptcy of 1811, which reduced the Austrian currency to one-fifth of its previous value.

Now a remarkable change in Austrian foreign policy took place. Shortly before the conclusion of the Treaty of Schönbrunn, Count (later Prince) Clemens Metternich, formerly ambassador to Napoleon's court, was appointed minister of foreign affairs in place of Stadion, whose anti-French policy had failed. Metternich conducted foreign policy for almost 40 years, until the outbreak of the Revolution of 1848. His first task was to shift from an anti-French policy, based partly on ideological grounds, to one of expedient cooperation until the day when new opportunities to restore Austria to its former rank as a great power would present themselves. He pursued this policy with great skill. One of his first moves was to persuade his imperial master to agree to Napoleon's request for

Metternich becomes minister of foreign affairs

the hand of Francis' eldest daughter, Marie-Louise (1810). Humiliating as acceptance of this demand by an upstart ruler was to an ancient dynasty, Metternich considered it conducive to Austrian interests.

In the War of 1812, Austria—France's new ally by marriage—was forced to put up an auxiliary corps under Karl Philipp, Prince zu Schwarzenberg, but Metternich's instructions were that any significant encounter with the Russian forces should be avoided. After the annihilation of the great French army in Russia and the continuation of the war in Germany by Russia and Prussia with the support of England and Sweden, the Habsburg Empire managed to stay neutral, thus raising the price for its subsequent intervention. It was clear that such intervention could only be on the side of the anti-French alliance, but Austria first offered Napoleon its "armed mediation," provided Napoleon would give up his overlordship of the German territories on the right bank of the Rhine and dissolve the Grand Duchy of Warsaw. The demand for the return of all Austrian territories ceded to France in the Treaty of Schönbrunn was raised. Napoleon, as expected, rejected the offer, and in August 1813 Austria became a partner in the War of Liberation, although the national issues previously raised by Stadion were played down by the conservative Metternich.

By its belated entry into the grand coalition, Austria had secured particularly favourable terms. Even though the Habsburg forces were smaller in number than those of Russia and Prussia, Prince zu Schwarzenberg was appointed commander in chief of the allied armies. Although a strategist of no better than average ability, he proved to be a skillful moderator among the ambitious generals of the coalition. His much abler chief of staff, Joseph, Graf Radetzky, must be credited with drawing up the plans for the great Battle of Leipzig (October 16–19), which broke the back of the French operations in Germany. Napoleon rejected an offer on the part of the allies that would have conceded the Rhine and Alp frontiers including Belgium and Holland to France. It is probable that Metternich at this time would have liked to keep a greatly weakened Napoleon in power as the best bulwark against the danger of a new French revolution.

On New Year's Eve, 1813, the war was carried into France. Had it not been for the tremendous superiority of the allies and the exhaustion of the French people, Schwarzenberg's indifferent strategy would hardly have secured victory. As it was, the allies were able to take Paris by the end of March 1814, force Napoleon's abdication, and secure the restoration of the Bourbons. The Treaty of Paris of May 30, 1814, gave France the relatively favourable frontiers of 1792. The reorganization of Europe was to be arranged at a congress that was to meet in Vienna in September 1814 under Metternich's chairmanship.

Austria and the Vienna Settlement, 1815

In the negotiations, which lasted until June 1815, Austria sided in general with Bourbon France and with England. Austria regained most of the territories that it had lost in the Treaty of Schönbrunn. Its former rule in the Austrian Netherlands and in southwest Germany was not restored, since Metternich saw little advantage in the control of noncontiguous areas. The Habsburg Empire was compensated in Italy: not only were Lombardy and the Venetia recovered; Tuscany, Modena, and—for the lifetime of Marie-Louise—Parma and Piacenza, also, were established as Habsburg semi-independent appendages in Italy. Napoleon's consort, now separated from him, was to rule in these two last-mentioned principalities. It is questionable whether the restoration of the Holy Roman Empire might not have served Austria's interests better than the establishment of the German Confederation (June 1815) under Austria's presidency.

In line with Emperor Francis' and Metternich's wishes, the confederation gave Austria, though only jointly with Prussia, far-reaching control over German affairs. This control was aimed in particular at preventing the establishment of representative constitutional governments and liberal institutions in any of the 50 German states. Reestablishment of the Holy Roman Empire would have struck a strong chord in the heart of the Austro-German peoples but this was precisely what Metternich, fearful of any expression of the popular will, did not want. Following the same line of thought, he believed that the dismemberment of Italy would prevent the future unification of the country under liberal national banners.

Metternich's skill restored Austria to great power status and even resulted in his diplomatic leadership as the so-called coachman of Europe. But the two major issues that were to severely weaken the position of the Habsburg Empire within the next half-century—the German and the Italian problems—were accentuated rather than solved by the settlement of 1815.

Reforms and their reversal, 1740–1815. The enlightened era in the Habsburg Empire comprises the reigns of Maria Theresa (1740–80) and those of her two brilliant sons, Joseph II (as co-regent from 1765 to 1780 and in his own right from 1780 to 1790) and Leopold II (1790–92). Maria Theresa, much better adjusted to reality than her immediate successor, drew chiefly on pragmatic experience. She wanted to secure the well-being of her subjects and to affirm the control of the state as far as compatible with traditions and customs. Joseph II intended to move faster and more in line with abstract, enlightened principles. He had little patience with references to tradition and was in some respects less prejudiced than his mother. Leopold II was, in his basic views, closer to his brother than to his mother, whom he resembled in his judicial temperament. While he would presumably have liked to expand Joseph's reforms, it was the main task of his all-too-short reign to quell the revolts in Hungary and the Austrian Netherlands and to settle the unrest in the Hereditary Lands and Bohemia. Thus he was forced to retreat in essence from the reforms of Joseph II to those of Maria Theresa. Under his son, Francis (1792–1835), the trend gradually became one of extreme conservatism and outright reaction, in part because of the preferences of this mediocre ruler but largely as a result of the counter-revolutionary spirit of the times.

Administrative reforms

The basic idea of the administrative reforms was to transform the estates system into a partially bureaucratic administration based on civil service rules, although Maria Theresa considered it expedient to preserve at least the external, but by then rather hollow, shell of the estates structure. Thus, on the provincial level, the speakers of the crownland Estates presided over most of the agenda of the provincial administration. On the top level of administration for the whole empire, the state chancellery of old was divided into a court chancellery entrusted with domestic agenda and a state chancellery proper for foreign affairs. An advisory state council was composed in part of great nobles and in part of high bureaucratic officials. A directory on public affairs for the Bohemian and Hereditary Lands was subsequently converted into the United Austrian and Bohemian Court Chancellery. A new commerce directory for the whole empire was established.

Maria Theresa introduced restrictions on the largely arbitrary patrimonial jurisdiction of the lords on their estates and transferred venue in matters of capital offenses to fewer and better courts. She steadfastly opposed the abolition of torture, though not on account of any basic cruelty of her character. She simply could not imagine how sufficient evidence could be gathered without forced confession. It was not until 1776 that she was finally persuaded to abolish torture. In this respect, Austria had lagged behind France, Prussia, and even Russia.

Joseph, who had much more understanding of judicial questions than did his mother, did much to improve civil and criminal procedure. He provided free legal counsel for peasants in litigation with lords. Although criminal justice administered on the basis of the strictly utilitarian philosophy of the Emperor was still extremely harsh, Joseph did much to improve civil law. The superb code of civil law of 1811, initiated in substance under Joseph, came to fruition only under Emperor Francis.

Economic policy

As to public finance, both the nobles and the church lost various privileges in regard to exemption from taxation. Craft guild restrictions, particularly those concerning the admission of apprentices, were loosened. Much was done to help the peasants in the newly gained trans-Carpathian territories (Galicia and Bukovina) by direct and indirect

government assistance, the abolition of customs duties for exports to other crownlands, and by the granting of various privileges for new settlers. The basically mercantilist economic policy of Charles VI's reign was somewhat changed in line with the influence of physiocratic and so-called populationist theories. Henceforth, skilled human labour, and not precious metal, was gradually to become the yardstick of national wealth. This led, on the one hand, to restrictions on emigration, and, on the other, to improvements in vocational training. Severe import restrictions on so-called luxury goods, which frequently had killed demand rather than encouraged the rise of competitive domestic industries, were somewhat modified. Joseph II went further. In regard to industrial and commercial enterprise, he was, much in contrast to his overall political philosophy, a strong supporter of private initiative.

Maria Theresa went a long way toward alleviating the lot of the unfree peasants. For the first time in Austrian history, the service obligations of the peasants were strictly defined. Above all, the ambiguous double role of the lord as landowner and official of local government was put under government supervision.

Joseph expanded the reforms of Maria Theresa. He further reduced the governmental functions of the lord and by legislation of 1781 abolished serfdom altogether outside of Hungary. Similar legislation was introduced in Hungary between 1784 and 1786. The mistaken belief of the Hungarian peasants that abolition of serfdom made them free owners of the land was, however, a major cause of the revolutionary situation at the time of the Emperor's death. The full conversion of the peasant's personal services outside of Hungary into obligations to be paid off in cash was somewhat precipitate, for money, in an agricultural economy still largely based on barter, was lacking. Leopold II reversed Joseph's peasant legislation so that things stood much as they had been at the time of the death of Maria Theresa. There was little further change until 1848.

Educational reforms of Maria Theresa

The greatest single achievement of Maria Theresa's reign was her educational reform at the elementary and intermediate levels. Three types of schools were introduced: (1) elementary schools in all but the smallest villages, in which reading, writing, and arithmetic were taught, with attendance being compulsory; (2) district schools in every administrative district, in which history, more advanced study of the vernacular language, geometry, drawing, and some vocational training were offered; and (3) so-called normal schools, established in the crownland capitals. Meant to be terminal schools for the urban middle class, they served also as teacher-training institutions. As for higher education, reforms under Maria Theresa were handicapped by her mistrust of—as she perceived them—radical enlightened ideas. She was, however, persuaded to transfer censorship from Jesuit control to a new and somewhat more liberal state agency. Some new chairs in the natural sciences and law were established at the University of Vienna, but progress in this respect was limited, and non-Catholics were altogether barred from graduating. Maria Theresa also founded some outstanding special schools. One of them was meant to train young nobles for public service, another, officers for the armed forces.

Joseph's reign proved to be disappointing as far as education was concerned. Censorship, it is true, was eliminated—at least as far as criticism of the government was concerned. But the Emperor's utilitarian objectives precluded practically any purpose in higher education other than the training of civil servants. The publication of literature that could not serve as a textbook for disciplines of immediate practical use was not encouraged. Under Emperor Francis, censorship was reintroduced in full force.

Radical church reforms are usually associated with Joseph's reign, but here also Joseph followed in the footsteps of his mother. Both rulers were devoutly religious, but both believed in firm state control of ecclesiastical matters outside of the strictly religious sphere. Following populationist doctrines, the Empress ordered restrictions of religious holidays and the prohibition of ecclesiastic vows prior to the 24th birthday. She insisted that clerics were subject to the jurisdiction of the state in nonecclesiastical matters. The acquisition of land by the church was to be controlled by the government. She took action against the Society of Jesus (Jesuits), but only in 1774, after the Pope had ordered its suppression.

Joseph's most radical measures were the issue of the Edict of Tolerance of 1781 and his monastic reforms. The edict and the legislation attached to it gave Protestants near equality and gave Jews the right to enter various trades, as well as permission to study at universities. In this respect the difference between the Emperor and his mother was fundamental. While Maria Theresa viewed Protestants as heretics and Jews as the embodiment of the Antichrist, Joseph fully respected other Christian denominations and entertained secret plans to establish an Austrian state church independent of Rome.

As to the monasteries, Joseph held that institutions not engaged in useful work for the community, above all agriculture, care of the sick, and education, should be dissolved. Consequently, about a third of the Austrian monasteries ceased to exist, their former members being ordered to learn skills adapted to secular life. The property of the dissolved institutions was used to pay for the upkeep of parishes and to finance the establishment of new parishes.

Control of church discipline and church property were further tightened by Joseph; seminaries for the training of the clergy were secularized. He even tried, without success, to simplify radically the Catholic liturgy. Many of his religious policies were discontinued in the reaction that followed, but the Edict of Tolerance and the monastic reform were maintained.

Joseph was unsuccessful in his efforts to achieve empire-wide administrative centralization. In particular, his attempt to enforce the use of German as the language of administration in Hungary was a failure and certainly accelerated the growth of Magyar nationalism and anti-German feeling there. On his accession, Leopold II was forced once more to recognize Hungary as a separate unit of the Habsburg lands.

THE AGE OF METTERNICH, 1815–48

Austria's leading diplomatic position after the conclusion of the second peace treaty of Paris in November 1815 was never anchored primarily in the power potential of the Habsburg Empire but in the skill of Metternich and his adviser, Friedrich von Gentz, in establishing a common conservative platform acceptable to east and west. Its ideological foundation was meant to be the Holy Alliance of the European powers of September 1815, as proposed by Tsar Alexander I and as opposed by the British government. It was meant to organize Europe on the basis of Christian authoritarian principles, implying the possibility of intervention by foreign powers in revolutionary or even merely liberal movements abroad.

The Concert of Europe

In the ensuing period of the Concert of Europe (an attempt to establish a directorate of the great powers over European affairs), which saw limited cooperation among the great powers at the conferences of Aix-la-Chapelle (1818), Troppau (1820), Laibach (1821), and Verona (1822), France was commissioned to put down a revolutionary rising in Spain and Austria was to suppress a revolt against the brutal oppression by the Bourbon regime in the Kingdom of the Two Sicilies. These actions caused Britain to withdraw from the concert of the five great powers. The shattering blow to Metternich's concept of the anti-revolutionary unity of the European powers, however, was Russia's support of the Greek independence movement between 1821 and 1830. Therewith his system in international relations had for all practical purposes broken down and could not be restored but merely patched up.

Two immediate problems for Metternich were the maintenance of Austria's hold in Italy and the struggle with Prussia for supremacy in Germany. As to Italy, the secret Carbonari Movement and the liberal Young Italy promoted by Giuseppe Mazzini were in full swing throughout the whole Restoration period. The French July Revolution of 1830, another defeat of the Metternich system, encouraged open revolt in the Austrian appendages of Parma and Piacenza and in the Papal states. Austrian troops had to restore the old order by force of arms.

The handling of the Italian question, while it did not really undermine Austria's power, gave Austria the image of a tyrannical oppressor of a freedom-loving, highly cultured people. That the Austrian administration in Lombardy-Venetia was neither corrupt nor by contemporary standards particularly inefficient counted little in its favour.

Even more serious was the German problem, which involved issues of real power for the whole Habsburg Empire. Such issues had great emotional impact on the Austro-Germans in general and in particular on the liberal intelligentsia. In their rejection of liberal, potentially revolutionary trends as dangerous to their rule, the German princes saw eye to eye, but the Emperor of Austria and the King of Prussia were deeply divided as regards the issue of supremacy in Germany.

The Wartburg Festival (1817) of German academic youth celebrating the tercentenary of the beginning of the Reformation had worried the princes deeply. The assassination of the playwright August von Kotzebue as an alleged Russian spy by a radical German student gave the conservative powers the opportunity for which they had been waiting. Under the leadership of Metternich and with the active cooperation of the increasingly reactionary Tsar Alexander, the Carlsbad Decrees were passed in August 1819. These put the German and Austrian universities under strict government control. Student associations were forbidden, censorship was strengthened. An investigatory commission was set up in Mainz, and teachers, writers, and students suspected of liberal views were blacklisted throughout Germany and Austria. In 1824 the German Confederal Assembly in Frankfurt renewed these provisions at the instigation of Metternich for an indefinite period. New oppressive measures on an even larger scale were again introduced at Metternich's behest by the German Confederation as answer to republican demonstrations at Hambach (Palatinate) in 1832 and at Frankfurt in 1833. The restrictions were in essence still in force at the time of the outbreak of the Revolution of 1848.

The Carlsbad Decrees, 1819

In the conflict between the two leading powers in the confederation, Prussia took the lead first in the economic field. In 1819 Prussia and its largely noncontiguous domains were merged into one customs association. Treaties of adherence by small neighbour states followed. By 1829 most German states had joined the association. There were some major exceptions—most notably Austria. The whole plan was indeed directed primarily against Austria. Counter movements such as a south German customs union and a more limited central German one collapsed. When, on January 1, 1834, the German customs union (the Zollverein) was completed, Frankfurt, Baden, and the Hansa cities stayed outside with Austria. Prussia had however won an important political as well as economic victory. It made the German north and west (the Rhineland) the centres of gravity of further industrial development.

At this time Metternich's power was not only externally but also internally in decline. In 1824 Franz Anton, Graf von Kolowrat, a great noble of Czech origin, was appointed minister of state. Somewhat more enlightened than Metternich, particularly in regard to the Austrian Slavs, he carried great weight in matters of domestic administration. The situation changed further when in 1835 the emperor Francis died and was succeeded by his eldest son, the feeble-minded crown prince Ferdinand. Metternich believed that even a feeble-minded prince could not be bypassed, but the actual power of the government was transferred to a state conference consisting of two archdukes (both of limited intelligence) and Kolowrat and Metternich as permanent members.

Metternich's decline

Metternich's last success occurred in 1846 when a revolt, initiated by Polish nobles in Galicia, was suppressed after the peasants, indirectly supported by the government, had turned against their oppressive masters. Because the revolutionary ferment had been fed from the city republic of Cracow, Russia and Prussia agreed that Austria should incorporate the ancient Polish coronation city into Galicia.

REVOLUTION AND COUNTERREVOLUTION, 1848–59

The revolutions of 1848–49. Metternich's victory was short-lived. Early in March 1848 a revolution began in Austria as soon as news about the success of the revolution in France had spread. In Vienna, crowds of people led by students and young academicians asked for liberalization of the regime. A clash with the military led to bloodshed. The riots, in which workers participated, thereupon spread further. The demand for the aged Metternich's resignation was met by the crown at once, for it was expected that after this symbol of reaction was overthrown, order would quickly be restored. But encouraged by this first and unexpected quick success, the revolution spread across the empire.

Three main aspects of the Austrian Revolution may be distinguished: social, democratic liberal, and national or multi-national.

As to the social revolution, the Habsburg Empire was less industrialized than any major European state west of Russia. Thus, while workers participated courageously in the uprisings in Vienna, the impact of their intervention was relatively small and had little effect on governmental policies. There existed a far stronger movement for the full emancipation of the peasants, which meant giving them clear title to the lands without any further obligation of service to the lords. The newly elected constituent assembly in Vienna, in September 1849, passed legislation to this effect. This legislation was sanctioned by the Emperor, but the actual enforcement of this sweeping reform, in particular in regard to the financial indemnity to be paid by the peasants, was left to the postrevolutionary regime. Still, the influence of peasant emancipation on the revolution was a powerful one. The largest and basically most conservative social class appeared to be satisfied, and by the autumn of 1848 it was no longer a major factor in the revolution.

Concerning the liberal democratic revolution, a moderately conservative new cabinet had by April 1848 drawn up a new constitution usually referred to as the Pillersdorf Constitution, after the name of the minister of the interior. This document was, on the whole, fairly democratic. At about the same time, a liberal government under Count Lajos Batthyány was formed in Hungary, in which some of the great leaders of the nation and the dominant figure of the more radical reform policy, Lajos Kossuth, participated. These men drew up a new constitution for Hungary. It provided far-reaching home rule for the country and, except for two provisions, was agreed to by the Emperor. The unresolved provisions were a demand for a separate budget and a more important demand that Hungarian troops not be called to action without the approval of the Hungarian government.

Developments in Hungary

In the meantime František Palacký, the great Czech historian and recognized intellectual leader of his people, had in a public letter rejected the participation of Czech representatives in the first freely elected German national assembly, which was to convene in May 1848 in Frankfurt. While the lands of the Bohemian crown were legally a portion of the territory of the Habsburg Empire that belonged to the German Confederation, Palacký held that the Czechs, who strongly affirmed the existence of a multinational Austria as a bulwark against Russian advances to the west, could never be part of Germany.

German Austrian liberals and enlightened conservatives participated gladly in the National Assembly in Frankfurt. One of the few enlightened, though not liberal, members of the imperial house, Archduke John, was elected temporary regent of the new Germany, while a moderate Austrian liberal, Anton Ritter von Schmerling, was appointed prime minister in September 1848. Inasmuch as the Frankfurt assembly had no executive power, these positions meant little in practical terms. The assembly immediately began to work on the draft of a constitution, and here the Austrian question represented one of the foremost divisive issues. The Grossdeutsch (Large German) faction wanted to include the Austrian Germans but was opposed to any overall association with the non-German majority of the Habsburg Empire. The Kleindeutsch (Small German) faction thought the only way to avoid this difficulty was to exclude Austria altogether. The solution adopted in the German federal constitution in May 1849 affirmed the incorporation of the German Austrian lands as long as they

had a constitution and administration separated from that of the non-Germanic parts of the Habsburg Empire. But the practical effect of these provisions was nil, because by the time the constitution was adopted the counter-revolution was in full swing. Hardly a month later the Austrian deputies at Frankfurt were recalled. The Prussian government followed suit and about a month later the remainder of the parliament, which had been transferred to Stuttgart, was dissolved by simple police action. In essence this meant the end of the revolution in Germany, but not the end of the Austro-Prussian conflict as it had developed during the revolution.

The Prussian government wanted to exclude Austria in a roundabout way from the confederation. A union scheme was therefore proposed by Prussia and put before a new, no longer revolutionary, assembly at Erfurt. Austria did not participate in these proceedings. According to the Erfurt plan, supported for a time by Saxony and Hanover, the German Confederation should be divided into two sections, an inner German section under the leadership of Prussia and a second, purely nominal, section consisting only of Austria in alliance with the inner section. The Austrian government, under its energetic prime minister, Felix, prince zu Schwarzenberg, rejected this plan and forced the states that supported Prussia to withdraw from the scheme. Finally, the old confederation was again called into session at Frankfurt. Schwarzenberg would in fact have liked to create a central European union including the whole of the Habsburg Empire. But this goal, which would have made Austria supreme in the whole of central Europe, was unobtainable.

Provisions of the Erfurt plan

In deciding to take his stand on a relatively minor issue, the question of the right of Prussia or Austria to intervene in a revolutionary situation in Electoral Hesse, Schwarzenberg forced Prussia to withdraw and hence to recognize the restoration of the Confederation of 1815 under Austria's presidency (the Punctation of Olmütz, November 1850). This was the last, and a merely diplomatic, victory of Austria over Prussia. It was achieved only because Tsar Nicholas I backed the Habsburg Empire, which seemed to him the more reliable conservative power. The Austrian triumph proved to be short-lived. It merely strengthened the Prussian resolve to undo the humiliation as soon as an opportunity offered itself.

Such an opportunity was not long in coming, since the lack of cohesion within the Habsburg Empire had become painfully obvious during the course of the revolution. While riots in Prague, Lwów, and Cracow could be quelled, events in Hungary took a collision course. The new government there, though eagerly introducing educational and social reforms, was at the same time set on a policy of rapid Magyarization. The result was risings among non-Magyar Hungarian national groups—Croats, Serbs, Slovaks, and Romanians. The conflict with the government in Vienna stiffened when the diplomatic Batthyány was replaced by the far more radical Kossuth, in September 1848.

A further aspect to be considered was Austria's involvement in a war with Piedmont-Sardinia, whose king, Charles Albert, intended to drive the Austrians out of northern Italy. His army invaded Lombardy in March 1848. By August, however, the Sardinians were decisively defeated in the Battle of Custoza. An armistice was concluded in late summer of 1848, but the war, because of violation of its provisions, was resumed by Sardinia in March 1849. After the new attack was repelled, peace was restored on the basis of the status quo in August 1849. Although the Sardinians were no match for the Austrian army, the Italian campaigns made it impossible for Austria to deal with the Hungarian revolution effectively.

The Slav problem

In the meantime, the Slavic question had become a major issue in the western part of the empire as well. In June 1848 a Slav congress was convoked in Prague, in which Czechs, Croats, Poles, Ruthenians, Serbs, Slovaks, and Slovenes were represented. Before the congress could terminate its deliberations, street riots offered the government a pretext to terminate the proceedings. Even though a final program of action could not be agreed upon, the results of the Prague Congress were of great importance in the history of Pan-Slavism. Beyond this, various plans for federalization and local autonomy within the empire were discussed.

By September 1848 the Hungarian situation had deteriorated further. Troops led by the ban (viceroy) of Croatia, Josip von Jelačić, entered the country under orders to restore royal authority. The action created general indignation in Magyar Hungary, and the imperial commander in Budapest was lynched during a riot. Thereupon the Hungarian Reichstag was dissolved by royal decree.

The situation in Hungary encouraged a new revolutionary rising in Vienna, in early October 1848. It was the last major attempt in the German-speaking orbit to regain the revolutionary initiative. The imperial minister of war, Theodor, Graf Latour, was lynched by a mob, and an imperial army under the command of the arch-reactionary Prince Alfred Windischgrätz occupied Vienna, meting out harsh retribution to the revolutionary leaders.

A momentous change took place on December 2, 1848. The feeble-minded Emperor Ferdinand, dubbed by official historiography "the Benign," abdicated in favour of his 18-year-old nephew, Francis Joseph, from whom a more energetic stand against the revolution could be expected. The first prime minister of the young Emperor was Schwarzenberg, a gifted conservative and an utterly ruthless and shrewd statesman, whose advice Francis Joseph accepted more indiscriminately than he did that of any other of his ministers.

Schwarzenberg was even less inclined to compromise in the internal affairs of the Habsburg Empire than in those concerning the German Confederation. Thus, an open break with Hungary occurred in mid-December 1848, and Windischgrätz's army marched into the country on a full wartime footing. Under this mediocre commander, the Austrians did poorly against the effective tactics of the insurgents. The Hungarian Reichstag, encouraged by this turn of events, in April 1849 declared that the Habsburgs had forfeited their right to rule. Hungary was accordingly proclaimed a republic under the presidency of Kossuth.

One factor in the Hungarian decision was the changed situation in Austria. By early March of 1849 the constitutional committee of the Reichstag, after prolonged and thorough discussion on a high intellectual level, had adopted the draft of an Austrian constitution (the Kremsier draft, after the Moravian town in which the Reichstag was reconvened). The draft provided for a constitutional monarchy, giving the sovereign only a suspensive veto against parliamentary legislation. Administrative organization along national lines was provided on the district level, yet crownland administration, the old historic boundaries, and the essence of the centralistic structure of the empire remained intact. A weakness of the draft was that it did not deal with the Hungarian problem. But, all things considered, the bill represented a reasonable compromise between the federalist and centralistic concepts, the former promoted mostly by Slavs, the latter primarily by German liberals.

The Kremsier constitution

The Kremsier constitution was the first reform plan drawn up by genuine representatives of the Austrian peoples, and it was precisely for this reason that the cunning Schwarzenberg decided to foil it. He had the Reichstag dissolved by police and warrants issued for the arrest of some of the reformers. At the same time he had the minister of the interior, Stadion, issue by decree a new, strictly unitary and centralistic constitution for the empire as a whole, including Hungary. The Stadion constitution was more conservative than the Kremsier draft, but it still subscribed to representative government. Enactment was, however, held in abeyance. Thus not only the Austrian peoples felt deceived but Stadion and other members of the Cabinet as well, since the constitution was never put into force and was even formally rescinded in December 1851. In the long history of Austrian government, the dissolution of the Reichstag of Kremsier was one of the most fatal governmental mistakes.

In March 1849 Piedmont-Sardinia had resumed military operations against Austria. This fact and the tense political situation in Germany caused Hungary's military situation to deteriorate rapidly. In April 1848 Windischgrätz was

replaced as commander, and after an interim the cruel and ruthless Julius, Freiherr von Haynau, was appointed as his successor. By mid-May 1849 the Hungarian revolutionary army had reconquered Budapest, presenting the young Francis Joseph with the painful alternative of risking his throne or asking the Tsar for help. Nicholas I, afraid of the possibility of the spread of the revolution to Russian Poland, complied with the Austrian Emperor's request. Russian armies entered Hungary and cooperated with Austrian forces. Budapest was reconquered by mid-July, and on August 13, 1849, the Hungarian troops capitulated. Kossuth and some of his followers managed to flee to Turkey. Even Tsar Nicholas recommended mercy for the gallant Hungarian military commanders. The answer of the Schwarzenberg-Haynau regime was the execution of 14 Hungarian generals—those who had surrendered to the Russians rather than to the Austrians—by hanging. About a hundred other executions, including that of Kossuth's moderate predecessor, Count Lajos Batthyány, followed. These actions as well as many long prison sentences and property confiscations imposed on minor rebels had only a limited deterrent effect, but they revolted public opinion across Europe. Hungary was dismembered and Transylvania, Croatia, and other areas were organized as separate crownlands under strictly authoritarian rule. The prostrate country was divided into five military districts and put under the administration of the stern Archduke Albrecht, whose intervention in the March 1848 Revolution in Vienna had made him hated by all liberals.

Defeat of the revolt in Hungary

All things considered, the revolution across the empire had not accomplished very much. Absolutism was seemingly more firmly entrenched than before, and the political clock had been put back beyond the regime of Maria Theresa. And yet a regime so badly shaken as Austria's could not hope to rule unchallenged in the future. The unresolved social, constitutional, and national issues became more intense, and new changes were soon in the offing.

The neoabsolutist era, 1849–60. The neoabsolutist era in Austria from the breakdown of the revolution in 1849 to 1860 must be judged from the point of view of the domestic policies of the regime—which were controversial but not entirely negative—and of a foreign policy that proved to be of disastrous consequence.

Positive domestic achievements were the establishment of a unified customs territory for the whole empire, distinct progress in industrialization, the promulgation of a code for trades and crafts, and some rudimentary beginnings of social legislation. Enactment of the full emancipation of the peasants, initiated by the revolutionary legislation, worked well. One-third of the cost was to be carried by the former owners of the land, one-third by the peasants themselves, and one-third by the government. This was, on the whole, a solution more equitable than that adopted in Prussia, and in Russia in the 1860s. Some improvements in standards were made in the universities and in the curricula of the Gymnasia. Overall credit for the reform policies belonged largely to Alexander Bach, the successor of Schwarzenberg, who had died in April 1852, lamented by few but the young Emperor.

Emancipation of the peasants

The regime's policies on other matters were more typically reactionary. Freedom of the press and jury and public trials were abandoned; corporal punishment by police orders was reintroduced. Informers flourished: the observation of the liberal reformer Adolf Fischhof that the regime rested on the support of a standing army of soldiers, a kneeling army of worshippers, and a crawling army of informers was exaggerated but not entirely unfounded. One of the most unwholesome developments was the conclusion in 1855 of a concordat with the Holy See that gave the church more power than it had possessed since the middle of the 18th century. Jurisdiction in marriage questions was handed over to the church, as well as control of censorship and elementary education. Church control extended indirectly to secondary education, also, because the priests, who were entrusted with compulsory religious education, had the right to see to it that instruction in any other field, be it physics or history, did not conflict with their teachings. In the second half of the 19th century, a regime of this type could possibly have stayed in power if it had been successful in the conduct of foreign affairs. But this was not to be the case.

Exclusion from Germany and Italy. In the protracted Crimean War crisis (1853–56) the Habsburg Empire took a stand against the Russian occupation of the Danube principalities (Moldavia and Walachia). By threatening military intervention on the side of the Western allies, Austria forced their evacuation by Russian troops and from 1854 occupied the territories itself for the duration of the war. In December 1854, Austria joined the Western alliance but refrained from a declaration of war on Russia and from active military participation. The continuing threat of such action forced Russia to accept the humiliating Treaty of Paris in March 1856.

The consequences for the Habsburg monarchy were grave. Russia, Austria's ally for well over a century, moved into the camp of its enemies. The tsars, Nicholas I and his son Alexander II, never forgave the alleged ingratitude for the Russian intervention in Hungary in 1849. The Western powers, on the other hand, were highly dissatisfied that the Habsburg Empire had refused to take the last decisive step and become a combatant in the war. In retaliation, and in payment of political debts, they supported the cause of Italian unification, skillfully engineered by the Sardinian prime minister, Count Cavour.

The end of Austria's alliance with Russia

Though Karl Ferdinand, Graf von Buol-Schauenstein, Metternich's successor as minister of foreign affairs, was blamed for allowing Austria to fall between two chairs, the fact is that the Habsburg Empire simply had been caught in an insoluble dilemma. By the nature of its own absolutist regime, it was drawn to tsarist despotism; but in justified fear of encirclement and of the effect of Russian-inspired Pan-Slavism on Austria's Slav population, the empire had to look for the support of the West with its alien political values. This was the basic contradiction in the policy of the Habsburg power.

Napoleon III, largely to distract attention from his own semidictatorial regime and to assuage the Liberals, deemed it advisable to support the cause of Italian independence. In the secret agreement of Plombières of July 1858, he pledged French military support for the liberation of Lombardy and Venetia. This was technically a defensive pact, but in face of a political situation in which three major European powers—France, Great Britain, and Russia—sided with the Italian cause, the Austrians would have been well advised to ignore any Piedmontese provocations. But Buol blundered Austria into an ultimatum by which in April 1859 it demanded Piedmont-Sardinia's demobilization within three days. This was all the justification Cavour and Napoleon III needed to start the Austro-French Piedmontese War. French and Italian military leadership and preparations were far from satisfactory, and conditions on

Austrian Empire, 1815–59.

the Austrian side were even worse. Under an inferior commander, Franz, Graf von Gyulai, the Austrians hesitated to take the offensive. In the Battle of Magenta on June 4, they were defeated and Milan had to be evacuated. Gyulai was discharged and the inexperienced emperor Francis Joseph took over the supreme command. On June 24, 1859, the Austrians were decisively beaten in the Battle of Solferino, and two weeks later Napoleon III and Francis Joseph, who was deeply shocked by the carnage of the encounter, concluded the preliminary Peace of Villafranca, followed in November 1859 by the permanent Peace of Zürich. According to its terms Austria had to cede Lombardy—except for Mantua and Peschiera—to Napoleon III, who in turn would give it to Piedmont-Sardinia. The rulers in the Austrian appendages, Modena and Tuscany, who had been driven out by their subjects in the course of the war, were to be restored. These terms represented a kind of compromise. Napoleon III was not anxious to continue a war that might have brought about Prussian intervention on the side of Austria.

The Schleswig-Holstein crisis

The underlying conflict between Austria and Prussia over supremacy in Germany erupted into a crisis as a result of the involvement of the two powers in Danish affairs. When in 1863 the King of Denmark decreed a union of Schleswig and Holstein under one constitution and finally incorporated Schleswig into Denmark, he thereby violated international agreements and the charter of the German Confederation, to which Holstein belonged. Protests by Austria and Prussia on behalf of the Confederation were of no avail, nor were they meant to be. Consequently the two major German powers and Denmark went to war in 1864.

The Habsburg Empire's interest in this conflict was not as peripheral as it seemed, for the government was afraid that if action was left to Prussia alone the war would end with unilateral Prussian aggrandizement. Secondly, and perhaps equally important, the issue of Schleswig-Holstein was of major concern to German nationalists. After a brief war, Denmark was forced, by the Peace of Vienna of October 1864, to cede Schleswig, Holstein, and the small duchy of Lauenburg to the Austrian and Prussian sovereigns. But it became increasingly clear that Bismarck did not want to establish the principalities as states within the German Confederation under a sovereign prince. He worked instead in an underhand way for annexation by Prussia. A temporary arrangement was, however, reached at the Convention of Gastein (August 1865), according to which Holstein was put under Austrian military administration and Schleswig under Prussian. Lauenburg was sold outright to Prussia.

The real reason behind this temporary arrangement was the desire of both sides to gain time to make military preparations for the showdown that Bismarck considered inevitable and the Austrian government likely. Further efforts to settle the status of the duchies on a permanent basis by compromise failed, chiefly because this issue served Bismarck with a useful pretext for war. In further preparation Bismarck in April 1866 concluded an alliance treaty with Italy, which promised Italy Prussia's support for the conquest of the Austrian-held Venetian province. The treaty was to lapse if Italy did not open hostilities against Austria within three months. Thus a time limit was set for the beginning of the war.

The pretext for the openings of hostilities was a minor one. When Austria convoked the Estates of Holstein in early June 1866, Prussia declared the Convention of Gastein violated and occupied the duchy by military force. Thereupon Austria asked for mobilization of the confederal armies against the aggressor, Prussia. All member states agreed. Prussia in turn declared the charter of the confederation void and invaded Saxony, Hanover, and Electoral Hesse. The great war for supremacy in Germany, sometimes also referred to as the war between brethren or the Seven Weeks' War, began on June 16, 1866. Four days later Italy joined in the hostilities.

Francis Joseph's initial and grave error was his selection of the commander in the northern theatre of war. Gen. Ludwig August, Ritter von Benedek, a subcommander with many years of experience in the Italian theatre, was against his will put in charge of the main forces against Prussia. Archduke Albrecht, cousin of the Emperor, was given the far less risky command in the south against Italy, so that a member of the dynasty would not be compromised in case of defeat.

The Prussian forces, in accordance with the superior strategy of the chief of staff, Helmuth von Moltke, started a three-pronged attack on Bohemia. Austrian army units were defeated in most of the preliminary engagements in Bohemia. Benedek wanted to withdraw to Moravia, but when the Emperor appealed by implication to his sense of honour, he accepted battle on July 3 at Sadowa (Königgrätz) against three converging Prussian armies. The Austrians, their brave resistance notwithstanding, were defeated and withdrew in disarray. Before the Prussian offensive could be carried to the gates of Vienna, a temporary truce was arranged at Nikolsburg, followed by the preliminary peace that was concluded there on July 26. Bismarck, concerned with the possibility of immediate French intervention and with long-range plans for future friendly relations with Austria, wanted to avoid unnecessary humiliation of the Habsburg power. The terms that were confirmed by the permanent Treaty of Prague of August 23 were therefore moderate. Austria would have to recognize the dissolution of the German Confederation and the reorganization of Germany without its participation. Austria's rights in Schleswig-Holstein were transferred to Prussia and it had to pay a relatively minor indemnity. Yet no territorial cessions were demanded, and as a point of honour it was allowed to secure the preservation of the territorial integrity of its most faithful ally, Saxony.

Defeat by Prussia at Sadowa

Before evaluating the peace, the outcome of the war against Italy must be considered. By 1866 the Emperor and most Austrian statesmen had belatedly realized that Austrian rule in Venetia in the face of the opposition of the overwhelming majority of the population there made little sense. Nonetheless, a secret semi-official Italian offer to buy the province was rejected as dishonourable. A conditional offer to cede Venetia outright to Italy came too late in view of the Prusso-Italian alliance. Instead Emperor Francis Joseph concluded on June 12, 1866, a strange agreement with Napoleon III. According to its main provisions in regard to Italy, Austria would cede Venetia, win or lose, to Napoleon, who in turn would give the province to the new Italian kingdom. This meant in effect that the Habsburg power would fight a regular war for the sake of prestige and medieval chivalry, although the outcome was settled before the fighting started. The Italians in turn refused to accept a gift from Napoleon and preferred to fight. The Austrians defeated the Italians at Custoza in Lombardy as well as in the naval Battle of Lissa (Vis) off the Dalmatian coast. But this was of no consequence because of Italy's partnership with Prussia and the latter's victory at Sadowa. By the Peace of Vienna with Italy on October 3, 1866, the cession of Venice, this time to Italy directly, was confirmed.

Significance of the defeat

Of all the wars in the long history of the Habsburg monarchy prior to World War I, the brief Seven Weeks' War of 1866 had probably the most far-reaching effect. Its outcome banished Austria from the rank of the genuine first-rate powers. Beleaguered German nationalism within the empire increasingly assumed a belligerent tone, quite different from the moderate German-directed centralism that had been dominant for many generations. This spirit was challenged not only by a proud Magyarism but also by the combined force of the empire's Slavs—about half the population. This in turn made the Habsburg power increasingly vulnerable to Russian pressure from the east and within 13 years forced it into a German alliance, not as an equal but as a junior partner. Equally important were the internal changes brought by military defeat in two wars within seven years.

THE TRANSITION TO CONSTITUTIONAL GOVERNMENT, 1860–66

In March 1860 Francis Joseph ordered that the Reichsrat, a kind of empire-wide, purely advisory council of state, should be enlarged by the addition of 38 members proposed by the diets and selected by the crown itself. Only

in matters of public finance was this body given a share in legislation, yet it was entrusted with the formidable task of advising the emperor concerning the promulgation of a new imperial constitution. No agreement, however, could be reached. The moderately liberal centralists, represented largely by the Germans, demanded a strong empire-wide legislature and restriction of the agenda of the old Estates diets. They were faced by conservative federalists, largely Magyar, Czech, and Polish nobles, who wanted to strengthen the diets' position. Magyar influence was again on the rise. The Emperor himself sided naturally enough with the conservative forces, which were federalist mainly on the strength of historic and not ethnic claims. The result was the October Diploma of 1860, a constitution proclaimed by decree. It enlarged the diet to 100 representatives and broadened the legislative functions of the Reichsrat in matters of finance, commerce, and industry. Foreign and military agenda remained the exclusive domain of the emperor. Hungary's constitutional status within the empire was restored as it had existed prior to the revolution of 1848, but the concessions agreed to in March 1848 were not recognized. The federalists, particularly the Magyars, objected because their demands had been met only halfway. The centralists rejected the constitution just as strongly, as fully at variance with their claims. In effect, the whole unfortunate legislation had to be abandoned, and on the advice of the new German centralist cabinet, a new one, technically a revision of the October Diploma, was decreed (the so-called February Patent of February 26, 1861).

Constitutional changes

The October Diploma was really no constitution at all in the representative sense; the February Patent was at least an inadequate one. It provided for a bicameral system, an empire-wide house of representatives composed of dietal delegates, and a house of lords, consisting partly of hereditary members and partly of men of special distinction appointed for life. Furthermore, a parliamentary body for the Habsburg lands exclusive of Hungary was established. Opposition of the national groups rendered the constitution unworkable, and in 1865 it had to be suspended. Absolutism was, for all practical purposes, restored under a new prime minister, Richard, Graf Belcredi. The crown could hardly expect that this renewed elimination of constitutional government would be permanent, and the outcome of the war of 1866 made this assumption a certainty. In the meantime, negotiations with the Magyars, who were under the leadership of the highly respected moderate liberal Ferenc Deák and Count Gyula Andrássy, continued. (R.A.Ka.)

AUSTRIA-HUNGARY, 1867–1918

The liberal ascendancy. *The Ausgleich of 1867.* The economic consequences resulting from the defeat in the war of 1866 (Seven Weeks' War) made it imperative that the constitutional reorganization of the Habsburg monarchy, under discussion since 1859, be brought to an early and successful conclusion. Personnel changes facilitated the solution of the Hungarian crisis. Friedrich Ferdinand, Freiherr (later Graf) von Beust, who had been prime minister of Saxony, took charge of Habsburg affairs, first as foreign minister (from October 1866) and then as chancellor (from February 1867). By abandoning the claim that Hungary be simply an Austrian province, he induced Francis Joseph I to recognize the negotiations with the Hungarian politicians (Deák and Andrássy) as a purely dynastic affair, excluding non-Hungarians from the discussion. On February 17, 1867, Francis Joseph I restored the Hungarian constitution; a ministry responsible to the Hungarian parliament was formed under Count Gyula Andrássy; and in May 1867 Law XII was approved by parliament, legalizing what became known as the *Ausgleich* ("compromise"). This agreement was a compromise between the Hungarian nation and the dynasty, not between Hungary and the rest of the empire; and it is symptomatic of the Hungarian attitude that Hungarians referred to Francis Joseph and his successor as their king and never called him emperor.

Beust becomes chancellor

In addition to regulating the constitutional relations between the king and the nation, Law XII accepted the unity of the Habsburg lands for purposes of conducting certain economic and foreign affairs in common. The compromise was thus the logical result of an attempt to blend traditional constitutional rights with the demands of modern administration. In December 1867, the *engerer* Reichsrat, the section of parliament representing the non-Hungarian lands of the Habsburg monarchy, approved the compromise. Though, after 1867, the Habsburg monarchy was popularly referred to as the Dual Monarchy, the constitutional framework actually was tripartite, comprising the common agencies for economics and foreign affairs, the agencies of the kingdom of Hungary, and the agencies of the rest of the Habsburg lands—commonly but incorrectly called "Austria." (The official title for these provinces remained "the kingdoms and lands represented in the Reichsrat" until 1915, when the term "Austria" was officially adopted for them.)

Under the Compromise of 1867, both parts of the Habsburg monarchy were constitutionally autonomous, each having its government and its parliament composed of an appointed upper and an elected lower house. The "common monarchy" consisted of the emperor and his court, the minister for foreign affairs, and the minister of war. There was no common prime minister and no common cabinet. The common affairs were to be considered at the "delegations," annual meetings composed of representatives from the two parliaments. For economic and financial cooperation, there was to be a customs union and a sharing of accounts, which was to be revised every ten years. (This decennial discussion of financial quotas became one of the main sources of conflict between the Hungarian and Austrian governments.) There would be no common citizenship, but such matters as weights, measures, coinage, and postal service were to be uniform in both areas.

Although there was no common prime minister or cabinet, there soon developed the so-called *gemeinsamer* Ministerrat, a kind of crown council in which the common ministers of foreign affairs and war and the prime ministers of both governments met under the presidency of the monarch. The common ministers were responsible to the crown only, but they reported annually to the delegations representing both parliaments.

The December constitution

The Compromise of 1867 for all practical purposes set up a personal union between the lands of the Hungarian crown and the western lands of the Habsburgs. The Hungarian success inspired similar movements for the restoration of states' rights in Bohemia and Galicia. But the monarch who only reluctantly had given in to Hungarian demands was unwilling to discontinue the centralist policy in the rest of his empire. Public opinion and parliament in Austria were dominated by German bourgeois liberals who opposed federalization of Austria. As a prize for their cooperation in compromising with the Hungarians, the German liberals were allowed to amend the February constitution of 1861; the Fundamental Laws, which were subsequently adopted in December 1867 and became known as the December constitution, lasted until 1918. They granted equality before the law and freedom of press, speech, and assembly and protected the interests of the various nationalities, stating that

> all nationalities in the state enjoy equal rights, and each one has an Inalienable right to the preservation and cultivation of its nationality and language. The equal rights of all languages in local use are guaranteed by the state in schools, administration, and public life.

The authority of parliament was also recognized. Such provisions, however, were more a promise than a reality. Although parliament, for instance, did theoretically have the power to deal with all varieties of matters, it was, in any case, not a fully representative parliament (suffrage was restricted, and it was tied to property provisions until 1907); and the king was authorized to govern without parliament in the event that the assembly should prove unable to work. Austrian affairs from 1867 to 1918 were, in fact, determined more by bureaucratic measures than by political initiative; Josephine traditions (see above *Foreign policy, 1763–92*) rather than capitalist interests characterized the Austrian liberals.

Domestic affairs. After the December constitution had been sanctioned, Emperor Francis Joseph appointed a new Cabinet, named the "bourgeois ministry" by the press, because most of its members came from the German middle class (though the prime minister belonged to the Austrian high aristocracy). In 1868 and 1869, this ministry was able to enact several liberal reforms, undoing parts of the Concordat of 1855. Civil marriage was restored; compulsory secular education was established; and interconfessional relations were regulated, in spite of a strong protest from the Catholic Church. In 1870, the Austrian government used the promulgation of the dogma of papal infallibility as pretext for the total abrogation of the concordat.

The progressive legislation of the bourgeois Cabinet stood in sharp contrast to its inability to cope with the demands of the non-German nationalities. In 1868 the Czechs and the Poles issued declarations demanding a constitutional status analogous to that of the Hungarians. The government in Vienna did give the Poles in Galicia a considerable amount of self-government, which was later used to Polonize the Ruthenian minority. In 1871 a ministry for Galician affairs was set up, and the Poles remained the staunchest supporters of the Austrian government well into World War I.

Czech demands for autonomy

The bourgeois ministry was split into a liberal-centralist and a conservative-federalist faction; its members could not reach an agreement among themselves on policies to be adopted. The liberal members of the Cabinet opposed Czech demands; the conservatives showed themselves willing to consider them. Francis Joseph, indignant because of the anti-clerical policy of the liberals, dismissed the prime minister, Fürst Carlos Auersperg, in 1868, replacing him with the conservative Eduard, Graf von Taaffe, his boyhood friend. A period of indecision nevertheless persisted. The Emperor wavered between the liberals, whose anti-clericalism and parliamentarianism he disliked but with whom he sympathized in their centralist, German-oriented policy, and the conservatives, who had his favour in political legislation but aroused his fears by their demands for federalization. Neither Taaffe nor his successors, Leopold Hasner (from December 1868) and Potocki (from April 1870), could solve the Czech problem. The Franco-German War of 1870–71 temporarily diverted public attention from the Czech demands, though public opinion was divided strictly along lines of nationality: Austro-Germans celebrated the victories of the Prussian army, whereas the Slavs were decidedly pro-French. The Austrian government remained neutral because conflicting international interests had blocked the Austro-French negotiations that had culminated in a meeting of Francis Joseph and Napoleon III at Salzburg in 1867. The victory of Chancellor Otto von Bismarck and the establishment of the Second German Empire under the leadership of the Prussian king gave finality to the military decision of 1866. Austria was definitely excluded from the German scene, and a reorientation of dynastic interests seemed a logical consequence. Francis Joseph decided to explore the possibilities of satisfying the Czechs with some measure of federalism. On February 5, 1871, he appointed as prime minister Karl Siegmund, Graf von Hohenwart, a staunch clericalist. The driving mind in Hohenwart's Cabinet, however, was the minister of commerce, Albert Schäffle, an economist whose socialism may not have appealed to the Emperor but whose federalism did.

Failure to satisfy Czech demands

As a first step toward conciliation with the Czechs, the Hohenwart Cabinet dissolved parliament and the provincial diets. When the Bohemian elections improved the federalist position, Hohenwart proceeded to deal directly with the Czechs, copying in certain measure the method used to conclude the compromise with Hungary. Secret talks with Czech leaders František Ladislav Rieger and František Palacký led to the issuance of an imperial rescript by Francis Joseph on September 12, 1871, promising the Czechs recognition of their ancient rights and showing his willingness to take the coronation oath. The Czechs answered this rescript on October 10, 1871, by submitting a constitutional program of 18 articles, called the Fundamental Articles. According to this program, Bohemian affairs should be regulated along the principles of the Hungarian compromise, raising Bohemia to a status equal to Hungary. With this, Hohenwart, who had been up against violent German opposition from the very first day of his appointment, aroused Hungarian resistance, too. Andrássy, fearing that the Czech program could incite minority groups in Hungary, succeeded in convincing Francis Joseph that the stability of the Habsburg monarchy was endangered by the Czech program. On October 27, 1871, Hohenwart was dismissed and Francis Joseph returned the government to the hands of the German liberals.

The new prime minister, Prince Adolf Auersperg, entrusted the key ministries of his Cabinet to university professors and lawyers. The "ministry of doctors," as it was nicknamed by the people, concentrated on legal and administrative reform and endeavoured to strengthen the German control in parliament. After the dismissal of Hohenwart, the Czechs turned to passive resistance, withdrawing from the Bohemian diet and again abstaining from attendance at the parliament in Vienna. This attitude gave the government the chance to weaken the federalist position by introducing a bill for electoral reform. Instead of the existing modus, whereby the diets selected the deputies that were sent to parliament, the new bill set up electoral districts, each of which was to elect one deputy directly to the Reichsrat. The new system, however, preserved the old division of the electorate into *curiae* (socioeconomic classes), making parliament in this way a representation of German bourgeois interests.

The economic crisis of 1873

By a strange coincidence, the political victory of German capitalism took place at the very moment of a severe economic crisis. In April 1873, the opening of the Vienna International Exhibition had been thought of as a manifestation of the material progress and economic achievements of the Habsburg monarchy. The so-called *Gründerjahre,* or years of expansive commercial enterprise during the late 1860s and early 1870s, however, were characterized not only by railroad and industrial expansion and the growth of the capital cities of Vienna and Budapest but also by reckless speculation. Warning signs of an imminent crisis were disregarded, and in May, soon after the opening of the exhibition, the stock market collapsed.

The ensuing depression forced the government to abandon liberal bourgeois principles. The state took over the railroads and instituted public-works projects in an attempt to alleviate popular distress. A far-reaching consequence of the stock-market crash of 1873 was the permeation of anti-Semitism into Austrian politics. Jews were accused of being responsible for the speculative stock-market activities, even though official investigations proved that many elements of the population, including some ministers and high aristocracy, had participated in the *Gründungsfieber,* or "speculative fever," and the attendant scandals. The government survived the crisis, however, and German liberal political rule continued for five more years. German liberalism passed into eclipse not because of economic or domestic crisis but as a consequence of its opposition to foreign expansion.

International relations: the Balkan orientation. After his appointment as foreign minister, on November 14, 1871, Count Gyula Andrássy conducted the foreign affairs of Austria-Hungary with the intention of preserving the status quo. Discarding the anti-Bismarck bias of his predecessor, Beust, he sought the friendship of the German *Reich* with the intention of strengthening his position in the unavoidable confrontation with Russia over Balkan problems. The Three Emperors' League (*Dreikaiserbund*) of 1873, by which Francis Joseph and the German and Russian emperors agreed to work together for peace, gave expression to this policy. It also represented Andrássy's intention to strengthen Austria's position in a possible confrontation with Russia over Balkan problems, because the league made a change of the status quo in the Balkans dependent on German consent.

The Three Emperors' League of 1873

The continuing decline of Ottoman power encouraged the Balkan nations in their opposition to Turkish rule, and in 1875 there were revolts and upheavals. Andrássy failed to induce the Turkish government to adopt a reform program, and by 1876 Russian intervention seemed to be imminent. Russia offered to join with Austria-Hungary in

partitioning the Balkans between them, but Andrássy was convinced that Austria-Hungary was a "saturated state" unable to cope with more nationalities and lands, and thus he temporarily resisted the offer. He was aware, however, that Russia could not be restrained altogether; and thus, through Bismarck's mediation, there were concluded two secret agreements, at Reichstadt (Zákupy) in July 1876 and at Budapest in January 1877, whereby Russia gave up its plans for a "great partition" and settled for the territory of Bessarabia and, in return, acquiesced in Austria-Hungary's acquiring Bosnia and Hercegovina. Austria-Hungary and Russia further agreed, however, to refrain from intervention for the time being, and it was only when great-power mediation proved unable to settle the conflict between Serbia and Turkey that Russia declared war on Turkey, in April of 1877, after having once more secured Austro-Hungarian neutrality. In February 1878, with the war won, the Russians did not content themselves with Bessarabia, but, in the Treaty of San Stefano, violated Austria-Hungary's Balkan interests by creating a Great Bulgaria. Having Great Britain as an ally in his opposition to the Russian advance in southeastern Europe and Bismarck as an "honest broker," Andrássy managed at the Congress of Berlin in July 1878 to force Russia into retreating from its excessive demands. Bulgaria was broken up again, Serbian independence was guaranteed, Russia retained Bessarabia, and Austria-Hungary was allowed to occupy Bosnia and Hercegovina. Military occupation of the two provinces turned out to be more than the expected mere formality. It took 150,000 Habsburg troops and several weeks of fighting before the lands were under Habsburg authority. Since no agreement could be reached on whether the newly acquired lands should aggrandize the Hungarian or the Austrian part of the monarchy, an ingenious solution placed them under the jurisdiction of the common Habsburg ministry of finance.

Decisions of the Congress of Berlin, 1878

National conflict and reform. *Taaffe's ministry.* The German liberals had opposed the Balkan policy of Andrássy; and, out of fear that the Slav element in the monarchy would be strengthened by the addition of new Slav population, they voted against the occupation of Bosnia and Hercegovina, in this way withdrawing support from the government. When Prime Minister Auersperg resigned, the era of German liberal predominance came to an end. In 1879, the same year in which the Dual Alliance with the German *Reich* bound the Habsburg monarchy to Germany's foreign policy, the appointment of Taaffe as prime minister signified a reorientation in domestic affairs. From 1879 onward, the German element in the Habsburg monarchy was on the defensive, fighting stubborn and senseless rearguard actions against the Slav drive for political and national equality.

For the elections of 1879, a coalition had formed, consisting of clericals, German aristocrats, and Slavs, which gave itself the name of the Iron Ring. Taaffe had first tried to form a cabinet above parties. It was to include even the liberal Karl, Edler von Stremayr, who had presided over a caretaker government after Auersperg's resignation. The situation in parliament had decisively changed when the Czechs were persuaded by Taaffe, in 1879, to give up their boycott. In April 1880, as a first step, language ordinances were issued that made Czech and German equal languages in the "outer [public] services" in Bohemia and Moravia. In 1882 the University of Prague was divided, giving to the Czechs a national university. In the same year, an electoral reform reduced the tax requirement for the right to vote from ten to five florins, thus enfranchising the more prosperous Czech peasants and weakening the hold of the German middle class. The Taaffe government is also remembered for social-reform legislation; the laws of 1884 fixed the maximum working day (at 11 hours), outlawed the employment of children under 12, required a Sunday rest day for workers, and set up compulsory insurance against accidents and sickness.

Reforms of the 1880s

Despite the conservative character of the government, political life in the Habsburg monarchy underwent a decisive change during the Taaffe period. In the 1880s, the traditional party lineup decomposed, and new alignments and parties formed that were essentially radical and aggressive. The Slav orientation of the Taaffe Cabinet did not satisfy the Czechs but rather encouraged a mood of belligerence; because the moderate Old Czechs failed to live up to radical demands, the nationalistic Young Czechs were able to gain support from the electorate. Similarly, in German Austria and, especially, in Vienna, the moderate liberals were increasingly challenged by extremist groups—notably, German nationalists. In 1882 their "Linz program" proposed the restoration of German dominance in Austrian affairs by detaching Galicia, Bukovina, and Dalmatia from the monarchy, reducing relations with Hungary to a purely personal union under the monarch, and establishing a customs union and other close ties with the German *Reich*. This Pan-Germanic program found its chief protagonist in Georg, Ritter von Schönerer, a deputy to the Reichsrat, who also introduced, for the first time, a note of anti-Semitism into German nationalism. Although his version of extreme chauvinism and racialism never attracted more than a small number of followers, in a modified and moderate way Pan-Germanism and anti-Semitism became the ideological support of the bureaucracy and officer corps; though these elements did not favour union with Germany, they did feel that the Habsburg monarchy had the task of bringing German culture to the "inferior" non-German nationalities. The period also witnessed the founding of parties for the masses. While Schönerer and Pan-Germanism appealed to the educated classes, Karl Lueger transformed the Christian Socialism of Karl, Freiherr von Voegelsang, into a political organization which appealed to small shopkeepers, artisans, tradesmen, and lower bourgeois circles of Vienna and the surrounding countryside. The 1880s finally saw the transition of the workers' movement from the welfare and adult education societies into a political party. Although workers' movements had been weakened in Austria by personal rivalries and government persecution, Victor Adler in 1889, at a conference in Hainfeld, managed to unite the competing Marxist groups into the Social Democratic Party. Political life in Austria from 1890 well into the 1920s was dominated by these three movements originating in the 1880s: Pan-Germanism, Christian Socialism, and Democratic Socialism.

Reaction of the German nationalists

Taaffe continued to probe for compromises between nationalities that were becoming increasingly radical in their demands. In 1890 he tried to negotiate an agreement between the Old Czechs and the German liberals whereby Bohemia would have been divided for administrative and judicial purposes along lines of nationality, but he was balked by the more chauvinistic Young Czechs and German nationalists, and his efforts led to riots in Prague in 1893. When Emil Steinbach joined Taaffe's Cabinet as minister of finance in 1891, he encouraged Taaffe and the Emperor to try electoral reform as an instrument of breaking nationalist opposition. It was hoped that, by extending the franchise, nationalistic antagonism could be allayed and the growing unrest among urban workers could be placated. On October 10, 1893, a suffrage bill was introduced, giving the vote to virtually every literate adult male (though preserving the traditional system of voting in *curiae*). The conservative groups of all nationalities joined forces against this bill, and, under pressure from the Hungarian government, Taaffe had to resign on November 11, 1893. Though failing in political matters, the Cabinet had been successful in introducing some economic and social reforms: between 1888 and 1892 a system of cooperative banks for farmers was organized; the taxation system was revised; Austrian currency was stabilized by a return to the gold standard; and the florin was replaced by the crown, which remained the Austrian currency until 1924.

Taaffe's later attempts to lessen national tensions

Badeni's ministry. The franchise question continued to dominate Austrian domestic affairs and became closely welded to the nationality conflicts. Alfred, Fürst zu Windischgrätz, sought to win the support of parliament by forming a cabinet in which the clerical conservatives, the Poles, and the German liberals were represented. They were united, however, only in opposition to universal suffrage. Each minister defended his national cause, and the ministry was torn by ceaseless conflict. The end came in June 1895, when the government fulfilled an old promise

and introduced Slovene classes into the grammar school at Cilli (Celje), in Styria. Because the school had been exclusively German, this was regarded as a grave blow to the German cause, and the German liberals resigned, forcing Windischgrätz himself to resign.

Deeply embittered by the conduct of the German liberals, Francis Joseph on October 2 entrusted the task of solving the country's problems to a Polish aristocrat, Kazimierz Felix, Graf Badeni, known as a "strong man" for the high-handed way in which he had acted as governor of Galicia. Little noticed at the time, the appointment of Badeni symbolized the breakdown of German control over the Habsburg monarchy. For the first time in Habsburg history, the Germans controlled none of the key positions of government. Not only the Prime Minister (Badeni) but also the Finance Minister (Leo, Ritter von Biliński) and the Foreign Minister (Gołuchowski, who had succeeded Count Gusztáv Kálnoky von Köröspatak the year before) came from the Polish part of the empire. Badeni managed to induce parliament to accept a compromise franchise bill that introduced qualified universal male suffrage but preserved the system of class voting (a fifth *curia* was even added).

Significance of Badeni's appointment

The shortcomings of the new system enraged the parties representing the masses of the population. In the 1870s and 1880s, decisive economic changes with far-reaching social consequences had occurred in the Habsburg lands. Though remaining primarily agrarian, the Habsburg lands had undergone an industrialization that had resulted in an unprecedented growth of urban centres. Vienna, which had about 430,000 inhabitants in 1851, found itself a metropolis of 1,800,000 at the turn of the century; and this phenomenon was paralleled in other areas, especially in Bohemia, which had become the industrial centre of the western part of the Habsburg lands. The socioeconomic development naturally began to affect politics. From 1890 on, the advance of the Social Democrats and Christian Socialists caused considerable tension in Vienna. In October 1894, the Social Democrats were able to organize their first impressive, orderly mass demonstration in the capital, and the communal elections of 1895 had made the Christian Socialists the strongest party in Vienna, ending the long liberal rule. When the Emperor refused to confirm Karl Lueger, the popular leader of the Christian Socialists, as mayor of Vienna, there were demonstrations and protests. Not until Lueger was elected mayor the fifth time did Francis Joseph agree to confirm him, in April 1897. Furthermore, a few weeks earlier, the elections held on the basis of the new suffrage had strengthened the radical elements in the Reichsrat; the Young Czechs, for instance, had completely overwhelmed the conservative Old Czechs.

Growing strength of socialist parties in the 1890s

Counting on support from the Slav and conservative parties in parliament, Badeni dared to take up the Bohemian language question again. In April 1897, he issued a famous language ordinance that introduced Czech as a language equal to German even in the "inner service"—that is, for communications within government departments. This decision would have meant that civil servants in Bohemia and Moravia would have to be able to speak and write Czech as well as German. Since the Germans refused to learn Czech, this would have put them in a definite disadvantage in Bohemia's administration. The publication of the ordinance thus provoked violent German reactions: university professors signed resolutions of protest; mass meetings incited the public; and German deputies in the Reichsrat began to obstruct all legislative activities. The protest reached its climax in November 1897, when parliamentary sessions turned into bedlam, and popular protests against Badeni led to street demonstrations. The mass protest was not restricted to Vienna; it was even worse in some German towns in Bohemia; in Graz, clashes between soldiers and the masses ended in the death of one demonstrator. For a moment it seemed as if 1848 was about to return. To pacify the public, Francis Joseph gave in; on November 28, 1897, he dismissed Badeni, and asked Paul, Freiherr Gautsch von Frankenthurn, a former minister of education, to form a government out of the German parties of parliament. Gautsch's attempts to appease the Germans ran into obstruction from the Czechs. The stage of violence was shifted from Vienna to Prague and from the Reichsrat to the Bohemian diet. In March 1898 Gautsch was replaced by the former governor of Bohemia, Franz Anton, Fürst von Thun und Hohenstein, who in turn failed within a year. neither Manfred, Graf Clary und Aldringen, who formally revoked the Badeni language ordinance, nor his successor, Wittek, who headed a short-lived cabinet of a few weeks, managed to solve the nationality problem.

Koerber's ministry. Finally, on January 18, 1900, Francis Joseph asked Ernst von Koerber, a former minister of the interior, to form a new Cabinet. Koerber was the first and only commoner to be appointed prime minister by Francis Joseph; as a leading bureaucrat, he formed his ministry from the ranks of other bureaucrats, concentrating, in the subsequent years, on the administration of public affairs and economic programs rather than trying to deal with political problems. First by imperial decree and then, after some political bargaining, by consent of parliament, Koerber carried through a program of economic expansion, social legislation, and administrative reform, liberating the press from government and police control. By devious politicking, Koerber managed to keep government activities free from national strife, but he could not prevent national emotions from becoming more and more extremist. The national conflict came to be fought over educational matters, and in the final years of Koerber's government the desire for national universities aroused the sentiment of the Italians, Slovenes, and Ruthenians, turning the traditional Czech-German conflict into a multinational one. In December 1904, Koerber's various manoeuvrings faltered, and he was driven from office by a combination of parties.

Nationalism and electoral reform. The political climate in Austria was further complicated by the worsening of relations between the Emperor and the Hungarian government. Magyar separatists had agitated for the separation of the Habsburg army, and when Francis Joseph used an address to the troops at Chlopy in 1903 for an unequivocal reaffirmation of the common and unified character of his army, a controversy developed that had repercussions in the Austrian half of the Dual Monarchy. The plan to use universal suffrage to break the opposition in Hungary furthered the cause of political democracy in Austria. The demand for universal and equal suffrage had increased since the Russian revolution in the winter of 1905; after Koerber's Cabinet had run aground over a minor financial matter toward the end of 1904, Gautsch was chosen by the Emperor to introduce universal franchise in Austria. Though the first bill, introduced to parliament by Gautsch in February 1906, ran into the opposition of the middle-class and conservative parties that still controlled parliament, the realization of this program could no longer be blocked. Imperial interest and popular pressure—the Social Democrats had organized mass rallies to support the bill—combined to overcome parliamentarian opposition. After Gautsch had resigned in March 1906 and Prince Conrad von Hohenlohe-Schillingsfürst had failed to master the situation, Max Wladimir, Freiherr von Beck (prime minister from June 1906), managed to carry the bill through parliament. In January 1907 Francis Joseph sanctioned the law giving the vote to every male of 24 or over and abolished the *curiae.* Membership of the Reichsrat was increased from 425 to 516; the returns of the election of 1907 made the Germans now inescapably a minority, with 233 members, though certainly the strongest national group. The Czechs could count on 107 seats, the Poles 82, the Ruthenians 33, the Slovenes 24, the Italians 19, the Serbo-Croats 13, and the Romanians 5.

Universal suffrage

Universal suffrage brought the expected decline of the chauvinistic parties. The Young Czechs as well as the Pan-Germans were reduced to small factions without parliamentarian influence, whereas the Christian Socialists and the Social Democrats returned as the two strongest parties out of more than 30 represented in parliament; the Socialist delegation in the Austrian parliament was, in fact, larger than in any other country. The Austrian constitution, however, did not force the emperor to form

his government according to the composition of the parliament. Neither the Social Democrats nor the Christian Socialists were able to acquire any significant influence on the shaping of Austrian government affairs.

Beck remained in office and satisfied the Christian Socialists with some concessions but for the most part based his policy on the support of the conservative parties. In 1905 the diet of Moravia had succeeded in finding a compromise between German and Czech national demands, and it was hoped a similar compromise could be achieved for Bohemia. But, within a short time, national conflicts got the upper hand again, and parliamentary debate and public opinion were once more excited by national strife. In 1908, however, international complications diverted attention from domestic affairs.

Foreign policy, 1878–1908. *The alliances.* The occupation of Bosnia and Hercegovina in 1878 had reasserted Habsburg interests in Balkan affairs. Facing the possibility of conflict with Russia in this area, Austria-Hungary looked for an ally, with the result that in 1879 Austria-Hungary and the German Reich had joined in the Dual Alliance, by which the two sovereigns promised each other mutual support in the case of Russian aggression. The signing of the Dual Alliance was Andrássy's last act as foreign minister, for he resigned shortly afterward, but the alliance survived as the main element in the international position of the Habsburg monarchy until the very last day of the empire. Under Andrássy's successors—Heinrich, Freiherr von Haymerle, and Kálnoky—Habsburg foreign policy continued its conservative course.

In 1881 an alliance with Serbia, which after the Congress of Berlin turned to Austria-Hungary for protection, made this Balkan state a satellite of the Habsburg monarchy.

The Three Emperors' Alliance of 1881

The Three Emperors' Alliance (Russia, Germany, Austria-Hungary) of the same year brought Russian recognition of Habsburg predominance in the western part of the Balkan peninsula. The signatories of this alliance promised to consult one another on any changes in the status quo in the Ottoman Empire, and, while Russia was given assurances that its position regarding the Straits and Bulgaria would be recognized, Austria-Hungary received from Russia the promise that there would be no objection to a possible annexation of Bosnia-Hercegovina in the future.

The Three Emperors' Alliance was an important element in the structure of alliances that Bismarck set up to stabilize the European continent. Having decided to rely on Austria-Hungary as the fundamental partner in international affairs, Bismarck had to endeavour to neutralize all the areas in which the Habsburg monarchy might possibly be drawn into a conflict. It was essential to avoid being involved in a controversy at an inopportune moment and in a region of little interest to Germany. Bismarck therefore attempted to lessen the possibility of a conflict between Austria-Hungary and Russia by making them partners in the Three Emperors' Alliance. And when, in 1882, Italy approached Germany to find a partner in its anti-French policy, Bismarck used the opportunity to neutralize another European trouble spot. He informed the Italian foreign minister that the road to Berlin led through

The Triple Alliance

Vienna, with the result that the Triple Alliance (Italy, Germany, Austria-Hungary) was signed in May 1882. It was primarily a defensive treaty against a French attack on Italy or Germany. It further stated that, in the event of any signatory coming to war with another power, the partners of the alliance would remain neutral. The treaty did not settle the problems still existing between the Habsburg monarchy and the Italian kingdom, but for Bismarck it sufficed that they were neutralized.

In 1883 Bismarck acted once more to reduce the danger of war in "Europe's backyard" by arranging a defensive agreement between Austria-Hungary and Romania. The Triple Alliance and the Romanian Alliance not only strengthened the international status quo but also gave security to the internal order of the Habsburg monarchy by weakening the irredentist movements in Transylvania and the Italian parts of Austria-Hungary.

The deterioration of German–French relations in the following years convinced Bismarck of the indispensability of the Triple Alliance, and he made every effort to force Vienna to renew the alliance in 1887. By threatening to withdraw protection against Russian aggression, Bismarck forced Kálnoky to consent to his demands, but there can be no doubt that Austria-Hungary was clearly impeded in its national interests by having to adapt its foreign policy to the German and Italian demand for the isolation of France. Although Kálnoky succeeded during the negotiations in avoiding any new obligation in western Europe, he was less successful in defending more immediate Austrian interests. He managed to evade the Italian request for the support of an active Italian colonial policy, but he was unable to keep Italy out of involvement in Balkan affairs. It might be that in view of his own conservative and defensive policy he saw an advantage in having Italy as a third partner in the maintenance of the status quo against possible Russian expansion. At any rate, it was on Kálnoky's initiative that the original Italian demand for a declaration in favour of the status quo along the Ottoman coasts and the Adriatic and Aegean seas was extended to the interior of the Balkan peninsula.

Kálnoky's Balkan policy

On top of this Kálnoky granted the Italians the right to ask for compensation in case of any change in the territorial status quo without defining this term. In a certain way, all the differences and clashes between Austrian and Italian Balkan policy in the first decade of the 20th century can be traced to the introduction of this clause (later formulated in article VII of the treaty) at the renewal of 1887. In the same year, Bismarck built around the Triple Alliance a system of alliances and agreements which amounted to complete isolation of France and obliged the major European powers to guarantee the status quo along the borders of the Ottoman Empire. The First and Second Mediterranean Agreements of 1887 joined Great Britain to the powers (Austria and Italy) interested in blocking Russia from the Straits, and enabled Kálnoky to abandon direct agreements with Russia. The Three Emperors' Alliance of 1881 was allowed to expire, and Austria-Hungary was thus left without any formal understanding with Russia. Count Agenor Gołuchowski, who followed Kálnoky as foreign minister in 1895, decided, however, that direct relations with St. Petersburg should be renewed. In April 1897, Francis Joseph and Gołuchowski visited St. Petersburg. The agreements signed as a result of this initiative aimed at excluding Italy from Balkan affairs and sought to entrust preservation of the Balkan order to the bilateral cooperation of the two eastern monarchies rather than to a multilateral alliance system. The final years of the 19th century were marked by a change from static continental policy to a more dynamic world policy, and the ensuing mobility in international relations reduced the value of the Triple Alliance.

The Bosnian crisis. The Austro-Russian agreements of 1897 came to bear when, in 1903, a major revolt occurred in Macedonia. Following a meeting of Tsar Nicholas II and Francis Joseph in October 1903, their foreign ministers drafted a reform program for the Ottoman Empire. A mutual neutrality agreement was added the following year, leaving Austria-Hungary a free hand in the event of a conflict with Italy and enabling Russia to turn and face Japan. Explicitly excluded from the agreement with Russia were Balkan conflicts. When King Alexander of Serbia was assassinated in a military revolt in 1903 and the Obrenović dynasty was replaced by the Karageorgević, Serbian relations with the Habsburg monarchy deteriorated. The Serbs adopted an expansionist policy of unifying all southern Slavs in the Serbian kingdom, and, in order to block a Serbian advance, the Habsburg monarchy applied economic pressure. In 1906 all livestock imports from Serbia into the Habsburg monarchy were prohibited. This conflict, the so-called Pig War, did not crush Serbia but rather pushed it into the Russian camp.

When, in 1906, Count Gołuchowski was replaced as foreign minister by the former ambassador to St. Petersburg, Alois, Freiherr Lexa von Aehrenthal, a turning point in Austrian foreign policy was signalled. Aehrenthal made a belated effort to free Austria-Hungary from its submission to German interests and to engage in a dynamic Balkan policy. A first step in this direction was his proposal for the construction of a railroad through the Sandjak of

Novi Pazar. The combined Russian and Serbian opposition forced Aehrenthal to abandon the project temporarily and made it clear that any advance in the Balkans would probably result in war with Serbia and perhaps with Russia as well. The danger of such a conflict arose within a short time. In July 1908, following a revolution in Turkey, the Young Turk movement announced the reform of the Turkish constitution. Afraid that this constitutional change could undermine the Habsburg position in Bosnia and Hercegovina, two provinces that nominally were still under Ottoman suzerainty, Aehrenthal decided to use the opportunity to fortify the Austro-Hungarian position in the Balkan peninsula. In September 1908, he met with the Russian foreign minister, Count A.P. Izvolsky, and secured, so he thought, Russian approval of the proposed annexation in return for Austria's support in having the Straits opened to Russian warships. On October 6, 1908, the annexation was announced, immediately bringing a violent reaction from Serbia. When Izvolsky found that his plans for the Straits were opposed by Great Britain and France, he retracted his tentative support of Austria and supported the Serbian position. The situation became serious, and for a while war seemed imminent. Franz, Freiherr Conrad von Hötzendorf, the chief of the general staff of the Habsburg monarchy, who had long advocated preventive war, pushed for an aggressive move, but Aehrenthal had apparently never planned more than going to the brink of war. In March 1909, a German ultimatum forced the Russians to withdraw their support from Serbia, and, since the Turkish government had agreed to the annexation of the two provinces in return for a monetary compensation, Serbia also had to come to terms with the Habsburg monarchy. The Bosnian crisis was settled, but the Serbians felt their national pride deeply wounded and continued to stir unrest in the southern Slav provinces of the Habsburg monarchy.

Annexation of Bosnia and Hercegovina

The last years of peace. *Conflicts of nationality.* The annexation crisis had repercussions among the other Slav nationalities in the monarchy. For several years, Czechs had been attracted by the Pan-Slav movement, and in July 1908 a Pan-Slav congress was held in Prague. During the diplomatic crisis of the following winter, the Czechs unabashedly took the side of the Serbs, and, on the day of the 60th anniversary of Francis Joseph's accession to the throne, martial law had to be declared in Prague. National strife broke out once more all over the monarchy, and parliamentary activities were all but blocked by filibustering and the riotous activities of the deputies. Prime Minister Beck had resigned in November 1908; and his successor, Richard, Freiherr von Bienerth, after having accomplished little with a cabinet of civil servants, tried to appease the nationalities by including *Landsmannminister* (national representatives) into his Cabinet (February 1909).

Obstruction in parliament continued. The Germans, in control of the government and the central administration, continued to assign to the monarchy the role of an outpost of German culture; the Slavs, however, increasingly wanted to make Austria the home of Slav national aspirations. The Czech agrarian leader František Udržal stated in parliament: "We wish to save the Austrian parliament but we wish to save it for the Slavs of Austria who form two-thirds of the population." A population census taken in 1910 confirmed the Slav claim: out of the 28,324,940 inhabitants of the western half of the Austro-Hungarian Empire, only 35.58 percent regarded themselves as German; 17.77 percent Poles; 12.58 percent Ruthenians; 23.02 percent Czechs and Slovaks; 4.48 percent Slovenes; 2.8 percent Serbs and Croats; and 2.75 percent Italians. The Slav predominance was weakened by the attitude of the Poles, who remained loyal to the central government, thus allowing the national conflict to assume the character of a primarily Czech–German quarrel. Even the Social Democratic Party could not overcome nationalist antagonism. In 1899, at the party congress at Brünn, the Social Democrats had presented a national reform program based on democratic federalism, granting the right of national decisions to territorial units formed on a basis of nationality. Karl Renner and Otto Bauer, who later became leaders of German–Austrian Socialism, drafted various programs for the solution of the nationality problem in books published between 1900 and 1910. But these efforts could not prevent the Socialists from splitting along national lines, too, and in 1910 the Czech Socialists declared themselves independent of the Austro-German Socialist Party.

National composition of the empire in 1910

Party rivalries. Such national differences weakened the Socialist position in the elections of 1911. Over 50 parties had competed in the campaign, and, since the German nationalist parties had allied in the Deutscher Nationalverband, they managed to return to parliament as the strongest single party, gaining 104 seats out of 516. The Christian Socialists, weakened by personal rivalry, suffered heavy losses, winning only 76 seats. The German Social Democrats received 44 seats and the Czech Socialists 24. The Czech parties were badly divided, those representing the Czech middle class gaining 64 seats. Bienerth found himself unable to form a workable ministry, and he was replaced by Gautsch, who tried to reconcile the Germans and the Czechs. For a while negotiations seemed quite successful, but extremist incidents deadlocked the talks, and the Gautsch Cabinet was replaced by a new ministry headed by Karl, Graf von Stürgkh (November 1911). Unable to deal with the nationality problem in a parliamentarian fashion, Stürgkh repeatedly suspended the Reichsrat. It was characteristic of the general political climate in Europe that Stürgkh had to concentrate his legislative program on the improvement of Austrian armament, for international crises overshadowed the nationality conflict.

Stürgkh's suspensions of the Reichsrat

Conflict with Serbia. Ever since the Bosnian crisis of 1909, Austrian diplomats had been convinced that war with Serbia was bound to come. Aehrenthal had fallen sick soon after the annexation of Bosnia and Hercegovina, and after a long illness he died (February 1912), at a moment when an Italian–Turkish conflict over Tripoli had provoked anti-Turkish sentiment in the Balkan states. Leopold, Graf Berchtold, who directed Austro-Hungarian foreign policy from 1912 on, did not possess the qualities required in such a critical period. Aehrenthal had been able to silence the warmongering activities of Conrad, who continued to advocate preventive war against Italy and Serbia, but Berchtold yielded to the aggressive policies of the military and the younger members of his ministry. During the Balkan Wars (1912–13), fought by the Balkan states over the remnants of the Ottoman Empire, Austria-Hungary twice tried to force Serbia to retract from positions gained by threatening it with an ultimatum. In February and October 1913, military action against Serbia was contemplated, but in both instances neither Italy nor Germany was willing to guarantee support. Austria-Hungary had to acquiesce in the territorial changes in the Balkan peninsula, changes that eliminated the Turks from Europe. By supporting Bulgaria against Serbia, Austria-Hungary alienated Romania, which country had shown resentment against the Habsburg monarchy because of the treatment of non-Magyar nationalities in Hungary. Romania thus joined Italy and Serbia in support of irredentist movements inside the Habsburg monarchy. By 1914, leading government circles in Vienna were convinced that offensive action against the foreign protagonists of irredentist claims was essential to the integrity of the empire.

The assassination of Francis Ferdinand

In June 1914, Archduke Francis Ferdinand, the heir of Francis Joseph, participated in army manoeuvres in the provinces of Bosnia-Hercegovina, disregarding warnings that his visit would arouse considerable hostility. When Francis Ferdinand and his wife were assassinated by a Bosnian nationalist at Sarajevo on June 28, 1914, the Austro-Hungarian foreign office decided to use the opportunity for a final reckoning with the Serbian danger. The support of Germany was sought and received, and the Austro-Hungarian foreign office proceeded to draft an ultimatum putting the responsibility for the assassination on the Serbian government and demanding full satisfaction. The attitude of the foreign office was shared by Conrad and by Stürgkh but was opposed by the Hungarian prime minister, Count István Tisza, who wanted an assurance that a military move against Serbia would not result in territorial acquisitions and thus increase the Serb element in the monarchy. His demand satisfied, Tisza joined the advocates of war. In ministerial meetings on

Peoples of Austria-Hungary in 1914.
Adapted from W. Shepherd, *Historical Atlas;* Barnes & Noble Books, New York

July 15 and 19, a deliberately provocative ultimatum was drafted in words that supposedly excluded the possibility of acceptance by Serbia. The ultimatum was handed to the Serbian government on July 23. The Serbian answer, handed in on time on July 25, was declared as being insufficient, though Serbia had agreed to practically all Austro-Hungarian demands with the exception of two that, in effect, entailed constitutional changes in the Serbian government. These were that certain unnamed Serbian officials be dismissed at the whim of Austria-Hungary and that Austro-Hungarian officials participate, on Serbian soil, in the suppression of organizations hostile to Austria-Hungary and in the judicial proceedings against their members. In its reply, the Serbian government pointed out that such demands were unprecedented in relations between sovereign states but nevertheless agreed to submit the matter to the Permanent Court of Arbitration or to the arbitration of the great powers. On receiving this reply, the Austro-Hungarian ambassador immediately left Belgrade, severing diplomatic relations between the two countries. Berchtold and his government were clearly determined to make war on Serbia, regardless of the fact that such action might result in war between the great powers. While the European governments frantically tried to offer compromise solutions, Austria decided on a *fait accompli.* On July 28, 1914, Berchtold asked Emperor Francis Joseph to sign the declaration of war, informing him that

> it cannot be excluded that the [Triple] Entente powers [Russia, France, Great Britain] might make another move to bring about a peaceful settlement of the conflict unless a declaration of war establishes a fait accompli [*eine klare Situation geschaffen*].

In the meantime the German government had taken control of the situation and, placing German strategic and national plans over Austro-Hungarian interests, had changed the Balkan conflict into a Continental war.

World War I. *Subordination to Germany.* The German declaration of war against France and Russia subordinated the Austro-Serbian conflict to the German aim of settling its own rivalries with France and Russia. According to the terms of the military agreement between Germany and Austria-Hungary, the Austro-Hungarian army had to abandon plans to conquer Serbia and instead protect the German invasion of France against Russian intervention. The setbacks that the Austrian army suffered in 1914 and 1915 can be attributed, to a large extent, to the fact that Austria-Hungary became a military satellite of Germany from the very first day of the war, though it cannot be denied that the Austrian high command proved to be quite incompetent. Conrad had clamoured for preventive war since 1906, but, when he received his chance, in July 1914, it turned out that the Austrian army had no plans for an expeditious offensive. Similarly, after Italy entered the war on the side of the Allies in May 1915, Conrad was unprepared. The fact that only after the Germans had taken command could the Russian front be stabilized and that Serbia and Romania were not defeated until 1915 and 1916, respectively, did little to enhance the prestige of the Austrian government.

Internal disintegration. In July 1914, parliament had been out of session, and Stürgkh had refused to convene it. This and the military censorship that was established immediately after the outbreak of the war concealed the discontent of the non-German population. While German public opinion in Austria had welcomed the war enthusiastically, and while some Polish leaders supported the war out of their anti-Russian resentment, the Czech population openly showed its animosity. The Czech leader Tomáš Garrigue Masaryk, who had acted as one of the most prominent spokesmen for the Czech cause, emigrated to western Europe. Karel Kramář, who had supported the Pan-Slav idea, was put on trial for high treason and declared guilty on the basis of shaky evidence. German nationalism was riding high, but in reality the German Austrians had little influence left. In military matters, they were practically reduced to executing German orders; in economic affairs, the Hungarians, who controlled the food supply, had the decisive influence. Count Tisza, who had opposed the war in July 1914, became the strong man of the empire. On his advice, Berchtold was dismissed in January 1915, and the foreign office was once again entrusted to a Magyar. But Count István Burián, who was

in charge of foreign affairs until December 1916, failed to keep Italy and Romania out of the war. German attempts to pacify the two states by concessions were unsuccessful, because Francis Joseph was unwilling to cede any territory in response to the irredentist demands of the two nations. How little the outward calm in the Habsburg lands corresponded to the sentiment of the population became apparent when Stürgkh was assassinated by Friedrich Adler, the pacifist son of the leader of Austrian Socialism, in October 1916. Francis Joseph made Ernst Koerber prime minister, but Koerber had no chance to develop a program of his own. On November 21, 1916, Francis Joseph died, at the age of 86, leaving the throne and the shaky empire to his 29-year-old grandnephew, Charles, who had had little preparation for his task until the death of Francis Ferdinand had made him the heir apparent. Full of the best intentions, Charles set out to save the monarchy by searching for peace in foreign affairs and by recognizing the rights of the non-German and non-Magyar nationalities of his empire. Charles relied heavily on the advice of politicians who had had the confidence of Francis Ferdinand. He dismissed Koerber in December 1916 and made Count Heinrich Clam-Martinic, a Czech aristocrat, prime minister. At the foreign office, he replaced Burián with Ottokar, Graf Czernin.

Assassination of Stürgkh

When parliament was reconvened in May 1917, it became manifest how far internal disintegration of the Habsburg monarchy had progressed. Parliament once again became the stage of unrelenting national conflicts. Finding so little support from the Czech side, Charles turned back to the German element, and in June 1917 made Ernst von Seidler, once his tutor in administrative and international law, prime minister. But, even though he tried to appease the Czechs, the stubborn insistence of the Germans not to yield any of their prerogatives made reform of the empire impossible.

Early peace feelers

At the same time, various moves to get Austria-Hungary out of the war ended in failure. After a U.S. offer of general mediation had miscarried in December 1916, Charles tried through secret channels to deal directly with the Entente powers. In the spring of 1917, an exchange of peace feelers took place through the mediation of his brother-in-law, Sixtus of Bourbon-Parma, but Italy's unwillingness to abandon some of the concessions granted to it in the Treaty of London (1915) made these talks abortive. Similarly, negotiations with Allied representatives carried on in Switzerland brought no results.

Since the Austro-Hungarian government was unable to extricate itself from the ties of the Dual Alliance, France and England ceased to have regard for the integrity of the Habsburg monarchy. Furthermore, the revolutionary events in Russia in 1917 and the entry of the United States into the war introduced a new, ideological element into Allied policy toward the Central Powers. The German-directed governments represented an authoritarian system of government, and national agitation in the Habsburg monarchy henceforth assumed the character of a democratic liberation movement, winning the sympathies of west European and American public opinion. From early 1918 on, the Allied governments began officially to promote the activities of the emigrés from Austria, foremost among them Tomáš Masaryk, the Czech leader, and in April 1918 a Congress of Oppressed Nationalities was organized in Rome. But the collapse of the Habsburg monarchy cannot be ascribed to the new Allied policy of supporting the independence claims of the Habsburg nationalities, which was only a belated adjustment to the changed conditions within Austria-Hungary. From the summer of 1917, the activities of the nationalist movements within the empire made the situation increasingly untenable, and, two days before U.S. Pres. Woodrow Wilson proclaimed his Fourteen Points, one of which demanded the reorganization of the Habsburg monarchy in accordance with the principles of national autonomy, the Czechs demanded outright independence (January 6, 1918). Within a month, Polish and South Slav deputies, together with the Czechs, presented to the Reichsrat a program demanding the establishment of independent constituent assemblies for nationally homogeneous areas.

The end of the Habsburg Empire. During the same period in which the national-independence movement reached its final stage, another dangerous development manifested itself. From 1915 on, the supply situation had worsened increasingly, and by January 1918 there were dangerous shortages, especially of food. Prompted by the difficult food situation and inspired by the Bolshevik victory in Russia, a strike movement developed. Demands for more bread and a demand for peace were combined with nationalist claims into open opposition to the government. The strikes among the civilian population were followed by mutinies in the army and navy. In January and February 1918, however, the army and the government succeeded in suppressing social unrest and antiwar demonstrations. But, from the same date, the national opposition movement gathered momentum.

Strikes, mutinies, and demonstrations

The hopes that the government had placed in peace settlements with the eastern states were not fulfilled, either. The peace treaty with the Ukraine (signed in February 1918), the Treaty of Brest-Litovsk with Soviet Russia (March 3, 1918), and the Treaty of Bucharest, which settled the peace with Romania (May 7, 1918), did not alleviate the supply situation and irritated the Poles because of certain provisions of the Ukrainian settlement.

In April 1918, Czernin was replaced as foreign minister by Burián. This change was the result of a conflict between Czernin and Charles over the desirability and possibility of Austria's concluding a separate peace with the Allies. Unknown to Czernin, Charles had in 1917 made certain secret overtures to the Allies, which were revealed by French premier Georges Clemenceau. The Germans were outraged, and Czernin was dismissed on their orders. Burián returned to the foreign office on April 16 and immediately reported to the German high command at Spa, where Emperor Charles and Burián had to assure the German Emperor of their unchanging loyalty. While this act of submission satisfied the German Austrians, it further incensed the Slav opposition. In May 1918 a Slav national celebration in Prague demonstrated the strength of the independence movements. But the Emperor and the German elements in the central government were still not aware of the extent of the disintegration. In July 1918, Prime Minister Seidler resigned, and his successor, Max Hussarek von Heinlein, began a belated effort to reorganize the Habsburg monarchy. Hussarek's efforts to federalize the empire in the moment of imminent military defeat unintentionally turned out to provide the basis for the formal liquidation of the Habsburg monarchy. On October 16, 1918, Emperor Charles issued a manifesto announcing the transformation of Austria into a federal union of four components (German, Czech, South Slav, and Ukrainian). The Poles were to be free to join a Polish state, and Trieste was to be given a special status. The lands of the Hungarian crown were to be excepted from this program. Within a few days, national councils were established in all the provinces of the empire and for all practical purposes acted as national governments. The Poles proclaimed the union of all Poles in a unified state and declared their independence at Warsaw on October 7, 1918. The South Slavs advocated union with Serbia, and on October 28, 1918, the Czechs proclaimed the establishment of an independent republic. The dissolution of the Habsburg monarchy was thus consummated by the end of October 1918—that is, before the war actually ended.

Belated attempts at reform

It was impossible for the country to survive another winter of hostilities, and on September 14, 1918, Burián published an appeal to all belligerents to discuss the possibilities of ending the war. When this move was opposed by the Germans as well as by the Allied powers, Burián tried for a separate peace settlement for Austria-Hungary. On October 14, 1918, he sent a note to President Wilson asking for an armistice on the basis of the Fourteen Points. On October 18, 1918, U.S. Secretary of State Robert Lansing replied that, in view of the political development of the preceding months and, especially, in view of the fact that Czechoslovakia had been recognized as being at war with the Central Powers, the U.S. government was unable to deal on the basis of the Fourteen Points anymore. On October 27, 1918, Count Gyula Andrássy, who had re-

placed Burián three days before as foreign minister, sent a new note to President Wilson; in asking for an armistice, he declared full adherence to the statements set forth in the U.S. note of October 18, thus explicitly recognizing the existence of an independent Czechoslovak state. From this moment on, it remained only to liquidate the war. On October 22, 1918, Heinrich Lammasch, a renowned authority in the field of international law and a respected pacifist, formed a new Cabinet. He hoped to save the Habsburg monarchy by drawing up a federative structure. But instead of saving the state, he found himself charged with the task of supervising the dissolution of the empire and bringing about an orderly transfer of power. The government could not influence events outside of Vienna anymore and from October 30, 1918, was even challenged in the central agencies by the German-Austrian state council. The hostilities were ended by an armistice signed on November 3, 1918. The Austro-Hungarian high command, which had blundered into the war unprepared in 1914, did little better at its conclusion. Due to inaccuracies in the wording of the documents, more than 300,000 soldiers were taken prisoner by the Italian army. For some days the government hoped that, in spite of the secession of the Slav areas, the Habsburg dynasty could survive in the remaining lands. But even the German Austrians had lost faith in the Habsburgs, and, with revolutionary agitation on the rise and republican passion widespread, Charles adhered to the advice of Lammasch and decided to waive his rights to exercise political authority. On November 11, 1918, he issued a proclamation acknowledging "in advance the decision to be taken by German Austria" and stating that he relinquished all part in the administration of the state. The declaration of November 11, 1918, marks the formal act of dissolution of the Habsburg monarchy.

THE FIRST REPUBLIC AND THE ANSCHLUSS

The war's aftermath. On October 21, 1918, the 210 German members of the imperial parliament (Reichsrat) of Austria formed themselves into a national assembly for Deutschösterreich, or German-Austria; and on October 30 they proclaimed this an independent state under the direction of a State Council (Staatsrat) composed of the leaders of the three main parties and other elected members. Revolutionary disturbances in Vienna and, more important, the news of the German revolution forced the State Council on the republican path. On November 12, the day after the emperor Charles's abdication, the National Assembly resolved unanimously that "German-Austria is a democratic republic" and "German-Austria is a component part of the German republic." Karl Renner, a leading Socialist, became head of a coalition government, with Otto Bauer, the acknowledged spokesman of the left wing of the Social Democrats, as foreign secretary. On November 22, the territory of the republic was further defined: the National Assembly claimed for the new state all the Habsburg lands in which a majority of the population was German. It also claimed the German areas of Bohemia and Moravia.

Dangers of a Communist revolution

From the first day, the republic was faced with the disastrous heritage of the war. Four years of war effort and the breakup of the Habsburg Empire had brought economic exhaustion and chaos. The resulting social distress and poverty inspired revolutionary activities, thus making Bolshevism appear the greatest danger to the new republic, especially after a Soviet republic was established in Hungary at the end of March 1919. The Austrian Social Democrats were determined to resist Bolshevism with their own forces without making an alliance (as the German Social Democrats did) with the old order. A Volkswehr (People's Guard) was organized and was twice effective (April 17 and June 15) against Communist attempts at a *Putsch.* Otto Bauer and Friedrich Adler staked their popularity on defeating the Communist agitation in the workers' and soldiers' councils, which had been set up on the Soviet model. By mid-1919, political and social order was restored on parliamentary lines, the Communist Party relapsing into insignificance. More dangerous was the tendency of the *Länder* (provinces, or states) to break away from Vienna or to claim almost complete independence. Though the principal motive of this was reluctance to send food supplies to Vienna, it also represented a genuine social, political, and ideological conflict: the administration of the industrialized capital was Socialist controlled, while the *Länder,* being predominantly agrarian, remained conservative and faithful to the Catholic tradition. This difference was aggravated by the fact that the monarchy had been the only bond between the German Austrian lands; with the abdication of the Emperor, no symbol of loyalty common to all *Länder* remained. Vorarlberg voted for union with Switzerland in May 1919, and Tirol also attempted to secede.

The constitutional settlement. In February 1919, elections for a constitutional assembly were held. The Social Democrats were returned as the largest single party, with 69 seats. Sixty-three were won by the Christian Socialists and 26 by the German Nationalists. When this assembly met (March 4), it had to make wide concessions to federalism in order to appease the provinces. In exchange, Vienna was also elevated to the rank of a state and the mayor made the equivalent of a state governor. This proviso subsequently enabled "Red Vienna" to pursue an autonomous policy, despite the fact that the *Bundesregierung* ("federal government") was controlled by the conservative parties from 1920 to 1934.

Autonomy of Vienna

The constituent assembly also settled the constitution of the federal republic (October 1, 1920). The State Council was abolished, and a bicameral legislative assembly, the Bundesversammlung, was established. The Bundesrat (upper house) was to exercise only a suspensive veto and was to be elected roughly in proportion to the population in each state. This represented a defeat for the federal elements in the states, which had wanted the Bundesrat to exercise an absolute veto and to be composed of equal numbers of members from each state. The lower house, or Nationalrat, was to be elected by universal suffrage on a basis of proportional representation. The Bundesversammlung in full session elected the president of the republic for a four-year term, but the federal government, with the chancellor at its head, was elected in the Nationalrat on a motion submitted by its principal committee; this committee was itself representative of the proportions of the parties in the house.

The foreign policy of Otto Bauer and representatives of the major political parties had insisted firmly on *Anschluss* ("union") with Germany, and as late as 1921 unauthorized plebiscites held in the western provinces returned overwhelming majorities in favour of union with Germany. But article 88 of the peace treaty of Saint-Germain, signed on September 10, 1919, forbade *Anschluss* without the consent of the League of Nations and also stipulated that the republic should cease to call itself Deutschösterreich (German-Austria); it became the Republik Österreich. The Austrian claim for the German-speaking areas of Bohemia and Moravia was denied by the peace conference, and Austria had to recognize the frontiers of Czechoslovakia along slightly rectified historical administrative lines. The southern frontier with Yugoslavia was threatened by Yugoslav armed invasion, and it was finally decided that the question should be settled by a plebiscite, which, on October 10, 1920, returned a majority of 59 percent in favour of Austria. The German-speaking districts of western Hungary were to be ceded to Austria outright; but Austria, in the face of Hungarian resistance, was obliged to hold a plebiscite. The area of Sopron was finally restored to Hungary.

After the elections of February 1919, Renner formed another coalition government, but after a government crisis in the summer of 1920 a caretaker cabinet under the Christian Socialist Michael Mayr was formed. This government prepared the draft of the constitution and introduced it into parliament. After its approval, new elections were held, on October 17, 1920. The Christian Socialists were returned as the strongest party, gaining 82 seats, while the Social Democrats were reduced to 66 and the German Nationalists to 20. Mayr formed a new cabinet composed of Christian Socialists; the Social Democrats went into opposition and never returned to the government throughout the First Republic. This political division hardened, and no decisive change took place during the following years.

Christian Socialist electoral victory (1920)

The system of proportional representation combined with the ideological background of Austrian parties made oscillations of political allegiance unlikely. Of the two mass parties, the Social Democrats had an unshakable majority in Vienna (in which about a third of all the inhabitants of the republic lived), while the Christian Socialists had an equally secure majority among the Catholic peasants and the conservative classes, the latter consisting largely of army officers, landowners, and big business. The urban middle classes, hostile to both workers and peasants, became German nationalists. But German nationalism was not limited to the middle classes. The workers and even the peasants felt themselves to be Germans and also responded to the national appeal.

Economic reconstruction. The main task of the non-Socialist governments in power in Austria from the autumn of 1920 on was to restore financial and economic stability. Between 1919 and 1921, the urban population of Austria lived largely on relief from the United States and Great Britain, and, although production improved, distress was heightened by inflation that threatened financial collapse in 1922. In October 1922, the chancellor, Ignaz Seipel, secured a large loan through the instrumentality of the League of Nations, enabling Austrian finances to be stabilized. In return, Austria had to undertake to remain independent for at least 20 years. The controller general appointed by the League of Nations reported in December 1925 that the the Austrian budget had been balanced satisfactorily, and in March 1926 international financial supervision was withdrawn.

Seipel's success in October 1922 gave Austria some years of stability and made economic reconstruction and relative prosperity possible. In Socialist-controlled Vienna, an ambitious program of working class housing, health schemes, and adult education was carried out under the leadership of Karl Seitz, Hugo Breitner, and Julius Tandler. "Red Vienna" thus acquired a unique reputation in Europe.

Political strife. In 1920 all three major parties spoke in democratic terms. Despite democratic phrases, however, preparations for possible civil war had never been abandoned. The Christian Socialists, led by Seipel, a believer in strong government, were convinced that they had to protect the existing social order against a Marxist revolution. In the provinces, reactionary forces (the Heimwehr, or "home defense forces"), originally formed for defense against the Yugoslavs or merely against international disorder, gradually acquired Fascist tendencies. The Social Democrats felt that their social-reform program was endangered by reaction. They possessed their own armed force, the Schutzbund (Defense League), descended from the People's Guard of 1918, and they and the reactionary forces regularly demonstrated against each other. In 1927, in the course of a clash between members of the Schutzbund and certain reactionary forces at Schattendorf, an old man and a child were accidentally shot by the reactionaries. When the latter were acquitted by a Vienna jury on July 14, the Social Democrats called for a mass demonstration, which got out of hand and ended in the burning down of the ministry of justice. In street fighting between the police and the demonstrators, almost 100 persons were killed. The Social Democrats then launched a general strike, but this had to be called off after four days. Seipel had used the opportunity for a violent assertion of government authority. The balance between Socialist and non-Socialist forces in Austria was never secure after this decisive date.

Emergence of Fascist groups

The Christian Socialists, pressed increasingly by the Heimwehr, now began to take the offensive against the Social Democrats. Wilhelm Miklas, a leading Christian Socialist, was elected president as successor to the non-party Michael Hainisch, who had been in office since December 1920. There were repeated attempts to revise the constitution, principally with the object of strengthening the power of the executive. After protracted negotiations, a compromise was reached late in 1929. On December 7, 1929, a series of constitutional amendments gave increased powers to the president. Of particular importance were the rights to appoint ministers and issue emergency decrees. But Vienna preserved its autonomy, and the democratic principle was preserved against the far-reaching authoritarian demands of the Heimwehr. In the elections of November 1930, the Social Democrats were returned as the largest single party, with 72 seats. The Christian Socialists held 66, the German Nationalists 19, and the Heimwehr, now posing as a Fascist party on the Italian model, 8.

These political events were overshadowed by the great world economic crisis. Though the Social Democratic leaders believed that the crisis should be met by the orthodox means of deflation and spending cuts, they were resolved not to be compromised by supporting these measures and refused to enter a coalition government. On the other hand, in October 1931 they acquiesced in suspending the election of the president by direct popular vote, as had been provided by the constitution of 1929, and agreed to the reelection of Miklas by parliament for a further four years. The government, meanwhile, led by Otto Ender and Johann Schober, was driven to desperate devices in order to stave off collapse. Schober, leader of the middle-class German Nationalists, launched the project for a customs union with Germany in March 1931; this provoked violent opposition from France and the alliance of the Little Entente (Czechoslovakia, Yugoslavia, and Romania) and was subsequently condemned by a majority of the International Court at The Hague. The bankruptcy in May 1931 of the Creditanstalt, the most influential banking house in Austria, brought Austria close to financial and economic disaster. This, together with the rise of the National Socialists in Germany, resulted in considerable support being given to the Nazis in Austria; and the provincial elections in 1932 showed that they were draining off votes from the conservative parties. The Nationalists began to demand a general election, and this demand was taken up by the Social Democrats, who saw a chance of winning a majority in parliament.

Proposed customs union with Germany (1931)

Authoritarianism: Dollfuss and Schuschnigg. After the election, when Engelbert Dollfuss came to form a Christian Socialist government on May 20, 1932, he could count on a majority of only one vote. Dollfuss belonged to a new generation that had been educated in the conservative conviction that the Western form of parliamentary government had been forced upon the central Europeans as a result of military defeat and Socialist revolution and that the political and social order could be restored only by the establishment of some kind of strong authority. The leaders of the Christian Socialist Party found themselves under attack from two ideological enemies, the Marxists and the Nazis, who apparently threatened the very basis of the conservative order. In reaction, Dollfuss determined to replace parliamentary government with an authoritarian system. The opportunity to do this came in March 1933, when, during a debate on a minor bill, an argument arose over alleged irregularities in the voting procedure. The president of the Nationalrat resigned; the two vice presidents followed his example; and Dollfuss declared that parliament had proved unworkable. It never met again in full, and Dollfuss governed thereafter by emergency decree.

The end of parliamentary government

By this time (spring of 1933), Adolf Hitler was in power in Germany, and Nazi propaganda for the incorporation of Austria was greatly increased. Dollfuss turned to Italy for help, convinced that British and French aid would be ineffective. This shift in foreign policy can also be attributed to the fact that Dollfuss had to rely on the help of the anti-Marxist Heimwehr to stay in power.

The Social Democrats were subjected to increasing provocation and on February 12, 1934, took to arms. Civil war followed. After four days of fighting, Dollfuss and the Heimwehr were victorious. The Social Democratic Party was declared illegal and driven underground. In the course of the same year, all political parties were abolished except the Vaterländische Front (Fatherland Front), which Dollfuss had founded in 1933 to unite all conservative groups. In April 1934, the rump of the parliament was brought together and accepted an authoritarian constitution. The executive was given complete control over the legislative branch of government; the elected assemblies disappeared and were replaced by advisory bodies, appointed in a complicated and futile fashion. The rights of man guaranteed

under the democratic constitution were also swept away. "Republic" was removed from the official name of the state, which became merely the Federal State of Austria.

Dollfuss murder

On July 25, 1934, a group of Nazis seized the chancellery and attempted to proclaim a Nazi government. Dollfuss, whom they had taken prisoner, was murdered. The plan, however, miscarried: the Nazis in the chancellery were compelled to surrender, and their leaders were executed; a Nazi rising in Styria was suppressed; and Hitler, faced with the mobilization of an Italian army on the Brenner Pass, repudiated his Austrian followers. Franz von Papen was sent as German ambassador to reduce Austria by other means. Kurt von Schuschnigg, who became chancellor on the death of Dollfuss, was a man of gentler personality and of less violent political passions. His administration of the authoritarian constitution was in the easygoing Austrian fashion, less oppressive than in Italy and Germany. Schuschnigg had a mild preference for restoring the Habsburgs, but he shrank from the international complications that this would involve. The regime drifted on without popular favour, weakened by the personal rivalries and ambitions of its leaders and sustained only by a guarantee from Italy. The temporary accord of Great Britain, France, and Italy in the "Stresa front" (April 1935) seemed to promise new security, but the Ethiopian crisis soon destroyed the unity of the Western powers, and Austria's isolation was complete when Hitler and Mussolini allied themselves in 1936. Schuschnigg had to negotiate a compromise with Germany, which was signed on July 11, 1936; Germany promised to respect Austrian sovereignty, and in return Austria acknowledged itself "a German state." The agreement left Austria open to Nazi infiltration. In January 1938, the Austrian police discovered a new Nazi conspiracy. Schuschnigg hoped to defeat this by a meeting with Hitler, but at Berchtesgaden, where Hitler received him on February 12, 1938, Schuschnigg was faced with threats of military intervention in support of the Austrian Nazis. He had to agree to give them a general amnesty and to include some leading Nazis in his Cabinet; the Ministry of the Interior had to be entrusted to Arthur Seyss-Inquart, the spokesman of Austrian Nazis. The open agitation of the Nazis threatened to destroy the government's authority, and confidential contacts in the European capitals brought Schuschnigg to realize that he could not count on the support of the great powers. He therefore resolved to challenge Hitler alone. On March 9 he announced that a plebiscite would be held on March 13 to decide in favour of Austrian independence.

Anschluss and World War II. Though the Austrian crisis had taken him unaware, Hitler acted with energy and speed. Mussolini's neutrality was assured, there was a ministerial crisis in France, and the British government had made it known for some time that it would not oppose union of Austria with Germany. On March 11, 1938, two peremptory demands were made for the postponement of the plebiscite and for the resignation of Schuschnigg. Schuschnigg gave way, and German troops, accompanied by Hitler himself, entered Austria on March 12. A Nazi government in Austria, headed by Arthur Seyss-Inquart, was established and collaborated with Hitler in proclaiming the *Anschluss* on March 13. France and Great Britain protested against the methods used by Hitler but accepted the *fait accompli,* as did all other governments. A plebiscite on April 10, held throughout greater Germany, recorded a vote of more than 99 percent in favour of Hitler.

The Anschluss

Austria was absorbed into Germany. Immediately after the invasion, the Nazis arrested the leaders of the Austrian political parties, and many Austrians, especially those of Jewish origin, went into exile. But the political antagonism that had previously weakened the status of the republic continued to block cooperation among the émigrés as well as among the resistance groups that formed inside Austria.

The possibility of reestablishing an independent Austria was far from dead, however, and, after the outbreak of World War II the Allied governments began to reconsider their attitude toward the *Anschluss.* In December 1941, Stalin informed the British that the Soviet Union would regard the restoration of an independent Austrian republic as an essential part of the postwar order in central Europe, and, at the meeting of the foreign ministers of Great Britain, the Soviet Union, and the United States in Moscow (October 1943), a declaration was published that declared the union with Germany null and void and pledged the Allies to restore Austrian independence. Though the British prime minister, Winston Churchill, continued to make proposals for setting up a central European federation comprising the former Habsburg lands and even southern Germany, the European Advisory Commission in London assumed that Austria would return to sovereignty within the borders of 1937. When Soviet troops liberated Vienna on April 13, 1945, representatives from the resistance movement and the former political parties were allowed to organize.

THE SECOND REPUBLIC

The Allied occupation. On April 27, 1945, Karl Renner set up a provisional government composed of Social Democrats, Christian Socialists, and Communists and proclaimed the reestablishment of Austria as a democratic republic. The Western powers, afraid that the Renner government might be an instrument of Communist expansion, withheld full recognition until the autumn of 1945. Because of similar suspicions, agreement on the division of Austrian zones of occupation was delayed until July 1945. Shortly before the Potsdam Conference (which stipulated that Austria would not have to pay reparations but assigned the German foreign assets of eastern Austria to the Soviet Union), control machinery was set up for the administration of Austria, giving supreme political and administrative powers to the military commanders of the four occupying armies. In September 1945 a conference of representatives of all provinces extended the authority of the Renner government to all parts of Austria. A general election held in November 1945, in which former Nazis were excluded from voting, returned 85 members of the Austrian People's Party (corresponding to the Christian Socialists of the prewar period), 76 Socialists (corresponding to the Social Democrats and Revolutionary Socialists), and four Communists. Renner was elected president of the republic; Leopold Figl, leader of the Austrian People's Party, became chancellor of a coalition Cabinet. The government decided not to draft a new constitution but to return to the constitution of 1920, as amended by the laws of 1929. In June 1946 the control agreement of July 1945 regulating the machinery of Allied political supervision was modified by restricting Allied interference essentially to constitutional matters. Denazification laws passed in 1946 and 1947 eliminated Nazi influence from the public life of Austria. In the postwar years, the Austrian People's Party and the Socialists were the sole partners in a coalition government that was formed in proportion to the parties' strength in parliament. This principle of proportional representation, originally introduced in 1919, was to be an important factor in Austrian political life after 1945.

General elections of November 1945

From 1945 to 1952, Austria had to struggle for survival. After liberation from Nazi rule, the country faced complete economic chaos. Aid provided by the United Nations Relief and Rehabilitation Administration (UNRRA) and, from 1948, support given by the United States under the Marshall Plan made survival possible. Heavy industry and banking were nationalized in 1946, and, by a series of wage–price agreements, the government tried to control inflation. Interference by military commanders in political and economic affairs in the Soviet zone of occupation caused a considerable migration of capital and industry from Vienna and Lower Austria to the formerly purely agricultural western provinces. This brought about a far-reaching transformation of the economic and social structure of the country. Austria continued to be occupied by U.S., British, French, and Soviet forces until 1955. A treaty restoring Austrian sovereignty was expected early, but the atmosphere of the Cold War made agreement among the former Allied powers impossible. In 1953, however, a heavy burden was removed from the Austrian economy when the Soviet government declared that it would pay its own occupation costs (as the United States had done since 1947). Thereupon, the British and the French followed suit.

In 1949 former Nazis were allowed to participate in the general election. The Union of Independents (later renamed the Freedom Party), corresponding to the former German Nationalist group but free from ideological ties, won 16 seats in parliament. In subsequent elections (1953, 1956, 1959, 1962), the relationship of the three parties remained stable. When Renner died (December 31, 1950) Theodor Körner, the Socialist mayor of Vienna, was elected president of the republic by direct popular vote. He was succeeded in 1957 by the leader of the Socialist Party, Adolf Schärf, followed in 1965 by Franz Jonas, former mayor of Vienna, and in 1974 by Rudolf Kirchschläger, former minister of foreign affairs.

The influence of the Socialists in the coalition government, which had been relatively strong under Leopold Figl's chancellorship, was reduced when the Austrian People's Party replaced Figl with Julius Raab in the spring of 1953 and had Reinhard Kamitz appointed minister of finance. The subsequent economic reconstruction and the advance to a prosperity unknown to Austrians since the years before World War I is generally identified with the so-called Raab–Kamitz course, based on a modified free-market economy. The nationalized steel industry, electrical-power plants, and oil fields, together with the privately owned lumber and textile industries and the tourist traffic, were the major economic assets. The Austrian economy came to be dominated to a disproportionate extent by a trend toward the tertiary sector because of the importance of *Fremdenverkehr* (tourist traffic), which transformed the economic and social character of the rural Alpine areas.

The Raab–Kamitz course

The Berlin conference of the foreign ministers of France, Great Britain, the Soviet Union, and the United States in January 1954 raised Austrian hopes for the conclusion of a peace treaty. For the first time, Austria was admitted as an equal conference partner, but the failure of the foreign ministers to agree on the future of Germany again prejudiced Austria's chances. It appeared that the Soviet government was not prepared to forgo the strategic advantages of maintaining its forces in Austria so long as Germany was not "neutralized." In February 1955 the Soviet government suddenly extended an invitation to the Austrian government for bilateral negotiations. An Austrian delegation visited Moscow in April 1955, and a memorandum was agreed on, according to which the Soviet government declared itself ready to restore full Austrian sovereignty and to evacuate its occupation troops in return for an Austrian promise to declare the country permanently neutral.

Restoration of sovereignty. The treaty was signed in Vienna on May 15, 1955, by the representatives of the four powers and Austria. It formally reestablished the Austrian republic in its pre-1938 frontiers as a "sovereign, independent and democratic state." It prohibited *Anschluss* between Austria and Germany as well as the restoration of the Habsburgs. It guaranteed the rights of the Slovene and Croatian minorities in Carinthia, Styria, and Burgenland. The United Kingdom, the United States, and France relinquished to Austria all property, rights, and interests held or claimed by them as former German assets or war booty. The Soviet Union, however, obtained tangible payment for the restoration of Austrian freedom. This included $150,000,000 for the confiscated former German enterprises, which Austria had to buy back from the Administration of Soviet Property in Austria; $2,000,000 for the confiscated German assets of the First Danube Steamshipping Company; and 10,000,000 metric tons of crude oil as the price of Austrian oil fields and refineries that had been Soviet war booty. The treaty came into force on July 27, 1955, and by October 25 all occupation forces were withdrawn. On October 26 a constitutional law of perpetual Austrian neutrality was promulgated. The Austrian government had never left any doubts that the pledge to neutrality could be interpreted only as a military one and never as an ideological one. Throughout the Soviet occupation, the Austrians had proved their anti-Communist attitude, and the spontaneous reaction of the Austrian people during the suppression of the Hungarian Revolution in 1956 demonstrated their sympathy with Western democratic ideas. Austria preserved political stability; changes in the personal and ideological structure of the government and political parties were effected without major political crisis.

Austrian neutrality

From 1962 disagreement over economic problems generated friction between the coalition parties. The annual budget led to grave disunity in the coalition, and in the autumn of 1965 the government resigned and called new elections. The election, held on March 6, 1966, brought a setback for the Socialist Party, and the People's Party was returned to parliament with an absolute majority. Negotiations for a new coalition government failed. The Socialists, led by a former foreign minister, Bruno Kreisky, went into opposition, and Josef Klaus formed the first one-party Cabinet of the Second Republic. Contrary to widespread misgivings, the political stability of the country was not disturbed, and parliament was given new vigour and influence. In ensuing provincial elections, the Socialist Party demonstrated recovery from the setback of 1966, and in the national elections of 1970 the Socialist Party managed to win a plurality of votes, becoming the strongest party in parliament, with 81 seats, but falling short of a majority. After negotiations for a new coalition Cabinet failed, in May 1970 Bruno Kreisky was appointed chancellor and formed the first Austrian all-Socialist Cabinet. Sensing increased support for the Socialists he called for new elections in October 1971, which gave his party a clear majority of 93 seats. In the subsequent elections of 1975 and 1979 the Austrian voters demonstrated their approval of Kreisky's policy of moderate social reform and economic stability by returning the Socialist Party to parliament in increasing strength: the elections of May 1979 gave the Socialists 95 seats, while the Austrian People's Party, weakened by problems of leadership, received only 77 seats and the Freedom Party only 11. In the elections of 1983 the Socialist Party lost its majority, gaining only 90 seats; it formed a coalition government with the Freedom Party, which won 12 seats.

The stability of Austrian politics is paralleled by an equally stable economy: besides having an elaborate system of social security and health insurance, the Austrians have enjoyed an unbroken prosperity with one of the lowest rates of unemployment in Europe. The Kreisky government carried through a number of reform programs, among which the reorganization of the legal code under the minister of justice, Christian Broda, had truly historical dimensions.

Austria became a member of the United Nations in 1955 and of the Council of Europe in 1956. Major problems of Austrian foreign relations were the conflict with Italy over Südtirol (Bolzano) and the problem of association with the European Economic Community (EEC). During the Paris Peace Conference of 1946 an agreement was signed guaranteeing the rights of the German-speaking population of Südtirol. The Austrian government, claiming that the Italians had not lived up to their obligations, initiated bilateral talks. In the early 1960s, acts of terrorism committed by German-speaking chauvinists interfered with the progress of the negotiations, but in 1969 agreement was finally reached on implementing the guarantees provided in the agreement of 1946. In 1958 Austria joined the European Free Trade Association, but a special arrangement with the European Economic Community, accompanied by prudent dealings with the Socialist neighbours, maintained Austria's status as a neutral nation. For current political history, see the annual issues of the *Britannica Book of the Year*.

Automata Theory

In simple terms an automaton represents a formalization of a set of rules for a computation, and automata theory, which is studied as part of the foundations of mathematics, is used in the building of such machines as all-purpose computers. An example of a typical automaton is a pendulum clock. In such a mechanism the gears can assume only one of a finite number of positions, or states, with each swing of the pendulum. Each state, through the operation of the escapement, determines the next succeeding state, as well as a discrete output, which is displayed as the discrete positions of the hands of the clock. As long as such a clock is wound and its operation is not interfered with, it will continue to operate unaffected by outside influences except the effect of gravity on the pendulum.

More general automata are designed to respond to changes in external conditions or to other inputs. For example, thermostats, automatic pilots of aircraft, missile guidance systems, telephone networks, and controls of certain kinds of automatic elevators are all forms of automata.

The internal states of such devices are not determined solely by their initial state, as is the case of the pendulum clock, but may be determined by an input from a human operator, from another automaton, or by an event or series of events in the environment. A thermostat, for instance, has an "on" or "off" state that depends on the temperature. The best known general automaton is the modern electronic computer, the internal states of which are determined by the data input and which operates to produce a certain output. (B.R./R.J.Ne)

This article is divided into the following sections:

NATURE AND ORIGIN OF MODERN AUTOMATA

The components of automata consist of specific materials and devices, such as wires, transistors, levers, relays, gears, and so forth, and their operation is based on the mechanics and electronics of these parts. The principles of their operation as a sequence of discrete states can, however, be understood independently of the nature or arrangement of their components. In this way, an automaton may be considered, abstractly, as a set of physically unspecified states, inputs, outputs, and rules of operation, and the study of automata as the investigation of what can be accomplished with these. This mode of abstraction yields mathematical systems that in certain respects resemble logical systems. Thus, an automaton can be described as a logically defined entity that can be embodied in the form of a machine, with the term automaton designating both the physical and the logical constructions.

In 1936 an English mathematician, Alan Mathison Turing, in a paper published in the *Proceedings of the London Mathematical Society* ("On Computable Numbers with an Application to the Entscheidungsproblem"), conceived a logical machine the output of which could be used to define a computable number. For the machine, time was considered to be discrete and its internal structure, at a given moment, was described simply as one of a finite set of states. It performed its functions by scanning an unbounded tape divided into squares, each of which either contained specific information in the form of one of a finite number of symbols or was blank. It could scan only one square at a time, and, if in any internal state except one called "passive," it was capable of moving the tape forward or backward one square at a time, erasing a symbol, printing a new symbol if the square was blank, and altering its own internal state. The number it computed was determined by symbols (the "program") provided on a finite portion of the tape and the rules of operation, which included stopping when the passive state was reached. The output number was then interpreted from the symbols remaining on the tape after the machine stopped.

The Turing machine

Automata theory since the middle of the 20th century has been extensively refined and has often found practical application in civilian and military machines. The memory banks of modern computers can store large (though finite) amounts of information. (For further information on computers and their applications, see INFORMATION PROCESSING AND INFORMATION SYSTEMS.) The original Turing machine had no limit to the memory bank because each square on the unbounded tape could hold information. The Turing machine continues to be a standard reference point in basic discussions of automata theory, and many mathematical theorems concerning computability have been proved within the framework of Turing's original proposal.

NEURAL NETS AND AUTOMATA

The finite automata of McCulloch and Pitts. Part of automata theory lying within the area of pure mathematical study is often based on a model of a portion of the nervous system in a living creature and on how that system with its complex of neurons, nerve endings, and synapses (separating gap between neurons) can generate, codify, store, and use information. The "all or none" nature of the threshold of neurons is often referred to in formulating purely logical schemata or in constructing the practical electronic gates of computers. Any physical neuron can be sufficiently excited by an oncoming impulse to fire another impulse into the network of which it forms a part, or else the threshold will not be reached because the stimulus is absent or inadequate. In the latter case, the neuron fails to fire and remains quiescent. When several neurons are connected together, an impulse travelling in a particular part of the network may have several effects. It can inhibit another neuron's ability to release an impulse; it can combine with several other incoming impulses each of which is incapable of exciting a neuron to fire but that, in combination, may provide the threshold stimulus; or the impulse might be confined within a section of the nerve net and travel in a closed loop, in what is called "feedback." Mathematical reasoning about how nerve nets work has been applied to the problem of how feedback in a computing machine can result in an essential ingredient in the calculational process.

Original work on this aspect of automata theory was done by Warren S. McCulloch and Walter Pitts at the Research Laboratory of Electronics at the Massachusetts Institute of Technology starting in the 1940s.

The definitions of various automata as used here are based on the work of two mathematicians, John von Neumann and Stephen Cole Kleene, and the earlier neurophysiological researches of McCulloch and Pitts, which offer a mathematical description of some essential features of a living organism. The neurological model is suggested from studies of the sensory receptor organs, internal neural structure, and effector organs of animals. Certain responses of an animal to stimuli are known by controlled observation, and, since the pioneering work of a Spanish histologist, Santiago Ramón y Cajal, in the latter part of the 19th and early part of the 20th century, many neural structures have been well known. For the purposes of this article, the mathematical description of neural structure, following the neurophysiological description, will be called a "neural net." The net alone and its response to input data are describable in purely mathematical terms.

A neural net may be conveniently described in terms of the kind of geometric configuration that suggests the physical structure of a portion of the brain. The component parts in the geometric form of a neural net are named (after the physically observed structures) neurons. Diagrammatically they could be represented by a circle and a line (together representing the body, or soma, of a physiological neuron) leading to an arrowhead or a solid dot (suggesting an endbulb of a neuron). A neuron may be assumed to have either an excitatory or an inhibitory effect on a succeeding one; and it may possess a threshold, or minimum number of unit messages, so to speak, that must be received from other neurons before it can be activated to fire an impulse. The process of transmission of excitation mimics that which is observed to occur in the nervous system of an animal. Messages of unit excitation are transmitted from one neuron to the next, and excitation is passed along the neural net in quantized form, a neuron either becoming excited or remaining nonexcited, depending on the states (excitatory or quiescent) of neurons whose endbulbs impinge upon it. Specifically, neuron N, with threshold h, will be excited at time t, if and only if h or more neurons whose excitatory endbulbs impinge upon it are excited at time $t-1$ and no neuron whose inhibitory endbulb impinges upon it is excited at time $t-1$. A consistent picture can be made of these conditions only if time and excitation are quantized (or pulsed). It is assumed conventionally that a unit of time is required for the transmission of a message by any neuron.

The neural net

Certain neurons in the configuration mathematically represent the physiological receptors that are excited or left quiescent by the exterior environment. These are called input neurons. Other neurons called output neurons record the logical value, excited or quiescent, of the whole configuration after time delay t and transmit an effect to an exterior environment. All the rest stimulate inner neurons.

Any geometric or logical description of the neural structure of an organism formulated as the basis of physical construction must be sufficiently simple to permit mechanical, electric, or electronic simulation of the neurons and their interconnections.

The basic logical organs. The types of events that can excite the automaton and the kinds of responses that it can make must next be considered. By stripping the description down to the most simple cases, the basic organs from which more complicated robots can be constructed may be discovered. Three basic organs (or elementary automata) are necessary, each corresponding to one of the three logical operations of language: the binary operations of disjunction and conjunction, leading to such propositions as $A \cup B$ (read "A or B"), $A \cap B$ (read "A and B"), and the unary operation of negation or complementation, leading to such propositions as A^c (read "not A" or "complement of A"). First to be considered are the stimulus-response pattern of these elementary automata.

Binary operations of disjunction and conjunction

Assuming that a neuron can be in only one of two possible states—*i.e.*, excited or quiescent—an input neuron at a given instant of time $t-1$ must be either excited or nonexcited by its environment. An environmental message transmitted to two input neurons N_1 and N_2 at time $t-1$ can then be represented numerically in any one of the four following ways, in which binary digit 1 represents excitation and binary digit 0 represents quiescence: (0, 0), (0, 1), (1, 0), (1, 1). The disjunction automaton must be such that a single output neuron M correspondingly registers at time t the response: 0, 1, 1, 1. The conjunction automaton must be such that a single output neuron M correspondingly registers at time t the response: 0, 0, 0, 1. The negation automaton considered as having two input neurons N_1 and N_2, of which N_1 is always excited, must respond to the environmental messages (1, 0) and (1, 1) with 1, 0, respectively, at the output neuron M.

The generalized automaton and Turing's machine. The construction of more complicated robots from these basic building blocks constitutes a large part of the theory of automata. The first step in the direction of generalization is to define the neural nets that correspond to formal expressions in n variables of the propositional calculus—that is, the formal system that concerns "or," "and," "not," and "implies." A single output automaton (of which the above three are simple examples) is a neural net with n input neurons, one output neuron, and with interconnections between neurons that conform to the rule that no neuron stimulated at time t can impinge upon a neuron that could have experienced its first stimulation at the same or an earlier time. The latter rule is the requirement of no feedback. Given this concept of a single output automaton, it is possible to examine the output response at time $t+s$, considered as a function of the configuration of stimuli at the n input neurons at time t. This response can be compared with the truth value of a logical statement (polynomial) from the propositional calculus. A logical statement is formed from n component propositions, each of which can assume the truth value either true or false.

Response of automata and truth value of statements

The comparison between automaton and logical statement is accomplished by matching response at the output neuron at time $t+s$ with truth value of the statement for every one of the 2^n cases in which the configuration of stimuli conforms to the configuration of truth values of the component propositions. If, in this sense of comparison, the functional response of the automaton is identical to the functional value of the logical statement (polynomial), the automaton is then said to compute the statement (polynomial) or the statement is said to be computable. A wider class of computable statements is introduced with the general automaton, yet to be defined, as with the more general Turing machine.

The important distinction between the logical statement and the automaton that computes it is that the first is free of any time ingredient while the second is defined only with reference to a time delay of length s.

A basic theorem states that for any polynomial P of the propositional calculus, there exists a time delay s and a single output automaton A, such that A computes P with time delay s. The proof of the theorem rests on the fact from the propositional calculus that all statements are composed from component propositions with the operations of disjunction, conjunction, and negation and the fact from the automata theory that all single output automata can be composed by interconnecting elementary automata of the disjunctive, conjunctive, and negative types.

A second step of generalization in the construction of robots proceeds from the single output automata to the neural net that possesses more than one output neuron and in which the internal connections may include feedback. Such a construction is called a "general automaton." The class of general automata includes all-purpose, electronic digital computers the memory-storage units of which are of fixed, though possibly of very considerable, size. It is within the context of the general automaton that the purely automated decision-making, computing, controlling, and other sophisticated neural functions so suggestive of the mental ability of human beings may appropriately be discussed.

The Turing machine can be defined not only as it was in the introduction (roughly following Turing's approach) but as a general automaton to which an unbounded memory unit (such as an unbounded tape) is added. Thus, the general automaton and the Turing machine differ in logical design only with respect to the extent of memory storage.

Extent of memory in a Turing machine

The distinction is critical, however, for Turing proposed that the class of numbers computable on his machine (a wider class than can be obtained by general automata) coincide with those that are effectively computable in the sense of constructive logics. A simple convention also makes it possible to interpret the output of a Turing machine as the computation of a function. The class of functions so computed, called "Turing computable" or "computable," are of basic importance at the foundations of mathematics and elsewhere. It can also be stated that a useful class of functions that are definable without reference to machines, namely, the so-called partial recursive functions, has the same membership as the class of computable functions. For the present purposes, then, no effort need be made to define the partial recursive functions.

Turing's approach admitted mathematical formalization to the extent that a finite list of symbols $q_1, q_2, q_3, \cdots, q_n$ could be used to denote internal states and a finite list of symbols $a, b, c, \cdots, \lambda$ could designate abstractly what is called "the alphabet"—that is, the list from which individual members could be chosen and printed into the squares of the machine's tape. If the symbols R and L, respectively, designate a move of the tape one square to the right and one square to the left, it remains only to list in some orderly fashion the alternative possible steps in the machine's operation in order to define it completely. Turing himself chose to list alternate steps, or instructions, in the form of quintuples of the above symbols. It is also possible to use quadruples to define a machine. Such a list, then, of, say, quadruples of instructions is equivalent to a Turing machine, and it is significant that the list is finite.

The finiteness of the list of quadruples of instructions leads to the idea that all Turing machines can be listed—that is, they are at most countable in number. This being the case, it can be proved that there is what Turing called a "universal" machine capable of operating like any given Turing machine. For a given partial recursive function of a single argument, there is a corresponding integer, called the Gödel number, that identifies the Turing machine capable of computing the given function. The Gödel number and the argument value of the function to be computed can be given as input data on the tape of the universal machine. From the Gödel number, the list of instructions, defined in the form of quadruples, that are necessary for the computation of the given recursive function at the specific argument value can be encoded by the universal machine on its own tape, and, from that point on, the universal machine will duplicate the required Turing machine.

The "universal" machine

Input: events that affect an automaton. Once having reached the definition of the general automaton and the more general universal Turing machine, a general definition of the events in the environment that stimulate it may be introduced. The automaton, which computes logical statements, is not defined without reference to time, a characteristic that distinguishes the machine itself from the logic. In the same way, stimuli are not definable, in general, without reference to time. These facts are indicative of the simulation features that the computing machine bears with respect to man.

For an automaton with n input neurons, $N_1, N_2, \cdots, N_n$, an individual history of stimulation, starting with the present moment, $t=0$, and continuing to the remote past, can be recorded as a sequence of n-tuples, $(\beta_1, \beta_2, \cdots, \beta_n)$, in which each binary digit, β_k, is either a 0 or a 1. Thus, the beginning of one such individual history for an automaton of four neurons might be recorded in tabular form as an unending list of quadruples of the type (1, 0, 1, 1) (see Box, display 1).

Events as collections of individual histories

An event is a collection of individual histories. This is a generalization of the idea already used to characterize an environmental message transmitted to the two input

neurons of an elementary automaton at time $t-1$. As an example, the stimulus (0, 1) is the same as the collection of all individual histories in which neuron N_2 was stimulated at time $t-1$ and neuron N_1 was not. As another example, the event that neuron N_2 (of a two-neuron automaton) is presently stimulated and has always been stimulated on alternate second can be represented as the collection of two individual histories (see 2). While some events require an infinite tabulation, others that specify the states of each neuron over a finite past (allowing that anything might have occurred before) permit a finite tabulation. Events of the second kind are called definite events, or stimuli.

The construction (either actual or theoretical) of a general automaton with the help of the logical components and interconnections of a neural net results in an entity that responds in reproducible ways to stimuli. A response becomes recorded as a configuration of binary digits, corresponding to the states of the finite number of output neurons at a specified time t in the future, while a stimulus is a collection of individual histories extending over the past and including the present. The logical construction implies a behaviour in the guise of a listing of responses to all possible stimuli. Reciprocally, for a given behaviour of the type defined, the possible structure of a machine that could produce such behaviour can be investigated.

PROBABILISTIC QUESTIONS

It was traditional in the early treatment of automata theory to identify an automaton with an algorithm, or rule of computation, in which the output of the automaton was a logically determined function of the explicitly expressed input. From the time of the invention of the all-mechanical escapement clock in Europe toward the end of the 13th century, through the mechanistic period of philosophy that culminated in the work of the French mathematician Pierre-Simon Laplace, and into the modern era of the logically defined Turing machine of 1936, an automaton was a mechanical or logical construction that was free of probabilistic components. It was also understood to be immersed in an environment (that is, activated or supplied with input data) that could be logically specified without the concept of chance.

Automata and the idea of chance

After the middle of the 20th century, mathematicians explicitly investigated questions concerning automata that included in their formulation the idea of chance, and in doing so they drew upon earlier applicable mathematical results. While the automata themselves are prototypes of deterministic machines, the U.S. mathematician Norbert Wiener showed that they may be programmed in such a way as to extrapolate certain types of random data that are introduced as input. A prediction of data that are not yet received as input can be accomplished, provided the data are what will later be defined to constitute a stationary time series and provided the prediction is restricted according to a well-defined optimization procedure. In this way a logically defined robot, or automaton, may be placed in an environment that evolves according to both deterministic and random processes (the bifurcation of the environment into deterministic and random processes being mathematically postulated by the designer of the robot) and may be seen to respond to the advantage of its designer: The robot can control a ship's rudder, guide an airplane to its landing, reorient a rocket on its course, predict weather, and so forth. The programming of an automaton so that it will react in a suitable way when placed in a naturalistic environment falls under the heading of prediction theory.

Of the types of probabilistic questions considered, four (which will be listed in arbitrary order) were predominant. The first, that of Wiener, was broached in 1948. It concerned the use of mathematically expressed algorithms or physically constructed computers to predict the future of a system, such as the weather, that includes random components—*i.e.*, an automaton in Turing's logical sense immersed in a random environment. The second, of von Neumann, was concerned with the reliability of large computing machines with many components and sought methods of design, called "multiplexing," that would reduce the chance for unwanted error during the machine calculation of a problem. In this context, the automaton was interpreted as a randomly operating device that in practice approximates the operation of a Turing machine under the influence of better and better design. The third, considered by various researchers, concerned the possibility of computing a wider class of sets than are accessible to Turing machines by adding a random component to the machine itself. In this context, the automaton was being interpreted as a Turing machine modified with the potentiality for injecting the output of a random number generating device into one or more of its operational steps. The fourth concerned the logical possibility of an automaton, such as a Turing machine, actually yielding as output a sequence of random numbers. In this context, the automaton was considered to be simultaneously a Turing machine and a generator of numbers that are indistinguishable from measurements on random phenomena.

Some results that have been achieved from examination of each of these four types of questions will constitute the remainder of this section.

The automaton and its environment. It must first be observed that, just as an automaton is an acceptable description (or model) of a neural structure, an automaton, though frequently thought of as a computing machine, is in general a response mechanism that produces output (or behaviour) as a consequence of the input (or environmental stimuli). "Environment" is then another name for the input and output of an automaton. Some poetic license in identifying automata with living things may justify the use of the term.

During his researches on cybernetics, Wiener recognized that, if computers could be programmed to solve certain mathematical equations, then the data read from physically generated time series (or numerical values indexed consecutively in time and related through a transformation) could be extrapolated. He saw that, if this process could be accomplished with sufficient speed, as would be possible with modern electronic circuits, then the extrapolated values would be obtained faster than the actual physically evolving process that produced the time series, and a prediction of the future would result. Errors would be inevitable because a complete history of data and adequate measurements would be unobtainable. For this reason, the mathematical equations that would be at the heart of such an extrapolation could be deduced, in part, from the objective of minimizing the errors. Thus, the matching of an automaton, or computer, with a real physical environment could result in the anticipation of the future, if certain mathematical equations were derived that minimized prediction error.

Matching an automaton with an environment
