Number Games

and Other Mathematical Recreations

Mathematical recreations comprise puzzles and games that vary from naive amusements to sophisticated problems, some of which have never been solved. They may involve arithmetic, algebra, geometry, theory of numbers, graph theory, topology, matrices, group theory, combinatorics (dealing with problems of arrangements or designs), set theory, symbolic logic, or probability theory. Any attempt to classify this colourful assortment of material is at best arbitrary. Included in this article are the history and the main types of number games and mathematical recreations and the principles on which they are based. Details, including descriptions of puzzles, games, and recreations mentioned in the article, will be found in the references listed in the bibliography.

At times it becomes difficult to tell where pastime ends and serious mathematics begins. An innocent puzzle requiring the traverse of a path may lead to technicalities of graph theory; a simple problem of counting parts of a geometric figure may involve combinatorial theory; dissecting a polygon may involve transformation geometry

and group theory; logical inference problems may involve matrices. A problem regarded in medieval times—or before electronic computers became commonplace—as very difficult may prove to be quite simple when attacked by the mathematical methods of today.

Mathematical recreations have a universal appeal. The urge to solve a puzzle is manifested alike by young and old, by the unsophisticated as well as the sophisticated. An outstanding English mathematician, G.H. Hardy, observed that professional puzzle makers, aware of this propensity, exploit it diligently, knowing full well that the general public gets an intellectual kick out of such activities.

The relevant literature has become extensive, particularly since the beginning of the 20th century. Some of it is repetitious, but surprisingly enough, successive generations have found the older chestnuts to be quite delightful, whether dressed in new clothes or not. Much newly created material is continually being added.

This article is divided into the following sections:

History

EARLY HISTORY

People have always taken delight in devising “problems” for the purpose of posing a challenge or providing intellectual pleasure. Thus, many mathematical recreations of early origin that have reappeared from time to time in new dress seem to have survived chiefly because they appeal to man’s sense of curiosity or mystery. A few survived from the ancient Greeks and Romans: little was known about them during the Dark Ages, but a strong interest in such problems arose during the Middle Ages, stimulated partly by the invention of printing, partly by enthusiastic writers of arithmetic texts, and partly by the rivalry and disputations among early algebraists and scholars. Such activities were most prominent on the Continent, particularly in Italy and Germany. Notable contributors included Rabbi ben Ezra (1140), Fibonacci (Leonardo of Pisa; 1202), Robert Recorde (1542), and Gerolamo Cardano (1545).

Kinds of problems. The problems in general were of two kinds: those involving the manipulation of objects, and those requiring computation. The first required little or no mathematical skill, merely general intelligence and ingenuity, as for example, so-called decanting and difficult crossings problems. A typical example of the former is how to measure out one quart of a liquid if only an eight-

a five-, and a three-quart measure are available. Difficult crossings problems are exemplified by the dilemma of three couples trying to cross a stream in a boat that will hold only two persons, with each husband too jealous to leave his wife in the company of either of the other men. Many variants of both types of problems have appeared over the years.

Some examples. Problems involving computation also took on a variety of forms; some were as follows:

Finding a number. Think of a number, triple it, and take half the product; triple this and take half the result; then divide by 9. The quotient will be one-fourth the original number.

“God-Greet-You” problems. For example, in “God greet you, all you 30 companions,” someone says: “If there were as many of us again and half as many more, then there would be 30 of us.” How many were there?

The chessboard problem. How many grains of wheat are required in order to place one grain on the first square, 2 on the second, 4 on the third, and so on for the 64 squares?

The lion in the well. This is typical of many problems dealing with the time required to cover a certain distance at a constant rate while at the same time progress is hindered by a constant retrograde motion. There is a lion in a well whose depth is 50 palms. He climbs $\frac{1}{7}$ of a palm

daily and slips back $\frac{1}{9}$ of a palm. In how many days will he get out of the well?

Courier problems. These are typified by the movements of bodies at given rates in which some position of these bodies is given and the time required for them to arrive at some other specified position is demanded.

PIONEERS AND IMITATORS

The 17th century produced books devoted solely to recreational problems not only in mathematics but frequently in mechanics and natural philosophy as well. The first important contribution was that of the Frenchman Claude-Gaspar Bachet de Méziriac, one of the earliest pioneers in this field, who is remembered for two mathematical works: his *Diophanti*, the first edition of a Greek text on the theory of numbers (1621), and his *Problèmes plaisans et delectables qui se font par les nombres* (1612). The latter passed through five editions, the last as late as 1959; it was the forerunner of similar collections of recreations to follow. The emphasis was placed on arithmetic rather than geometric puzzles. Among the outstanding problems given by Bachet were questions involving number bases other than 10; card tricks; watch-dial puzzles depending on numbering schemes; the determination of the smallest set of weights that would enable one to weigh any integral number of pounds from one pound to 40, inclusive; and difficult crossings or ferry problems.

In 1624 a French Jesuit, Jean Leurechon, writing under the pen name of van Etten, published *Récréations mathématiques*. This volume struck the popular fancy, passing through at least 30 editions before 1700, despite the fact that it was based largely on the work of Bachet, from whom he took the simpler problems, disregarding the more significant portions. Yet it did contain some original work, and it served as a model for others, including Mydorge and Schwenter. The first English edition (1633) bore the title: *Mathematicall Recreations, or a Collection of Sundrie Problemes, extracted out of the Ancient and Moderne Philosophers, as Secrets in Nature, and Experiments in Arithmetick, Geometrie, Cosmographie, Horologographie, Astronomie, Navigation, Musick, Opticks, Architecture, Staticke, Machanicks, Chimestrie, Waterworks, Fireworks, etc. Not vulgarly made manifest until this Time Most of which were written first in Greeke and Latine, lately compiled in French, by HENRY VAN ETTEN Gent. And now delivered in the English Tongue with the Examinations, Corrections, and Augmentations* [translated by William Oughtred].

The rising tide of interest was exploited by French mathematicians Claude Mydorge, whose *Examen du livre des récréations mathématiques* was published in 1630, and Denis Henrion, whose *Les Récréations mathématiques avec l'examen de ses problèmes en arithmétique, géométrie, mécanique, cosmographie, optique, catoptrique, etc.*, based largely upon Mydorge's book, appeared in 1659. Leurechon's book, meanwhile, had found its way into Germany: Daniel Schwenter, a professor of Hebrew, Oriental languages, and mathematics, assiduously compiled a comprehensive collection of recreational problems based on a translation of Leurechon's book, together with many other problems that he himself had previously collected. This work appeared posthumously in 1636 under the title *Deliciae Physico-mathematicae oder Mathematiche und Philosophische Erquickstunden*. Immensely popular, Schwenter's book was enlarged by two supplementary editions in 1651–53. For some years thereafter Schwenter's enlarged edition was the most comprehensive treatise of its kind, although in 1641–42 the Italian Jesuit Mario Bettini had issued a two-volume work called *Apiaria Universae Philosophiae Mathematicae in Quibus Paradoxa et Nova Pleraque Machinamenta Exhibentur*, which was followed in 1660 by a third volume entitled *Recreationum Mathematicarum Apiaria Novissima Duodecim* And in 1665 one Johann Mohr in Schleswig published an imitation of Schwenter under the title of *Arithmetische Lustgarten*.

In England, somewhat belatedly, William Leybourn, a mathematics teacher, textbook writer, and surveyor, in 1694, published his *Pleasure with Profit: Consisting of*

Recreations of Divers Kinds, viz., Numerical, Geometrical, Mechanical, Statical, Astronomical, Horometrical, Cryptographical, Magnetical, Automatical, Chymical, and Historical. The title page further states that the purpose of the book was to "recreate ingenious spirits and to induce them to make farther scrutiny into these sublime sciences, and to divert them from following such vices, to which Youth (in this Age) are so much inclined." Much of the volume is conventional textbook material, for most of Leybourn's published works grew out of his teaching.

18TH AND 19TH CENTURIES

The 18th century saw a continuation of this interest. Published in England were volumes by Edward Hatton, Thomas Gent, Samuel Clark, and William Hooper. In 1775 Charles Hutton published five volumes of extracts from the *Ladies' Diary* dealing with "entertaining mathematical and poetical parts." On the Continent there appeared several writers, including: Christian Pescheck, Abat Bonaventura, the Dutch writer Paul Halcken, and A.H. Guyot's four volumes of *Nouvelles Récréations physiques et mathématiques*, etc. (1769, 1786). But by far the outstanding work was that of Jacques Ozanam, the precursor of books to follow for the next 200 years. First published in four volumes in 1694, his *Récréations mathématique et physiques* went through many editions; based on the works of Bachet, Mydorge, Leurechon, and Schwenter, it was later revised and enlarged by Montucla, then translated into English by Charles Hutton (1803, 1814) and again revised by Edward Riddle (1840, 1844).

The first half of the 19th century produced only a moderate number of lesser writers on mathematical recreations, but the second half of the 19th century witnessed a crescendo of interest, culminating in the outstanding contributions of Édouard Lucas, C.L. Dodgson (Lewis Carroll), and others at the turn of the century. Lucas' four-volume *Récréations mathématiques* (1882–94) became a classic. The mathematical recreations of Dodgson included *Symbolic Logic* and *The Game of Logic*; *Pillow Problems* and *A Tangled Tale*, 2 vol. (1885–95).

20TH CENTURY

Among the more colourful figures at the turn of the 20th century were two Americans named Sam Loyd, father and son. Tremendously successful in making puzzles, the elder Loyd sold his weekly puzzle column to a national syndicate for years, and, in addition, created or adapted hundreds of mechanical puzzles fashioned of cardboard, wood, and metal that were also financially rewarding. When Loyd II died in 1934 at the age of 60, it was estimated that he had produced at least 10,000 puzzles.

In Germany, Hermann Schubert published *Zwölf Geduldspiele* in 1899 and the *Mathematische Mussestunden* (3rd ed., 3 vol.) in 1907–09. Between 1904 and 1920 Wilhelm Ahrens published several works, the most significant being his *Mathematische Unterhaltungen und Spiele* (2 vol., 1910) with an extensive bibliography.

Among British contributors, Henry Dudeney, a contributor to the *Strand Magazine*, published several very popular collections of puzzles that have been reprinted from time to time (1917–67). The first edition of W.W. Rouse Ball's *Mathematical Recreations and Essays* appeared in 1892; it soon became a classic, largely because of its scholarly approach. After passing through 10 editions it was revised by the British professor H.S.M. Coxeter in 1938; it is still a standard reference.

Outstanding work was that of Maurice Kraitchik, editor of the periodical *Sphinx* and author of several well-known works published between 1900 and 1942.

About the middle third of the 20th century, there was a gradual shift in emphasis on various topics. Up to that time interest had focussed largely on such amusements as numerical curiosities; simple geometric puzzles; arithmetical story problems; paper folding and string figures; geometric dissections; manipulative puzzles; tricks with numbers and with cards; magic squares; those venerable diversions concerning angle trisection, duplication of the cube, squaring the circle, as well as the elusive fourth dimension. By the middle of the century, interest be-

Books and
collections

The work
of Ozanam

Modern
shift in
emphasis

gan to swing toward more mathematically sophisticated topics: cryptograms; recreations involving modular arithmetic, numeration bases, and number theory; graphs and networks; lattices, group theory; topological curiosities; packing and covering; flexagons; manipulation of geometric shapes and forms; combinatorial problems; probability theory; inferential problems; logical paradoxes; fallacies of logic; and paradoxes of the infinite.

Types of games and recreations

ARITHMETIC AND ALGEBRAIC RECREATIONS

Number patterns and curiosities. Some groupings of natural numbers, when operated upon by the ordinary processes of arithmetic, reveal rather remarkable patterns, affording pleasant pastimes. For example:

$$\begin{array}{lll} 1 \times 8 + 1 = 9 & 3 \times 37 = 111 & (1)^2 = 1 \\ 12 \times 8 + 2 = 98 & 6 \times 37 = 222 & (11)^2 = 121 \\ 123 \times 8 + 3 = 987 & 9 \times 37 = 333 & (111)^2 = 12321 \\ 1234 \times 8 + 4 = 9876 & 12 \times 37 = 444 & (1111)^2 = 1234321 \\ \text{etc.} & \text{etc.} & \text{etc.} \end{array}$$

Another type of number pleasantries concerns multigrades; i.e., identities between the sums of two sets of numbers and the sums of their squares or higher powers—e.g.,

$$1^n + 6^n + 8^n = 2^n + 4^n + 9^n \text{ (for } n = 1 \text{ or } 2).$$

An easy method of forming a multigrade is to start with a simple equality—e.g., $1 + 5 = 2 + 4$ —then add, for example, 5 to each term: $6 + 10 = 7 + 9$. A second-order multigrade is obtained by “switching sides” and combining, as shown below:

$$1^n + 5^n + 7^n + 9^n = 2^n + 4^n + 6^n + 10^n \text{ (} n = 1 \text{ or } 2).$$

On each side the sum of the first powers (S_1) is 22 and of the second powers (S_2) is 156.

Ten may be added to each term to derive a third-order multigrade:

$$11^n + 15^n + 17^n + 19^n = 12^n + 14^n + 16^n + 20^n \text{ (} n = 1 \text{ or } 2).$$

Switching sides and combining, as before:

$$\begin{aligned} 1^n + 5^n + 7^n + 9^n + 12^n + 14^n + 16^n + 20^n \\ = 2^n + 4^n + 6^n + 10^n + 11^n + 15^n + 17^n + 19^n \\ \text{(} n = 1, 2, \text{ or } 3). \end{aligned}$$

In this example $S_1 = 84$, $S_2 = 1,152$, and $S_3 = 17,766$.

This process can be continued indefinitely to build multigrades of successively higher orders. Similarly, all terms in a multigrade may be multiplied or divided by the same number without affecting the equality. Many variations are possible: for example, palindromic multigrades that read the same backward and forward, and multigrades composed of prime numbers.

Other number curiosities and oddities are to be found. Thus, narcissistic numbers are numbers that can be represented by some kind of mathematical manipulation of their digits. A whole number, or integer, that is the sum of the n th powers of its digits (e.g., $153 = 1^3 + 5^3 + 3^3$) is called a perfect digital invariant. On the other hand, a recurring digital invariant is illustrated by:

$$\begin{aligned} 55: 5^3 + 5^3 &= 250; \\ 250: 2^3 + 5^3 + 0^3 &= 133; \\ 133: 1^3 + 3^3 + 3^3 &= 55. \end{aligned}$$

(From *Mathematics on Vacation*, Joseph Madachy; Charles Scribner's Sons.)

A variation of such digital invariants is

$$165,033 = 16^3 + 50^3 + 33^3.$$

Another curiosity is exemplified by a number that is equal to the n th power of the sum of its digits:

$$\begin{aligned} 81 &= (8 + 1)^2 = 9^2; \\ 4913 &= (4 + 9 + 1 + 3)^3 = 17^3. \end{aligned}$$

An automorphic number is an integer whose square ends with the given integer, as $(25)^2 = 625$, and $(76)^2 = 5776$. Strobogrammatic numbers read the same after having been rotated through 180° ; e.g., 69, 96, 1001.

It is not improbable that such curiosities should have

suggested intrinsic properties of numbers bordering on mysticism.

Digital problems. The problem of the four n 's calls for the expression of as large a sequence of integers as possible, beginning with 1, representing each integer in turn by a given digit used exactly four times. The answer depends upon the rules of operation that are admitted. Two partial examples are shown.

For four 1s:

$$\begin{aligned} 1 &= 1 + \frac{1}{1} - 1 \\ 2 &= 1 + 1 + 1 - 1 \\ 3 &= 1 + 1 + \frac{1}{1} \\ 4 &= 1 + 1 + 1 + 1 \\ 5 &= (1 + 1 + 1)! - 1 \\ \text{etc.} \end{aligned}$$

For four 4s:

$$\begin{aligned} 1 &= \left(\frac{4}{4}\right) \cdot \left(\frac{4}{4}\right) \\ 2 &= \frac{4}{4} + \frac{4}{4} \\ 3 &= \frac{4}{4} + 4/\sqrt{4} \\ 4 &= \sqrt{(4)(4)} \cdot \left(\frac{4}{4}\right) \\ 5 &= \sqrt{4} + \sqrt{4} + \frac{4}{4} \\ \text{etc.} \end{aligned}$$

(In M. Bicknell & V. Hoggatt, “64 Ways to Write 64 Using Four 4's,” *Recreational Mathematics Magazine*, No. 14, Jan.-Feb. 1964, p. 13.)

Obviously, many alternatives are possible; e.g., $7 = 4 + \sqrt{4} + 4/4$ could also be expressed as $4!/4 + 4/4$, or as $44/4 - 4$. The factorial of a positive integer is the product of all the positive integers less than or equal to the given integer; e.g., “factorial 4,” or $4! = 4 \times 3 \times 2 \times 1$. If the use of factorial notation is not allowed, it is still possible to express the numbers from 1 to 22 inclusive with four “4s”; thus $22 = (4 + 4)/4 + \sqrt{4}$. But if the rules are extended, many additional combinations are possible.

A similar problem requires that the integers be expressed by using the first m positive integers, $m > 3$ (“ m is greater than three”) and the operational symbols used in elementary algebra. For example, using the digits 1, 2, 3, and 4:

$$\begin{aligned} 2 &= 4 - 3 + 2 - 1 \\ 4 &= \sqrt{4} + 3 - 2 + 1 \\ 6 &= \sqrt{4} + 3 + 2 - 1 \\ 8 &= \sqrt{4} + 3 + 2 + 1 \\ 9 &= 4 + 3 + (2 \cdot 1). \end{aligned}$$

Such problems have many variations; for example, more than 100 ways of arranging the digits 1 to 9, in order, to give a value of 100 have been demonstrated.

All of these digital problems require considerable ingenuity but involve little significant mathematics.

Cryptarithms. The term “crypt-arithmic” was introduced in 1931, when the following multiplication problem appeared in the Belgian journal *Sphinx*:

$$\begin{array}{r} \text{ABC} \\ \text{DE} \\ \text{FEC} \\ \text{DEC} \\ \text{HGBC} \end{array}$$

The shortened word cryptarithm now denotes mathematical problems usually calling for addition, subtraction, multiplication, or division and replacement of the digits by letters of the alphabet or some other symbols.

An analysis of the original puzzle suggested the general method of solving a relatively simple cryptarithm:

1. In the second partial product $D \times A = D$, hence $A = 1$.
2. $D \times C$ and $E \times C$ both end in C; since for any two digits 1-9 the only multiple that will produce this result is 5 (zero if both digits are even, 5 if both are odd), $C = 5$.
3. D and E must be odd. Since both partial products have only three digits, neither D nor E can be 9. This leaves only 3 and 7. In the first partial product $E \times B$ is a number of two digits, while in the second partial product $D \times B$ is a number of only one digit. Thus E is larger than D, so $E = 7$ and $D = 3$.
4. Since $D \times B$ has only one digit, B must be 3 or less. The only two possibilities are 0 and 2. B cannot be zero because 7B is a two digit number. Thus $B = 2$.
5. By completing the multiplication, $F = 8$, $G = 6$, and $H = 4$.
6. Answer: $125 \times 37 = 4,625$.

Narcis-
sistic
numbers

Problem
of the
four n 's

(From *150 Puzzles in Crypt-Arithmetic* by Maxey Brooke; Dover Publications, Inc., New York, 1963. Reprinted through the permission of the publisher.)

Such puzzles had apparently appeared, on occasion, even earlier. Alphametics refers specifically to cryptarithms in which the combinations of letters make sense, as in one of the oldest and probably best known of all alphametics:

$$\begin{array}{r} \text{SEND} \\ + \text{MORE} \\ \hline \text{MONEY} \end{array}$$

Unless otherwise indicated, convention requires that the initial letters of an alphametic cannot represent zero, and that two or more letters may not represent the same digit. If these conventions are disregarded, the alphametic must be accompanied by an appropriate clue to that effect. Some cryptarithms are quite complex and elaborate and have multiple solutions. Electronic computers have been used for the solution of such problems.

Paradoxes and fallacies. Mathematical paradoxes and fallacies have long intrigued mathematicians. A mathematical paradox is a mathematical conclusion so unexpected that it is difficult to accept even though every step in the reasoning is valid. A mathematical fallacy, on the other hand, is an instance of improper reasoning leading to an unexpected result that is patently false or absurd. The error in a fallacy generally violates some principle of logic or mathematics, often unwittingly. Such fallacies are quite puzzling to the tyro, who, unless he is aware of the principle involved, may well overlook the subtly concealed error. A sophism is a fallacy in which the error has been knowingly committed, for whatever purpose. If the error introduced into a calculation or a proof leads innocently to a correct result, the result is a "howler," often said to depend on "making the right mistake."

Many paradoxes arise from the concepts of infinity and limiting processes. For example, the infinite series

$$1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \cdots$$

has a continually greater sum the more terms are included, but the sum always remains less than 2, although it approaches nearer and nearer to 2 as more terms are included. On the other hand, the series

$$1 + \frac{1}{2} + \frac{1}{3} + \frac{1}{4} + \frac{1}{5} + \frac{1}{6} + \cdots$$

is called divergent: it has no limit, the sum becoming larger than any chosen value if sufficient terms are taken. Another paradox is the fact that there are just as many even natural numbers as there are even and odd numbers altogether, thus contradicting the notion that "the whole is greater than any of its parts." This seeming contradiction arises from the properties of collections containing an infinite number of objects. Since both are infinite, they are for both practical and mathematical purposes equal.

Zeno's
paradoxes

The so-called paradoxes of Zeno (c. 450 BC) are, strictly speaking, sophisms. In the race between Achilles and the tortoise, the two start moving at the same moment, but, if the tortoise is initially given a lead and continues to move ahead, Achilles can run at any speed and never catch up. Zeno's argument rests on the presumption that Achilles must first reach the point where the tortoise started, by which time the tortoise will have moved ahead to another point, and so on. Obviously, Zeno did not believe what he claimed; his interest lay in locating the error in his argument. The same observation is true of the three remaining paradoxes of Zeno, the *Dichotomy*, "motion is impossible"; the *Arrow*, "motionless even while in flight"; and the *Stadium*, or "a given time interval is equivalent to an interval twice as long." Beneath the sophistry of these contradictions lie subtle and elusive concepts of limits and infinity, only completely explained in the 19th century when the foundations of analysis became more rigorous and the theory of transfinite numbers had been formulated.

Common algebraic fallacies usually involve a violation of one or another of the following assumptions:

1. If $a = b$, then $a/k = b/k$, provided $k \neq 0$.
2. If $a > b$, then $ka > kb$, provided k is positive.
3. If a is nonnegative, then $\sqrt{a^2} = +a$.

Three examples of such violations follow:

- A. Solve: $6x - 18 = 4x - 12$
Factoring: $3(2x - 6) = 2(2x - 6)$
Dividing by $(2x - 6)$: $3 = 2$
- B. Since $+1/-1 = -1/+1$, then $\sqrt{+1}/\sqrt{-1} = \sqrt{-1}/\sqrt{+1}$, and so $(\sqrt{+1})(\sqrt{+1}) = (\sqrt{-1})(\sqrt{-1})$, hence $+1 = -1$
- C. Given two positive numbers, a and b :
then, $a > -b$ also, $b > -a$
 $b > -b$ $a > -a$
Multiplying: $ab > b^2$ $ab > a^2$
Or $a > b$ $b > a$

Thus a is both greater than b and less than b .

An example of an illegal operation or "lucky boner" is:

$$\frac{16}{64} = \frac{16}{64} = \frac{1}{4}$$

Polygonal and other figurate numbers. Among the many relationships of numbers that have fascinated man are those that suggest (or were derived from) the arrangement of points representing numbers into series of geometrical figures. Such numbers, known as figurate or polygonal numbers, appeared in 15th-century arithmetic books and were probably known to the ancient Chinese; but they were of especial interest to the ancient Greek mathematicians. To the Pythagoreans (c. 500 BC), numbers were of paramount significance; everything could be explained by numbers, and numbers were invested with specific characteristics and personalities. Among other properties of numbers, the Pythagoreans recognized that numbers had "shapes." Thus, the triangular numbers, 1, 3, 6, 10, 15, 21, etc., were visualized as points or dots arranged in the shape of a triangle.

The
"shapes"
of numbers

Figure 1: Square numbers shown formed from consecutive triangular numbers.

From *The Number of Things: Pythagoras, Geometry and Humming Strings* by Evans G. Valens, copyright © 1964 by Evans G. Valens; published by E.P. Dutton & Co., Inc., and used with their permission

Square numbers are the squares of natural numbers, such as 1, 4, 9, 16, 25, etc., and can be represented by square arrays of dots, as shown in Figure 1. Inspection reveals that the sum of any two adjacent triangular numbers is always a square number.

Figure 2: Oblong numbers formed by doubling triangular numbers.

From *The Number of Things: Pythagoras, Geometry and Humming Strings* by Evans G. Valens, copyright © 1964 by Evans G. Valens; published by E.P. Dutton & Co., Inc., and used with their permission

Oblong numbers are the numbers of dots that can be placed in rows and columns in a rectangular array, each row containing one more dot than each column. The first few oblong numbers are 2, 6, 12, 20, and 30. This series of numbers is the successive sums of the series of even numbers or the products of two consecutive numbers: $2 = 1 \cdot 2$; $6 = 2 \cdot 3 = 2 + 4$; $12 = 3 \cdot 4 = 2 + 4 + 6$; $20 = 4 \cdot 5 = 2 + 4 + 6 + 8$; etc. An oblong number also is formed by doubling any triangular number (see Figure 2).

The gnomons include all of the odd numbers; these can be represented by a right angle, or a carpenter's square, as illustrated in Figure 3. Gnomons were extremely use-

Figure 3: Odd numbers shown as gnomons.

From *The Number of Things: Pythagoras, Geometry and Humming Strings* by Evans G. Valens, copyright © 1964 by Evans G. Valens; published by E.P. Dutton & Co., Inc., and used with their permission

Figure 4: Addition of gnomons to squares to form larger squares.

ful to the Pythagoreans. They could build up squares by adding gnomons to smaller squares and from such a figure could deduce many interrelationships: thus $1^2 + 3 = 2^2$, $2^2 + 5 = 3^2$, etc.; or $1 + 3 + 5 = 3^2$, $1 + 3 + 5 + 7 = 4^2$, $1 + 3 + 5 + 7 + 9 = 5^2$, etc.; (see Figure 4). Indeed, it is quite likely that Pythagoras first realized the famous relationship between the sides of a right triangle, represented by $a^2 + b^2 = c^2$, by contemplating the properties of gnomons and square numbers, observing that any odd square can be added to some even square to form a third square. Thus

$$3^2 + 4^2 = 5^2, \text{ where } 3^2 = 4 + 5;$$

$$5^2 + 12^2 = 13^2, \text{ where } 5^2 = 12 + 13;$$

and, in general, $a^2 + b^2 = c^2$, where $a^2 = b + c$. This is a special class of Pythagorean triples (see below).

Besides these, the Greeks also studied numbers having pentagonal, hexagonal, and other shapes. Many relationships can be shown to exist between these geometric patterns and algebraic expressions.

Polygonal numbers constitute a subdivision of a class of numbers known as figurate numbers. Examples include the arithmetic sequences

$$\begin{aligned} &1, 2, 3, 4, \dots, r \\ \text{and} &1, 3, 5, 7, \dots, (2r - 1). \end{aligned}$$

When new series are formed from the sums of the terms of these series, the results are, respectively,

$$\begin{aligned} &1, 3, 6, 10, \dots \\ \text{and} &1, 4, 9, 16, \dots \end{aligned}$$

These series are not arithmetic sequences but are seen to be the polygonal triangular and square numbers. Polygonal number series can also be added to form three-dimensional figurate numbers; these sequences are called pyramidal numbers.

The significance of polygonal and figurate numbers lies in their relation to the modern theory of numbers. Even the simple, elementary properties and relations of numbers often demand sophisticated mathematical tools. Thus, it has been shown that every integer is either a triangular number, the sum of two triangular numbers, or the sum of three triangular numbers; e.g., $8 = 1 + 1 + 6$, $42 = 6 + 36$, $43 = 15 + 28$, $44 = 6 + 10 + 28$.

Pythagorean triples. The study of Pythagorean triples as well as the general theorem of Pythagoras leads to many unexpected byways in mathematics. A Pythagorean triple is formed by the measures of the sides of an integral right triangle; i.e., any set of three positive integers such that $a^2 + b^2 = c^2$. If a , b , and c are relatively prime—i.e., if no two of them have a common factor—the set is a primitive Pythagorean triple.

A formula for generating all Pythagorean triples is

$$a = p^2 - q^2, b = 2pq, c = p^2 + q^2,$$

in which p and q are relatively prime, p and q are neither both even nor both odd, and $p > q$. By choosing p and q appropriately, for example, primitive Pythagorean triples such as the following are obtained:

p	q	(a) $p^2 - q^2$	(b) $2pq$	(c) $p^2 + q^2$
2	1	3	4	5
3	2	5	12	13

The only primitive triple that consists of consecutive integers is 3, 4, 5.

Certain characteristic properties are of interest:

1. Either a or b is divisible by 3.
2. Either a or b is divisible by 4.
3. Either a or b or c is divisible by 5.
4. The product of a , b , and c is divisible by 60.
5. One of the quantities a , b , $a + b$, $a - b$ is divisible by 7.

It is also true that if n is any integer, then $2n + 1$, $2n^2 + 2n$, and $2n^2 + 2n + 1$ form a Pythagorean triple.

Some of the properties of Pythagorean triples were known to the ancient Greeks; e.g., that the hypotenuse of a primitive triple is always an odd integer. It is now known that, for an odd integer R to be the hypotenuse of a primitive triple, a necessary and sufficient condition is that every prime divisor of R be of the type $4k + 1$, in which k is a positive integer.

Perfect numbers and Mersenne numbers. Most numbers are either "abundant" or "deficient." In an abundant number, the sum of its proper divisors (i.e., including 1 but excluding the number itself) is greater than the number; in a deficient number, the sum of its proper divisors is less than the number. A perfect number is an integer that equals the sum of its proper divisors. For example, 24 is abundant, its divisors giving a sum of 36; 32 is deficient, giving a sum of 31. The number 6 is a perfect number, since $1 + 2 + 3 = 6$; so is 28, since $1 + 2 + 4 + 7 + 14 = 28$. The next two perfect numbers are 496 and 8,128. The first four perfect numbers were known to the ancients. Indeed, Euclid suggested that any number of the form $2^{n-1}(2^n - 1)$ is a perfect number whenever $2^n - 1$ is prime, but it was not until the 18th century that the Swiss mathematician Leonhard Euler proved that every even perfect number must be of the form $2^{n-1}(2^n - 1)$, where $2^n - 1$ is a prime.

A number of the form $2^n - 1$ is called a Mersenne number after the French mathematician Marin Mersenne; it may be prime (i.e., having no factor except itself or 1) or composite (composed of two or more prime factors). A necessary though not sufficient condition that $2^n - 1$ be a prime is that n be a prime. Thus, all even perfect numbers have the form $2^{n-1}(2^n - 1)$ where both n and $2^n - 1$ are prime numbers. Until comparatively recently, only 12 perfect numbers were known. In 1876 the French mathematician Édouard Lucas found a way to test the primality of Mersenne numbers. By 1952 the U.S. mathematician Raphael M. Robinson had applied Lucas' test and, by means of electronic digital computers, had found the Mersenne primes for $n = 521$; 607; 1,279; 2,203; and 2,281, thus adding five more perfect numbers to the list. By 1989 there were more than 30 known perfect numbers.

It is known that to every Mersenne prime there corresponds an even perfect number and vice versa. But two questions are still unanswered: the first is whether there are any odd perfect numbers; and the second is whether there are infinitely many perfect numbers.

Many remarkable properties are revealed by perfect numbers. All perfect numbers, for example, are triangular. Also, the sum of the reciprocals of the divisors of a perfect number (including the reciprocal of the number itself) is always equal to 2. Thus

$$\text{for } 6: \frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{6} = 2$$

$$\text{and for } 28: \frac{1}{1} + \frac{1}{2} + \frac{1}{4} + \frac{1}{7} + \frac{1}{14} + \frac{1}{28} = 2.$$

Fibonacci numbers. In 1202 the mathematician Leonardo of Pisa, also called Fibonacci, published an influential treatise, *Liber abaci*. It contained the following recreational problem: "How many pairs of rabbits can be produced from a single pair in one year if it is assumed that every month each pair begets a new pair which from the second month becomes productive?" Straightforward calculation generates the following sequence:

Month:	1	2	3	4	5	6	7	8	9	10	11	12
No. of pairs:	1	1	2	3	5	8	13	21	34	55	89	144

The second row represents the first 12 terms of the sequence now known by Fibonacci's name, in which each term (except the first two) is found by adding the two terms immediately preceding; in general, $x_n = x_{n-1} + x_{n-2}$, a relation that was not recognized until about 1600.

Properties of perfect numbers

Over the years, especially in the middle decades of the 20th century, the properties of the Fibonacci numbers have been extensively studied, resulting in a considerable literature. Their properties seem inexhaustible; for example, $x_{n+1} \cdot x_{n-1} = x_n^2 + (-1)^n$. Another formula for generating the Fibonacci numbers is attributed to Édouard Lucas:

$$x_n = \frac{1}{\sqrt{5}} \left\{ \left(\frac{1+\sqrt{5}}{2} \right)^n - \left(\frac{1-\sqrt{5}}{2} \right)^n \right\}.$$

The ratio $(\sqrt{5} + 1) : 2 = 1.618 \dots$, designated as Φ , is known as the golden number; the ratio $(\sqrt{5} - 1) : 2$, the reciprocal of Φ , is equal to $0.618 \dots$. Both these ratios are related to the roots of $x^2 - x - 1 = 0$, an equation derived from the Divine Proportion of the 15th-century Italian mathematician Luca Pacioli, namely, $a/b = b/(a+b)$, when $a < b$, by setting $x = b/a$. In short, dividing a segment into two parts in mean and extreme proportion, so that the smaller part is to the larger part as the larger is to the entire segment, yields the so-called Golden Section, an important concept in both ancient and modern artistic and architectural design. Thus, a rectangle the sides of which are in the approximate ratio of 3 : 5 ($\Phi^{-1} = 0.618 \dots$), or 8 : 5 ($\Phi = 1.618 \dots$), is presumed to have the most pleasing proportions, aesthetically speaking.

Raising the golden number to successive powers generates the sequence that begins as follows:

$$\begin{array}{ll} \Phi = (\sqrt{5} + 1)/2 & \Phi^4 = (3\sqrt{5} + 7)/2 \\ \Phi^2 = (\sqrt{5} + 3)/2 & \Phi^5 = (5\sqrt{5} + 11)/2 \\ \Phi^3 = (2\sqrt{5} + 4)/2 & \Phi^6 = (8\sqrt{5} + 18)/2 \end{array}$$

In this sequence the successive coefficients of the radical $\sqrt{5}$ are Fibonacci's 1, 1, 2, 3, 5, 8, while the successive second terms within the parentheses are the so-called Lucas sequence: 1, 3, 4, 7, 11, 18. The Lucas sequence shares the recursive relation of the Fibonacci sequence; that is, $x_n = x_{n-1} + x_{n-2}$.

If a golden rectangle ABCD is drawn and a square ABEF is removed, the remaining rectangle ECDF is also a golden rectangle. If this process is continued and circular arcs are drawn, the curve formed approximates the logarithmic spiral, a form found in nature (see Figure 5). The

Figure 5: Golden rectangles and the logarithmic spiral.

logarithmic spiral is the graph of the equation $r = k^\theta$, in polar coordinates, where $k = \Phi^{2/\pi}$. The Fibonacci numbers are also exemplified by the botanical phenomenon known as phyllotaxis. Thus, the arrangement of the whorls on a pinecone or pineapple, of petals on a sunflower, and of branches from some stems follows a sequence of Fibonacci numbers or the series of fractions

$$\frac{1}{1}, \frac{1}{2}, \frac{2}{3}, \frac{3}{5}, \frac{5}{8}, \frac{8}{13}, \text{ etc.}$$

GEOMETRIC AND TOPOLOGICAL RECREATIONS

Optical illusions. The creation and analysis of optical illusions may involve mathematical and geometric principles such as the proportionality between the areas of similar figures and the squares of their linear dimensions. Some involve physiological or psychological considerations, such as the fact that, when making visual comparisons, relative lengths are more accurately perceived than relative areas.

For treatment of optical illusions and their illusory effects, including unorthodox use of perspective, distorted angles, deceptive shading, unusual juxtaposition, equivocal contours or contrasts, colour effects, chromatic aberration, and afterimages, see the article PERCEPTION.

Geometric fallacies and paradoxes. Some geometric fallacies include "proofs": (1) that every triangle is isosceles (*i.e.*, has two equal sides); (2) that every angle is a right angle; (3) that if ABCD is a quadrilateral in which $AB = CD$, then AD must be parallel to BC; and (4) that every point in the interior of a circle lies on the circle.

The explanations of fallacious proofs in geometry usually include one or another of the following: faulty construction; violation of a logical principle, such as assuming the truth of a converse, or confusing partial inverses or converses; misinterpretation of a definition, or failing to take note of "necessary and sufficient" conditions; too great dependence upon diagrams and intuition; being trapped by limiting processes and deceptive appearances.

Impossible figures. At first glance, drawings such as those in Figure 6 appear to represent plausible three-dimensional objects, but closer inspection reveals that they

Schaap's bookshelf

"something to make"

drawing on Swedish postage stamp

Figure 6: Impossible figures.

cannot; the representation is flawed by faulty perspective, false juxtaposition, or psychological distortion. Among the first to produce these drawings—also called undecidable figures—was Oscar Reutersvard of Sweden, who made them the central features of a set of Swedish postage stamps.

In 1958 L.S. Penrose, a British geneticist, and his son Roger Penrose, a mathematical physicist, introduced the undecidable figures called strange loops. One of these is the Penrose square stairway (Figure 7), which one could apparently traverse in either direction forever without get-

Figure 7: The endless stair.

ting higher or lower. Strange loops are important features of some of M.C. Escher's lithographs, including "Ascending and Descending" (1960) and "Waterfall" (1961). The concept of the strange loop is related to the idea of infinity and also to logical paradoxes involving self-referential statements, such as that of Epimenides (see below *Logical paradoxes*).

Pathological curves. A mathematical curve is said to be pathological if it lacks certain properties of continuous curves. For example, its tangent may be undefined at some—or indeed any—point; the curve may enclose a finite area but be infinite in length; or its curvature may be undefinable. Some of these curves may be regarded as the limit of a series of geometrical constructions; their lengths or the areas they enclose appear to be the limits of sequences of numbers. Their idiosyncrasies constitute paradoxes rather than optical illusions or fallacies.

Von Koch's snowflake curve, for example, is the figure obtained by bisecting each side of an equilateral triangle and replacing the centre segment by two sides of a smaller equilateral triangle projecting outward, then treating the resulting figure the same way, and so on. The first two stages of this process are shown in Figure 8. As the con-

Figure 8: Von Koch's snowflake curve.

struction proceeds, the perimeter of the curve increases without limit, but the area it encloses does approach an upper bound, which is $\frac{8}{5}$ the area of the original triangle.

In seeming defiance of the fact that a curve is "one-dimensional" and thus cannot fill a given space, it can be shown that the curve produced by continuing the stages in Figure 9, when completed, will pass through *every* point in the square. In fact, by similar reasoning, the curve can be made to fill completely an entire cube.

Figure 9: A space-filling curve (see text).

The Sierpinski curve, the first few stages of which are shown in Figure 10, contains every point interior to a square, and it describes a closed path. As the process of forming the curve is continued indefinitely, the length of the curve approaches infinity, while the area enclosed by it approaches $\frac{5}{12}$ that of the square.

A fractal curve, loosely speaking, is one that retains the same general pattern of irregularity regardless of how much it is magnified; von Koch's snowflake is such a curve. At each stage in its construction, the length of its perimeter increases in the ratio of 4 to 3. The mathematician Benoit Mandelbrot has generalized the term dimension, symbolized D , to denote the power to which 3 must be raised to produce 4; that is, $3^D = 4$. The dimension that characterizes von Koch's snowflake is therefore $\log 4 / \log 3$, or approximately 1.26.

Beginning in the 1950s Mandelbrot and others have intensively studied the self-similarity of pathological curves, and they have applied the theory of fractals in modelling natural phenomena. Random fluctuations induce a statistical self-similarity in natural patterns; analysis of these patterns by Mandelbrot's techniques has been found useful in such diverse fields as fluid mechanics, geomor-

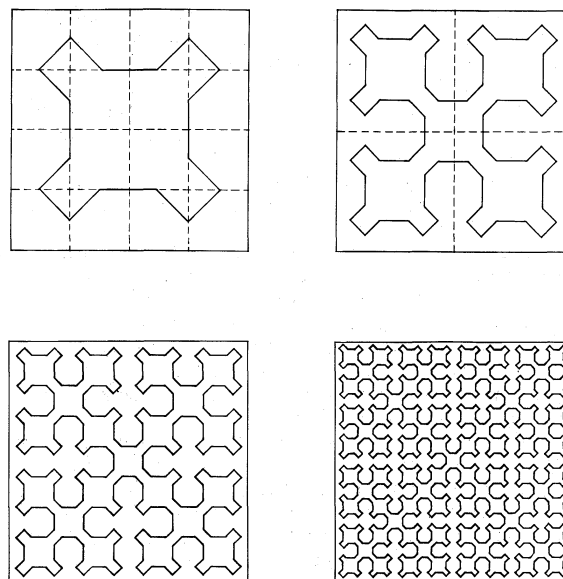

Figure 10: The Sierpinski curve.

phology, human physiology, economics, and linguistics. Specifically, for example, characteristic "landscapes" revealed by microscopic views of surfaces in connection with Brownian movement, vascular networks, and the shapes of polymer molecules are all related to fractals.

Mazes. A maze having only one entrance and one exit can be solved by placing one hand against either wall and keeping it there while traversing it; the exit can always be reached in this manner, although not necessarily by the shortest path. If the goal is within the labyrinth, the "hand-on-wall" method will also succeed, provided that there is no closed circuit; *i.e.*, a route that admits of complete traverse back to the beginning (Figure 11).

From Martin Gardner, *The Second Scientific American Book of Mathematical Puzzles and Diversions* (copyright © 1961 by Martin Gardner); reprinted by permission of Simon and Schuster, Inc.

Figure 11: Examples of mazes. (Left) "Simply connected" maze. (Right) "Multiply connected" maze (see text).

If there are no closed circuits—*i.e.*, no detached walls—the maze is "simply connected"; otherwise the maze is "multiply connected." A classic general method of "threading a maze" is to designate a place where there is a choice of turning as a node; a path or node that has not yet been entered as a "new" path or node; and one that has already been entered as an "old" path or node.

The procedure is as follows:

1. Never traverse a path more than twice.
2. When arriving at a new node, select either path.
3. When arriving at an old node or at a dead end by a new path, return by the same path.
4. When arriving at an old node by an old path, select a new path, if possible; otherwise, an old path.

Although recreational interest in mazes has diminished, two areas of modern science have found them to be of value: psychology and communications technology. The former is concerned with learning behaviour, the latter with improved design of computers.

Geometric dissections. Geometric dissection problems involve the cutting of geometric figures into pieces that can be arranged to form other geometric figures; for example, cutting a rectangle into parts that can be put together in

the form of a square and vice versa. Interest in this area of mathematical recreations began to manifest itself toward the close of the 18th century when Montucla called attention to this problem. As the subject became more popular, greater emphasis was given to the more general problem of dissecting a given polygon of any number of sides into parts that would form another polygon of equal area. Then, in the early 20th century, interest shifted to finding the *minimum* number of pieces required to change one figure into another.

According to a comprehensive theory of equidecomposable figures that was outlined in detail about 1960, two polygons are said to be equidecomposable if it is possible to dissect, or decompose, one of them into a finite number of pieces that can then be rearranged to form the second polygon. Obviously, the two polygons have equal areas.

According to the converse theorem, if two polygons have equal areas, they are equidecomposable.

In the method of complementation, congruent parts are added to two figures so as to make the two new figures congruent. It is known that equicomplementable figures have equal areas and that, if two polygons have equal areas, they are equicomplementable. As the theory advanced, the relation of equidecomposability to various motions such as translations, central symmetry, and, indeed, to groups of motions in general, was explored. Studies were also extended to the more difficult questions of dissecting polyhedra.

On the "practical" side, the execution of a dissection, such as converting the Greek cross into a square (Figure 12), may require the use of ingenious procedures, some of which have been described by H. Lindgren (see *Bibliography*).

Figure 12: Greek cross converted by dissection into a square.

From *The Number of Things: Pythagoras, Geometry and Humming Strings* by Evans G. Valens, copyright © 1964 by Evans G. Valens, published by E.P. Dutton & Co., Inc., and used with their permission

A quite different and distinctly modern type of dissection deserves brief mention, the so-called squaring the square, or squared rectangles. Thus, the problem of subdividing a square into smaller squares, no two of which are alike, which was long thought to be unsolvable, has been solved by the means of network theory. In this connection, a

From Martin Gardner, *The Second Scientific American Book of Mathematical Puzzles and Diversions* (copyright © 1961 by Martin Gardner); reprinted by permission of Simon and Schuster, Inc.

Figure 13: Squared rectangle (see text).

squared rectangle is a rectangle that can be dissected into a finite number of squares; if no two of these squares are equal, the squared rectangle is said to be perfect. The order of a squared rectangle is the number of constituent squares. It is known that there are no perfect rectangles of orders less than 9, and that there are exactly two perfect rectangles of order 9. (One of these is shown as Figure 13.) The dissection of a square into unequal squares, deemed impossible as early as 1907, was first reported in 1939.

Graphs and networks. The word graph may refer to the familiar curves of analytic geometry and function theory, or it may refer to simple geometric figures consisting of points and lines connecting some of these points; the latter are sometimes called linear graphs, although there is little confusion within a given context. Such graphs have long been associated with puzzles.

If a finite number of points are connected by lines (Figure 14A), the resulting figure is a graph; the points, or corners, are called the vertices, and the lines are called the edges. If every pair of vertices is connected by an edge, the graph is called a complete graph (Figure 14B).

Figure 14: Examples of linear graphs.

(A) Graph. (B) Complete graphs. (C) Nonplanar graph. (D) Nonplanar graph of (C) changed to equivalent planar graph.

A planar graph is one in which the edges have no intersection or common points except at the edges. (It should be noted that the edges of a graph need not be straight lines.) Thus a nonplanar graph can be transformed into an equivalent, or isomorphic, planar graph, as in Figures 14C and 14D. An interesting puzzle involves the problem of the three wells. Here (Figure 15) A, B, and C represent three neighbours' houses, and R, S, and T three wells. It

Figure 15: Three wells problem (see text).

is desired to have paths leading from each house to each well, allowing no path to cross any other path. The proof that the problem is impossible depends on the so-called Jordan curve theorem that a continuous closed curve in a plane divides the plane into an interior and an exterior region in such a way that any continuous line connecting a point in the interior with a point in the exterior must intersect the curve. Planar graphs have proved useful in the design of electrical networks.

A connected graph is one in which every vertex, or point (or, in the case of a solid, a corner), is connected to every other point by an arc; an arc denotes an unbroken suc-

Problem of the three wells

cession of edges. A route that never passes over an edge more than once, although it may pass through a point any number of times, is called a path.

Modern graph theory (in the sense of linear graphs) had its inception with the work of Euler in connection with the Königsberg bridge problem and was, for many years, associated with curves now called Eulerian paths; *i.e.*, figures that can be drawn without lifting the pencil from the paper. The city of Königsberg (now Kaliningrad) embraces the banks and an island of the forked Pregel (Pregolya) River; seven bridges span the different branches. The problem was: Could a person leave home, take a walk, and return, crossing each bridge just once? Euler showed why it is impossible.

Briefly stated, Euler's principles (which apply to any closed network) are as follows:

1. The number of even points—*i.e.*, those in which an even number of edges meet—is of no significance.
2. The number of odd points is always even; this includes the case of a network with only even points.
3. If there are *no odd points*, one can start at any point and finish at the same point.
4. If there are *exactly two odd points*, one can start at either of the odd points and finish at the other odd point.
5. If there are *more than two odd points*, the network cannot be traced in one continuous path; if there are $2n$ odd points and no more, it can be traced in n separate paths.

Thus Figures 16B and 16C can be traversed by Eulerian paths; Figures 16D and 16E cannot; Figure 16F shows a network corresponding to the Königsberg bridge problem, in which the points represent the land areas and the edges the seven bridges.

Figure 16: Illustrations of Euler's principles. (A) Königsberg bridge problem. (B) and (C) Eulerian networks. (D) and (E) Non-Eulerian networks. (F) Network corresponding to Königsberg bridge problem.

Networks are related to a variety of recreational problems that involve combining or arranging points in a plane or in space. Among the earliest was a puzzle invented by an Irish mathematician, Sir William Rowan Hamilton (1859), which required finding a route along the edges of a regular dodecahedron that would pass once and only once through every point. In another version, the puzzle was made more convenient by replacing the dodecahedron by a graph isomorphic to the graph formed by the 30 edges of the dodecahedron (Figure 17). A Hamilton circuit is one that passes through each point exactly once but does not, in general, cover all the edges; actually, it covers only two of the three edges that intersect at each vertex. The route shown in heavy lines is one of several possible Hamilton circuits.

Graph theory, being a branch of mathematics known as combinatorial topology, lends itself to a variety of problems involving combinatorics: for example, designing a network to connect a set of cities by railroads or by telephone lines; planning city streets or traffic patterns; matching

Figure 17: Hamilton circuit.

jobs with applicants; arranging round-robin tournaments such that every team or individual meets every other team or individual.

Map-colouring problems. Although geographers have long known that maps depicting subdivisions of areas can be coloured in such a way that any two subdivisions having a common boundary show different colours and no more than four distinct colours need be used, the celebrated "four-colour map problem" bears little or no relation, historically, to cartography. The mathematical question was originally framed in 1850 and publicized in 1878. Essentially, the problem is: How many colours are needed to colour any map so that no two regions sharing a common border (edge) will have the same colour? Are four colours both necessary and sufficient? In short, is it possible to construct a map for which five colours are necessary? No one was sure until 1977, when a group of mathematicians proved that four colours are sufficient for every possible configuration. The proof occupied 170 pages of text and diagrams derived from more than 1,000 hours of calculations on a large electronic computer; it is treated in more detail in the article COMBINATORICS.

Flexagons. A flexagon is a polygon constructed from a strip of paper or thin metal foil in such a way that the figure possesses the property of changing its faces when it is flexed. First discussed in 1939, flexagons have become a fascinating mathematical recreation. One of the simplest flexagons is the trihexaflexagon, made by cutting a strip of suitable material and marking off 10 equilateral triangles. By folding appropriately several times and then gluing the last triangle onto the reverse side of the first triangle, the resulting model may be flexed so that one of the faces disappears and another face takes its place.

MANIPULATIVE RECREATIONS

Puzzles involving configurations. One of the earliest puzzles and games that require arranging counters into some specified alignment or configuration was Lucas' Puzzle: in a row of seven squares, each of the three squares at the left end is occupied by a black counter, each of the three squares at the right end is occupied by a white counter, and the centre square is vacant. The object is to move one counter at a time until the squares originally occupied by white counters are occupied by black, and vice versa; black counters can be moved only to the right and white only to the left. A counter may move to an adjacent vacant square or it may jump one counter of the other colour to occupy a vacant square. The puzzle may be enlarged to any number of counters of each colour. For n counters of each kind the number of required moves is $n(n+2)$.

A similar puzzle uses eight numbered counters placed on nine positions. The aim is to shift the counters so that they will appear in reverse numerical order; only single moves and jumps are permitted.

Well known, but by no means as trivial, are games for two players, such as Ticktacktoe and its more sophisticated variations, one of which calls for each player to begin with three counters (3 black, 3 white); the first

The four-colour problem

Lucas' Puzzle

Ticktacktoe

The Hamilton circuit

player places a counter in any cell, except the center cell, of a 3×3 diagram; the players then alternate until all the counters are down. If neither has won by getting three in a row, each, in turn, is permitted to move a counter to an adjacent square, moving only horizontally or vertically. Achieving three in a row constitutes a win. There are many variations. The game can be played on a 4×4 diagram, each player starting with four counters; sometimes diagonal moves are permitted. Another version is played on a 5×5 pattern. Yet another interesting modification, popular in Europe, is variously known as Mill or Nine Men's Morris, played with counters on a board consisting of three concentric squares and eight transversals.

Another game of this sort is played on a diamond-shaped board of tessellated hexagons, usually 11 on each edge, where by "tessellated" we mean fitted together like tiles to cover the board completely. Two opposite edges of the diamond are designated "white"; the other two sides, "black." Each player has a supply of black or white counters. The players alternately place a piece on any vacant hexagon; the object of the game is for each player to complete an unbroken chain of his pieces between the sides designating his colour. Though the game does not end until one of the players has made a complete chain, it may meander across the board; it cannot end in a draw because the only way one player can block the other is by completing his own chain. The game was created by Piet Hein in 1942 in Denmark, where it quickly became popular under the name of Polygon. It was invented independently in the United States in 1948 by John Nash, and a few years later one version was marketed under the name of Hex.

In addition to the aforementioned varieties of a class of games that can be loosely described as "three in a row" or "specified alignment," many others also exist, such as three- and four-dimensional Ticktacktoe and even a computer Ticktacktoe. The game strategy in Ticktacktoe is by no means simple; an excellent mathematical analysis is given by F. Schuh (see *Bibliography*).

Chessboard problems. Recreational problems posed with regard to the conventional chessboard are legion. Among the most widely discussed is the problem of how to place eight queens on a chessboard in such a way that none of the queens is attacking any other queen; the problem interested the great German mathematician C.F. Gauss (c. 1850). Another group of problems has to do with the knight's tour; in particular, to find a closed knight's tour that ends at the starting point, that does not enter any square more than once, but that passes through all the squares in one tour. Problems of the knight's tour are intimately connected with the construction of magic squares. Other chessboard problems are concerned with determining the relative values of the various chess pieces; finding the maximum number of pieces of any one type that can be put on a board so that no one piece can take any other; finding the minimum number of pieces of any one type that can be put on a board so as to command all cells; and how to place 16 queens on a board so that no three of them are in a straight line.

The Fifteen Puzzle. One of the best known of all puzzles is the Fifteen Puzzle, which was invented by Sam Loyd the elder about 1878. It is also known as the Boss Puzzle, Jeu de Taquin, and Diablotin. It became popular all over Europe almost at once. It consists essentially of a shallow square tray that holds 15 small square counters numbered from 1 to 15, and one square blank space. With the 15 squares initially placed in random order and with the blank space in the lower right-hand corner, the puzzle is to rearrange them in numerical order by sliding only, with the blank space ending up back in the lower right-hand corner. It may overwhelm the reader to learn that there are more than 20,000,000,000,000 possible different arrangements that the pieces (including the blank space) can assume. But in 1879 two American mathematicians proved that only one-half of all possible initial arrangements, or about 10,000,000,000,000, admitted of a solution. The mathematical analysis is as follows. Basically, no matter what path it takes, as long as it ends its journey in the lower right-hand corner of the tray, any numeral must pass through an even number of boxes. In

the normal position of the squares (Figure 18A), regarded row by row from left to right, each number is larger than all the preceding numbers; i.e., no number *precedes* any number smaller than itself. In any other than the normal arrangement, one or more numbers will precede others smaller than themselves. Every such instance is called an inversion. For example, in the sequence 9, 5, 3, 4, the 9 precedes three numbers smaller than itself and the 5 precedes two numbers smaller than itself, making a total of five inversions. If the total number of *all* the inversions in a given arrangement is *even*, the puzzle can be solved by bringing the squares back to the normal arrangement; if the total number of inversions is *odd*, the puzzle cannot be solved. Thus, in Figure 18B there are two inversions,

Figure 18: (A) Fifteen Puzzle with no inversions. (B) With two inversions. (C) With five inversions.

and the puzzle can be solved; in Figure 18C there are five inversions, and the puzzle has no solution. Theoretically, the puzzle can be extended to a tray of $m \times n$ spaces with $(mn - 1)$ numbered counters.

The Tower of Hanoi. The puzzle of the Tower of Hanoi is believed to have been originated in 1883 by Lucas, under the name of M. Claus. Ever popular, made of wood or plastic, it still can be found in toy shops. It consists essentially of three pegs fastened to a stand and of eight circular disks, each having a hole in the centre. The disks, all of different radii, are initially placed (see Figure 19) on

Figure 19: Tower of Hanoi.

one of the pegs, with the largest disk on the bottom and the smallest on top; no disk rests upon one smaller than itself. The task is to transfer the individual disks from one peg to another so that no disk ever rests on one smaller than itself, and, finally, to transfer the tower; i.e., all the disks in their proper order, from their original peg to one of the other pegs. It can be shown that for a tower of n disks, there will be required $2^n - 1$ transfers of individual disks to shift the tower completely to another peg. Thus for 8 disks, the puzzle requires $2^8 - 1$, or 255 transfers. If the original "needle" (peg) was a tower with 64 disks, the number of transfers would be $2^{64} - 1$, or 18,446,744,073,709,551,615; this is exactly the same number required to fill an 8×8 checkerboard with grains of wheat, 1 on the first square, 2 on the second, 4 on the next, then 8, 16, 32, etc.

Polyominoes. The term polyomino was introduced in 1953 as a jocular extension of the word domino. A polyomino is a simply connected set of equal-sized squares, each joined to at least one other along an edge. The simpler polyomino shapes are shown in Figure 20A. Somewhat more fascinating are the pentominoes, of which there are exactly 12 forms (Figure 20B). Asymmetrical pieces, which have different shapes when they are flipped over, are counted as one.

The number of distinct polyominoes of any order is a function of the number of squares in each, but, as yet, no general formula has been found. It has been shown that there are 35 types of hexominoes and 108 types of heptominoes, if the dubious heptomino with an interior "hole" is included.

Manipulating squares

Figure 20: Shapes made of squares. (A) Monomino with simple polyominoes. (B) Pentominoes. (C) Heptomino with interior "hole."

From Martin Gardner, *The Scientific American Book of Mathematical Puzzles and Diversions* (copyright © 1959 by Martin Gardner); reprinted by permission of Simon and Schuster, Inc.

Recreations with polyominoes include a wide variety of problems in combinatorial geometry, such as forming desired shapes and specified designs, covering a chessboard with polyominoes in accordance with prescribed conditions, etc. Two illustrations may suffice.

The 35 hexominoes, having a total area of 210 squares, would seem to admit of arrangement into a rectangle 3×70 , 5×42 , 6×35 , 7×30 , 10×21 , or 14×15 ; however, no such rectangle can be formed.

Can the 12 pentominoes, together with one square tetromino, form an 8×8 checkerboard? A solution of the problem was shown around 1935. It is not known how many solutions there are, but it has been estimated to be at least 1,000. In 1958, by use of a computer, it was shown that there are 65 solutions in which the square tetromino is exactly in the centre of the checkerboard.

Soma Cubes. Piet Hein of Denmark, also known for his invention of the mathematical games known as Hex and Tac Tix, stumbled upon the fact that all the irregular shapes that can be formed by combining three or four congruent cubes joined at their faces can be put together to form a larger cube. There are exactly seven such shapes, called Soma Cubes; they are shown in Figure 21. No two shapes are alike, although the fifth and sixth are mirror images of each other. The fact that these seven pieces (comprising 27 "unit" cubes) can be reassembled to form one large cube is indeed remarkable.

Many interesting solid shapes can be formed from the seven Soma Cubes, shapes resembling, for example, a sofa, a chair, a castle, a tunnel, a pyramid, and so on. Even the assembling of the seven basic pieces into a large cube can be done in more than 230 essentially different ways.

As a recreation, the Soma Cubes are fascinating. With experience, many persons find that they can solve Soma problems mentally. Psychologists who have used them find that the ability to solve Soma problems is roughly correlated with general intelligence, although there are some strange anomalies at both ends of the distribution of intelligence. In any event, people playing with the cubes do not appear to want to stop; the variety of interesting structures possible seems endless.

Coloured squares and cubes. There is a wide variety of puzzles involving coloured square tiles and coloured cubes. In one, the object is to arrange the 24 three-colour patterns, including repetitions, that can be obtained by subdividing square tiles diagonally, using three different colours, into a 4×6 rectangle so that each pair of touching edges is the same colour and the entire border of the rectangle is the same colour.

More widely known perhaps is the 30 Coloured Cubes Puzzle. If six colours are used to paint the faces there result 2,226 different combinations. If from this total only those cubes that bear all six colours on their faces are selected, a set of 30 different cubes is obtained; two cubes are regarded as "different" if they cannot be placed side by side

so that all corresponding faces match. Many fascinating puzzles arise from these coloured squares and cubes; many more could be devised. Some of them have appeared commercially at various times under different names, such as the Mayblox Puzzle, the Tantalizer, and the Katzenjammer. Stimulating discussions may be found in books by MacMahon, Winter, and O'Beirne (see *Bibliography*).

A revival of interest in coloured-cube problems was aroused by the appearance of a puzzle known as Instant Insanity, consisting of four cubes, each of which has its faces painted white, red, green, and blue in a definite scheme. The puzzle is to assemble the cubes into a $1 \times 1 \times 4$ prism such that all four colours appear on each of the four long faces of the prism. Since each cube admits of 24 different orientations, there are 82,944 possible prismatic arrangements; of these only two are the required solutions.

This puzzle was soon superseded by Rubik's Cube, developed independently by Ernő Rubik (who obtained a Hungarian patent in 1975) and Terutoshi Ishigi (who obtained a Japanese patent in 1976). The cube appears to be composed of 27 smaller cubes, or cubelets; in its initial state, each of the six faces of the cube is made up of nine cubelet faces all of the same colour. In the commercial versions of the puzzle, an internal system of pivots allows any layer of nine cubelets to be rotated with respect to the rest, so that successive rotations about the three axes cause the cubelet faces to become scrambled. The challenge of restoring a scrambled cube to its original configuration

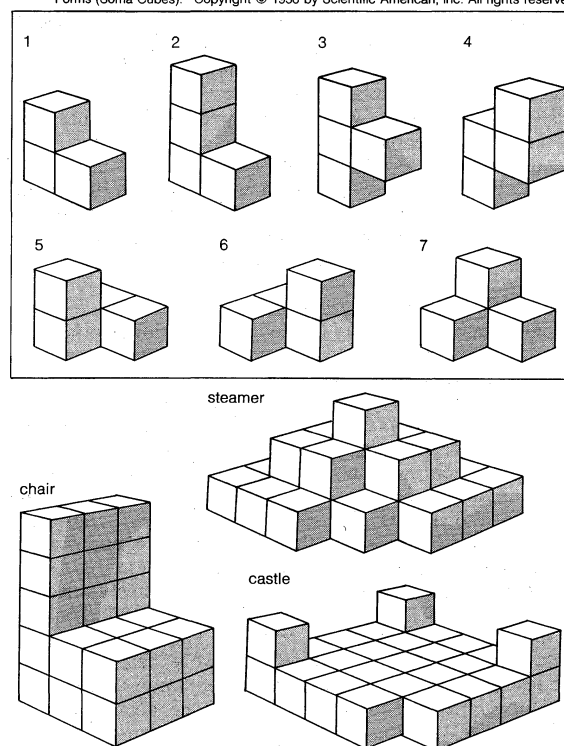

Figure 21: Soma Cubes. (Top) The seven basic pieces. (Bottom) Examples of some of the shapes that can be built from Soma pieces.

is formidable, inasmuch as more than 10^{19} states can be reached from a given starting condition. A thriving literature quickly developed for the exposition of systematic solutions (based on group theory) of scrambled cubes.

Nim and similar games. A game so old that its origin is obscure, Nim lends itself nicely to mathematical analysis. In its generalized form, any number of objects (counters) are divided arbitrarily into several piles. Two people play alternately; each, in turn, selects any one of the piles and removes from it all the objects, or as many as he chooses, but at least one object. The player removing the last object wins. Every combination of the objects may be considered "safe" or "unsafe"; i.e., if the position left by a player after his move assures a win for that player, the position

"Safe" and "unsafe" positions is called safe. Every unsafe position can be made safe by an appropriate move, but every safe position is made unsafe by any move. To determine whether a position is safe or unsafe, the number of objects in each pile may be expressed in binary notation: if each column adds up to zero or an even number, the position is safe. For example, if at some stage of the game, three piles contain 4, 9, and 15 objects, the calculation is:

$$\begin{array}{r} 4 \rightarrow 100 \\ 9 \rightarrow 1001 \\ 15 \rightarrow 1111 \\ \hline 2212 \end{array}$$

Since the second column from the right adds up to 1, an odd number, the given combination is unsafe. A skillful player will always move so that every unsafe position left to him is changed to a safe position.

A similar game is played with just two piles; in each draw the player may take objects from either pile or from both piles, but in the latter event he must take the same number from each pile. The player taking the last counter is the winner.

Games such as Nim make considerable demands upon the player's ability to translate decimal numbers into binary numbers and vice versa. Since digital computers operate on the binary system, however, it is possible to program a computer (or build a special machine) that will play a perfect game. Such a machine was invented by E.U. Condon and an associate; their automatic Nimatron was exhibited at the New York World's Fair in 1940.

Games of this sort seem to be widely played the world over. The game of Pebbles, also known as the game of Odds, is played by two people who start with an odd number of pebbles placed in a pile. Taking turns, each player draws one, or two, or three pebbles from the pile. When all the pebbles have been drawn, the player who has an odd number of them in his possession wins.

Predecessors of these games, in which players distribute pebbles, seeds, or other counters into rows of holes under varying rules, have been played for centuries in Africa and Asia and are known as Mancala games.

PROBLEMS OF LOGICAL INFERENCE

Logical puzzles. Many challenging questions do not involve numerical or geometrical considerations but call for deductive inferences based chiefly on logical relationships. Such puzzles are not to be confounded with riddles, which frequently rely upon deliberately misleading or ambiguous statements, a play on words, or some other device intended to catch the unwary. Logical puzzles do not admit of a standard procedure or generalized pattern for their solution and are usually solved by some trial-and-error method. This is not to say that the guessing is haphazard; on the contrary, the given facts (generally minimal) suggest several hypotheses. These can be successively rejected if found inconsistent, until, by substitution and elimination, the solution is finally reached. The use of various techniques of logic may sometimes prove helpful, but in the last analysis, success depends largely upon that elusive capacity called ingenuity. For convenience, logic problems are arbitrarily grouped in the following categories.

The brakeman, the fireman, and the engineer. The brakeman-fireman-engineer puzzle has become a classic. The following version of it appeared in O. Jacoby and W.H. Benson's *Mathematics for Pleasure* (1962).

The names, not necessarily respectively, of the brakeman, fireman, and engineer of a certain train were Smith, Jones, and Robinson. Three passengers on the train happened to have the same names and, in order to distinguish them from the railway employees, will be referred to hereafter as Mr. Smith, Mr. Jones, and Mr. Robinson. Mr. Robinson lived in Detroit; the brakeman lived halfway between Chicago and Detroit; Mr. Jones earned exactly \$2,000 per year; Smith beat the fireman at billiards; the brakeman's next-door neighbour, one of the passengers, earned exactly three times as much as the brakeman; and the passenger who lived in Chicago had the same name as the brakeman. What was the name of the engineer?

Overlapping groups. The following problem is typical

of the overlapping-groups category. Among the members of a high-school language club, 21 were studying French; 20, German; 26, Spanish; 12, both French and Spanish; 10, both French and German; nine, both Spanish and German; and three, French, Spanish, and German. How many club members were there? How many members were studying only one language?

Truths and lies. Another kind of logical inference puzzle concerns truths and lies. One variety is as follows: Some of the natives of a certain South Pacific island are pure-blooded and the rest are half-breeds, but they all look alike. The pure-blooded always tell the truth, but the half-breeds always lie. A visitor to the island, meeting three natives, asks them whether they are full-blooded or half-breeds. The first says something inaudible. The second, pointing to the first, says, "He says that he is pure-blooded." The third, pointing to the second, says, "He lies." Knowing beforehand that only one is a half-breed, the visitor decides what each of the three is.

In a slightly different type, four men, one of whom was known to have committed a certain crime, made the following statements when questioned by the police:

Archie: Dave did it.

Dave: Tony did it.

Gus: I didn't do it.

Tony: Dave lied when he said I did it.

If only one of these four statements is true, who was the guilty man? On the other hand, if only one of these four statements is false, who was the guilty man? (From *101 Puzzles in Thought and Logic* by C.R. Wylie, Jr.; Dover Publications, Inc., New York, 1957. Reprinted through the permission of the publisher.)

The smudged faces. The problem of the smudged faces is another instance of pure logical deduction. Three travellers were aboard a train that had just emerged from a tunnel, leaving a smudge of soot on the forehead of each. While they were laughing at each other, and before they could look into a mirror, a neighbouring passenger suggested that although no one of the three knew whether he himself was smudged, there was a way of finding out without using a mirror. He suggested: "Each of the three of you look at the other two; if you see at least one whose forehead is smudged, raise your hand." Each raised his hand at once. "Now," said the neighbour, "as soon as one of you knows for sure whether his own forehead is smudged or not, he should drop his hand, but not before." After a moment or two, one of the men dropped his hand with a smile of satisfaction, saying: "I know." How did that man know that his forehead was smudged?

The unexpected hanging. A final example might be the paradox of the unexpected hanging, a remarkable puzzle that first became known by word of mouth in the early 1940s. One form of the paradox is the following: A prisoner has been sentenced on Saturday. The judge announces that "the hanging will take place at noon on one of the seven days of next week, but you will not know which day it is until you are told on the morning of the day of the hanging." The prisoner, on mulling this over, decided that the judge's sentence could not possibly be carried out. "For example," said he, "I can't be hanged next Saturday, the last day of the week, because on Friday afternoon I'd still be alive and I'd know for sure that I'd be hanged on Saturday. But I'd known this *before* I was told about it on Saturday morning, and this would contradict the judge's statement." In the same way, he argued, they could not hang him on Friday, or Thursday, or Wednesday, Tuesday, or Monday. "And they can't hang me tomorrow," thought the prisoner, "because I know it today!"

Careful analysis reveals that this argument is false, and that the decree can be carried out. The paradox is a subtle one. The crucial point is that a statement about a future event can be known to be a true prediction by one person but not known to be true by another person until *after* the event has taken place.

Logical paradoxes. Highly amusing and often tantalizing, logical paradoxes generally lead to searching discussions of the foundations of mathematics. As early as the 6th century BC, the Cretan prophet Epimenides allegedly observed that "All Cretans are liars," which, in effect,

Solution
of logical
problems

means that "All statements made by Cretans are false." Since Epimenides was a Cretan, the statement made by him is false, so that all statements made by Cretans are *not* false. Thus the initial statement is self-contradictory. A similar dilemma was given by an English mathematician, P.E.B. Jourdain, in 1913, when he proposed the card paradox. This was a card on one side of which was printed:

"The sentence on the other side of this card is TRUE."

On the other side of the card the sentence read:

"The sentence on the other side of this card is FALSE."

The barber paradox

The barber paradox, offered by Bertrand Russell, was of the same sort: The only barber in the village declared that he shaved everyone in the village who did not shave himself. On the face of it, this is a perfectly innocent remark until it is asked "Who shaves the barber?" If he does not shave himself, then he is one of those in the village who does not shave himself and so is shaved by the barber, namely, himself. If he shaves himself, he is, of course, one of the people in the village who is not shaved by the barber. The self-contradiction lies in the fact that a statement is made about "all" the members of a certain class, when the statement or the object to which the statement refers is itself a member of the class. In short, the Russell paradox hinges on the distinction between those classes that are members of themselves and those that are not members of themselves. Russell attempted to resolve the paradox of the class of all classes by introducing the concept of a hierarchy of logical types but without much success. Indeed, the entire problem lies close to the philosophical foundations of mathematics.

Number Theory

Number theory is a branch of mathematics that grew out of human curiosity concerning properties of the positive integers 1, 2, 3, 4, 5, . . . , also called whole numbers, natural numbers, or counting numbers. These numbers were the first mathematical creation of the human mind; interest in them is as old as civilization itself.

Number theory has always fascinated amateurs as well as professional mathematicians. In contrast to other branches of mathematics, many of the problems and theorems of number theory can be understood by laymen, although solutions to the problems and proofs of the theorems often require sophisticated mathematical background. The intellectual challenge of number theory's unsolved problems has attracted noted mathematicians from the time of Pythagoras (c. 540 BC). Work on these problems has often led to the creation of new branches of mathematics.

Until the mid-20th century, number theory was considered the purest branch of mathematics, with no direct applications to the real world. The advent of digital computers and digital communications revealed that number theory could provide unexpected answers to real-world problems. At the same time, improvements in computer

technology enabled number theorists to make remarkable advances in factoring large numbers, determining primes, testing conjectures, and solving numerical problems once considered out of reach.

Modern number theory is a broad subject that encompasses topics only indirectly connected with the integers. It is classified into subheadings such as elementary number theory, algebraic number theory, analytic number theory, geometric number theory, and probabilistic number theory. These categories reflect the methods used to shed light on problems concerning the integers. For example, algebraic number theory makes extensive use of abstract algebra, while analytic number theory employs calculus and complex function theory. Most of this article deals with elementary number theory and can be read with profit by anyone with a good background in high school algebra. More advanced topics, such as algebraic and analytic number theory, are discussed in later sections.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 10/21 and 10/22, and the *Index*.

This article is divided into the following sections:

ELEMENTARY NUMBER THEORY

Divisibility and prime numbers. The integers consist of the natural numbers 1, 2, 3, 4, 5, . . . , together with their negatives $-1, -2, -3, -4, -5, \dots$, and 0 (zero). Addition, subtraction, and multiplication of two integers always produces an integer. Division of two integers does not always produce an integer. For example, when 147 is divided by 10, the result is 14.7, which is not an integer. But, when 147 is divided by 7, the result is 21, an integer. In number theory 147 is said to be divisible by 7 but not by 10. More generally, an integer n is said to be divisible by an integer d if the quotient n/d is an integer c , so that $n = cd$. If so, n is called a multiple of d , and d is called a divisor, or factor, of n . This relation is expressed by the notation $d|n$, read " d divides n ." The notation $d \nmid n$ means that d does not divide n . Thus, $7|147$, but $10 \nmid 147$.

Every positive integer is divisible by itself and 1. If an integer is greater than 1 and has only itself and 1 as positive divisors, it is called a prime.

The first few primes are 2, 3, 5, 7, 11, 13, 17, and 19. By mathematical convention, 1 is not a prime; this makes it possible to state propositions about primes without introducing qualifications. There are exactly 25 primes below 100. They can be found easily by the following "sifting" method, discovered by Eratosthenes of Cyrene around 200 BC: List the integers from 2 to 100 in increasing order. Strike out the even numbers greater than 2 (4, 6, 8, 10, . . .); they are divisible by 2 and therefore are not primes. Among the numbers that remain, strike out all multiples of 3 greater than 3 (9, 15, 21, 27, . . .); they are

divisible by 3 and therefore are not primes. Continue the sifting process by crossing out multiples of 5 greater than 5, then multiples of 7 greater than 7. The numbers that remain are all the primes less than 100:

2, 3, 5, 7, 11, 13, 17, 19, 23, 29, 31, 37, 41, 43,
47, 53, 59, 61, 67, 71, 73, 79, 83, 89, and 97.

This sifting process, though laborious to do by hand, is highly efficient. It is not necessary to sift out multiples of 11 because the next such multiple not already crossed out is $11^2 = 121$, which is greater than 100. For the general case, when the sieve of Eratosthenes is used to find all the primes below a given integer n , only the multiples of primes smaller than \sqrt{n} need be struck out.

All integers greater than 1 that are not primes are called composite numbers. A composite number is the product of two integers, each greater than 1. By repeated factorization, every composite number can be expressed as the product of primes, some of which may be repeated. For example, $147 = 7 \cdot 21 = 7 \cdot 7 \cdot 3$. Because every integer greater than 1 is a prime or a product of primes, the study of integers depends ultimately on properties of prime numbers.

Tables of primes reveal great irregularity in their distribution, from pairs of "twin" primes, differing only by 2, such as 3 and 5, 11 and 13, and 71 and 73, to primes separated by arbitrarily large gaps. A simple example shows why such gaps must occur. Let n be the product of all the positive integers from 1 to 100. The 99 consecutive integers $n + 2, n + 3, \dots, n + 100$ are composite because

Sieve of
Eratosthenes

Distribu-
tion of
primes

they are divisible, respectively, by 2, 3, ..., 100. The same type of argument, with 100 replaced by any positive integer, demonstrates that there are arbitrarily long strings of consecutive composite numbers and consequently arbitrarily large gaps between successive primes.

The distribution of primes appears to be more regular if they are counted in large blocks, say in groups of 1,000 consecutive integers. The first six blocks of length 1,000 contain, successively,

168, 135, 127, 120, 119, and 114

prime numbers. These figures suggest that the number of primes decreases in successive blocks of 1,000. But, as is often the case in number theory, the data can be misleading. The next four blocks contain

117, 107, 110, and 112

primes. Thus, the numbers of primes in successive blocks do not always decrease. But they do decrease on the average, with the 10,000th block (between 9,999,001 and 10,000,000) containing only 53 primes. The primes themselves become rarer and rarer among the large integers.

This observation raises the question of whether the primes terminate after some point. It has been known since antiquity that they do not. A proof is given in Euclid's *Elements* (Book IX, proposition 20) and is based on the idea that for any finite collection of primes, say

$$p_1, p_2, \dots, p_k,$$

there is always another prime that is not one of these. To see why this is so, simply multiply the primes together and add 1 to form the number

$$N = 1 + p_1 p_2 \cdots p_k.$$

This number, being greater than 1, has at least one prime divisor; that divisor cannot be any of p_1, p_2, \dots, p_k , because division of N by each of these primes leaves a remainder of 1. Therefore N must be divisible by a prime other than these (which may be N itself), so that the collection of all primes cannot be finite.

There are many other proofs of the infinitude of primes, but none is as elegant as the one in Euclid. For example, in 1845 the French mathematician Joseph Bertrand verified that for every integer n from 2 to 6,000,000 there is always at least one prime number between n and $2n$. The general proposition, without the 6,000,000 limitation on n , became known as Bertrand's postulate, and in 1851 the Russian mathematician Pafnuty Lvovich Chebyshev proved that it is true for all n . This result implies that there are infinitely many primes. It also implies that, if the primes are listed in increasing order as p_1, p_2, \dots , then each prime is less than twice its predecessor: $p_{n+1} < 2p_n$. A different type of proof makes use of the sum of the reciprocals of the primes. It can be shown that for every positive integer n there is a finite set of primes, the sum of whose reciprocals exceeds n . If there were only finitely many primes in all, say k of them, take n in the previous sentence to be k , and a contradiction follows at once. In the terminology of infinite series, the sum of the reciprocals of all the primes is a divergent series.

Evidence suggests that the number of twin primes is infinite, but this has not been proved or disproved. It is known that the sum of the reciprocals of all the twin primes cannot exceed 3. Whether their number is finite or infinite, twin primes are comparatively rare.

The ancient Greeks knew that every integer greater than 1 is a product of prime factors, but it was not until 1801 that Carl Friedrich Gauss stated and proved that this factorization can be done in only one way, apart from the order of the factors (*i.e.*, it does not matter whether the factorization of 21 is written as $7 \cdot 3$ or $3 \cdot 7$). Of course, some integers can be factored in different ways using composite factors. For example, $600 = 15 \cdot 40 = 12 \cdot 50 = 8 \cdot 75$. But the factorization into prime factors, $600 = 2 \cdot 2 \cdot 2 \cdot 3 \cdot 5 \cdot 5$, is unique (apart from the order of the factors). This basic result about unique factorization is known as the fundamental theorem of arithmetic. The primes are building blocks out of which every natural number greater than 1 can be obtained in one and only one way by multiplication.

The factorization of a number into primes is often written as a product of powers of distinct primes. For example, $600 = 2^3 \cdot 3^1 \cdot 5^2$. In general, every integer n greater than 1 can be expressed as a product of the form

$$n = p^A \cdot q^B \cdots,$$

where p, q, \dots are the distinct prime factors of n , and the exponents A, B, \dots indicate how many times the corresponding prime occurs in the factorization. Once this factorization is known, it is easy to determine all the positive divisors of n . Simply take all products of the form $p^a \cdot q^b \cdots$, where the exponent a takes the values 0, 1, ..., A , the exponent b takes the values 0, 1, ..., B , and so on. For example, the positive divisors of 600 are all numbers of the form $2^a \cdot 3^b \cdot 5^c$, where a is 0, 1, 2, or 3, b is 0 or 1, and c is 0, 1, or 2. In this case there are four choices for a , two choices for b , and three choices for c , giving a total of $4 \cdot 2 \cdot 3 = 24$ positive divisors of 600 (including 1 and 600). This illustrates the general theorem that, if $n = p^A \cdot q^B \cdots$, where p, q, \dots are distinct primes, then the total number of positive divisors of n is $(A+1)(B+1) \cdots$. In particular, if n is the product of k distinct primes, then the number of positive divisors of n is 2^k .

The greatest common divisor of two or more integers. Any two positive integers whose only common positive divisor is 1 are said to be relatively prime, or coprime. For example, the numbers $8 = 2^3$ and $9 = 3^2$ are relatively prime, as are

$$600 = 2^3 \cdot 3 \cdot 5^2 \text{ and } 77 = 7 \cdot 11,$$

because they have no prime factors in common. If two positive integers a and b have a common divisor greater than 1, then the prime factors of that common divisor must also divide both a and b . The largest positive common divisor of a and b is known as the greatest common divisor (GCD) of a and b and is denoted by the symbol (a, b) . It can be obtained by multiplying together the common prime factors of a and b , each factor raised to the highest power to which it occurs in both a and b . For example, to find the GCD of 500 and 600, one can first determine that $500 = 2^2 \cdot 5^3$ and $600 = 2^3 \cdot 3 \cdot 5^2$, so that $(500, 600) = 2^2 \cdot 5^2 = 100$.

If the prime factorizations of a and b are known, their greatest common divisor is easily determined by the method just described. But there is a simpler method, called the Euclidean algorithm, that does not require prime factorization. If a is greater than b and b is not zero, division of a by b produces a quotient q and a remainder r , where r is nonnegative and less than b . This can be expressed in the form

$$a = bq + r, \text{ where } 0 \leq r < b.$$

Division of b by the remainder r produces a new quotient and remainder, and the process is repeated. Because the remainders form a decreasing sequence of nonnegative integers, they eventually reach zero. The last nonzero remainder is the GCD of a and b . For the case $a = 78,696$ and $b = 19,332$, there are six steps in the algorithm:

$$\begin{aligned} 78,696 &= 19,332 \cdot 4 + 1,368 \\ 19,332 &= 1,368 \cdot 14 + 180 \\ 1,368 &= 180 \cdot 7 + 108 \\ 180 &= 108 \cdot 1 + 72 \\ 108 &= 72 \cdot 1 + 36 \\ 72 &= 36 \cdot 2 + 0. \end{aligned}$$

The last nonzero remainder, 36, occurs in step five and is the GCD of 78,696 and 19,332. If the two integers a and b are relatively prime, the last nonzero remainder in the algorithm is 1.

The Euclidean algorithm also shows that the GCD can be written as a linear combination of a and b ; that is,

$$(a, b) = ax + by,$$

where x and y are integers. For the above example, one choice of x and y can be obtained as follows. Write the next to last equation as

$$36 = 108 - 72 \cdot 1.$$

The
Euclidean
algorithm

This expresses the GCD as a linear combination of the previous quotient, 108, and the previous remainder, 72. Use the next equation up to replace 72 by $180 - 108 \cdot 1$ and obtain

$$36 = 108 - (180 - 108 \cdot 1) \\ = 2 \cdot 108 - 1 \cdot 180,$$

a linear combination of the quotient and remainder in step three. Use the next equation up to eliminate 108 and obtain

$$36 = 2 \cdot 1,368 - 15 \cdot 180.$$

Continue eliminating remainders in this way, working back up the list of equations in the algorithm to obtain finally

$$36 = 212 \cdot 78,696 - 863 \cdot 19,332.$$

This has the form $36 = ax + by$, with $x = 212$ and $y = -863$ representing one choice of x and y .

The Euclidean algorithm is described in Euclid's *Elements* (Book VII, proposition 2). The process, which was probably known much earlier by the Pythagoreans, is efficient and easy to use and has become a basic tool in number theory and modern algebra. The French mathematician Gabriel Lamé (1795–1870) showed that the number of divisions in the Euclidean algorithm never exceeds five times the number of digits in the smaller number.

The GCD of more than two integers can be found by repeated use of the Euclidean algorithm. For three positive integers a, b, c , first find the GCD of two of them, say $D = (a, b)$, and then find the GCD (D, c) . This will be the GCD of all three numbers a, b, c , denoted (a, b, c) . The result is independent of which two integers are selected first and is a linear combination of the three integers:

$$(a, b, c) = ax + by + cz$$

for some integers x, y, z . The same process works for four or more integers. For example, to find the GCD of a, b, c, d , let

$$D_1 = (a, b), D_2 = (D_1, c), \text{ and } D_3 = (D_2, d).$$

Then D_3 is the GCD of a, b, c, d , denoted (a, b, c, d) . Moreover, there exist integers x, y, z , and w , such that

$$(a, b, c, d) = ax + by + cz + dw.$$

Perfect numbers and Mersenne primes. The true origin of number theory is usually attributed to the Pythagoreans, who were the first to classify integers in various ways, such as even, odd, prime, and composite. The Pythagoreans called 6 a perfect number because $6 = 1 + 2 + 3$, the sum of all its proper divisors (that is, the sum of all divisors less than 6). The next perfect number is 28, whose proper divisors are 1, 2, 4, 7, and 14. The Greeks referred to the proper divisors of a number as its “parts,” and they considered a number perfect if it was equal to the sum of all its parts. They also proposed the problem of determining all perfect numbers, which is the oldest unsolved problem in number theory. In Euclid's *Elements* (Book IX, proposition 36) it is shown that an even number is perfect if (in modern notation) it has the form $2^{p-1}(2^p - 1)$, where both p and $2^p - 1$ are primes. In 1757 the Swiss mathematician Leonhard Euler proved that, conversely, every even perfect number must be of Euclid's type. For example, when $p = 2, 3, 5$, and 7 , the quantity $(2^p - 1)$ has the values 3, 7, 31, and 127, all of which are primes, and Euclid's formula gives the perfect numbers 6, 28, 496, and 8,128; these are the first four perfect numbers. For $p = 11$, the quantity $2^p - 1$ is composite and $2^{p-1}(2^p - 1)$ is not perfect. The next perfect number, corresponding to $p = 13$, is 33,550,336, discovered in the 5th century A.D.

Numbers of the form $2^n - 1$ are called Mersenne numbers (denoted M_n) after the French mathematician Marin Mersenne, who studied them in 1644. If M_n is prime, it is easy to show that n itself must be prime. (The converse is not true, because $M_{11} = 2,047 = 23 \cdot 89$, a composite number.) If a Mersenne number is a prime, it is called a Mersenne prime. Mersenne numbers are of interest because each new Mersenne prime leads to a new perfect number. In 1750 Euler showed that M_{31} is prime, and in

1876 the French mathematician Édouard Lucas developed a method for testing whether M_p is prime and used it to prove that M_{127} is prime.

The Lucas primality test, as refined by the American mathematician Derrick Henry Lehmer in 1930, involves a sequence of numbers $S_2 = 4, S_3 = 14, S_4 = 194, \dots$, where for $n > 2$ the S_n are defined successively by the formula $S_n = S_{n-1}^2 - 2$. The Lucas-Lehmer test states that a Mersenne number M_p with $p > 2$ is prime if M_p divides S_p but is composite otherwise. Lucas showed that S_{127} is divisible by M_{127} and deduced that M_{127} is prime. This was a formidable computational task because the numbers S_{127} and M_{127} are quite large, the latter having 39 digits. Nevertheless, the work was manageable because divisibility by M_{127} could be determined without actually computing S_{127} .

No further Mersenne primes were found until the mid-20th century, when the advent of high-speed electronic computing machines working in the binary scale made divisibility by numbers of the form $2^p - 1$ relatively simple. In a series of investigations begun by D.H. Lehmer and Raphael M. Robinson and continued by others, the Lucas-Lehmer test was used to discover many new Mersenne primes. In 1978 two American high school students, Laura Nickel and Curt Noll, found the 25th and 26th Mersenne primes, requiring 440 hours on a large computer. By mid-1989, 31 perfect numbers were known, corresponding to the following values of p in Euclid's formula:

$$p = 2, 3, 5, 7, 13, 17, 19, 31, 61, 89, \\ 107, 127, 521, 607, 1,279, 2,203, 2,281, \\ 3,217, 4,253, 4,423, 9,689, 9,941, 11,213, \\ 19,937, 21,701, 23,209, 44,497, 86,243, \\ 110,503, 132,049, \text{ and } 216,091.$$

The largest known Mersenne prime was also the largest known prime number in mid-1989.

No odd perfect numbers are known, and it is not known if any exist. But if any do exist they must be larger than 10^{60} and must have at least eight distinct prime factors. It has been conjectured, but not proved, that the number of Mersenne primes is infinite. Thus, the Pythagorean problem of determining all perfect numbers remains unsolved.

Formulas that produce prime numbers. The irregularity in the distribution of primes suggests that there is no simple formula for producing all the primes. Some formulas do yield many primes. For example, the quadratic polynomial $x^2 - x + 41$, introduced by Euler in 1772, gives a prime for each of the 81 integer values of x from -40 to 40 . However, in 1752 the German-Russian mathematician Christian Goldbach proved that no polynomial with integer coefficients can give a prime for all integer values of x , even if cubes and higher powers are used.

Some polynomials represent infinitely many primes. The linear polynomial $2x + 1$, where x is any positive integer, gives all the odd numbers, hence infinitely many primes. Each of the linear polynomials $4x + 1$ and $4x + 3$ also represents an infinite number of primes. In 1837 the German mathematician Peter Gustav Lejeune Dirichlet proved that, if h and k are relatively prime positive integers, the linear polynomial $kx + h$ gives infinitely many primes as x runs through the positive integers. This result is known as Dirichlet's theorem on the existence of primes in a given arithmetic progression. To prove this theorem, Dirichlet went outside the discrete realm of integers and appealed to continuity, using tools of calculus such as limits and infinite series. He thereby laid the foundations for the branch of mathematics called analytic number theory, in which methods of real and complex mathematical analysis are applied to problems about the integers (see below *Analytic number theory*).

It is not known whether there is any quadratic polynomial $ax^2 + bx + c$ with $a \neq 0$ that represents infinitely many primes. But Dirichlet proved that, if $a, 2b$, and c are relatively prime positive integers with $b^2 \neq ac$, then the quadratic polynomial in two variables $ax^2 + 2bxy + cy^2$ represents infinitely many primes as x and y run through the positive integers.

Although no simple formula gives all the primes, it is known that there is a polynomial in 10 variables with integer coefficients such that the set of primes is equal to

Lucas-Lehmer test for primes

the set of positive values of this polynomial obtained as the variables run through all nonnegative integers.

At first glance it seems likely that primes could be produced by taking a high power of a fixed integer k and adding or subtracting 1. It is easy to show that, if $k^m - 1$ is prime, then $k = 2$ and m is prime, so the problem is reduced to that of Mersenne primes. But, for $k^m + 1$ to be prime, k must be even and the exponent m must be a power of 2. Numbers of the form $2^{2^n} + 1$ were studied by the 17th-century French mathematician Pierre de Fermat, who conjectured that they would always give a prime for $n = 0, 1, 2, \dots$. These numbers are called Fermat numbers and are denoted by F_n . The first five are

$$F_0 = 3, F_1 = 5, F_2 = 17, F_3 = 257, \text{ and } F_4 = 65,537,$$

and all of these are primes. But in 1732 Euler found that F_5 is a composite number. This is easily verified on a hand calculator that displays 10 or more digits, because

$$F_5 = 2^{32} + 1 = 4,294,967,297 = 641 \cdot 6,700,417.$$

Beyond F_4 , no further Fermat primes have been found. In fact, F_n is composite for all n from 5 to 20 and for many higher values of n , although for some composite Fermat numbers not all the factors are known. Euler knew that if F_n is composite, it has a factor of the form $k \cdot 2^{n+2} + 1$ for some k . This is how he discovered the factor $641 = 5 \cdot 2^7 + 1$ in F_5 . Similarly, the large Fermat number $F_{3,310}$, which has more than 10^{990} digits, is known to be composite because it has the factor $5 \cdot 2^{3,312} + 1$. Fermat's conjecture that F_n is always prime is clearly false. Some mathematicians think there may be no further Fermat primes beyond F_4 , or perhaps a finite number at most.

The Fermat numbers have an interesting connection with the classical problem of constructing a regular polygon by Euclidean methods (*i.e.*, by the use of an unmarked straightedge and compass). In 1796 Gauss, at the age of 19, solved a problem that had perplexed professional and amateur mathematicians for 2,000 years. He proved that a circle could be divided into n equal parts with a straightedge and compass if and only if n is the product of distinct Fermat primes and a nonnegative power of 2. For example, regular polygons with n sides can be constructed with a straightedge and compass for $n = 3, 4, 5, 6, 8, 10, 12, 15, 16, 17, 20, 24, 30, \dots$ but not for $n = 7, 9, 11, 13, 14, 18, 19, 21, 22, 23, 25, \dots$. This spectacular accomplishment inspired the young Gauss to become a mathematician rather than a philologist.

Formulas have been contrived to produce all the primes, but they usually involve numbers that cannot be determined without previous knowledge of the primes themselves. One example involves a positive number A less than 1 whose decimal representation is

$$A = 0.2003000050000007000000011 \dots$$

The nonzero digits in A are the primes listed in increasing order. Enough zeros are inserted between successive primes so that the last digit of the n th prime p_n occurs at the decimal place at position n^2 . Thus, 2 occurs at the first decimal place, 3 at the fourth, 5 at the ninth, and 7 at the 16th place. The number of decimal places between the prime p_n and its predecessor p_{n-1} is the difference $n^2 - (n-1)^2 = 2n - 1$. Each prime p_n can be recovered from the number A by using the formula

$$p_n = [10^{n^2}A] - 10^{2n-1}[10^{(n-1)^2}A],$$

where the square bracket symbol $[x]$ denotes the largest integer contained in x . For example, when $n = 2$, the formula states that

$$p_2 = [10^4A] - 10^3[10A].$$

Now $10^4A = 2,003.00005 \dots$, hence $[10^4A] = 2,003$. Similarly, $[10A] = 2$, so $10^3[10A] = 2,000$, and the formula gives $p_2 = 2,003 - 2,000 = 3$.

Although the formula expresses p_n in terms of A , it is useless for determining primes, because to calculate the quantity $10^{n^2}A$ in the square bracket it is necessary to know the first n^2 decimal places of A , and this requires knowing the primes p_1, p_2, \dots, p_n . Formulas such as these are regarded as amusing but of little value.

Congruences and residue classes. If a positive integer m divides the difference $a - b$, then $a = b + qm$ for some integer q . Gauss modified this equation by writing

$$a \equiv b \pmod{m}$$

(read " a is congruent to b modulo m "). This is called congruence notation and is an alternative way of writing $m \mid (a - b)$. The divisor m is called the modulus and is assumed to be positive, but the integers a and b can be positive, negative, or zero. Examples of congruences are

$$17 \equiv 5 \pmod{12}, -47 \equiv 2 \pmod{7}, \text{ and } 120 \equiv 0 \pmod{5}.$$

A familiar application is in clock arithmetic, where the 24 hours in a day are represented by the numbers 1, 2, \dots , 12. The hours beyond 12 noon are given by the remainders obtained on division by 12. Thus,

$$13 \equiv 1, 17 \equiv 5, \text{ and } 21 \equiv 9 \pmod{12}.$$

Gauss's congruence notation made a significant impact on the development of number theory. One reason is that congruences share many properties with equations. For example, every number is congruent to itself, $a \equiv a \pmod{m}$, and, if $a \equiv b \pmod{m}$, then $b \equiv a \pmod{m}$. Also, if $a \equiv b \pmod{m}$ and $b \equiv c \pmod{m}$, then $a \equiv c \pmod{m}$. For a given modulus, congruences can be added, subtracted, and multiplied as though they were equations. Thus, if $a \equiv b \pmod{m}$ and $c \equiv d \pmod{m}$, then

$$a + c \equiv b + d, a - c \equiv b - d, \text{ and } ac \equiv bd \pmod{m}.$$

For example, to verify the result for the sum, write

$$(a + c) - (b + d) = (a - b) + (c - d)$$

and note that m divides both $a - b$ and $c - d$. The conclusion for the product follows from the identity $ac - bd = a(c - d) + d(a - b)$, because both $a(c - d)$ and $d(a - b)$ are divisible by m .

Common nonzero factors cannot always be canceled from both sides of a congruence as they can in equations. Both sides of the congruence $42 \equiv 12 \pmod{15}$ are divisible by 6, but when the common factor 6 is canceled, the result, $7 \equiv 2 \pmod{15}$, is incorrect. The cancellation law for congruences states that $ac \equiv bc \pmod{m}$ implies $a \equiv b \pmod{m/d}$, where $d = (c, m)$, the GCD of c and m . In particular, common factors relatively prime to the modulus can always be canceled: $ac \equiv bc \pmod{m}$ implies $a \equiv b \pmod{m}$ if $(c, m) = 1$. In the congruence $42 \equiv 12 \pmod{15}$ the common factor 2 is relatively prime to the modulus and can be canceled, giving a correct congruence $21 \equiv 6 \pmod{15}$. When the common factor 3 is canceled, the modulus must also be divided by 3 because $(3, 15) = 3$. Thus, canceling the common factor 3 in the congruence $42 \equiv 12 \pmod{15}$ gives $14 \equiv 4 \pmod{5}$.

Congruences place special emphasis on remainders. If a and b leave the same remainder when divided by m , then $a \equiv b \pmod{m}$. Numbers that are congruent mod m are said to belong to the same residue class mod m . There are exactly m distinct residue classes, each of which contains exactly one of the remainders $0, 1, 2, \dots, m - 1$. For example, the residue class that contains 0 also contains all multiples of m . This is called the residue class 0 mod m and can be displayed as follows:

$$\text{residue class } 0 \pmod{m} = \{0, \pm m, \pm 2m, \pm 3m, \dots\}.$$

Similarly, the residue classes 1 and 2 consist of all numbers congruent, respectively, to 1 and 2 mod m :

$$\begin{aligned} \text{residue class } 1 \pmod{m} &= \{1, 1 \pm m, 1 \pm 2m, 1 \pm 3m, \dots\}, \\ \text{residue class } 2 \pmod{m} &= \{2, 2 \pm m, 2 \pm 2m, 2 \pm 3m, \dots\}. \end{aligned}$$

The final entry in this list is

$$\begin{aligned} \text{residue class } m - 1 \pmod{m} &= \\ \{m - 1, m - 1 \pm m, m - 1 \pm 2m, m - 1 \pm 3m, \dots\}. \end{aligned}$$

A complete residue system mod m is a set of m integers, one selected from each of the m residue classes. For example, the six numbers $\{0, 1, 2, 3, 4, 5\}$ form a complete residue system mod 6, as do the numbers

$$\{0, 1, -1, 2, -2, 3\} \text{ or } \{60, -53, -32, 23, 63, 14\}.$$

In fact, any six integers will form a complete residue sys-

Fermat numbers

Congruence notation

Residue classes

tem mod 6 provided no two of them are congruent mod 6.

Some problems in number theory require solving congruences containing an unknown integer x . For example, a solution of the congruence $2x \equiv 7 \pmod{4}$ is any integer x that satisfies the congruence. This congruence has no solutions because $2x - 7$ is odd for every x and cannot be divisible by 4. But the congruence $2x \equiv 7 \pmod{13}$ does have solutions. Trying the numbers

$$0, 1, 2, \dots, 12$$

in a complete residue system mod 13 shows that only one of these numbers, $x = 10$, is a solution. Therefore, all solutions are given by $x \equiv 10 \pmod{13}$, which means that any number in the residue class 10 mod 13 is a solution.

The same congruence can be solved algebraically without trying all possible candidates. In the linear algebraic equation $2x = 7$, simple division by 2 yields the solution. But the linear congruence $2x \equiv 7 \pmod{13}$ cannot be solved this way because 2 does not divide 7. However, 7 is congruent to some even number mod 13, for example, $7 \equiv 20 \pmod{13}$, so the original congruence is equivalent to $2x \equiv 20 \pmod{13}$. Division by 2 now gives $x \equiv 10 \pmod{13}$, the same set of solutions obtained by trial.

Linear congruences

In general, for given values of a , b , and m , a congruence of the form

$$ax \equiv b \pmod{m}$$

has a solution x if and only if b is divisible by (a, m) , the GCD of the coefficient of x and the modulus. If (a, m) is denoted by d and if $d|b$, then the congruence has exactly d solutions in any complete residue system mod m . For example, the congruence

$$6x \equiv 9 \pmod{15}$$

has exactly three solutions in any complete residue system mod 15 because the GCD of 6 and 15 is 3, which divides 9. In fact, the solutions in this case are

$$x \equiv 4, x \equiv 9, \text{ and } x \equiv 14 \pmod{15}.$$

If the coefficient of x in a linear congruence

$$ax \equiv b \pmod{m}$$

is relatively prime to the modulus, then the congruence has exactly one solution in any complete residue system. In particular, when $b = 1$, the solution of the congruence $ax \equiv 1 \pmod{m}$ is called the reciprocal of a mod m and is often denoted by \bar{a} . If the reciprocal \bar{a} is known, the more general linear congruence $ax \equiv b \pmod{m}$ can be solved by multiplying both members by \bar{a} to obtain

$$x \equiv b\bar{a} \pmod{m}.$$

For example, the reciprocal of 2 mod 9 is 5 because $2 \cdot 5 \equiv 1 \pmod{9}$. To solve the congruence

$$2x \equiv b \pmod{9},$$

multiply both members by 5 to obtain $x \equiv 5b \pmod{9}$.

If $(a, m) = 1$, the reciprocal \bar{a} can always be determined by testing all the numbers in a complete residue system to find which one satisfies $ax \equiv 1 \pmod{m}$. A more expeditious method was introduced by Euler and is based on the following idea. Starting with a complete residue system mod m , such as $0, 1, 2, \dots, m-1$, all integers not relatively prime to m are deleted. What remains is called a reduced residue system and contains fewer than m integers. Euler introduced the symbol $\phi(m)$ to denote the number of integers in a reduced residue system. For example, if $m = 14$ and if the multiples of 2 and 7 are removed, the reduced residue system consists of the six integers 1, 3, 5, 9, 11, and 13, so $\phi(14) = 6$. Euler proved that, if $(a, m) = 1$, then $a^{\phi(m)} \equiv 1 \pmod{m}$. Consequently, the reciprocal \bar{a} is $a^{\phi(m)-1}$, and the solution of the linear congruence $ax \equiv b \pmod{m}$ is $x \equiv ba^{\phi(m)-1} \pmod{m}$.

If the modulus m is a prime p , then $\phi(p) = p-1$, and Euler's theorem states that $a^{p-1} \equiv 1 \pmod{p}$ if $(a, p) = 1$. Therefore $a^p \equiv a \pmod{p}$, and this holds whether or not a is relatively prime to p . The result $a^{p-1} \equiv 1 \pmod{p}$ for prime moduli was discovered by Fermat in 1640 and is called the little Fermat theorem. The first known proof seems to have been given by the German mathematician

Gottfried Wilhelm Leibniz. Euler extended it in 1760 to any modulus by showing that

$$a^{\phi(m)} \equiv 1 \pmod{m} \text{ if } (a, m) = 1.$$

An important congruence known as Wilson's theorem, named after the 18th-century English mathematician John Wilson, states that $(p-1)! \equiv -1 \pmod{p}$ for any prime p . (The symbol $n!$, read " n factorial," denotes the product of all the integers from 1 to n .) Wilson's theorem can be proved for odd primes by using reciprocals mod p . The numbers 1 and $p-1$ are the only positive integers less than p that are their own reciprocals mod p . Therefore, in the product $(p-1)! = 1 \cdot 2 \cdot 3 \cdots (p-3)(p-2)(p-1)$, the integers from 2 to $p-2$ can be grouped into pairs by pairing each integer with its reciprocal. The product of each pair is congruent to 1 mod p , hence $(p-1)! \equiv p-1 \equiv -1 \pmod{p}$.

Wilson's theorem

The converse of Wilson's theorem is also true; that is, if m is a positive integer greater than 1 such that $(m-1)! \equiv -1 \pmod{m}$, then m is prime. Although the converse of Wilson's theorem provides a test for determining whether an integer is prime, it is not a useful test because of the large number of multiplications required to calculate the residue of $(m-1)! \pmod{m}$.

The Chinese remainder theorem. The Chinese remainder theorem, sometimes called the Formosa theorem, was described in early Chinese manuscripts that posed problems such as the following: Find an integer that when divided by 3 has remainder 2, when divided by 5 has remainder 3, and when divided by 7 has remainder 4. In the language of congruences, the problem is to find an integer x that simultaneously satisfies the following three congruences:

$$x \equiv 2 \pmod{3}, x \equiv 3 \pmod{5}, x \equiv 4 \pmod{7}.$$

This problem can be solved by considering the congruences individually. For the third congruence every solution is given by $x = 4 + 7k$, where k is an integer. The numbers of this form less than 105 are 4, 11, 18, 25, 32, 39, 46, 53, 60, 67, 74, 81, 88, 95, and 102. Of these, only 18, 53, and 88 satisfy the second congruence, and only 53 satisfies the first congruence. Thus, 53 is the only solution less than 105. This result can now be used to obtain all solutions. If x is any solution, then $x - 53$ is divisible by 3, 5, and 7 and also by their product, 105, so $x - 53 \equiv 0 \pmod{105}$. Therefore, all solutions are given by $x = 53 + 105t$, where t is any integer.

The existence of a solution in the foregoing example is guaranteed by the Chinese remainder theorem, which states that a system of congruences in different moduli

$$\begin{aligned} x &\equiv a_1 \pmod{m_1} \\ x &\equiv a_2 \pmod{m_2} \\ &\vdots \\ x &\equiv a_k \pmod{m_k} \end{aligned}$$

always has a solution if the moduli are relatively prime in pairs. Moreover, the solution is unique mod m , where $m = m_1 m_2 \cdots m_k$, the product of the moduli.

Several methods are available to determine the actual solution. One of these begins by solving k pairs of congruences:

$$y_i \equiv 1 \pmod{m_i}, \quad y_i \equiv 0 \pmod{q_i},$$

where $q_i = m/m_i$ and $i = 1, 2, \dots, k$. The moduli m_i and q_i are relatively prime, so this pair of congruences has a unique solution mod m : $y_i \equiv t_i q_i \pmod{m}$, where t_i is the reciprocal of $q_i \pmod{m_i}$. The solution of the original system is then easily verified to be

$$x \equiv a_1 y_1 + \cdots + a_k y_k \pmod{m}.$$

To solve the problem given at the beginning of this section by this method, first solve the three pairs of congruences:

$$\begin{aligned} y_1 &\equiv 1 \pmod{3}, y_1 \equiv 0 \pmod{35}, \\ y_2 &\equiv 1 \pmod{5}, y_2 \equiv 0 \pmod{21}, \\ y_3 &\equiv 1 \pmod{7}, y_3 \equiv 0 \pmod{15}. \end{aligned}$$

Solutions easily found by inspection are $y_1 = 70$, $y_2 = 21$, and $y_3 = 15$, so all solutions x are given by

$$x \equiv 2y_1 + 3y_2 + 4y_3 \equiv 263 \equiv 53 \pmod{105},$$

in agreement with the result found earlier.

The Chinese remainder theorem is applicable only when the moduli are relatively prime in pairs. If two or more moduli have a common factor greater than 1, a solution may or may not exist. An extension of the Chinese remainder theorem states that the general system will have a solution if and only if for every pair of moduli m_i and m_j the difference $a_i - a_j$ is divisible by the GCD (m_i, m_j). For example, the system

$$x \equiv 12 \pmod{20}, x \equiv 3 \pmod{45}, x \equiv 57 \pmod{72}$$

has no solution because $12 - 3$ is not divisible by the GCD (20, 45). But the system

$$x \equiv 13 \pmod{20}, x \equiv 3 \pmod{45}, x \equiv 57 \pmod{72}$$

does have a solution. To determine all solutions, use the first congruence to write $x = 13 + 20k$ and substitute this in the second congruence to obtain $13 + 20k \equiv 3 \pmod{45}$, or $20k \equiv -10 \pmod{45}$, which implies $4k \equiv -2 \pmod{9}$. Multiplication by 2 gives $k \equiv 4 \pmod{9}$, so that $k = 4 + 9s$ for some integer s , and $x = 13 + 20k = 13 + 20(4 + 9s) = 93 + 180s$. Now use this in the third congruence to obtain $93 + 180s \equiv 57 \pmod{72}$, or $180s \equiv -36 \pmod{72}$. Divide by 36 to obtain $s \equiv 1 \pmod{2}$, $s = 2t + 1$. This gives $x = 93 + 180(2t + 1) = 273 + 360t$, where t is any integer.

The solutions of the congruence $x \equiv a \pmod{m}$ can be written as $x = a + tm$, where t runs through all the integers. The solutions form an arithmetic progression in which consecutive terms have a common difference m , and they can be displayed as an infinite sequence:

$$\dots, a - 3m, a - 2m, a - m, a, \\ a + m, a + 2m, a + 3m, \dots$$

The question as to whether $x \equiv a \pmod{m}$ and $x \equiv b \pmod{n}$ have a simultaneous solution is the same as asking whether the progression

$$\dots, b - 3n, b - 2n, b - n, b, b + n, b + 2n, b + 3n, \dots$$

has a term in common with the preceding progression. The theory shows that these two sequences have a term in common if and only if $a - b$ is divisible by the GCD of the moduli m and n . Furthermore, if there is one term in common, there are infinitely many terms in common.

The Chinese remainder theorem has become a useful tool in applications of number theory to other fields. A later section describes how it is used to increase efficiency in machine computation.

Quadratic congruences and the quadratic reciprocity law. Quadratic congruences of the form

$$Ax^2 + Bx + C \equiv 0 \pmod{m}$$

can be reduced to those of a simpler type, $x^2 \equiv a \pmod{p}$, where p is an odd prime and a is not divisible by p . These congruences may or may not have solutions, depending on the value of a . For example, the congruence $x^2 \equiv 3 \pmod{11}$ has two solutions, $x \equiv \pm 5 \pmod{11}$, whereas the congruence $x^2 \equiv 2 \pmod{11}$ has no solutions.

Throughout this section it is assumed that p is an odd prime and a is not divisible by p . If the congruence

$$x^2 \equiv a \pmod{p}$$

has a solution, then a is called a quadratic residue mod p . Otherwise, a is called a quadratic nonresidue mod p . For example, when $p = 11$ the quadratic residues can be found by squaring the numbers from 1 to 10 and reducing mod 11. Squaring the numbers from 1 to 5 gives

$$1^2 \equiv 1, 2^2 \equiv 4, 3^2 \equiv 9, 4^2 \equiv 5, 5^2 \equiv 3 \pmod{11}.$$

Squaring the numbers from 6 to 10 yields the same residues in reverse order:

$$6^2 \equiv (-5)^2 \equiv 3, 7^2 \equiv (-4)^2 \equiv 5, 8^2 \equiv (-3)^2 \equiv 9, \\ 9^2 \equiv (-2)^2 \equiv 4, 10^2 \equiv (-1)^2 \equiv 1 \pmod{11}.$$

Thus, the quadratic residues mod 11 are 1, 3, 4, 5, 9, and the nonresidues are 2, 6, 7, 8, 10. In general, every reduced residue system mod p contains exactly $(p-1)/2$

quadratic residues and exactly $(p-1)/2$ nonresidues. The quadratic residues are obtained by squaring the numbers $1, 2, \dots, (p-1)/2$ and reducing mod p . The quadratic congruence $x^2 \equiv a \pmod{p}$ has exactly two solutions if a is a quadratic residue mod p , and no solutions if a is a quadratic nonresidue mod p .

A remarkable theorem known as the quadratic reciprocity law connects pairs of quadratic congruences on the question of their solvability. If p and q are primes of the form $4n+3$, such as 3 and 1,999, then one and only one of the congruences $x^2 \equiv p \pmod{q}$ and $x^2 \equiv q \pmod{p}$ is solvable. On the other hand, if one or both of the odd primes p and q is of the form $4n+1$, and if one of the two congruences is solvable, so is the other. Thus, either both congruences are solvable or neither is.

For example, both primes $p = 1,999$ and $q = 3$ are of the form $4n+3$. The first congruence,

$$x^2 \equiv 1,999 \pmod{3},$$

reduces to the solvable congruence $x^2 \equiv 1 \pmod{3}$, and therefore, by the reciprocity law, the second congruence, $x^2 \equiv 3 \pmod{1,999}$, has no solution. One could, of course, verify directly that this congruence has no solution by testing each of the numbers from 1 to 999, but the reciprocity law solves the problem without any need for testing.

If $q = 5$, the congruences $x^2 \equiv 1,999 \pmod{5}$ and $x^2 \equiv 5 \pmod{1,999}$ provide an example where at least one of the primes p and q is of the form $4n+1$. The first congruence reduces to $x^2 \equiv 4 \pmod{5}$ and has the solutions $x \equiv \pm 2 \pmod{5}$. By the quadratic reciprocity law the other congruence, $x^2 \equiv 5 \pmod{1,999}$, must also be solvable. This guarantees that a search for a solution of the second congruence will not be in vain.

If a is a quadratic residue mod p , there are methods for finding a solution of $x^2 \equiv a \pmod{p}$ without squaring all the numbers from 1 to $(p-1)/2$. If p is of the form $4n+3$, one solution is $x = a^{(p+1)/4}$. For example, the congruence $x^2 \equiv 5 \pmod{1,999}$ has the solution $x \equiv 5^{500} \pmod{1,999}$. With modern calculators the residues of the powers of 5 can be easily computed mod 1,999 to give $x \equiv 100 \pmod{1,999}$; the other solution is, of course, $x \equiv -100 \pmod{1,999}$.

The quadratic reciprocity law was first stated by Euler in the period 1744–46 and rediscovered in 1785 by Adrien-Marie Legendre, who provided a partial proof. In 1795 Gauss discovered the result independently (at the age of 18), and a year later he gave the first complete proof. Gauss was fascinated by the quadratic reciprocity law, which he called “the golden theorem of number theory,” and produced at least six different proofs of it. The 19th-century mathematicians Augustin-Louis Cauchy, Karl Gustav Jacob Jacobi, and Leopold Kronecker later devised proofs of their own, as they wanted to determine for themselves why such a deep reciprocal relationship should exist between simple congruences linking any pair of odd primes.

In addition to the quadratic reciprocity law, there are supplementary results that are helpful in solving quadratic congruences. For example, if a and b are not divisible by the odd prime p , then at least one of the three congruences $x^2 \equiv a \pmod{p}$, $x^2 \equiv b \pmod{p}$, and $x^2 \equiv ab \pmod{p}$ is solvable, and, if more than one is solvable, all three must be solvable. This implies that the product of two quadratic residues mod p is a quadratic residue, as is the product of two nonresidues. However, the product of a residue and a nonresidue is a nonresidue. Another result states that $x^2 \equiv -1 \pmod{p}$ is solvable if p is of the form $4k+1$ but not if p is of the form $4k+3$. Also, the congruence $x^2 \equiv 2 \pmod{p}$ is solvable if p is of the form $8k+1$ or $8k+7$ but not if p is of the form $8k+3$ or $8k+5$.

If the modulus is not a prime, a quadratic congruence can have more than two solutions. For example, the congruence $x^2 \equiv 29 \pmod{35}$ has four solutions: $x \equiv 8, 13, 22, \text{ and } 27 \pmod{35}$. The solutions are found in the following manner. Every solution x must satisfy both congruences $x^2 \equiv 29 \pmod{5}$ and $x^2 \equiv 29 \pmod{7}$. The first has two solutions, $x \equiv \pm 2 \pmod{5}$, and the second has two solutions, $x \equiv \pm 1 \pmod{7}$. The Chinese remainder theorem is now applied to each of the four combinations.

Quadratic reciprocity law

Composite moduli and higher-degree congruences

For example, the combination $x \equiv 2 \pmod{5}$ and $x \equiv -1 \pmod{7}$ gives

$$x \equiv 27 \pmod{35}.$$

In general, any solution x to the quadratic congruence $x^2 \equiv a \pmod{m}$, where m is a composite modulus, must also satisfy each of the congruences

$$x^2 \equiv a \pmod{p'}$$

for every prime power p' that divides m . And for any odd prime p the congruence $x^2 \equiv a \pmod{p'}$ is solvable if and only if $x^2 \equiv a \pmod{p}$ is solvable.

The theory of higher-degree congruences is more complicated. One important result, discovered by the 18th-century French mathematician Joseph-Louis Lagrange, states that, if $f(x)$ is a polynomial of degree n with integer coefficients, then the congruence $f(x) \equiv 0 \pmod{p}$ has at most n solutions if the modulus p is prime. If the modulus is not prime, there may be more than n solutions. For example, the quadratic congruence $x^2 \equiv 29 \pmod{35}$ has four solutions, and the cubic congruence $x^3 - x \equiv 0 \pmod{6}$ has six solutions. The problem of solving a polynomial congruence $f(x) \equiv 0 \pmod{m}$ with a composite modulus m can be reduced to that of solving a system of congruences $f(x) \equiv 0 \pmod{p'}$ for every prime power p' that divides m . Each of these congruences, in turn, can be reduced to a polynomial congruence mod p plus a set of linear congruences.

Primitive roots. The positive powers of an integer g form a geometric progression g, g^2, g^3, \dots . If g is relatively prime to a positive integer m , then every member of this progression is also relatively prime to m . There is a smallest positive exponent f such that $g^f \equiv 1 \pmod{m}$. In fact, the Euler-Fermat theorem states that

$$g^{\phi(m)} \equiv 1 \pmod{m},$$

and hence the smallest exponent f cannot exceed $\phi(m)$. If the smallest exponent f is equal to $\phi(m)$, the integer g is called a primitive root mod m . In this case any two powers g^a and g^b are congruent mod m if, and only if, the exponents a and b differ by a multiple of $\phi(m)$. Therefore, if g is a primitive root mod m , the $\phi(m)$ numbers

$$g, g^2, \dots, g^{\phi(m)}$$

form a reduced residue system mod m .

Primitive roots are important because they permit a reduced residue system to be expressed as members of a geometric progression. Gauss proved that a modulus m has primitive roots if, and only if, m has one of the special values

$$m = 1, 2, 4, p^a, \text{ or } 2p^a,$$

where p is an odd prime and $a \geq 1$. For each such m the number of primitive roots mod m is exactly $\phi(\phi(m))$. For example, if $m = 17$, then $\phi(m) = 16$ and $\phi(\phi(m)) = \phi(16) = 8$, so 17 has eight primitive roots. Determining the primitive roots, when they exist, often requires a great deal of computation, especially for large moduli. The following table lists the smallest primitive root $g(p)$ for all primes p less than 50.

p	2	3	5	7	11	13	17	19	23	29	31	37	41	43	47
$g(p)$	1	2	2	3	2	2	3	2	5	2	3	2	6	3	5

The table shows, for example, that for $p = 17$ the smallest primitive root is $g = 3$. The powers

$$3, 3^2, \dots, 3^{16},$$

when reduced mod 17, form a reduced residue system mod 17. In the following table, the first row contains the powers of 3, and the second row contains their residues mod 17.

3	3 ²	3 ³	3 ⁴	3 ⁵	3 ⁶	3 ⁷	3 ⁸	3 ⁹	3 ¹⁰	3 ¹¹	3 ¹²	3 ¹³	3 ¹⁴	3 ¹⁵	3 ¹⁶
3	9	10	13	5	15	11	16	14	8	7	4	12	2	6	1

Primitive roots provide a useful tool for attacking problems and proving theorems involving reduced residue systems. The following example illustrates how primitive roots can be used to give an alternate proof of Wilson's theorem, $(p-1)! \equiv -1 \pmod{p}$ for an odd prime p . If g is a primitive root mod p , then $\phi(p) = p-1$ and the numbers g, g^2, \dots, g^{p-1} are congruent, in some order, to the numbers $1, 2, \dots, p-1$. Therefore their products are congruent mod p , and hence

$$\begin{aligned} (p-1)! &\equiv g \cdot g^2 \cdot \dots \cdot g^{p-1} \pmod{p} \\ &\equiv g^{1+2+\dots+(p-1)} \pmod{p} \\ &\equiv g^{p(p-1)/2} \pmod{p}. \end{aligned}$$

But $g^{(p-1)/2}$ satisfies the congruence $x^2 \equiv 1 \pmod{p}$ because of the Euler-Fermat theorem. This congruence is the same as $(x-1)(x+1) \equiv 0 \pmod{p}$, whose only solutions are $x \equiv \pm 1 \pmod{p}$. The number $g^{(p-1)/2}$ cannot be congruent to 1 mod p because the exponent $(p-1)/2$ is smaller than $\phi(p)$. Therefore

$$g^{(p-1)/2} \equiv -1 \pmod{p}$$

and hence

$$(p-1)! \equiv g^{p(p-1)/2} \equiv (-1)^p \equiv -1 \pmod{p}$$

because p is odd. This proves Wilson's theorem.

Primitive roots are especially useful in the study of quadratic residues mod p . If g is a primitive root of an odd prime p , the even powers g^2, g^4, \dots, g^{p-1} are the quadratic residues mod p , and the odd powers g, g^3, \dots, g^{p-2} are the quadratic nonresidues mod p . Some properties of quadratic residues and nonresidues are easily deduced from this representation. For example, the product of two quadratic residues is also a quadratic residue, because the product of two even powers of g is another even power. On the other hand, the product of a quadratic residue with a nonresidue is a nonresidue because the product of an even power of g with an odd power is another odd power. Also, the product of two quadratic nonresidues is a quadratic residue, because the product of two odd powers of g is an even power.

Primitive roots can also be used to study congruences of higher degree of the form

$$x^n \equiv a \pmod{m},$$

where a and m are relatively prime. This is called a binomial congruence of degree n . If m has a primitive root g then $a \equiv g^c \pmod{m}$ for some positive exponent c not exceeding $\phi(m)$. Any solution x of the binomial congruence is congruent mod m to some power of g , say $x \equiv g^y \pmod{m}$ for some positive exponent y not exceeding $\phi(m)$. Therefore the binomial congruence becomes

$$g^{ny} \equiv g^c \pmod{m}.$$

Because the two powers of g are congruent mod m , the exponents ny and c differ by a multiple of $\phi(m)$. Therefore

$$ny \equiv c \pmod{\phi(m)}.$$

This auxiliary linear congruence for y has a solution if, and only if, the GCD of n and $\phi(m)$ divides c . For example, to study the binomial congruence

$$x^{10} \equiv 7 \pmod{17},$$

take $g = 3$, a primitive root mod 17, and write $x \equiv 3^y$ and $7 \equiv 3^{11} \pmod{17}$. The auxiliary linear congruence for y becomes

$$10y \equiv 11 \pmod{16}.$$

This has no solution because the GCD of 10 and 16 does not divide 11. Therefore the original binomial congruence $x^{10} \equiv 7 \pmod{17}$ has no solution. On the other hand, if the same method is applied to the binomial congruence $x^{10} \equiv 2 \pmod{17}$, then $2 \equiv 3^{14} \pmod{17}$ and the auxiliary linear congruence is $10y \equiv 14 \pmod{16}$ or $5y \equiv 7 \pmod{8}$. This has the solution $y = 3$, giving the value

$$x \equiv 3^3 \equiv 10 \pmod{17}$$

as a solution of the binomial congruence of degree 10. In other words, $10^{10} \equiv 2 \pmod{17}$.

The same method can be used to study congruences of the form

$$a^x \equiv b \pmod{m},$$

where a and b are given integers relatively prime to m . These are called exponential congruences because the unknown x appears as an exponent. If m has a primitive root g , then a and b can be expressed as powers of $g \pmod{m}$, say $a \equiv g^c$, $b \equiv g^d \pmod{m}$, for some choice of positive exponents c and d not exceeding $\phi(m)$. The exponential congruence $a^x \equiv b \pmod{m}$ now becomes

$$g^{cx} \equiv g^d \pmod{m}.$$

This implies that the exponents differ by a multiple of $\phi(m)$, and hence

$$cx \equiv d \pmod{\phi(m)}.$$

This auxiliary linear congruence has a solution if, and only if, the GCD of c and $\phi(m)$ divides d . For example, to solve the exponential congruence

$$10^x \equiv 9 \pmod{17},$$

write $10 \equiv 3^3$, and $9 \equiv 3^2 \pmod{17}$, and the exponential congruence becomes

$$3^{3x} \equiv 3^2 \pmod{17}.$$

The auxiliary linear congruence is $3x \equiv 2 \pmod{16}$, which has the solution $x = 6$. Therefore, $x = 6$ is a solution of the exponential congruence, and hence

$$10^6 \equiv 9 \pmod{17}.$$

If 9 is replaced by any integer b , the exponential congruence $10^x \equiv b \pmod{17}$ always has a solution because in the auxiliary linear congruence,

$$3x \equiv d \pmod{16},$$

the numbers 3 and 16 are relatively prime and the congruence is always solvable.

When this method is used to study binomial or exponential congruences of the form $x^n \equiv a \pmod{p}$, or $a^x \equiv b \pmod{p}$, where p is a prime, the major difficulties are to find a primitive root $g \pmod{p}$ and to express the given integers a and b as powers of $g \pmod{p}$. The smallest nonnegative power k such that $a \equiv g^k \pmod{p}$ is called the index of a to the base $g \pmod{p}$. Extensive tables exist that give the smallest primitive root of many primes, together with a corresponding table of indices of all integers in a reduced residue system modulo these primes. A table of indices reduces the problem of solving a binomial or exponential congruence to the simpler problem of solving an auxiliary linear congruence.

The first large collection of tables of indices for all primes less than 1,000 was the *Canon arithmeticus*, computed under the direction of Jacobi and published in 1839. A revised and extended version was issued in 1956. Since then, high-speed computing machines have been used to extend the range of these tables. For example, one table lists all the primitive roots of the primes less than 5,000. Another lists the smallest primitive root for all primes up to 50,021.

Arithmetical functions. Functions $f(n)$ of the positive integer n that express some arithmetical property of n are called arithmetical functions. An important example is Euler's function $\phi(n)$, which counts the number of integers in a reduced residue system mod n . Alternatively, $\phi(n)$ is the number of positive integers less than n that are relatively prime to n , with the value $\phi(1) = 1$ defined separately. The following examples are concerned with divisors of n :

$$\begin{aligned} d(n) &= \text{the number of positive divisors of } n, \\ \sigma(n) &= \text{the sum of the positive divisors of } n, \\ \sigma_k(n) &= \text{the sum of the } k\text{th powers of the} \\ &\quad \text{positive divisors of } n. \end{aligned}$$

The divisor function $\sigma_k(n)$ can be expressed in summation notation as follows:

$$\sigma_k(n) = \sum_{d|n} d^k,$$

where the sum is extended over all positive divisors of n . The functions $d(n)$ and $\sigma(n)$ are, of course, special cases of $\sigma_k(n)$ with $k = 0$ and $k = 1$, respectively.

All these examples have the two special properties:

$$f(1) = 1, \text{ and } f(mn) = f(m)f(n) \text{ whenever } (m, n) = 1.$$

Arithmetical functions with these properties are called multiplicative; they are completely determined by their values at the prime powers. Thus, if n is a product of powers of distinct primes, say $n = p^a \cdot q^b \cdots$, then $f(n) = f(p^a)f(q^b) \cdots$. For example,

$$\begin{aligned} \sigma_2(24) &= \sigma_2(3)\sigma_2(2^3) \\ &= (1^2 + 3^2)(1^2 + 2^2 + 4^2 + 8^2) \\ &= 10 \cdot 85 \\ &= 850. \end{aligned}$$

Because of the multiplicative property, this calculation is simpler than adding the squares of all the positive divisors of 24.

The values of the foregoing functions at the prime powers are given by

$$\phi(p^a) = p^a - p^{a-1},$$

$$d(p^a) = a + 1,$$

$$\sigma(p^a) = 1 + p + p^2 + \cdots + p^a = \frac{p^{a+1} - 1}{p - 1},$$

and

$$\sigma_k(p^a) = \frac{p^{ak+k} - 1}{p^k - 1} \text{ if } k \neq 0.$$

Any arithmetical function $f(n)$ can be used to generate another,

$$F(n) = \sum_{d|n} f(d),$$

by summing $f(d)$ over all positive divisors d of n . This can also be written as $\sum_{d|n} f(n/d)$, because as d runs through all positive divisors of n , from smallest to largest, n/d runs through the same divisors in opposite order, from largest to smallest. If the function $f(n)$ is multiplicative, so is the divisor sum $F(n)$, and conversely, if the divisor sum $F(n)$ is multiplicative, so is $f(n)$.

Any arithmetical function $f(n)$ can be determined from a knowledge of its divisor sum $F(n)$ by the Möbius inversion formula,

$$f(n) = \sum_{d|n} \mu(d)F\left(\frac{n}{d}\right),$$

where $\mu(n)$ is a multiplicative arithmetical function called the Möbius function, after the German mathematician August Ferdinand Möbius. Its values are 0, 1, and -1 and are obtained as follows:

$$\begin{aligned} \mu(1) &= 1, \\ \mu(p) &= -1 \text{ for each prime } p, \\ \mu(p^k) &= 0 \text{ if } k > 1. \end{aligned}$$

Because $\mu(n)$ is multiplicative, $\mu(n) = 0$ if n is divisible by the square of any prime, and $\mu(n) = (-1)^r$ if n is the product of r distinct primes. The divisor sum

$$\sum_{d|n} \mu(d)$$

is equal to 0 if $n > 1$ and is equal to 1 if $n = 1$.

The Möbius inversion formula often reveals hidden properties of arithmetical functions. For example, it can be used to prove that the Euler function $\phi(n)$ is multiplicative, a result that is not immediately evident. Each integer k from 1 to n has a GCD $d = (k, n)$ with n ; then k/d and n/d are relatively prime. Just as $\phi(n)$ counts the number of integers from 1 to n that are relatively prime to n , so $\phi(n/d)$ counts the number of integers $q = k/d$ from 1 to n/d that are relatively prime to n/d . Therefore $\phi(n/d)$ is also the number of k for which $(k, n) = d$. But there are n values of k altogether, so

$$n = \sum_{d|n} \phi\left(\frac{n}{d}\right) = \sum_{d|n} \phi(d).$$

The Möbius inversion formula gives

Multiplicative arithmetical functions

Möbius inversion formula

$$\varphi(n) = \sum_{d|n} \mu(d) \frac{n}{d} \quad \text{or} \quad \frac{\varphi(n)}{n} = \sum_{d|n} \frac{\mu(d)}{d}.$$

Thus $\varphi(n)/n$ is the divisor sum of the multiplicative function $\mu(n)/n$, so $\varphi(n)/n$ is also multiplicative, hence $\varphi(n)$ is multiplicative.

Integers as
sums of
squares

Another arithmetical function of great interest is $r_2(n)$, the number of ways that n can be written as a sum of squares of two integers, positive, negative, or zero. In counting the number of ways, reversal of order is allowed. For example, there are four ways of writing 1 as a sum of two squares:

$$1 = 1^2 + 0^2 = (-1)^2 + 0^2 = 0^2 + 1^2 = 0^2 + (-1)^2,$$

so that $r_2(1) = 4$. Similarly, $r_2(2) = 4$, $r_2(3) = 0$, $r_2(4) = 4$, $r_2(5) = 8$, and $r_2(6) = 0$. This function is not multiplicative because $r_2(1) \neq 1$. However, $r_2(n)/4$ is multiplicative.

Let p be a prime divisor of n with $p \equiv 3 \pmod{4}$, and let p^k be the highest power of p that divides n . Euler proved that n is the sum of two squares if and only if k is even for every such prime divisor p . In other words, $r_2(n) = 0$ if and only if n has at least one maximal prime power divisor p^k with $p \equiv 3 \pmod{4}$ and k odd. There are infinitely many such n , the first few being $n = 3, 6, 7, 11, 12, 14, 15, 19, 21, 22, 23, 24, 27, 28, 30$.

Some arithmetical functions are described by giving the first two function values $f(1)$ and $f(2)$ and then expressing $f(n)$ for $n \geq 3$ in terms of $f(n-1)$ and $f(n-2)$. For example, the Fibonacci numbers are defined by

Fibonacci
numbers

$$f(1) = 1, f(2) = 1, \text{ and } f(n) = f(n-1) + f(n-2)$$

for $n \geq 3$. In this particular case, the function values $f(n)$ are often written as F_n . The first few terms are

$$1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, 233, 377.$$

These numbers have many interesting properties. For example,

$$F_{2n+1} = 1 + F_2 + F_4 + F_6 + \cdots + F_{2n}$$

and (for those familiar with matrix multiplication) the n th

power of the matrix $A = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}$ is

$$A^n = \begin{bmatrix} F_{n+1} & F_n \\ F_n & F_{n-1} \end{bmatrix}$$

for every $n \geq 2$. The relation $(-1)^n = F_{n+1}F_{n-1} - F_n^2$ is obtained by equating determinants in this matrix equation.

Fibonacci numbers also have an interesting divisibility property:

$$F_n | F_m \text{ whenever } n | m.$$

For example, $F_7 | F_{14}$ because $7 | 14$. This is easily verified because $F_7 = 13$ and $F_{14} = 377 = 13 \cdot 29$.

Linear
recurrence
sequence

Fibonacci numbers are just one example of a linear recurrence sequence, which is given by any two starting numbers x_1 and x_2 coupled with a recurrence relation of the form $x_n = Ax_{n-1} + Bx_{n-2}$ for $n \geq 3$, where A and B are given constants. This tells how to determine each term x_n from the two earlier terms x_{n-1} and x_{n-2} . Explicit formulas are available for expressing x_n in terms of x_1, x_2 , and the roots of the quadratic equation $x^2 = Ax + B$. The formula for the Fibonacci numbers is

$$F_n = \frac{\alpha^n - \beta^n}{\alpha - \beta},$$

where α and β are the roots of the quadratic equation $x^2 = x + 1$, given by

$$\alpha = \frac{1 + \sqrt{5}}{2} \text{ and } \beta = \frac{1 - \sqrt{5}}{2}.$$

The number α , which also appears as a ratio in various geometric figures, is called the golden ratio. The ancient Greeks considered rectangles whose sides have ratio α to be the most pleasantly proportioned of all rectangles, aside from the square. They called them golden rectangles and believed that, for the ideal beauty of any figure (including the human form), the various parts should have the proportions of the golden ratio.

Diophantine equations. In elementary algebra the linear equation $6x - 9y = 29$ with two unknowns x and y has infinitely many solutions. It can be satisfied by taking any value for x and letting $y = (6x - 29)/9$. But, if it is required that x and y be integers, there are no solutions because $6x - 9y$ is divisible by 3 for all integers x and y , whereas 29 is not. Equations involving one or more unknowns to be solved for integer or rational values of the unknowns are called Diophantine equations in honour of Diophantus of Alexandria, who dealt with such problems in his treatise *Arithmetica* (c. AD 250).

Diophantine equations fall into three classes: those with no solutions, those with only finitely many solutions, and those with infinitely many solutions. The equation $6x - 9y = 29$ has no solutions, but the equation $6x - 9y = 30$, which upon division by 3 reduces to $2x - 3y = 10$, has infinitely many. For example, $x = 20$, $y = 10$ is a solution, and so is $x = 20 + 3t$, $y = 10 + 2t$ for every integer t , positive, negative, or zero. This is called a one-parameter family of solutions, with t being the arbitrary parameter.

Congruence methods provide a useful tool in determining the number of solutions to a Diophantine equation. Applied to the simplest Diophantine equation, $ax + by = c$, where a, b , and c are nonzero integers, these methods show that the equation has either no solutions or infinitely many. If the GCD d of a and b does not divide c , there are no solutions. But if d divides c , there are infinitely many solutions, and they form a one-parameter family,

$$x = x_0 + \frac{bt}{d}, \quad y = y_0 - \frac{at}{d},$$

where x_0, y_0 is any particular solution and t is an arbitrary integer. The integer x_0 can be obtained by solving the linear congruence $ax \equiv c \pmod{|b|}$, and then y_0 can be taken equal to $(c - ax_0)/b$, which is one of the solutions of $by \equiv c \pmod{|a|}$. (The symbol $|a|$ denotes the absolute value of a , that is, $|a| = a$ if a is positive, and $|a| = -a$ if a is negative.)

Similarly, the linear Diophantine equation in n unknowns,

$$a_1x_1 + a_2x_2 + \cdots + a_nx_n = c,$$

where the coefficients a_1, a_2, \dots, a_n and c are integers, has a solution in integers x_1, x_2, \dots, x_n if and only if c is divisible by the GCD (a_1, a_2, \dots, a_n) . The equation

$$6x + 10y + 15z = 1$$

is solvable because the GCD $(6, 10, 15) = 1$. One solution is $x = 1, y = 1, z = -1$. In this case there is a two-parameter family of solutions given by

$$x = 1 + 5t, \quad y = 1 + 6t - 3s, \quad z = -1 - 6t + 2s,$$

where t and s are arbitrary integers.

Above it was shown that the Diophantine equation $6x - 9y = 29$ has no integer solutions because the left member is divisible by 3 while the right member is not. This illustrates a general method that is often used to show that a Diophantine equation has no solutions. If a solution exists, the corresponding congruence $(\text{mod } m)$ will be satisfied for every modulus m . Therefore, if there is some modulus for which the congruence cannot be satisfied, the equation itself cannot be satisfied. The choice of an appropriate modulus is not always obvious. For example, the Diophantine equation $15x^2 - 7y^2 = 9$, if written mod 7, becomes $x^2 \equiv 9 \pmod{7}$, which is solvable. But if it is written mod 5 it becomes $-2y^2 \equiv 4 \pmod{5}$, or $y^2 \equiv 3 \pmod{5}$, which is not solvable because 3 is a quadratic nonresidue mod 5, the only quadratic residues being 1 and 4. Therefore, the original equation $15x^2 - 7y^2 = 9$ has no integer solutions.

Even if a Diophantine equation has no solutions, it is possible that the corresponding congruence mod m can be satisfied for every $m \geq 2$. For example, the equation

$$(x^2 - 13)(x^2 - 17)(x^2 - 221) = 0$$

has no integer solution x because none of 13, 17, or 221 is a square. Nevertheless, with the aid of the quadratic reciprocity law it can be shown that the congruence

$$(x^2 - 13)(x^2 - 17)(x^2 - 221) \equiv 0 \pmod{m}$$

is solvable for every modulus $m \geq 2$.

The method of congruences can be used to give a partial proof of Euler's theorem on representing numbers as a sum of two squares. According to Euler's theorem, for any prime p the Diophantine equation $x^2 + y^2 = p$ has integer solutions if $p = 2$ and if $p \equiv 1 \pmod{4}$ but not if $p \equiv 3 \pmod{4}$. The nonexistence of solutions can be seen by writing the equation as a congruence mod 4. If $p \equiv 3 \pmod{4}$ the congruence becomes $x^2 + y^2 \equiv 3 \pmod{4}$. This is not solvable because the square of any integer is congruent to 0 (mod 4) if the integer is even, and congruent to 1 (mod 4) if the integer is odd, so the sum $x^2 + y^2$ cannot be congruent to 3 (mod 4). It is more difficult to prove that the equation $x^2 + y^2 = p$ is solvable if $p \equiv 1 \pmod{4}$. The number of solutions in this case is finite because both x^2 and y^2 are less than p .

A well-known theorem of Lagrange states that every positive integer n is expressible as a sum of four squares of integers. For example, $39 = 1 + 4 + 9 + 25$. However, 39 is not the sum of three squares. In fact, if n is any positive integer of the form $8k + 7$, the Diophantine equation $x^2 + y^2 + z^2 = n$ has no integer solutions. This can be shown by writing the equation as a congruence mod 8,

$$x^2 + y^2 + z^2 \equiv 7 \pmod{8}.$$

The square of an integer is congruent to 0, 1, or 4 (mod 8), and the sum of three such numbers cannot be congruent to 7 mod 8.

One of the oldest Diophantine equations comes from the theorem of Pythagoras, which states that $x^2 + y^2 = z^2$, where x , y , and z are the lengths of the three sides of a right triangle. If the equation is satisfied with integer values of x , y , and z , the triple (x, y, z) is called a Pythagorean triple. The examples (3, 4, 5) and (5, 12, 13) were known to the Babylonians 1,200 years before the time of Pythagoras. A method for obtaining all Pythagorean triples is outlined in Euclid's *Elements* and can be summarized by the formulas

$$x = t(a^2 - b^2), y = 2tab, z = t(a^2 + b^2),$$

where t , a , and b are arbitrary positive integers such that $a > b$, a and b are relatively prime, and one of a or b is odd and the other even. When $t = 1$, the numbers x , y , z have no prime factor in common and the triple is called primitive. The primitive triples (3, 4, 5) and (5, 12, 13) are obtained by taking $a = 2$, $b = 1$, and $a = 3$, $b = 2$.

There are various ways to derive the formulas for the Pythagorean triples. One method is to factor the left member of the equation $x^2 + y^2 = z^2$ using complex numbers:

$$(x + iy)(x - iy) = z^2,$$

where $i^2 = -1$. If x and y are integers, the complex numbers $x + iy$ and $x - iy$ are called Gaussian integers. If the product of two relatively prime positive integers is a square, according to the fundamental theorem of arithmetic each factor separately must be a square. The same property holds for Gaussian integers, so each of $x + iy$ and $x - iy$ (or with x and y interchanged in both of these) is the square of a Gaussian integer, say

$$x + iy = (a + ib)^2 \text{ and } x - iy = (a - ib)^2.$$

The equations $x = a^2 - b^2$ and $y = 2ab$ follow by equating real and imaginary parts.

A quadratic form is a polynomial in one or more variables all of whose terms are of degree 2, as in the example

$$f(x, y, z) = 3x^2 + y^2 + 20z^2 + 2xy - 14xz - 8yz.$$

The corresponding Diophantine equation $f(x, y, z) = 0$ can be studied by introducing a change of variables that reduces the quadratic form to a simpler quadratic form containing square terms but no cross product terms such as xy , xz , or yz . For example, if x , y , and z are expressed in terms of new variables u , v , w by means of the equations

$$x = u + 2v + 3w, y = 2u + v + 4w, z = u + v + 2w,$$

then the quadratic form $f(x, y, z)$ given above is transformed into a new quadratic form

$$g(u, v, w) = u^2 + v^2 - w^2.$$

This is easily verified, after some algebra, by direct substitution. Because each of x , y , z is a linear combination of u , v , w with integer coefficients, integer values of u , v , w produce integer values of x , y , z . Therefore, any integer solution of the equation

$$g(u, v, w) = 0$$

leads to an integer solution of $f(x, y, z) = 0$.

For example, the well-known Pythagorean triple

$$(u, v, w) = (3, 4, 5),$$

which satisfies $g(u, v, w) = 0$, gives the solution $(x, y, z) = (26, 30, 17)$ for the equation $f(x, y, z) = 0$. Another Pythagorean triple $(u, v, w) = (4, 3, 5)$ gives a different solution $(x, y, z) = (25, 31, 17)$. The obvious solution $(u, v, w) = (1, 0, 1)$ produces the not-so-obvious solution $(x, y, z) = (4, 6, 3)$. The formulas

$$u = t(a^2 - b^2), v = 2tab, w = t(a^2 + b^2),$$

which give solutions of

$$u^2 + v^2 = w^2,$$

can be substituted into the equations for x , y , z to give formulas for a family of solutions of $f(x, y, z) = 0$. Because of the lack of symmetry, this method does not give all solutions of $f(x, y, z) = 0$. Further solutions (x, y, z) are obtained by starting with

$$u = 2tab, v = t(a^2 - b^2), w = t(a^2 + b^2).$$

In this particular example, the three linear equations relating the variables can be solved for u , v , w in terms of x , y , z , the result being

$$u = -2x - y + 5z, v = -y + 2z, w = x + y - 3z.$$

Because each of u , v , w is a linear combination of x , y , z with integer coefficients, integer values of x , y , z produce integer values of u , v , w . Therefore, any integer solution of the equation $f(x, y, z) = 0$ leads to an integer solution of $g(u, v, w) = 0$. Consequently, there is a one-to-one correspondence between integer solutions of

$$f(x, y, z) = 0$$

and integer solutions of $g(u, v, w) = 0$. As this example suggests, a basic problem in the theory of quadratic forms is to determine linear transformations of the variables that reduce complicated quadratic forms such as $f(x, y, z)$ to simpler forms such as $g(u, v, w)$ that are more easily studied.

The best-known of all Diophantine problems is Fermat's last theorem, which states that, for every integer $n \geq 3$, the equation

$$x^n + y^n = z^n$$

has no solutions in positive integers x , y , z . A note by Fermat, inscribed in the margin of his copy of Diophantus' *Arithmetica*, asserted that he had found a wonderful proof of this statement, but "the margin is too narrow to contain it." Despite Fermat's assertion, no complete proof has been given, and the statement is now regarded as a conjecture. There is much evidence in favor of the conjecture. It is known that it is true for all exponents n from 3 to 150,000. Also, if the theorem is true for any value of n , then it is also true for kn , for all positive integers k . In 1983 the German mathematician Gerd Faltings proved that for any fixed $n \geq 3$, the Fermat equation $x^n + y^n = z^n$ has at most a finite number of integer solutions with $(x, y) = 1$.

Because $x^4 + y^4 = z^4$ has no solutions in positive integers, there is no right triangle whose legs and hypotenuse are squares of integers. In 1772 Euler considered a three-dimensional version of this result and conjectured that $x^4 + y^4 + z^4 = t^4$ has no solutions in positive integers. In 1948 Morgan Ward proved that there is no solution with $t \leq 10^4$, but in 1987 the American mathematician Noam D. Elkies disproved Euler's conjecture when he found the solution

$$2,682,440^4 + 15,365,639^4 + 18,796,760^4 = 20,615,673^4$$

and showed that there are infinitely many solutions. In 1988 Roger Frye found the solution

Fermat's
last
theorem

Pythagorean
triples

$$95,800^4 + 217,519^4 + 414,560^4 = 422,481^4$$

and proved that there are no solutions with smaller positive integers. Euler made the more general conjecture that at least n n th powers are required to sum to an n th power if $n > 2$. This was disproved for $n = 5$ in 1966 by the Americans Leon J. Lander and Thomas R. Parkin, who observed that

$$27^5 + 84^5 + 110^5 + 133^5 = 144^5.$$

This is the smallest instance in which four fifth powers sum to a fifth power.

As discussed earlier, for each prime $p \equiv 1 \pmod{4}$ the Diophantine equation $x^2 + y^2 = p$ has at most a finite number of solutions because both x^2 and y^2 are less than p . By contrast, there is no apparent reason why the Diophantine equation $x^3 - y^2 = 2$ should have at most a finite number of integer solutions. In fact, Fermat showed that this equation has only two solutions, $x = 3$ and $y = \pm 5$. This result was extended by the German mathematician Carl Ludwig Siegel (1896–1981), who proved that if $P(x)$ is a polynomial with integer coefficients, the Diophantine equation $y^2 = P(x)$ has at most a finite number of integer solutions x, y if $P(x)$ has at least three distinct linear factors. By the fundamental theorem of algebra, $P(x)$ can always be factored as follows:

$$P(x) = a_0(x - a_1)(x - a_2) \cdots (x - a_n),$$

where a_0 is an integer and a_1, a_2, \dots, a_n are complex numbers. Siegel's theorem requires that at least three of these complex numbers must be different.

For $n \geq 3$, let

$$g(x, y) = a_0 x^n + a_1 x^{n-1} y + \cdots + a_{n-1} x y^{n-1} + a_n y^n$$

be a homogeneous polynomial with integer coefficients that cannot be factored as a product of polynomials of the same type of lower degree. A theorem of the Norwegian mathematician Axel Thue (1863–1922) states that for every integer m the Diophantine equation $g(x, y) = m$ has at most a finite number of integer solutions x, y . In 1967 the British mathematician Alan Baker proved that for any solution, both $|x|$ and $|y|$ cannot exceed a certain constant C whose value can be calculated explicitly in terms of n, m and the coefficients a_0, a_1, \dots, a_n . On the other hand, the Soviet mathematician Yuri Matijasevic, completing earlier work by the Americans Martin Davis, Hilary Putnam, and Julia Robinson, showed in 1970 that there cannot exist any algorithm for determining whether an arbitrary Diophantine equation does or does not have a solution.

Applications of number theory. Number theory has been applied to such diverse areas as physics, biology, chemistry, computing, cryptography, acoustics, communications, and graphic design. In particular, congruence arithmetic has been used in constructing perpetual calendars, scheduling round-robin tournaments, splicing telephone cables, devising systematic methods for storing computer files, constructing magic squares, and generating random numbers. This section describes two simple applications of congruences in machine computation and cryptography.

Efficiency in machine computation involving large numbers is often limited by the machine's memory (the amount of space available for storing data) and by the length of time required to perform computations. Even simple operations such as addition, subtraction, and multiplication of integers can overwhelm the memory or take an unreasonable amount of time if the integers are large and if millions of these operations must be performed in a given calculation. The Chinese remainder theorem can be used to increase efficiency by making use of relatively small numbers in most of the calculation. Suppose, for example, that a lengthy calculation involves many 10-digit integers. Most of the calculation can be done with five-digit integers by adopting the following procedure. Choose four relatively prime moduli m_1, m_2, m_3 , and m_4 of five digits each, for example, $2^{16} - 3$, $2^{16} - 1$, $2^{16} + 1$, and $2^{16} + 3$. Their product $m = m_1 m_2 m_3 m_4$ has 20 digits, which is twice the number of digits in the data. By the Chinese remainder theorem each integer in the data can

be uniquely represented by its residues mod m_1, m_2, m_3 , and m_4 , respectively. Because each of these residues has no more than five digits, the required arithmetic can be performed efficiently on these residues with respect to each of the moduli, yielding integer answers $a_1 \pmod{m_1}$, $a_2 \pmod{m_2}$, $a_3 \pmod{m_3}$, and $a_4 \pmod{m_4}$, where each a_i has no more than five digits. These numbers, in turn, are combined via the Chinese remainder theorem to obtain the final result mod m , which will be accurate to 20 digits. Even though the lengthy calculation is repeated four times, once for each modulus, most of it only uses five-digit integers and is accomplished quickly without overwhelming the memory.

An application to cryptography relies on the disparity in computer time required to find large primes and to factor large integers. For example, a code maker chooses two large primes, say p and q , of about 100 decimal digits each. There are procedures for finding such primes that require only a few minutes of computer time. The primes p and q are kept secret, but their product $n = pq$, a 200-digit number, is made public. A message is coded by a procedure that requires only the knowledge of n . (Because n is made public, these are often called public key codes.) But to decode the message, both factors p and q must be known. With the most efficient computer techniques yet devised, factoring a 200-digit number such as n could require billions of years of computer time on a single computer. For this reason, the codes are considered unbreakable, at least with the present state of knowledge of how to factor large numbers.

The actual procedure for coding the message can be described as follows. Each letter of the message is replaced by two digits, say $A = 01, B = 02, \dots, Z = 26$, and the entire message is broken into pieces of convenient length, where each piece is an integer smaller than the public value n . Each piece is coded separately by the following method. A prime r is chosen that does not divide either $p - 1$ or $q - 1$. Like n , the number r is made public. Let x denote the piece to be coded, raise x to the power r , and reduce this mod n to obtain an integer y between 1 and n . Thus $y \equiv x^r \pmod{n}$ and $1 \leq y < n$. The number y is the coded form of x .

To decode, one must obtain x from y . If p and q are known, this can be done very simply as follows. Let s denote the reciprocal of $r \pmod{\phi(n)}$, so that

$$sr \equiv 1 \pmod{\phi(n)}.$$

Then $sr = 1 + t\phi(n)$ for some integer t . By the Euler–Fermat theorem, $x^{\phi(n)} \equiv 1 \pmod{n}$, hence

$$x^{sr} \equiv 1 \pmod{n}.$$

But

$$y^s \equiv x^{rs} \equiv x^{1+t\phi(n)} \equiv x \pmod{n},$$

so y^s is the same as x modulo n . In other words, to obtain x from y , simply raise y to the power s and reduce mod n . If p and q are known, s and y^s can be determined (mod n) by straightforward computations that require only a few minutes of machine time. But if p and q are not known, the problem of recovering x from y seems insurmountable.

Recreational number theory. Newspapers and magazines challenge their readers with mathematical puzzles, games, and problems that can be understood by the layperson. This section describes some examples drawn from number theory.

Start with any three-digit number, such as 529. Extend it to a six-digit number 529,529 by repeating the digits. Divide the six-digit number by 7. The quotient is 75,647, with no remainder. Now divide this quotient by 11. Again the division is exact, and the new quotient is 6,877. When this quotient is divided by 13 the result is 529, the original number. The problem is to explain why this happens, not only for 529 but for any three-digit number. The explanation is that repetition of the digits is the same as multiplying the original number by 1001, which happens to be the product of 7, 11, and 13, so division by each of these factors restores the original number.

Some problems in recreational number theory, although easily comprehended, are difficult to solve. One well-known example is the $3n + 1$ problem. Start with any

Cryptography

The $3n + 1$ problem

integer n greater than 1. If n is even, replace n by $n/2$. If n is odd, replace it by $3n + 1$. Then repeat the process until 1 is obtained. For example, starting with $n = 3$ the sequence is 3, 10, 5, 16, 8, 4, 2, 1. Is it true that, starting with any initial integer n , the number 1 will always be obtained after a finite number of steps? To date this question is unresolved, although many professional and amateur mathematicians have worked on it.

Magic squares. Magic squares are among the oldest mathematical amusements. A magic square is a square array of integers in which the rows, columns, and diagonals have the same sums. A square containing the consecutive integers from 1 to n^2 is said to be of order n . The sum of the integers from 1 to n^2 is $n^2(n^2 + 1)/2$, so in a magic square the numbers in each row, column, and diagonal have the magic sum $n(n^2 + 1)/2$. The following magic squares have orders 3 and 4, respectively:

8	1	6
3	5	7
4	9	2

16	3	2	13
5	10	11	8
9	6	7	12
4	15	14	1

The square of order 3, with magic sum 15, occurs in Chinese writings as early as 2200 bc. The square of order 4, with magic sum 34, appears in Albrecht Dürer's engraving "Melencolia I." The date of the work, 1514, appears as part of the fourth row.

Interest in magic squares spread from China to Japan, India, and the Middle East, and they were introduced to Europe in Byzantine times.

Many methods are known for constructing magic squares of orders greater than 2, but despite intense efforts by professional and amateur mathematicians (including the celebrated American amateur Benjamin Franklin), no methods are known for constructing all such magic squares. There are exactly eight magic squares of order 3, containing the numbers 1 to 9:

8	1	6
3	5	7
4	9	2

4	9	2
3	5	7
8	1	6

2	9	4
7	5	3
6	1	8

6	1	8
7	5	3
2	9	4

8	3	4
1	5	9
6	7	2

4	3	8
9	5	1
2	7	6

2	7	6
9	5	1
4	3	8

6	7	2
1	5	9
8	3	4

These squares can be obtained by interchanging the first and third rows of the Chinese square to construct a second square, interchanging the first and third columns of the second square to construct a third square, and interchanging the first and third rows of the third square to construct a fourth square. The rows and columns of each of these four squares are then interchanged to obtain four new ones, for a total of eight altogether.

Methods for constructing magic squares usually prescribe rules for entering the numbers $1, 2, \dots, n^2$ into the cells of the square. One method that works for any odd order n was given in 1693 by Simon de la Loubère, who learned of it while ambassador to Siam from the court of Louis XIV. In 1929 D.N. Lehmer applied congruences to investigate the uniform step method, a generalization of Loubère's method. The uniform step method can be described as follows. Two positive integers a and b , each relatively prime to n and less than n , are chosen in advance. The cells of the square are assigned coordinates (x, y) , x being the number of the column counting from the left, and y the number of the row counting from the bottom. The number 1 is put in an arbitrary cell with coordinates (p, q) . The number 2 is then placed in the cell $(p + a, q + b)$, the number 3 in the cell $(p + 2a, q + 2b)$, and so on, pro-

ceeding from one cell to the next by making the uniform step (a, b) , the coordinates being reduced to their least positive residues mod n to keep the numbers inside the square. This procedure places the number $n + 1$ in the cell $(p + na, q + nb)$, which, mod n , is the same as (p, q) , the cell already occupied by 1. The uniform step (a, b) is said to fail at this point because two numbers occupy the same cell. A new step (c, d) , called a break step, is now used, and the number $n + 1$ is placed in the cell $(p + c, q + d)$, where c and d are chosen to arrive at an unoccupied cell. The uniform step (a, b) is again resorted to; $n + 2$ is placed in the cell $(p + c + a, q + d + b)$, $n + 3$ in the cell $(p + c + 2a, q + d + 2b)$, and so on. The uniform step fails again when $2n + 1$ is placed in $(p + c + na, q + d + nb)$, which, mod n , is the cell already occupied by $n + 1$, namely $(p + c, q + d)$. The break step (c, d) is then used once more to get out of this occupied cell, and $2n + 1$ is placed in the cell $(p + 2c, q + 2d)$. Then the uniform step (a, b) is returned to, with $2n + 2, 2n + 3, \dots$ being placed in the cells $(p + 2c + a, q + 2d + b)$, $(p + 2c + 2a, q + 2d + 2b)$, \dots . If all five numbers a, b, c, d , and $ad - bc$ are relatively prime to n , this method will fill the square, and the rows and columns will have the magic sum. The diagonals will also have the magic sum if the coordinates of the initial cell (p, q) satisfy the congruences $2p \equiv a + c + 1 \pmod{n}$, and $2q \equiv b + d + 1 \pmod{n}$.

In the Chinese square of order 3, the initial cell (p, q) is $(2, 3)$, the uniform step (a, b) is $(1, 1)$, the break step is $(2, 1)$, and $ad - bc = -1$. The other magic squares of order 3 containing integers 1 to 9 can all be obtained by the uniform step method, with different choices of initial cell (p, q) , uniform step (a, b) , or break step (c, d) . However, the method does not produce all magic squares of order n except for $n = 3$.

Magic squares with entries $1, 2, \dots, n^2$ can be used to construct new magic squares whose entries are not necessarily consecutive integers. For example, if each entry in the Chinese square is multiplied by 2 and these numbers are added, entry by entry, to the second square of order 3, a new magic square will be produced whose rows, columns, and diagonals have the magic sum 45:

20	11	14
9	15	21
16	19	10

In general, if the entries of a magic square with magic sum S are multiplied by an integer A , a new magic square is obtained with magic sum AS . If two magic squares of the same size with magic sums S_1 and S_2 are added, entry by entry, a new magic square is obtained with magic sum $S_1 + S_2$.

Wythoff's game. A game that was popular in the United States in the 19th century involves two players and a number of objects (counters) arranged in several heaps. Each player, in turn, takes counters from a heap; a player may take only one or any number up to the entire heap but is allowed to touch one heap only. The player who takes the last counter wins the game. The game was analyzed mathematically in 1902 by the American mathematician Charles Leonard Bouton, who gave it the name "Nim" and showed that one of the players can always force a win. A simple variation of this game, invented by W.A. Wythoff in 1907, is described here. Two players A and B take turns removing counters from two heaps. Each player in turn must take either any number of counters from the first heap, or any number from the second heap, or the same number from both heaps. Whoever takes the last counter from the table wins the game.

A remarkable feature of this game is that the first player A will always win if A knows a special sequence of number pairs that begins as follows:

(1, 2), (3, 5), (4, 7), (6, 10), (8, 13), (9, 15), (11, 18),
(12, 20), (14, 23), (16, 26), (17, 28), \dots

If the two heaps have the same number of counters, A takes everything and wins. Otherwise, A leaves the num-

The
uniform
step
method

bers of counters in the two piles to be one of the number pairs in the sequence. For example, A could leave 14 counters in one pile and 23 in the other, represented by the pair (14, 23). Whatever player B does with this pair, the outcome will be a pair not in the list, and then A can move back to another pair in the list. For example, if B is faced with the pair (14, 23) and removes nine counters from each pile to produce the pair (5, 14), then A can remove 11 counters from the 14 to get (5, 3), which appears in the list as (3, 5).

Two general properties of the sequence explain why it is a list of winning positions for the first player. If (a, b) is the n th pair in the sequence, then a is the smallest positive integer not present in any of the earlier pairs of the sequence, and $b = a + n$. These properties suffice to determine all pairs in the list, starting with (1, 2) and extending beyond those given. The winning strategy depends on the following theorem of the Canadian mathematician Samuel Beatty, proved in 1926, that gives an alternative way of constructing the sequence: for any two positive irrational numbers α and β satisfying the equation

$$\frac{1}{\alpha} + \frac{1}{\beta} = 1,$$

the two sequences

$$[a], [2a], [3a], \dots \text{ and } [\beta], [2\beta], [3\beta], \dots$$

together contain every positive integer exactly once. Here $[x]$ denotes the greatest integer in x . For example, if a is the golden ratio, $a = (1 + \sqrt{5})/2$, and, if $\beta = a^2$, it is easily verified that $a^2 = 1 + a$, hence

$$\frac{1}{a} + \frac{1}{\beta} = 1.$$

For this choice of a and β , the sequence of pairs of integers $([na], [n\beta])$ is the list of winning positions.

Approximating irrational numbers by rational numbers. One of the most interesting numbers in mathematics is π , which can be defined as the ratio of the circumference of a circle to its diameter or as the ratio of the area of a circle to the square of its radius. Its numerical value has been calculated to more than a billion decimal places, the first 10 being given by 3.1415926535...

The number π is irrational; that is, it is not the quotient of two integers. (Quotients of integers are called rational numbers.) Rational approximations of π to any desired degree of accuracy can be obtained by truncating its decimal expansion. For example, each of the first few decimal approximations 3.1, 3.14, 3.141, 3.1415, and 3.14159 can be written in the form h/k , where h and k are relatively prime integers, giving the following rational approximations:

$$\frac{31}{10}, \frac{157}{50}, \frac{3,141}{1,000}, \frac{6,283}{2,000}, \frac{314,159}{100,000}.$$

On the other hand, the fraction $22/7 = 3.142857 \dots$ approximates π nearly as well as $3,141/1,000$, even though its denominator, 7, is very small compared to 1,000. An approximation better than any of these is the fraction

$$\frac{355}{113} = 3.141592920 \dots,$$

whose first six decimals agree with those of π , yet its denominator, 113, is very small compared to that of its nearest competitor in the above list, $314,159/100,000$. In fact, no fraction with denominator less than 113 is closer to π than $355/113$.

An important branch of number theory has to do with approximating a given irrational number by rational numbers h/k whose denominators are not too large. One approach is to use continued fractions, which are obtained in the following manner.

Every real number x can be written as a sum, $x = [x] + (x)$, where $[x]$ denotes the integer part of x (the largest integer not exceeding x), and (x) denotes the difference $x - [x]$, called the fractional part of x . If x is an integer the fractional part (x) is zero. If x is not an integer the fractional part (x) is positive and less than 1, so it can be written as $1/y$ for some real $y > 1$. The number y in turn can be written as the sum $[y] + (y)$, giving

$$x = [x] + \frac{1}{y} = [x] + \frac{1}{[y] + (y)}.$$

If $(y) = 0$, then $x = [x] + 1/[y]$, a rational number, and the continued fraction terminates. But if $(y) > 0$, then $(y) = 1/z$ for some $z > 1$, and

$$x = [x] + \frac{1}{[y] + \frac{1}{[z] + (z)}}.$$

Repetition of this process gives a continued fraction representation of x ,

$$x = a_0 + \frac{1}{a_1 + \frac{1}{a_2 + \frac{1}{a_3 + \dots}}}$$

where $a_0 = [x]$, $a_1 = [y]$, $a_2 = [z]$, and so on. This is written more simply as $x = [a_0; a_1, a_2, a_3, \dots]$, where all the integers after a_0 are positive. If x is rational the process terminates after a finite number of steps and the continued fraction is finite. For example,

$$\frac{22}{7} = [3; 7] \text{ and } \frac{355}{113} = [3; 7, 16].$$

But if x is irrational the continued fraction is infinite. The continued fraction for π begins as follows:

$$\pi = [3; 7, 15, 1, 292, 1, 1, 1, 2, 1, 3, 1, 14, 2, 1, 1, 2, 2, \dots].$$

Truncating the continued fraction of an irrational number θ at the integer a_n produces a rational number

$$\frac{p_n}{q_n} = [a_0; a_1, \dots, a_n],$$

called the n th convergent to θ . Continued fractions are useful because p_n/q_n is closer to θ than any other rational number h/k with denominator k not exceeding q_n . For example, the third convergent to π is

$$[3; 7, 15, 1] = \frac{355}{113},$$

a fraction closer to π than any other fraction with denominator less than 113. Moreover, it can be shown that the n th convergent p_n/q_n to any irrational θ is smaller than θ if n is even, larger than θ if n is odd, and no farther away from θ than $1/q_n^2$, as summarized by the inequality

$$\left| \theta - \frac{p_n}{q_n} \right| < \frac{1}{q_n^2}.$$

In 1891 the German mathematician Adolf Hurwitz proved that infinitely many convergents satisfy the stronger inequality

$$\left| \theta - \frac{p}{q} \right| < \frac{1}{\sqrt{5}q^2},$$

but this is not true for all θ if $\sqrt{5}$ is replaced by any larger number. The golden ratio

$$a = \frac{1 + \sqrt{5}}{2}$$

illustrates this last point. If $A > \sqrt{5}$, it can be shown that the inequality

$$\left| a - \frac{p}{q} \right| < \frac{1}{Aq^2}$$

is satisfied only by a finite number of fractions p/q .

The continued fraction for the golden ratio is

$$a = [1; 1, 1, 1, \dots],$$

with an endless succession of 1s, as is easily verified by noting that

$$a = 1 + \frac{1}{a} = 1 + \frac{1}{1 + \frac{1}{a}} = \dots$$

The golden ratio a satisfies $a^2 = a + 1$, a quadratic equation easily put into the form $ax^2 + bx + c = 0$, where a , b , and c are integers. Irrational numbers with this property are called real quadratic irrationals and have the form

$(A + \sqrt{B})/C$, where A , B , and C are integers, with B positive and not a perfect square. They can also be described as those irrational numbers whose continued fractions are periodic; that is, the continued fraction consists of endless repetition of the same block of terms, except possibly for a few terms at the beginning. Examples are

$$\begin{aligned}\sqrt{7} &= [2; \overline{1, 1, 1, 4, 1, 1, 1, 4, 1, 1, 1, 4, \dots}] \\ &= [2; \overline{1, 1, 1, 4}]\end{aligned}$$

and

$$\begin{aligned}\frac{63 + \sqrt{30}}{13} &= [5; \overline{3, 1, 2, 1, 4, 1, 2, 1, 4, 1, 2, 1, 4, \dots}] \\ &= [5; \overline{3, 1, 2, 1, 4}].\end{aligned}$$

A bar over a block of numbers denotes endless repetition of that block. Another example is

$$\sqrt{43} = [6; \overline{1, 1, 3, 1, 5, 1, 3, 1, 1, 12}].$$

Although the n th convergent in the continued fraction of any irrational number θ can be made arbitrarily close to θ by making n sufficiently large, the rate of convergence is very slow if θ has a periodic continued fraction. For example, the first four convergents to $\sqrt{43} = 6.557438 \dots$ are

$$[6; 1] = 7,$$

$$[6; 1, 1] = 6.5,$$

$$[6; 1, 1, 3] = \frac{46}{7} = 6.571 \dots,$$

$$[6; 1, 1, 3, 1] = \frac{59}{9} = 6.555 \dots,$$

the fourth of which agrees with $\sqrt{43}$ to two decimals. By contrast, the third convergent to π ,

$$[3; 7, 15, 1] = \frac{355}{113} = 3.141592920 \dots,$$

agrees with π to six decimals.

Algebraic and transcendental numbers. Besides classification into rational and irrational numbers, real numbers can also be classified as algebraic or transcendental numbers. A number is said to be algebraic if it is the root of a polynomial equation of the form

$$a_n x^n + a_{n-1} x^{n-1} + \dots + a_2 x^2 + a_1 x + a_0 = 0,$$

where the coefficients are integers and not all zero. The real roots are called real algebraic numbers. If the coefficient a_n of the highest power of x is 1, the roots are called algebraic integers. For example, the roots of the equation $x^3 - 1 = 0$ are algebraic integers, only one of which, $x = 1$, is real. The other two roots are complex numbers, $x = (-1 \pm i\sqrt{3})/2$, where $i^2 = -1$.

If an algebraic number θ is a root of the polynomial equation given above and is not a root of any equation of this type of lower degree, then θ is said to be algebraic of degree n . For example, none of the roots of $x^3 - 1 = 0$ is algebraic of degree 3 because they all satisfy polynomial equations of lower degree with integer coefficients. The root $x = 1$ satisfies $x - 1 = 0$ and therefore is algebraic of degree 1, whereas the other two roots satisfy $x^2 + x + 1 = 0$, which makes them algebraic of degree 2. Algebraic numbers of degree 1 are rational numbers, while algebraic integers of degree 1 are the usual integers, often referred to as "rational integers" in algebraic number theory to distinguish them from irrational algebraic integers of higher degree, such as $a = (1 + \sqrt{5})/2$, which is of degree 2 because it satisfies $x^2 - x - 1 = 0$.

A real number that is not algebraic is called transcendental. Such numbers were first shown to exist in 1844, when the French mathematician Joseph Liouville proved that there is a strong restriction on how well algebraic numbers can be approximated by rational numbers. Specifically, if θ is a real algebraic number of degree n and if C is any positive constant, there is at most a finite number of rational fractions p/q such that

$$\left| \theta - \frac{p}{q} \right| < \frac{C}{q^{n+1}}.$$

This inequality can be used to show that any number θ with infinitely many very good rational approximations must necessarily be transcendental. An example is the Liouville number $\lambda = 0.110001000 \dots$, where a 1 is placed in the r th decimal place if $r = m!$ for some positive integer m , and the remaining digits are 0s. Thus, 1 appears in the r th decimal place for $r = 1, 2, 6, 24, 120, 720, \dots$. The number λ can be written as an infinite series,

$$\lambda = \sum_{m=1}^{\infty} \frac{1}{10^{m!}},$$

and good rational approximations to λ can be obtained by taking the sum of the first k terms,

$$\lambda_k = \sum_{m=1}^k \frac{1}{10^{m!}} = \frac{c_k}{10^{k!}}$$

where c_k is an integer. The difference between λ and λ_k is

$$\sum_{m=k+1}^{\infty} 10^{-m!} < \frac{2}{10^{(k+1)!}},$$

which can be written as

$$|\lambda - \lambda_k| = \left| \lambda - \frac{c_k}{10^{k!}} \right| < \frac{2}{(10^{k!})^{k+1}}.$$

It follows that λ cannot be an algebraic number of degree n for any n because there are infinitely many integers $k > n$, contradicting Liouville's theorem that there is at most a finite number of rational fractions p/q satisfying the inequality

$$\left| \lambda - \frac{p}{q} \right| < \frac{2}{q^{n+1}}.$$

An irrational number θ is said to be approximated to order n if there is a constant C , depending only on θ , such that the inequality

$$\left| \theta - \frac{p}{q} \right| < \frac{C}{q^n}$$

has infinitely many solutions in integers p and q . The number λ defined above can be approximated to any order whatever. It has already been observed that every irrational θ can be approximated to order 2 at least, and that a real algebraic number of degree n cannot be approximated to order $n + 1$. This result was improved by many authors until 1955, when the British mathematician Klaus Friedrich Roth established the best possible conclusion, that no irrational algebraic number can be approximated to any order greater than 2.

In 1882 the German mathematician Ferdinand Lindemann proved that π is a transcendental number. This settled the ancient question of squaring the circle: given any circle, is it possible to construct a square of equal area, using Euclidean constructions, with an unmarked straightedge and compass? The answer is no, because from any given unit length, the only lengths that can be constructed with an unmarked straightedge and compass are algebraic numbers.

If θ is irrational and if p_n/q_n is the n th convergent to θ , then the inequality relating p_n/q_n to θ ,

$$\left| \theta - \frac{p_n}{q_n} \right| < \frac{1}{q_n^2},$$

implies

$$|q_n \theta - p_n| < \frac{1}{q_n},$$

which is satisfied with arbitrarily large values of q_n . Therefore, the product $q_n \theta$ can be made arbitrarily close to the integer p_n by taking n sufficiently large, which makes the fractional part $(q_n \theta)$ arbitrarily close to 0 or 1. In 1884 Kronecker proved a more general result: for any irrational θ and any prescribed real number x in the interval from 0 to 1, there are positive integers n such that $(n\theta)$ lies arbitrarily close to x . This result is described by saying that the fractional parts $(n\theta)$ are dense in the unit interval. Even more is known about the distribution of these numbers. About half of them lie in any interval of length $1/2$, about one-third lie in any interval of length $1/3$, and so on. More precisely, if I is any subinterval of length L

Impossibility of squaring the circle

Transcendental numbers

lying within the interval from 0 to 1, and if N denotes the number of fractional parts (θ) , (2θ) , \dots , $(n\theta)$ that lie in I , then the quotient N/n approaches L as a limit as n tends to infinity. This property is described by saying that the fractional parts $(n\theta)$ are uniformly distributed over the unit interval.

ALGEBRAIC NUMBER THEORY

Algebraic integers and unique factorization. As discussed in the previous section, an algebraic number θ of degree n is any root of a polynomial equation of degree n with integer coefficients that is not a root of any such equation of lower degree. If the equation is

$$a_n x^n + a_{n-1} x^{n-1} + \dots + a_2 x^2 + a_1 x + a_0 = 0,$$

with $a_n = 1$, then θ is called an algebraic integer. The algebraic integers of degree 1 are the ordinary rational integers.

Examples of algebraic integers of degree 2 are the quadratic irrationals $\sqrt{3}$, $1 + \sqrt{3}$, and $(1 + \sqrt{5})/2$. They satisfy, respectively, the quadratic equations $x^2 - 3 = 0$, $x^2 - 2x - 2 = 0$, and $x^2 - x - 1 = 0$. Because a quadratic equation with integer coefficients can have complex roots, algebraic integers of degree 2 can be complex numbers. Examples are

$$i, 1 + i, \text{ and } \frac{1 + i\sqrt{3}}{2},$$

which satisfy, respectively,

$$x^2 + 1 = 0, \quad x^2 - 2x + 2 = 0, \quad \text{and} \quad x^2 - x + 1 = 0.$$

More generally, the algebraic integers of degree 2 can be described in terms of \sqrt{d} , where d is any square-free integer (that is, d is not divisible by the square of any prime, and $d \neq 1$). The permissible values of d are 2, 3, 5, 6, 7, 10, 11, \dots , together with their negatives and also -1 . All numbers of the form $a + b\sqrt{d}$, where a and b are rational integers, are algebraic integers of degree 2; they satisfy the quadratic equation $x^2 - 2ax + a^2 - db^2 = 0$. But if $d \equiv 1 \pmod{4}$, numbers of the form $(a + b\sqrt{d})/2$ with a and b odd are also algebraic integers of degree 2; they satisfy the quadratic equation

$$x^2 - ax + \frac{a^2 - db^2}{4} = 0.$$

The number $(a^2 - db^2)/4$ is a rational integer in this case because $a^2 \equiv b^2 \equiv d \equiv 1 \pmod{4}$.

Gauss systematically extended the ideas of number theory to algebraic integers, beginning with those of degree 2. He considered algebraic integers of the form $a + bi$, where a and b are rational integers. These are called Gaussian integers, and they share many properties with ordinary rational integers. For example, the sum, difference, or product of two Gaussian integers is a Gaussian integer. But the quotient of two Gaussian integers, although an algebraic number, need not be a Gaussian integer, as illustrated by the quotient $1/(1 + i) = (1 - i)/2$.

Divisibility of Gaussian integers (denoted here by Greek letters) is defined in the same way as for rational integers. An integer β is called a divisor of an integer α if there is an integer γ such that $\alpha = \beta\gamma$. If so, then γ is also a divisor (or factor) of α . A nonzero integer α is said to be prime if there are no integers β and γ , neither equal to ± 1 or $\pm i$, such that $\alpha = \beta\gamma$. This restriction on β and γ rules out such factorings as $1 + 2i = i(2 - i)$; if this were allowed there would be no primes. The four integers ± 1 and $\pm i$ are examples of units. More generally, an algebraic integer α (Gaussian or not) is called a unit if it is a divisor of 1, that is, if there is another algebraic integer β such that $\alpha\beta = 1$. The other factor, β , is also a unit. If α is a unit and if γ is any algebraic integer, then α and $\alpha\gamma$ are called associates. For example, every Gaussian integer γ has four associates, $\pm\gamma$ and $\pm i\gamma$.

Rational primes of the form $4k + 3$ are also Gaussian primes, but the rational prime 2 and those of the form $4k + 1$ can be factored as the product of two Gaussian primes. For example,

$$\begin{aligned} 2 &= (1 + i)(1 - i), \\ 5 &= (2 + i)(2 - i), \end{aligned}$$

$$\begin{aligned} 13 &= (2 + 3i)(2 - 3i), \\ 73 &= (8 + 3i)(8 - 3i), \end{aligned}$$

each factor being a Gaussian prime. In the factorization of 2, the two factors are associates because $1 + i = i(1 - i)$, but in the other examples the factors are not associates. The Gaussian primes consist of the rational primes $p \equiv 3 \pmod{4}$ and their associates, the Gaussian prime factors of 2 and their associates, and the Gaussian prime factors of the rational primes $p \equiv 1 \pmod{4}$ and their associates.

The unique factorization property holds for Gaussian integers. That is, every Gaussian integer a other than zero and the four units ± 1 and $\pm i$ can be factored into Gaussian primes in exactly one way, apart from the order of the factors and ambiguities between associated primes. Thus, if

$$a = \pi_1 \pi_2 \cdots \pi_r$$

is one factorization into primes, then

$$a = (\varepsilon_1 \pi_1)(\varepsilon_2 \pi_2) \cdots (\varepsilon_r \pi_r)$$

is essentially the same factorization if each of $\varepsilon_1, \varepsilon_2, \dots, \varepsilon_r$ is one of the four units and the product $\varepsilon_1 \varepsilon_2 \cdots \varepsilon_r = 1$.

If θ is a given nonzero algebraic number of degree n , the set of numbers of the form

$$q_0 + q_1 \theta + q_2 \theta^2 + \dots + q_{n-1} \theta^{n-1},$$

where the coefficients q_0, q_1, \dots, q_{n-1} are rational numbers, is denoted by $Q(\theta)$ and is called an algebraic number field of degree n . It is the largest set of numbers obtainable from θ and the rational numbers by addition, subtraction, multiplication, and division (with division by zero excluded). The power θ^n and all higher powers of θ are already included in this set because of the basic equation that makes θ an algebraic number of degree n . The quotient of two numbers in this set (division by zero excluded) is also a number in the set. When $\theta = 1$, $Q(1)$ is a field of degree 1 and consists of all the rational numbers. If $\theta = \sqrt{d}$, where d is a square-free rational integer, then $Q(\sqrt{d})$ is a field of degree 2, called a real quadratic field if d is positive and an imaginary quadratic field if d is negative.

Algebraic number theory studies properties of the algebraic integers in a given field $Q(\theta)$. One of the basic questions is that of unique factorization. For the Gaussian integers, which lie in the imaginary quadratic field $Q(i)$, unique factorization holds. There is also unique factorization in the real quadratic fields $Q(\sqrt{d})$ for $d = 2, 3, 5, 6$, and 7 but not for $d = 10$. Gauss conjectured that there are infinitely many real quadratic fields with the unique factorization property, but this conjecture has not been proved.

Unique factorization also holds in the imaginary quadratic fields $Q(\sqrt{-d})$ for $d = 1, 2$, and 3 but not for $d = 5$. For example, 6 and 21 have two factorizations in $Q(\sqrt{-5})$,

$$6 = 2 \cdot 3 = (1 + \sqrt{-5})(1 - \sqrt{-5})$$

and

$$21 = 3 \cdot 7 = (4 + \sqrt{-5})(4 - \sqrt{-5}),$$

the factors 2, 3, 7, $1 \pm \sqrt{-5}$, and $4 \pm \sqrt{-5}$ being primes in the field $Q(\sqrt{-5})$. Gauss noted that $Q(\sqrt{-d})$ has the unique factorization property in the nine cases

$$d = 1, 2, 3, 7, 11, 19, 43, 67, \text{ and } 163,$$

and he conjectured that there are no other imaginary quadratic fields with this property. Little progress was made on this problem until 1934, when Hans Heilbronn and Edward Linfoot proved that there is at most one more d not in this list. Computations by D.H. Lehmer established that d would have to be enormously large. In 1967 the American mathematician Harold M. Stark proved that there is no 10th case, and therefore Gauss's list of nine imaginary quadratic fields with unique factorization is complete. Such detailed analysis has not yet been achieved for general algebraic fields.

Algebraic integers and Diophantine equations. A significant difference between real and imaginary quadratic fields is revealed by the number of units in the field. Ev-

Unique factorization in quadratic fields

Properties of Gaussian integers

every imaginary quadratic field has only a finite number of units, all of which are roots of unity, that is, solutions of the equation $x^n = 1$ for some n . For example, the units in the Gaussian field $\mathbb{Q}(i)$ are ± 1 and $\pm i$, the roots of $x^4 = 1$. The only units in $\mathbb{Q}(\sqrt{-2})$ are ± 1 , whereas in $\mathbb{Q}(\sqrt{-3})$ there are six units, the roots of $x^6 = 1$. By contrast, every real quadratic field has infinitely many units, each of which can be represented in the form $\pm \varepsilon^n$, where ε is a particular unit (called a fundamental unit) and $n = 0, \pm 1, \pm 2, \dots$. For example, in the field $\mathbb{Q}(\sqrt{2})$ the number $\varepsilon = 1 + \sqrt{2}$ is a fundamental unit.

Fundamental units in real quadratic fields can be surprisingly large. For example, the number $1,520 + 273\sqrt{31}$ is a fundamental unit in $\mathbb{Q}(\sqrt{31})$, and the number

$$2,143,295 + 221,064\sqrt{94}$$

is one in $\mathbb{Q}(\sqrt{94})$. One method for determining fundamental units uses continued fractions. Another, which will be described here, makes use of Diophantine equations. As noted in the previous section, the algebraic integers θ in $\mathbb{Q}(\sqrt{d})$ consist of those of the form $\theta = a + b\sqrt{d}$, where a and b are rational integers, together with those of the form $\theta = (a + b\sqrt{d})/2$ with both a and b odd if $d \equiv 1 \pmod{4}$. The other root of the quadratic equation satisfied by θ is $\theta' = a - b\sqrt{d}$ if $\theta = a + b\sqrt{d}$, or $\theta' = (a - b\sqrt{d})/2$ if $\theta = (a + b\sqrt{d})/2$. The algebraic integer θ is a unit in $\mathbb{Q}(\sqrt{d})$ if $\theta\theta' = \pm 1$, which means $a^2 - db^2 = \pm 1$ or $a^2 - db^2 = \pm 4$ if both a and b are odd and $d \equiv 1 \pmod{4}$. Therefore, finding the units in $\mathbb{Q}(\sqrt{d})$ amounts to finding all solutions of the Diophantine equation $x^2 - dy^2 = \pm 1$, together with all odd solutions of $x^2 - dy^2 = \pm 4$ if $d \equiv 1 \pmod{4}$. These Diophantine equations are called Pell equations, after the English mathematician John Pell (1610–1685). The name is the result of a misunderstanding on Euler's part, because Pell never studied these equations.

If $d > 0$ and $d \equiv 2$ or $3 \pmod{4}$, the quadratic field $\mathbb{Q}(\sqrt{d})$ has a fundamental unit $\varepsilon = x + y\sqrt{d}$ where x and y are the least positive solutions of the Pell equation $x^2 - dy^2 = 1$, if positive solutions exist; otherwise x and y are the least positive solutions of $x^2 - dy^2 = -1$, which always exist. A fundamental unit is similarly obtained by solving one of the Pell equations $x^2 - dy^2 = \pm 4$ if $d > 1$ and $d \equiv 1 \pmod{4}$.

Algebraic number theory is often used to study Diophantine equations. For example, in the Diophantine equation $y^3 - x^2 = 1$, both x and y cannot be even and both cannot be odd because then the difference $y^3 - x^2$ would be even. Also, x cannot be odd when y is even because in that case $y^3 - x^2 \equiv -1 \pmod{4}$. Therefore, in any solution x must be even and y odd. One such solution is $x = 0$, $y = 1$, and this is the only solution with $x = 0$. A method to show that there are no further solutions is to enlarge the setting to the field $\mathbb{Q}(i)$ and write the equation in the form

$$y^3 = x^2 + 1 = (x - i)(x + i),$$

where x is assumed to be nonzero. Neither factor is a unit because $x \neq 0$. If the Gaussian integers $x + i$ and $x - i$ had a common divisor π among the primes of $\mathbb{Q}(i)$, then π would divide their difference $2i$, so π would be either $1 + i$ or $1 - i$, the prime divisors of 2. In that case $\pi^2 = \pm 2i$, which is impossible because π^2 divides y^2 and y is odd. Unique factorization implies that both $x + i$ and $x - i$ are cubes of integers in $\mathbb{Q}(i)$. Hence $x + i = (a + bi)^3$ for some choice of rational integers a and b , from which it follows, by equating real and imaginary parts, that $x = a^3 - 3ab^2$ and $1 = 3a^2b - b^3 = b(3a^2 - b^2)$. Thus, $b = \pm 1$ and $3a^2 - b^2 = \pm 1$, from which it follows that $b = -1$, $a = 0$. Thus, $x = 0$, $y = 1$ is the only solution in integers of $y^3 - x^2 = 1$.

A similar argument can be used to show that the Diophantine equation $y^3 = x^2 + 2$ has only two solutions in integers, $x = \pm 5$, $y = 3$. The argument makes use of unique factorization of integers in the field $\mathbb{Q}(\sqrt{-2})$. There are only two units in this field, ± 1 , which simplifies matters.

Unique factorization of integers in the field $\mathbb{Q}(\sqrt{-3})$ can be used to show that the Diophantine equation $z^3 = x^3 + y^3$ has no solutions in positive integers. This field has six units, the three cube roots of 1 and their negatives. The roots are determined by solving the cubic equation

$$u^3 = 1, \text{ or } (u - 1)(u^2 + u + 1) = 0.$$

The solutions are 1, ω , and ω^2 , where

$$\omega = \frac{-1 + \sqrt{-3}}{2} \text{ and } \omega^2 = \frac{-1 - \sqrt{-3}}{2}.$$

The number $\sqrt{-3}$ is a prime in this field. The Diophantine equation can now be written in the form

$$z^3 = (x + y)(x + \omega y)(x + \omega^2 y),$$

from which it can be shown that each factor on the right is the cube of an integer in the field $\mathbb{Q}(\sqrt{-3})$ multiplied by a unit of the field and some power of the prime $\sqrt{-3}$. This information suffices to show that the equation $z^3 = x^3 + y^3$ has no solutions in positive integers. The argument makes essential use of unique factorization in the field $\mathbb{Q}(\sqrt{-3})$.

In the mid-19th century the German mathematician Ernst Eduard Kummer and others attempted to extend this argument to prove the Fermat conjecture that for any positive integer $n > 2$ there are no solutions of $x^n + y^n = z^n$ in positive integers. It suffices to consider only the case in which n is an odd prime $p > 3$. The idea was to factor $x^p + y^p$ into linear factors and rewrite the equation in the form

$$z^p = (x + y)(x + \zeta y)(x + \zeta^2 y) \cdots (x + \zeta^{p-1} y),$$

where

$$\zeta = \cos \frac{2\pi}{p} + i \sin \frac{2\pi}{p}.$$

The number ζ satisfies $\zeta^p = 1$, so ζ is a p th root of 1. The field $\mathbb{Q}(\zeta)$ is called a cyclotomic field. Kummer realized that if the factor $x + \zeta y$ has the form εa^p for some algebraic integer a and some unit ε in the cyclotomic field $\mathbb{Q}(\zeta)$, he could settle the Fermat conjecture by an argument similar to that described above for the case $p = 3$. In fact, he showed that the equation $x + \zeta y = \varepsilon a^p$, with x and y not divisible by p , implies $x \equiv y \pmod{p}$. A similar argument applied to the equation $x^p + (-z)^p = (-y)^p$ shows that $x \equiv -z \pmod{p}$. Therefore

$$2x^p \equiv x^p + y^p \equiv z^p \equiv -x^p \pmod{p},$$

so that $3x^p \equiv 0 \pmod{p}$. But this is a contradiction because $p > 3$ and p does not divide x .

The equation $x + \zeta y = \varepsilon a^p$, which is crucial to the foregoing argument, is valid if unique factorization holds for the integers in the cyclotomic field $\mathbb{Q}(\zeta)$. The smallest prime p for which unique factorization fails in $\mathbb{Q}(\zeta)$ is $p = 23$, but for values of p for which unique factorization holds, Kummer's argument shows that the Fermat equation $x^p + y^p = z^p$ has no positive solutions.

Kummer was aware that the unique factorization property does not hold in every cyclotomic field, and he searched for another way to deduce the crucial equation $x + \zeta y = \varepsilon a^p$. He succeeded, in part, by introducing a new kind of complex number, which he called an ideal complex number and which permitted him to generalize the concept of unique factorization. He was then able to prove that the Fermat equation $x^p + y^p = z^p$ has no solutions for all primes p satisfying two special properties, but he was not able to determine whether all primes have these properties. The German mathematician Richard Dedekind rephrased Kummer's ideas and introduced the concept of an ideal.

Ideals and class numbers of algebraic number fields. An ideal I is a set of algebraic integers in an algebraic number field K with the following three properties: I contains 0; if a and β are in I , their sum and difference are also in I ; and, if a is in I and if β is any algebraic integer in K , then $a\beta$ is in I .

For example, suppose $K = \mathbb{Q}(1)$, the field of rational numbers. The set of all integer multiples of a fixed integer a is an ideal, denoted by (a) and called a principal ideal. Thus, the principal ideal (7) consists of all multiples of 7. Another ideal is the set of all linear combinations $7m + 3n$, where m and n run through all the rational integers. This ideal is denoted by $(7, 3)$ and is said to be generated by 7 and 3. The ideal $(14, 49)$, generated by 14 and 49, is easily seen to be the same as the principal ideal (7) because $7 = 49 - 3 \cdot 14$, a linear combination of 14 and 49.

Pell equations

Cyclotomic fields

In any algebraic number field K , the set of all algebraic integers in K is itself an ideal, in fact a principal ideal, denoted by (1). The ideal (α, β) generated by two algebraic integers α and β is the set of all linear combinations $\lambda\alpha + \mu\beta$, where λ and μ run through all algebraic integers in K .

If the algebraic integers in K have the unique factorization property, then every ideal is principal and the introduction of ideals is superfluous. But in a field where the unique factorization property fails, ideals can be used to restore unique factorization. This is done by introducing multiplication of ideals in a very natural way. The product AB of two ideals A and B in an algebraic number field K is the ideal obtained by taking all products $\alpha\beta$ of an element α in A with an element β in B , together with all sums and differences of such products. For example, the product of any ideal A with the principal ideal (1) is A , so the principal ideal (1) plays the role of the number 1 in the arithmetic of ideals.

Unique factorization by prime ideals

A prime ideal is one that is not the principal ideal (1) and that is not the product of two ideals unless one factor is the principal ideal (1). Unique factorization holds for the algebraic integers in K if and only if all ideals are principal. The failure of unique factorization in the field $\mathbb{Q}(\sqrt{-5})$ is illustrated by the example $6 = 2 \cdot 3 = (1 + \sqrt{-5})(1 - \sqrt{-5})$. Unique factorization can be restored by factoring the ideal (6) as a product of four prime ideals,

$$(6) = (2, 1 + \sqrt{-5})(2, 1 - \sqrt{-5})(3, 1 + \sqrt{-5})(3, 1 - \sqrt{-5}).$$

More generally, in any algebraic number field K , every nonzero ideal other than the principal ideal (1) can be factored as a product of prime ideals, and this factorization is unique apart from the order of the factors.

For fields in which not all ideals are principal, Kummer introduced a way of measuring the extent to which unique factorization fails. He did this by considering two ideals A and B to be equivalent if there are two nonzero principal ideals (α) and (β) such that $(\alpha)A = (\beta)B$. With this definition of equivalence, the ideals of an algebraic number field are separated into equivalence classes, of which there are only finitely many, one of them being the class of principal ideals. This finite number of equivalence classes is called the class number of the field. The class number is 1 if and only if the algebraic integers in the field have the unique factorization property, which, of course, means that all ideals are principal. The size of the class number is a rough measure of how badly unique factorization fails to hold. Let $h(d)$ denote the class number of the quadratic field $\mathbb{Q}(\sqrt{d})$. Some examples of class numbers are $h(-1) = 1$, $h(-5) = 2$, $h(-127) = 5$, $h(-329) = 24$, and $h(235) = 6$. Except for the first one, these numbers are not easy to calculate. It is known, however, that there are algebraic number fields with arbitrarily large class numbers.

The class field tower

Given any algebraic number field K with class number greater than 1, there is a larger field L containing K , called the class field of K , which has the significant property that every ideal in K becomes a principal ideal in L . This does not mean that L has class number 1, even though every ideal in K is a principal ideal in the larger field L , because some new ideals in L may have arisen that are not principal. Iteration of the process leading from K to the class field L gives the class field of L , and so on, ultimately producing a class field tower. It was hoped that the class field tower would be finite, terminating in a class field at the top of the tower with class number 1. However, in 1964 the Russian mathematicians Yevgeny Solomonovich Golod and Igor Rostislavovich Shafarevich gave an example of a starting field K that had an infinite class field tower.

ANALYTIC NUMBER THEORY

Although most of the following discussion requires only a good knowledge of algebra, some arguments draw on concepts from elementary calculus, such as limits, summations, the natural logarithm, the exponential function, infinite series, and infinite products. In these sections the symbol $\log x$ is used for the natural logarithm of x (the logarithm of x to the base e). The notation $\zeta(s)$ represents the sum of the infinite series

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s},$$

which converges if $s > 1$.

The order of magnitude of arithmetical functions. Many investigations in number theory are concerned with the behaviour of arithmetical functions $f(n)$ for large values of n . The difficulty in determining this behaviour is exemplified by $d(n)$, the number of divisors of n , whose values fluctuate considerably. This function has the value 2 whenever n is prime; it therefore has the value 2 infinitely often. It also takes on arbitrarily large values when n has a large number of divisors. For example, if n is the product of the first k primes, say $n = 2 \cdot 3 \cdot 5 \cdots p_k$, then $d(n) = 2^k$ because $d(n)$ is multiplicative and $d(p) = 2$ for each prime p . If k is large, the prime number theorem (see below) implies that k is approximately $\log n / \log \log n$, so that $d(n)$ is approximately $2^{\log n / \log \log n}$. This idea leads to the following inequalities for $d(n)$: For every positive number ε there is an integer $N(\varepsilon)$ (depending on ε) such that

$$d(n) < 2^{(1+\varepsilon) \log n / \log \log n}$$

for all $n \geq N(\varepsilon)$, whereas

$$d(n) > 2^{(1-\varepsilon) \log n / \log \log n}$$

for infinitely many n . There are analogous inequalities for the Euler function $\phi(n)$ involving a certain positive constant c less than 1. For every positive number ε there exists an integer $N(\varepsilon)$ such that

$$\phi(n) > (1-\varepsilon) \frac{cn}{\log \log n}$$

for all $n \geq N(\varepsilon)$, whereas

$$\phi(n) < (1+\varepsilon) \frac{cn}{\log \log n}$$

for infinitely many n .

For these and other examples, it is more fruitful to study the arithmetic mean,

$$\hat{f}(n) = \frac{1}{n} \sum_{k=1}^n f(k),$$

because fluctuations tend to cancel one another on the average. For example, Dirichlet showed that the average of the divisor function increases at the same rate as $\log n$ because the ratio $\hat{d}(n)/\log n$ approaches 1 as a limit as n approaches infinity (denoted $n \rightarrow \infty$). This is a consequence of a formula of Dirichlet which states that

$$\sum_{k=1}^n d(k) = n \log n + (2C-1)n + O(\sqrt{n}),$$

where $C = 0.57721 \dots$ is Euler's constant, and the symbol $O(\sqrt{n})$ represents an unspecified function of n whose absolute value is less than some constant times \sqrt{n} . The principal term, $n \log n$, is called the asymptotic value of the sum; the other two terms are of smaller order and represent the error made by approximating the sum by its asymptotic value. The error term $O(\sqrt{n})$ has been improved to $O(n^\theta)$ for various values of θ less than $1/2$, but θ cannot be replaced by $1/4$. Determining the smallest exponent θ in the error term is an unsolved problem called the Dirichlet divisor problem. By 1988 it was known that θ can be any number greater than $7/22$.

Asymptotic formulas of this type have been found for many arithmetical functions. The following examples are typical, although in many cases the error terms have been improved beyond what appears here.

$$\sum_{k=1}^n \phi(k) = \frac{3}{\pi^2} n^2 + O(n \log n)$$

$$\sum_{k=1}^n \sigma_1(k) = \frac{\pi^2}{12} n^2 + O(n \log n)$$

$$\sum_{k=1}^n \sigma_a(k) = \frac{\zeta(a+1)}{a+1} n^{a+1} + O(n^a) \quad (a > 1)$$

$$\sum_{k=1}^n r_2(k) = \pi n + O(\sqrt{n})$$

The Dirichlet divisor problem

$$\sum_{k=1}^n |\mu(k)| = \frac{6}{\pi^2}n + O(\sqrt{n})$$

The last formula contains the absolute value of the Möbius function, $|\mu(k)|$, not $\mu(k)$ itself. Determining the asymptotic behaviour of the summatory function

$$M(n) = \sum_{k=1}^n \mu(k)$$

is one of the most difficult unsolved problems in number theory. For a long time it was thought that perhaps $|M(n)| < \sqrt{n}$, but in 1984 Andrew Odlyzko and Herman te Riele showed that this inequality is violated infinitely often. It has been conjectured that the inequality $|M(n)| < n^{1/2+\varepsilon}$ holds for every $\varepsilon > 0$. If this were true it would have important implications concerning the distribution of primes. It is known that $M(n)/n \rightarrow 0$ as $n \rightarrow \infty$, a result equivalent to the prime number theorem.

The prime number theorem. The search for the order of magnitude of two arithmetical functions related to primes led to one of the most profound theorems in number theory, the prime number theorem. If p_n denotes the n th prime number and $\pi(n)$ denotes the number of primes in the interval from 1 to n , Euclid's theorem on the infinitude of primes guarantees that $\pi(n) \rightarrow \infty$ as $n \rightarrow \infty$. It is natural to ask how p_n and $\pi(n)$ grow as functions of n for large n . Irregularities in the distribution of primes and the lack of a simple formula for determining primes suggest that precise answers to these questions might be difficult or impossible to obtain. It seems astonishing to learn that answers can be obtained, and they are remarkably simple: For large n , the n th prime p_n grows as $n \log n$, whereas $\pi(n)$ grows as $n/\log n$. Each of these statements implies the other, and each is known as the prime number theorem. More precisely, the prime number theorem can be stated in two equivalent forms:

$$\lim_{n \rightarrow \infty} \frac{\pi(n)}{n/\log n} = 1, \quad (1)$$

and

$$\lim_{n \rightarrow \infty} \frac{p_n}{n \log n} = 1. \quad (2)$$

These relations are written more simply as $\pi(n) \sim n/\log n$ and $p_n \sim n \log n$ and are expressed verbally by saying that $\pi(n)$ is asymptotic to $n/\log n$ and that p_n is asymptotic to $n \log n$, respectively.

The first form was conjectured independently by Gauss and by Legendre around 1800, but neither provided proof. Gauss was led to his conjecture by examining a table of primes $\leq 10^6$. He calculated $\pi(n)$ simply by counting the number of primes in the interval from 1 to n . This is similar to the exercise done in an earlier section, in which primes were counted in blocks of 1,000 consecutive integers. However, if the blocks are not of equal length but are allowed to grow by a factor of 100, the following values of $\pi(n)$ and of the ratio $n/\pi(n)$ are obtained:

n	$\pi(n)$	$n/\pi(n)$
10^2	25	4.000
10^4	1,229	8.137
10^6	78,498	12.739
10^8	5,761,455	17.537
10^{10}	455,052,511	21.975
10^{12}	37,607,912,018	26.590
10^{14}	3,204,941,750,802	31.202

The table shows that the ratio $n/\pi(n)$ grows very slowly compared to n . As the exponents on the powers of 10 increase by 2, the ratio $n/\pi(n)$ seems to increase by about 4.6, or 2.3 times the exponent of 10. The exponent of 10 is the logarithm of n to the base 10, so the table indicates that $n/\pi(n)$ grows at about 2.3 times this logarithm. But 2.3 times the logarithm of a number to base 10 is approximately equal to the natural logarithm of that number. Comparison of the natural logarithm $\log n$ with the ratio $n/\pi(n)$ reveals the following values:

n	$\log n$	$n/\pi(n)$	$\frac{\log(n)}{n/\pi(n)}$
10^2	4.605	4.000	1.151
10^4	9.210	8.137	1.132
10^6	13.816	12.739	1.085
10^8	18.421	17.357	1.061
10^{10}	23.026	21.975	1.048
10^{12}	27.631	26.590	1.039
10^{14}	32.236	31.202	1.033

This remarkable agreement between $\log n$ and $n/\pi(n)$ suggests that their ratio approaches 1 as $n \rightarrow \infty$. Gauss, Legendre, and many other eminent mathematicians of the early 19th century tried unsuccessfully to prove this conjecture. The first step toward a proof was made in 1851 by Chebyshev, who showed that if $\pi(n)\log n/n$ has a limit as $n \rightarrow \infty$, then this limit must equal 1.

In 1859 Bernhard Riemann attacked the problem with a new method, using a formula of Euler relating the sum of the reciprocals of the powers of the positive integers with an infinite product extended over the primes. Euler's product formula, devised in 1737, states that, for every real $s > 1$,

$$\sum_{n=1}^{\infty} \frac{1}{n^s} = \prod_{p=1}^{\infty} \frac{1}{1 - \frac{1}{p^s}},$$

where the product runs through all the primes. Euler derived this formula by writing each factor on the right as an infinite geometric series

$$\frac{1}{1-x} = 1 + x + x^2 + x^3 + \cdots,$$

with $x = p^{-s}$. When all these series are multiplied together and the denominators are arranged in increasing order, the result is the series on the left (because of the fundamental theorem of arithmetic).

Riemann replaced the real variable s in Euler's product formula with a complex number and showed that the distribution of prime numbers is intimately related to properties of the function $\zeta(s)$ defined by the series (now called the Riemann zeta function). Riemann came close to proving the prime number theorem, but not enough was known during his lifetime about the theory of functions of a complex variable to complete the proof successfully.

Thirty years later the necessary analytic tools were at hand, and in 1896 Jacques-Salomon Hadamard and Charles Jean de la Vallée-Poussin independently proved the first form of the prime number theorem. The proof was one of the great achievements of analytic number theory. Subsequently, new proofs were discovered, including an elementary proof found in 1949 by Paul Erdős and Atle Selberg that makes no use of complex function theory.

The second form of the prime number theorem is easily deduced from the first form by taking logarithms of both members of equation (1) and then removing a factor $\log n$ to obtain

$$\lim_{n \rightarrow \infty} \left\{ \log n \left(\frac{\log \pi(n)}{\log n} + \frac{\log \log n}{\log n} - 1 \right) \right\} = 0.$$

Because $\log n \rightarrow \infty$, the factor multiplying $\log n$ must tend to zero. The quotient $\log \log n / \log n$ also tends to zero, hence

$$\lim_{n \rightarrow \infty} \frac{\log \pi(n)}{\log n} = 1.$$

This relation, multiplied by equation (1), yields

$$\lim_{n \rightarrow \infty} \frac{\pi(n) \log \pi(n)}{n} = 1.$$

Now replace n by the n th prime, p_n , in this equation. Then $\pi(p_n) = n$, and the equation becomes

$$\lim_{n \rightarrow \infty} \frac{n \log n}{p_n} = 1,$$

which implies equation (2). Equation (1) can also be

The distribution of primes

Riemann's zeta function

deduced from (2), so the two statements are equivalent.

Each of the following statements involving the Möbius function is also equivalent to the prime number theorem:

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=1}^n \mu(k) = 0, \text{ and } \lim_{n \rightarrow \infty} \sum_{k=1}^n \frac{\mu(k)}{k} = 0.$$

The prime number theorem is important not only because it makes an elegant and simple statement about primes and has many applications but also because much new mathematics was created in the attempts to find a proof. This is typical in number theory. Some problems, very simple to state, are often extremely difficult to solve, and mathematicians working on these problems often create new areas of mathematics of independent interest. Another example is the creation of algebraic number theory as a result of work on the Fermat conjecture.

Primes in arithmetic progressions. An arithmetic progression of integers with first term h and common difference k consists of all numbers of the form $kn + h$ as n runs through the nonnegative integers $0, 1, 2, \dots$. If h and k have a common prime factor p , each term of the progression is divisible by p , and there can be no more than one prime in the progression. In 1803 Legendre considered whether there must be infinitely many primes in the progression if h and k have no common prime factor. For example, all odd numbers fall into two progressions, one containing numbers of the form $4n - 1$, and the other containing numbers of the form $4n + 1$, so at least one of these progressions must contain infinitely many primes. In fact, both of these progressions contain infinitely many primes. This is easily proved for the progression $4n - 1$ by a minor modification of the Euclidean proof of the infinitude of primes. The proof is as follows: For any finite set S of primes of the form $4n - 1$, let p be the largest prime in S , and consider the integer $N = 4 \cdot 3 \cdot 5 \cdots p - 1$, where the product $3 \cdot 5 \cdots p$ contains all the odd primes $\leq p$ as factors. Because N is greater than p it cannot be in S . No prime $\leq p$ divides N , and so all the prime factors of N must exceed p . But all the prime factors of N cannot be of the form $4n + 1$ because the product of two such numbers, and therefore the product of any finite collection of such numbers, is again of the same form. Hence there must be some prime factor of N of the form $4n - 1$ that is not in S . This proves that there must be an infinite number of primes of the form $4n - 1$.

This argument breaks down for the progression $4n + 1$, because the product of two numbers in this progression is again of the form $4n + 1$. But an elementary argument of a different type can be used to show that the progression $4n + 1$ also contains infinitely many primes. There are also elementary arguments showing that there are infinitely many primes in other special arithmetic progressions such as $5n - 1$, $8n - 1$, $8n - 3$, and $8n + 3$. For any positive integer k , the sequence $\{kn + 1 : n = 1, 2, 3, 4, \dots\}$ contains infinitely many primes. This special case of Dirichlet's theorem has been proved by elementary methods, but the proof is not as simple as in the other cases cited.

In a celebrated memoir published in 1837, Dirichlet showed that every arithmetic progression $kn + h$, where h and k are relatively prime, contains infinitely many primes. This was the first major triumph of analytic number theory. Dirichlet was guided by Euler's proof of Euclid's theorem on the infinitude of primes, which shows that the sum of the reciprocals of the primes diverges. Dirichlet used an ingenious argument to show that the sum of the reciprocals of all the primes in the progression $kn + h$ also diverges. The method can be understood by referring to the following asymptotic formula for the partial sums of the series of reciprocals of the primes:

$$\sum_{p \leq x} \frac{1}{p} = \log(\log x) + O(1),$$

where the sum is extended over all primes $p \leq x$, and the symbol $O(1)$ represents a quantity that remains bounded for all x . This formula shows that the partial sums are asymptotic to $\log(\log x)$ and therefore tend to ∞ as $x \rightarrow \infty$. Dirichlet's method gives a corresponding formula for sums extended over those primes $p \leq x$ that also lie in the arithmetic progression $kn + h$:

$$\sum_{\substack{p \leq x \\ p \equiv h \pmod{k}}} \frac{1}{p} = \frac{1}{\phi(k)} \log(\log x) + O(1),$$

where the notation $p \equiv h \pmod{k}$ indicates that each prime in the sum is congruent to h mod k . Again, the principal term on the right tends to ∞ as $x \rightarrow \infty$, so there must be infinitely many primes $p \equiv h \pmod{k}$, hence infinitely many in the progression $kn + h$. Because the principal term is independent of h , the formula also shows that each of the $\phi(k)$ residue classes mod k makes the same contribution to the principal term.

The key to Dirichlet's method was the introduction of new arithmetical functions $\chi(n)$, now called Dirichlet characters mod k . These are multiplicative functions that have period k and vanish only on the numbers not relatively prime to k . There are exactly $\phi(k)$ Dirichlet characters mod k , and they make it possible to extract the integers congruent to h mod k from a given set of integers.

Dirichlet's memoir also introduced functions analogous to the Riemann zeta function $\zeta(s)$ of prime number theory. These functions, now called Dirichlet L -functions, are defined by infinite series of the form

$$L(s, \chi) = \sum_{n=1}^{\infty} \frac{\chi(n)}{n^s},$$

Dirichlet
 L -functions

where $\chi(n)$ is a Dirichlet character mod k and s is a real number greater than 1 (or a complex number with real part greater than 1). The study of L -functions is an active area of contemporary mathematical research that has profound applications to both analytic and algebraic number theory.

Generating functions. Dirichlet's work on L -functions led to the description of a more general class of functions defined by infinite series of the form

$$F(s) = \sum_{n=1}^{\infty} \frac{f(n)}{n^s},$$

where $f(n)$ is a given arithmetical function. This is called a Dirichlet series with coefficients $f(n)$, and the function $F(s)$ is called a generating function of the coefficients. The prototype is the Riemann zeta function $\zeta(s)$, which generates the constant function $f(n) = 1$ for all n ,

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}.$$

The square of the zeta function generates the divisor function $d(n)$,

$$\zeta(s)^2 = \sum_{n=1}^{\infty} \frac{d(n)}{n^s},$$

and the reciprocal of the zeta function generates the Möbius function $\mu(n)$,

$$\frac{1}{\zeta(s)} = \sum_{n=1}^{\infty} \frac{\mu(n)}{n^s}.$$

More generally, if a Dirichlet series $F(s)$ generates an arithmetical function $f(n)$, and another Dirichlet series $G(s)$ generates $g(n)$, then the product $F(s)G(s)$ generates the arithmetical function

$$h(n) = \sum_{d|n} f(d)g\left(\frac{n}{d}\right),$$

called the Dirichlet product of the two arithmetical functions f and g . The appearance of the Dirichlet product is seen by multiplying the two Dirichlet series and rearranging terms, as follows:

$$\begin{aligned} F(s)G(s) &= \sum_{n=1}^{\infty} \frac{f(n)}{n^s} \sum_{m=1}^{\infty} \frac{g(m)}{m^s} \\ &= \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} \frac{f(n)g(m)}{(nm)^s} = \sum_{k=1}^{\infty} \frac{h(k)}{k^s}, \end{aligned}$$

where

$$h(k) = \sum_{nm=k} f(n)g(m) = \sum_{d|k} f(d)g\left(\frac{k}{d}\right).$$

The results are valid whenever the series for $F(s)$ and $G(s)$ converge absolutely.

Products of Dirichlet series can be used to generate many arithmetical functions occurring in multiplicative number theory. For example,

$$\frac{\zeta(s-1)}{\zeta(s)} = \sum_{n=1}^{\infty} \frac{\varphi(n)}{n^s}$$

and

$$\zeta(s)\zeta(s-a) = \sum_{n=1}^{\infty} \frac{\sigma_a(n)}{n^s}.$$

In additive number theory it is more convenient to use generating functions represented by power series. A function $A(x)$ with the power series expansion

$$A(x) = \sum_{n=0}^{\infty} a(n)x^n$$

is said to generate the coefficients $a(n)$. If $B(x)$ generates the coefficients $b(m)$, so that

$$B(x) = \sum_{m=0}^{\infty} b(m)x^m,$$

then, for those x for which both series converge absolutely, the product of the two series is given by

$$\begin{aligned} A(x)B(x) &= \sum_{n=0}^{\infty} a(n)x^n \sum_{m=0}^{\infty} b(m)x^m \\ &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} a(n)b(m)x^{n+m} = \sum_{k=0}^{\infty} c(k)x^k, \end{aligned}$$

where

$$c(k) = \sum_{n+m=k} a(n)b(m).$$

The new sequence $c(k)$ is called the Cauchy product of the two sequences $a(n)$ and $b(m)$.

For example, suppose $a(n) = 1$ if n is a square, and $a(n) = 0$ otherwise, so that

$$A(x) = 1 + x + x^4 + x^9 + x^{16} + \cdots + x^{n^2} + \cdots.$$

Thus, $A(x)$ involves only exponents that are squares. The square of $A(x)$ is given by the series

$$\begin{aligned} A(x)^2 &= 1 + 2x + x^2 + 2x^4 + 2x^5 + x^8 + 2x^9 + \cdots \\ &\quad + b(n)x^n + \cdots, \end{aligned}$$

where $b(n)$ is the number of ways that n can be expressed as the sum of two squares of nonnegative integers, with the order of the summands taken into account. The fourth power of $A(x)$ is given by

$$\begin{aligned} A(x)^4 &= 1 + 4x + 6x^2 + 4x^3 + 5x^4 + 12x^5 + \cdots \\ &\quad + c(n)x^n + \cdots, \end{aligned}$$

where $c(n)$ is the number of ways that n can be expressed as the sum of four nonnegative squares. For example, there are exactly six ways of writing 2 as the sum of four nonnegative squares:

$$\begin{aligned} 2 &= 1 + 1 + 0 + 0 = 1 + 0 + 1 + 0 \\ &= 1 + 0 + 0 + 1 = 0 + 1 + 0 + 1 \\ &= 0 + 1 + 1 + 0 = 0 + 0 + 1 + 1, \end{aligned}$$

hence $c(2) = 6$. Euler observed that Lagrange's four squares theorem is equivalent to the statement that $c(n)$ is positive for every n , but he did not succeed in showing that $c(n) > 0$.

If squares of negative numbers are also allowed among the summands, the number of representations of an integer as a sum of squares is much greater. For example, if squares of -1 are allowed, there are 24 ways to represent 2 as a sum of four squares. The number of representations of an integer n as a sum of k squares of integers (positive, negative, or zero) is denoted by $r_k(n)$. Its generating function is

$$\theta(x)^k = 1 + \sum_{n=1}^{\infty} r_k(n)x^n,$$

where $\theta(x)$, called a theta function, is defined by the infinite series

$$\theta(x) = \sum_{m=-\infty}^{\infty} x^{m^2}.$$

The example $r_2(n)$ was mentioned above.

Jacobi showed that properties of theta functions often lead to information concerning representations of integers by squares. For example, one of Jacobi's identities from the theory of elliptic functions implies that

$$\theta(x)^2 = 1 + 4 \sum_{n=1}^{\infty} (d_1(n) - d_3(n))x^n,$$

where $d_1(n)$ and $d_3(n)$ are the number of divisors of n congruent to 1 and 3 mod 4, respectively. When the coefficient of x^n in this formula is compared with the coefficient of x^n in the generating function for $r_2(n)$, it gives the explicit formula

$$r_2(n) = 4(d_1(n) - d_3(n))$$

for the number of representations of n as the sum of two squares. By similar methods, Jacobi also showed that $r_4(n) = 8\sigma(n)$ if n is odd, whereas $r_4(n) = 24$ times the sum of the odd divisors of n if n is even. Explicit formulas for $r_k(n)$ have been obtained by similar methods for $k = 6, 8, 10$, and 12, but they are more complicated. Explicit formulas for $r_k(n)$ are known for all even $k \leq 24$. Formulas for odd values of k are more difficult to derive.

Additive number theory. In contrast to multiplicative number theory, which is concerned with properties arising from prime factorization, additive number theory is concerned with arithmetical functions related to additive properties of the integers. The basic problem of additive number theory is that of expressing a given positive integer n as a sum of integers from some set

$$A = \{a_1, a_2, \dots\},$$

where the summands a_i are special numbers such as primes, squares, cubes, and so on. Each representation of n as a sum of elements from A is called a partition of n . The number of such partitions is often of great interest.

The problem of representation by squares was discussed in the previous section. Another famous problem of additive number theory is the Goldbach conjecture, formulated in 1742, which states that every even number greater than 4 is the sum of two odd primes. This conjecture has been confirmed numerically up to very large numbers but remains unproved. In 1937 the Russian mathematician Ivan Matveyevich Vinogradov proved that every sufficiently large odd number is the sum of three odd primes, and in 1966 the Chinese mathematician Chen Jing-run (Ch'en Ching-jun) showed that every sufficiently large even integer is the sum of a prime plus a number with no more than two prime factors.

Waring's problem is named after the English mathematician Edward Waring, who in 1770 stated, without proof and with limited numerical evidence, that every positive integer n is the sum of four squares, of nine cubes, of 19 fourth powers, and so on. The problem is to determine, for a given positive integer k , whether there is an integer s (depending only on k) such that the equation

$$n = x_1^k + x_2^k + \cdots + x_s^k$$

has integer solutions for all $n \geq 1$. The least value of s that exists for a given k is denoted by $g(k)$. Similarly, $G(k)$ denotes the smallest s required to so represent all sufficiently large n .

In 1770 Lagrange proved that $g(2) = 4$, and during the next 139 years the existence of $g(k)$ was shown for $k = 3, 4, 5, 6, 7, 8$, and 10. In 1909 the German mathematician David Hilbert proved the existence of $g(k)$ for every k but did not determine its numerical value. The exact value of $g(k)$ is now known for every k . For example, $g(3) = 9$, $g(4) = 19$, $g(5) = 37$, $g(6) = 73$, $g(7) = 143$, and $g(8) = 279$. A general formula states that

$$g(k) \geq 2^k + \left\lceil \frac{3^k}{2^k} \right\rceil - 2$$

for all $k \geq 2$, with equality if $4 \leq k \leq 200,000$.

The existence of $G(k)$ follows from that of $g(k)$ because $G(k) \leq g(k)$, but only the values $G(2) = 4$ and $G(4) = 16$

Integers
expressed
as sums of
squares

Waring's
problem

are known exactly. Some upper bounds smaller than $g(k)$ are known, for example, $G(3) \leq 7$, $G(5) \leq 23$, $G(6) \leq 36$, $G(7) \leq 53$, and $G(8) \leq 73$. The British mathematicians Godfrey Harold Hardy and John E. Littlewood conjectured that $G(k) < 2k + 1$ when k is not a power of 2 and that $G(k) \leq 4k$ when it is, but the most that is known is $G(k) < ck \log k$ for some constant c .

Perhaps the most fundamental arithmetical function in additive number theory is the unrestricted partition function $p(n)$, which counts the number of ways that a positive integer n can be written as a sum of natural numbers not exceeding n . For example, $p(5) = 7$ because there are 7 partitions of 5, given by

$$\begin{aligned} 5 &= 4 + 1 \\ &= 3 + 2 \\ &= 3 + 1 + 1 \\ &= 2 + 2 + 1 \\ &= 2 + 1 + 1 + 1 \\ &= 1 + 1 + 1 + 1 + 1. \end{aligned}$$

In counting partitions, the number of summands (parts) is unrestricted, repetition is allowed, and the order of the summands is not taken into account.

Euler showed that the reciprocal of the infinite product

$$\varphi(x) = \prod_{m=1}^{\infty} (1 - x^m)$$

is a generating function for $p(n)$:

$$\frac{1}{\varphi(x)} = \sum_{n=0}^{\infty} p(n)x^n,$$

where $p(0) = 1$. He also showed that

$$\varphi(x) = 1 - x - x^2 + x^5 + x^7 - x^{12} - x^{15} + \dots,$$

where the exponents 1, 2, 5, 7, 12, 15, ... are called pentagonal numbers; they can be derived from the expressions $(3k^2 - k)/2$ and $(3k^2 + k)/2$ by taking $k = 1, 2, 3, 4, \dots$. By multiplying the power series for $\varphi(x)$ with that for its reciprocal $1/\varphi(x)$, Euler obtained the following recursion formula for computing $p(n)$:

$$p(n) = p(n-1) + p(n-2) - p(n-5) - p(n-7) + \dots,$$

where $p(k) = 0$ if $k < 0$. Another recursion formula, obtained by logarithmic differentiation of the generating function $1/\varphi(x)$, reveals a remarkable connection between $p(n)$ and the function $\sigma(n)$ of multiplicative number theory:

$$np(n) = \sum_{k=1}^n \sigma(k)p(n-k).$$

The function $p(n)$ grows rapidly. For example, $p(10) = 42$, $p(100) = 190,569,292$, and $p(200) = 3,972,999,029,388$. In 1917 Hardy and the Indian mathematician Srinivasa Ramanujan used the transformation theory of elliptic modular functions to show that $p(n)$ has the asymptotic value

$$p(n) \sim \frac{e^{K\sqrt{n}}}{4n\sqrt{3}},$$

where $K = \pi\sqrt{2/3}$. In 1937 the German-American mathematician Hans Rademacher showed that $p(n)$ could be expressed as the sum of a convergent series, the first term of which gives the foregoing asymptotic value.

Ramanujan discovered a number of remarkable identities that imply divisibility properties of the partition function. For example, the Ramanujan identity

$$5 \frac{\varphi(x^5)}{\varphi(x)^6} = \sum_{m=0}^{\infty} p(5m+4)x^m$$

implies that $p(5m+4) \equiv 0 \pmod{5}$. He also found that $p(7m+5) \equiv 0 \pmod{7}$ and $p(11m+6) \equiv 0 \pmod{11}$.

Investigations on the partition function in the early 20th century initiated a new era of research that has revealed profound connections among elliptic modular functions, abstract algebra, and number theory.

Lattice point problems. In a rectangular coordinate system, each point in the plane is represented by a pair of real numbers (x, y) , its rectangular coordinates. Those points with integer coordinates are called lattice points, and they form a configuration of equally spaced rows and columns called the unit square lattice. Since the time of Gauss,

many interesting and deep properties of the integers have been discovered by studying the unit square lattice. These investigations, together with their extension to higher-dimensional space, led to the creation of a new branch of mathematics called geometric number theory, or the geometry of numbers. This section describes a small sample of theorems concerning lattice points and illustrates some of the methods used to prove them. Most of the discussion is concerned with lattice points in the plane, with some indication of how the results are extended to spaces of higher dimension.

If a plane is covered with unit squares, like those on graph paper, the vertices of the squares form the unit square lattice. The same lattice can be generated by covering the plane with parallelograms having lattice points as vertices, provided there are no further lattice points inside or on the boundary of each parallelogram. Any parallelogram whose vertices generate the unit square lattice has area equal to 1 (that is, equal to the area of one unit square of the lattice). This fact is easily deduced from a theorem, discovered by the Austrian mathematician Georg Pick, concerning polygons whose vertices are lattice points (lattice polygons). The theorem states that the area of the region enclosed by any lattice polygon is one less than the number of lattice points inside the polygon plus half the number on the boundary. An example is shown in Figure 1. Therefore, any lattice parallelogram that generates the unit square lattice has area 1, because there are no lattice points inside the parallelogram and exactly four on the boundary.

Pick's theorem also implies that every regular lattice polygon must necessarily be a square. Thus, for example, there is no equilateral lattice triangle. This can be proved by calculating the area of such a polygon in two ways. If the regular polygon has n sides and is subdivided into n isosceles triangles with a common vertex at the center, its area is a rational multiple of $\cot(\pi/n)$. However, Pick's theorem implies that the area is rational, because the area is either an integer or an integer plus $1/2$; this implies that $\cot(\pi/n)$ must be a rational number. But it is known that, for $n \geq 3$, $\cot(\pi/n)$ is rational only for $n = 4$. For example, $\cot(\pi/3) = 1/\sqrt{3}$, an irrational number. Thus, there is no equilateral lattice triangle.

Because lattice polygons are special figures, it is not surprising that there is a simple formula for determining their areas by counting lattice points. But no three-dimensional analogue of Pick's formula can exist for finding the volume of a lattice polyhedron by counting lattice points inside, on the faces, and on the vertices. This can be demonstrated with a tetrahedron whose vertices are at the lattice points $(0, 0, 0)$, $(0, 1, 0)$, $(0, 0, 1)$, and $(1, 1, k)$, where k is a positive integer. There are lattice points at the four vertices but none inside, on the faces of, or on the edges of this tetrahedron. As k increases the volume of the tetrahedron increases, but the number of lattice points inside the figure or on its boundary does not change. Therefore, no three-dimensional analogue of Pick's formula can exist.

Figure 1: A polygon whose vertices are lattice points. It contains 15 lattice points inside and 18 on the boundary. By Pick's theorem the area of the region enclosed is $15 + 9 - 1 = 23$ (see text).

The number of lattice points inside a plane figure can change quite drastically if the figure is translated, even by a small amount. For example, a rectangle with vertices at the four lattice points $(0, 0)$, $(3, 0)$, $(3, 1)$, and $(0, 1)$ has exactly eight lattice points on its boundary and none inside. If this figure is shifted slightly to the right, the number of lattice points on the boundary decreases to six, again with none inside. If the figure is now shifted upward a small amount, the number of lattice points on the boundary drops to zero and the number inside increases to three. This simple example shows that the number of lattice points captured in a given region will depend on where the region is placed on the unit square lattice. It also shows that relations between areas of plane regions and numbers of lattice points captured may be harder to derive if the regions are not bounded by lattice polygons.

Blichfeldt's
theorem

In 1914 the American mathematician Hans Frederick Blichfeldt discovered a remarkable theorem relating areas and lattice points: Any bounded plane region with positive area A placed in any position on the unit square lattice can be translated so that the number of lattice points inside the region will be at least A . The theorem allows the shape of the region to be arbitrary. The only requirements are that the region be bounded (which means that it can be enclosed inside some large square) and have positive area. If the area A is an integer, say $A = 14$, the theorem asserts that the region can be translated so that it encloses at least 14 lattice points inside. If A is not an integer, say $A = 14.2$, the region can be translated so that the number of lattice points inside is at least 15, the next integer larger than A . An example is shown in Figure 2.

Blichfeldt's theorem can be extended to higher-dimensional space. The version for three-dimensional figures states that any bounded solid region with positive volume V placed on the unit cubic lattice in any position can be translated so that the number of lattice points inside the region will be at least V . There is also an n -dimensional version in which V is the n -dimensional volume.

Minkowski's
convex
body
theorem

The use of geometric methods in number theory was introduced in 1889 by Hermann Minkowski when he created a subject he called the "geometry of numbers." The cornerstone of this theory is his convex body theorem: A bounded plane convex region, symmetric about a lattice point and with area greater than 4, must contain at least three lattice points in its interior. (A region is called convex if for every pair of points in the region the line segment joining them also lies in the region. Familiar examples of convex regions are those bounded by parallelograms, circles, or ellipses. A region is symmetric about a point P if for every point Q in the region, Q' is also present, where P is the midpoint of the straight line segment QQ' .)

Minkowski's theorem can be deduced from Blichfeldt's theorem. Denote the convex plane region by K and assume that its centre of symmetry is at the origin. Denote by $K/2$ the region obtained by multiplying all the coordinates of points of K by $1/2$. The new region $K/2$ has the same shape as K but is only half as large. In the language of geometry, $K/2$ is similar to K with similarity ratio $1/2$. Therefore, the region $K/2$ is also convex and symmetric about the origin, but its area is $1/4$ that of K , because areas of similar figures are related by the square of the similarity ratio. The area of K is greater than 4, so the area of $K/2$ is greater than 1. By Blichfeldt's theorem, some translation of $K/2$ contains at least two distinct lattice points in its interior. Denote these lattice points by x and y in vector notation, and let a be the vector through which $K/2$ was translated to capture x and y . (See Figure 3.) The lattice points x and y came from two points $x - a$ and $y - a$ interior to $K/2$. These are not necessarily lattice points because the translation vector a need not have integer coordinates. Because $K/2$ is symmetric about the origin, the point $a - x$ is also interior to $K/2$. Now $K/2$ is convex, so the point midway between $y - a$ and $a - x$, that is, the point $(y - x)/2$, is also interior to $K/2$. Therefore, the point with coordinates twice as large, $y - x$, is interior to K . But $y - x$ is a lattice point, different from the origin. This lattice point, together with the symmetric point $x - y$ and the origin, are three lattice points interior to K , and this proves Minkowski's theorem.

Figure 2: An example illustrating Blichfeldt's theorem. The lower region of area 14.2 (with 12 lattice points inside), has been translated to the upper region to capture 15 lattice points inside.

The three-dimensional version of Minkowski's theorem asserts that a bounded convex body, symmetric about a lattice point and with volume greater than 8, must contain at least three lattice points in its interior. The most important applications require an n -dimensional version of the theorem, in which the number 8 is replaced by 2^n . A proof, virtually identical to the one given above for the two-dimensional case, can be based on the n -dimensional version of Blichfeldt's theorem.

Minkowski extended his theorem to nonrectangular lattices in which the unit squares of the rectangular lattice are replaced by parallelograms of area $|\Delta|$, where Δ is a number called the determinant of the lattice. In the three-dimensional case the parallelograms become parallelepipeds of volume $|\Delta|$. For these more general lattices, the n -dimensional version of Minkowski's theorem states

Figure 3: Minkowski's convex body theorem deduced from Blichfeldt's theorem. The lattice points x and y are in a translation of $K/2$. The lattice points $x - y$ and $y - x$ are in K .

that a bounded convex body, symmetric about a lattice point and with n -dimensional volume greater than $2^n|\Delta|$, contains at least three lattice points in its interior.

Minkowski's convex body theorem provides a new method for proving some fundamental facts about algebraic number theory. The theorem can also be used to derive new proofs of some theorems from elementary number theory. In particular, it can be used to prove Lagrange's theorem that every positive integer is the sum of four squares, or the theorem of Euler and Fermat that every prime number of the form $4k+1$ is the sum of two squares.

The theorems of Blichfeldt and Minkowski can be regarded as existence theorems. Prescribed information about the size and shape of a region implies the existence of one or more lattice points inside the region. A number of results of this type involve both the area and perimeter of plane regions. For example, in 1947 the Polish mathematician Maria Nosarzewska found that the number N of lattice points inside a convex plane region of area A and perimeter P satisfies the inequalities

$$A - \frac{1}{2}P < N \leq A + \frac{1}{2}P + 1.$$

In particular, if the area exceeds half the perimeter, the leftmost inequality implies that $N > 0$, hence $N \geq 1$. In other words, any convex plane region of area A and perimeter P with $A/P > 1/2$ contains at least one lattice point in its interior. This last result has been extended to higher dimensions. If the n -dimensional volume V of a convex body in n -dimensional space exceeds half the $(n-1)$ -dimensional surface area S , then the body contains at least one lattice point in its interior. Nosarzewska's inequality improves a theorem of the Czech mathematician Vojtech Jarnik, which states that $|N - A| < P$ for any plane region, convex or not, with perimeter $P \geq 1$.

Many problems in number theory involve counting lattice points in special regions. For example, while investigating the number of representations of a number as a sum of two squares, Gauss proposed the problem of counting the number $N(r)$ of lattice points inside or on the boundary of a large circle of radius r with centre at the origin. Because every lattice point in the plane can be regarded as belonging to exactly one square of the unit square lattice (for example, that square having the lattice point as its lower left corner), counting lattice points in a region is essentially the same as counting squares in the region. Therefore, the number $N(r)$ should be approximately πr^2 , the area of the region, with an error of the order of magnitude of the circumference, $2\pi r$. Gauss showed that $N(r) = \pi r^2 + E(r)$, where the error $E(r)$ satisfies $|E(r)| \leq 2\sqrt{2}\pi r$. Jarnik's inequality implies $|E(r)| \leq 2\pi r$ if $r \geq 1/(2\pi)$, a minor improvement. In 1904 the Polish mathematician Wacław Sierpiński showed that $|E(r)| \leq Cr^{2/3}$ for some constant C . Later it was shown that the exponent $2/3$ could be replaced by a smaller exponent but not by $1/2$. Determining the smallest possible exponent θ for which $|E(r)| \leq Cr^\theta$ is called the Gauss circle problem. The best inequality known is $1/2 < \theta \leq 7/11 = 0.6363636 \dots$. The Gauss circle problem has been extended from plane regions bounded by circles to those bounded by ellipses, hyperbolas, and other curves. It has also been generalized to higher dimensions.

Another category of lattice point problems is concerned with the concept of visibility. Two lattice points (x, y) and (x', y') are called mutually visible if the line segment joining them contains no further lattice points. This is equivalent to saying that the differences $x - x'$ and $y - y'$ are relatively prime. Lattice points visible from the origin (called visible points) have relatively prime coordinates. There are infinitely many lattice points visible from the origin, and it is natural to ask how they are distributed among all the lattice points. One way of answering this question is to count the total number N' of visible points in a large square centred at the origin, then divide this number by the total number N of lattice points in the square. As the square expands to cover all lattice points, the limiting value of the ratio N'/N is $6/\pi^2$, called the density of the visible points. This result can be stated in the language of probability. If a lattice point is selected at

random from the unit square lattice, the probability that it is visible from the origin is $6/\pi^2$. Or, if two integers are selected at random, the probability that they are relatively prime is $6/\pi^2$. The density of visible points in an n -dimensional lattice is $1/\zeta(n)$, where $\zeta(n)$ is the sum of the reciprocals of the n th powers of all the positive integers.

UNSOLVED PROBLEMS

There are hundreds of unsolved problems in number theory, some of which have already been mentioned in this article. This concluding section lists examples of problems that are easy to state but which remain unsolved.

Prime numbers and divisibility. Are there infinitely many even perfect numbers?

Are there any odd perfect numbers?

Is there an even number greater than 2 that is not the sum of two primes?

Is there an even number greater than 2 that is not the difference of two primes?

Are there infinitely many twin primes—that is, primes p such that $p+2$ is also prime?

Are there infinitely many primes of the form $2p+1$, where p is prime?

Are there infinitely many Mersenne primes $2^p - 1$ with prime p ?

Are there infinitely many Fermat primes—that is, primes of the form $2^{2^n} + 1$?

Are there infinitely many composite numbers $2^{2^n} + 1$?

Are there infinitely many primes of the form $x^2 + k$, where k is a given integer?

Are there infinitely many primes of the form $n! + 1$?

Are there infinitely many primes that are the sum of three cubes—that is, primes of the form $x^3 + y^3 + z^3$, where x, y, z are integers?

Is there always a prime between n^2 and $(n+1)^2$ for every positive integer n ?

Are there infinitely many primes p satisfying the congruence $2^{p-1} \equiv 1 \pmod{p^2}$?

Are there infinitely many composite n satisfying the congruence $a^{n-1} \equiv 1 \pmod{n}$ for all a relatively prime to n ?

Diophantine equations. For an arbitrary integer $n \geq 2$, are there positive integers x, y, z such that

$$\frac{4}{n} = \frac{1}{x} + \frac{1}{y} + \frac{1}{z}?$$

Are there integer solutions to the equation

$$x^3 + y^3 + z^3 = 3$$

other than the four solutions

$(x, y, z) = (1, 1, 1), (4, 4, -5), (4, -5, 4), \text{ and } (-5, 4, 4)$?

Are there integer solutions to the equation

$$x^3 + y^3 + z^3 = 30?$$

Are there positive integers x, y, z and $n > 2$ such that

$$x^n + y^n = z^n?$$

Does the equation $x^x y^y = z^z$ have solutions in odd integers x, y, z greater than 1?

Arithmetical functions. Is there a composite n such that Euler's function $\phi(n)$ divides $n-1$?

Is there an integer n for which the equation $\phi(x) = n$ is satisfied for exactly one integer x ?

If $\pi(x)$ is the number of primes $\leq x$, is the inequality

$$\pi(x+y) \leq \pi(x) + \pi(y)$$

satisfied for all integers x and y greater than 1?

Irrational and transcendental numbers. Does the digit 1 occur infinitely often in the decimal expansion of $\sqrt{2}$?

Does the decimal expansion of π contain the sequence of nine digits 123456789 in succession?

Is the number $e + \pi$ transcendental?

The intellectual challenge of unsolved problems in number theory has kept the subject alive and active since the time of the ancient Greeks. Because new problems arise more rapidly than the old ones are solved, number theory will continue to thrive and to stimulate other branches of mathematics for centuries to come.

BIBLIOGRAPHY. Among the many books on number theory, the following are recommended for readers with a good background in high-school algebra: H. DAVENPORT, *The Higher Arithmetic: An Introduction to the Theory of Numbers*, 5th ed. (1982); IVAN NIVEN and HERBERT S. ZUCKERMAN, *An Introduction to the Theory of Numbers*, 4th ed. (1980); KENNETH H. ROSEN, *Elementary Number Theory and Its Applications*, 2nd ed. (1988); WACŁAW SIERPIŃSKI, *Elementary Theory of Numbers*, trans. from Polish (1964); and HAROLD M. STARK, *An Introduction to Number Theory* (1970). Introductory books at a slightly more advanced level include GEORGE E. ANDREWS, *Number Theory* (1971); and G.H. HARDY and E.M. WRIGHT, *An Introduction to the Theory of Numbers*, 5th ed. (1979, reprinted 1983). See also J.S. CHAHAL, *Topics in Number Theory* (1988). Collections of abstracts of articles published in *Mathematical Reviews* are found in WILLIAM J. LEVEQUE (ed.), *Reviews in Number Theory*, 6 vol. (1974), covering 1940–72; and RICHARD K. GUY (ed.), *Reviews in Number Theory 1973–83*, 6 vol. (1984).

Topics in analytic and algebraic number theory are presented in TOM M. APOSTOL, *Introduction to Analytic Number Theory* (1976); EMIL GROSSWALD, *Topics from the Theory of Numbers*, 2nd ed. (1984); and LOO KENG HUA (LO-KENG HUA), *Introduction to Number Theory* (1982; originally published in Chinese, 1957). More advanced treatments are Z.I. BOREVICH and I.R. SHAFAREVICH, *Number Theory* (1966; originally published in Russian, 1964); and KENNETH IRELAND and MICHAEL ROSEN, *A Classical Introduction to Modern Number Theory* (1982).

For the history of number theory, see LEONARD EUGENE DICKSON, *History of the Theory of Numbers*, 3 vol. (1919–23, reprinted 1966); OYSTEIN ORE, *Number Theory and Its History* (1948, reprinted 1988); and ANDRÉ WEIL, *Number Theory: An Approach Through History from Hammurapi to Legendre* (1984).

Specialized topics are covered by GEORGE E. ANDREWS, *The Theory of Partitions* (1976, reissued 1984); J.W.S. CASSELS, *An Introduction to Diophantine Approximation* (1957, reprinted 1972), and *An Introduction to the Geometry of Numbers* (1959, reprinted 1971); HAROLD M. EDWARDS, *Fermat's Last Theorem: A Genetic Introduction to Algebraic Number Theory* (1977); MARK KAC, *Statistical Independence in Probability, Analysis and Number Theory* (1959, reprinted 1964); L.J. MORDELL, *Diophantine Equations* (1969); IVAN NIVEN, *Irrational Numbers* (1956); C.D. OLDS, *Continued Fractions* (1963, reprinted 1975); PAULO RIBENBOIM, *13 Lectures on Fermat's Last Theorem* (1979), and *The Book of Prime Number Records* (1988); and M.R. SCHROEDER, *Number Theory in Science and Communication: With Applications in Cryptography, Physics, Digital Information, Computing, and Self-Similarity*, 2nd enl. ed. (1986).

Books devoted primarily to problems in number theory are RICHARD K. GUY, *Unsolved Problems in Number Theory* (1981); WŁADYSŁAW NARKIEWICZ, *Classical Problems in Number Theory* (1986); DANIEL SHANKS, *Solved and Unsolved Problems in Number Theory*, 3rd ed. (1985); WACŁAW SIERPIŃSKI, *A Selection of Problems in the Theory of Numbers*, trans. from Polish (1964), and *250 Problems in Elementary Number Theory* (1970); and I.M. VINOGRADOV, *Elements of Number Theory* (1954; originally published in Russian, 5th ed., 1949).

DERRICK HENRY LEHMER, *Guide to Tables in the Theory of Numbers* (1941), is a highly recommended, comprehensive, and descriptive account. Tables of primitive roots and indices are found in C.G.J. JACOBI (ed.), *Canon arithmeticus*, rev. and expanded ed. edited by HEINRICH BRANDT (1956); A.E. WESTERN and J.C.P. MILLER, *Tables of Indices and Primitive Roots* (1968); and HERBERT HAUPTMAN, EMANUEL VEGH, and JANET FISHER, *Tables of All Primitive Roots for Primes Less Than 5000* (1970). (T.M.A./I.N.)

Numerical Analysis

Numerical analysis comprises three related activities: the study of a problem by the computation of numerical values that solve the mathematical equations (called mathematical models) describing the behaviour of some system, the development of methods (called numerical algorithms) for finding those values, and the analysis of the properties of those methods. The mathematical models are developed by professionals in various subject areas of application, that is, by scientists, engineers, or economists. A numerical analyst is a person who develops or analyzes methods for computing the numerical values.

Mathematical models are the starting point for the numerical analyst. Examples of models include an astronomer's mathematical description of the motion of a planet or a satellite (called its equations of motion), the equations used by a designer to describe the radioactivity in a nuclear reactor and the operation of its control system, the equations hypothesized by a research chemist to describe a chemical reaction, the equations used by government planners to express the relationships between economic and social indicators such as gross national product (GNP), prime rate, and unemployment rate, and the equations used in computer-aided tomography (CAT scans) to construct a view of the interior of a human body from an X-ray scan.

Among the uses of models are the following: prediction of future behaviour—for example, the determination of the future locations of the heavenly bodies (a matter of continuing interest in scientific calculation but of great concern in previous centuries because of its importance to navigation before the development of modern instruments); the selection of the best design—for example, the choice of the lowest cost nuclear reactor that meets the requirements of power output and safety; the comparison of computed values with experimental observations to test the validity of the theory represented by the model or to estimate the values of unknown constants that appear in the model—for example, the research chemist's effort to

determine the rate at which materials react by comparing changes in chemical concentrations predicted from model equations with the values measured in the laboratory; and the determination of values that are not directly observable from other values that are—for example, in computer-aided tomography, the use of X-ray observations to provide the average density of a large set of narrow, pencil-shaped sections of the body, which then are used to construct a map of the density of the interior of the body.

Some problems are described by models so simple that they can be manipulated without numerical computation. For example, if a metal rod is subject to a stretching force (the stress, F) and it lengthens a certain amount (the strain, L), the stress-strain relationship might be modeled by the equation $L = \lambda F$, in which λ is a numerical constant. This says that the stretching is linearly proportional to the applied force, so that if the force is doubled, the stretching doubles. A person can understand this relationship and use it to solve problems such as "What force is needed to stretch the rod L millimetres?" in the symbolic or explicit form $F = L/\lambda$, so that it is unnecessary to compute actual values until they are needed in a design task. However, many models are so complex that it is not possible to solve problems explicitly or to understand the relationships expressed by the model. In that case, the model user turns to numerical methods, either to compute specific solutions or to study the behaviour of the model as it is changed.

The goal of numerical analysis is the efficient computation of accurate approximations of the values that satisfy mathematical equations. Two major problems confront the numerical analyst: the round-off errors that unavoidably arise during computation, and the representation of problems involving infinite amounts of information with the finite number of values that a person (or computer) can handle.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 10/23, and the *Index*. This article is divided into the following sections:

ERRORS

Most problems involve infinite sets of values, each of which can potentially require an infinite number of digits for exact representation. Digital computation, either human, mechanical, or electronic, is, by its very nature, finite: it involves a finite set of numerical values, each of which is represented in a finite set of digits. These two approximations of infinite quantities by finite ones lead to the two types of error in numerical computation, round-off and truncation error. A numerical analyst is interested in determining the size of possible errors in a calculation. Analysts try to find bounds on errors or estimates of errors. A bound is a value that the analyst can guarantee the error will not exceed. An estimate is a value that the analyst believes is an approximation of the error (error estimates typically vary from the true error by a factor of 2). The word *error* is unfortunate because it suggests a mistake or sin. Round-off and truncation errors are unavoidable: the

job of the numerical analyst is to find out how to compute accurately and efficiently in their presence.

Finite-precision errors: round-off. The precision of a value is indicated by the number of digits used in its representation. It is typically between seven and 15 decimal digits, depending on the type of computer and calculation. Finite precision means that most values cannot be represented exactly, but that there is some round-off error in the computed approximation. For example, if $\frac{1}{3}$ is represented by five significant decimal digits as 1.3333 (the most accurate possible using five digits), there is a round-off error of 0.0000333... or $\frac{1}{3} \times 10^{-4}$, as illustrated below:

	decimal representation
correct value	1.3333333...
5-digit representation	1.3333
round-off error	0.0000333...

Bounds
and
estimates
of errors

All calculations are subject to the effects of round-off errors. Round-off errors, which are proportional to the size of the value containing the error when a fixed number of significant digits is used, can be as large as 5 in the first neglected place or one-half in the last retained place. When a value is added to a much smaller value, the round-off can be large relative to the smaller value. For example, if 23,456 is added to 10.518 in five digits, the result is 23,467, with a round-off error of -0.482 . If 23,456 is subtracted from the answer, the result is 11. Thus, in five-digit arithmetic, $(23,456 + 10.518) - 23,456 = 11.0$, which has an error in the third place. After the addition, the error was less than one-half in the last place, but the subtraction removed the three leading digits, 234, moving this error to the third place. This phenomenon is called cancellation. It does not cause errors but makes the size of errors already introduced larger relative to the computed result. Thus, although round-off errors are small, their effect in the final answer can be large, so that one of the tasks of the numerical analyst is to devise or modify computational schemes to minimize the effect of these errors.

The effect of a change in the computational scheme is illustrated by a simple example related to an exterior ballistics problem. (Exterior ballistics deals with the trajectory of a projectile after it leaves the barrel of a gun. Much early numerical table building and computing was devoted to this problem, which is related to the orbit problem.) When a projectile is fired from ground level (that is, from an initial height, $h = 0$) and with an initial vertical velocity of v_0 , its height, h , after t seconds is $h = tv_0 - t^2g/2$, where g is the acceleration due to the force of gravity. The projectile will hit a target at height h_0 at a time that satisfies the quadratic equation

$$h_0 = tv_0 - t^2 \frac{g}{2}. \quad (1)$$

This equation can be rewritten in the form of the standard quadratic equation $ax^2 + bx + c = 0$ whose roots, r , are given by the formula

$$r = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}.$$

Upon replacing a , b , and c by $g/2$, $-v_0$, and h_0 , the roots of (1) are found to be

$$r = \frac{v_0 \pm \sqrt{v_0^2 - 2gh_0}}{g}.$$

For the case $v_0 = 500$, $h_0 = 75$, and $g = 9.82$, the two roots can be computed from

$$r = \frac{500 \pm \sqrt{250,000 - 2 \times 9.82 \times 75}}{9.82}.$$

The value of the quantity under the square root symbol is 248,527. If three-digit arithmetic is used, it becomes 249,000 (trailing zeros do not count as significant digits). The square root of 249,000 is 499 correct to three digits. Hence the two roots are computed as $(500 + 499)/9.82 = 102$ and $(500 - 499)/9.82 = 0.102$ to three digits. The correct solutions to three digits are 102 and 0.150. The 50 percent error in the smaller root occurs because the root is computed by the subtraction of the two nearly equal values 500 and 499. This illustrates the phenomenon of cancellation. Because of three-digit accuracy, each of these two values can be in error by as much as 0.5. In fact, to six digits the second value is 498.525 so that the approximation 499 is in error by 0.475. After subtraction, the computed result of $500 - 499$ is 1.0, instead of 1.475, and is in error in the second place. This large error can be avoided by computing the smaller root with a different version of the formula. It is easy to show (by dividing (1) by t^2 and solving for $1/t$) that the second root is given by

$$r = \frac{2h_0}{v_0 + \sqrt{v_0^2 - 2gh_0}},$$

from which the result, 0.150, can be computed using three-digit arithmetic. In the article "What Is a Satisfactory Quadratic Equation Solver?" George E. Forsythe discusses further the difficulties that can arise even in this simple problem.

The quadratic equation above is a problem whose solutions can be computed accurately if the calculation is organized correctly. Numerical analysis is used to investigate the errors that can arise in such computations. In some problems it is very difficult to compute accurate answers because a slight change in the problem can cause a large change in the answer. Such problems are said to be ill-conditioned. In some types of problems, an arbitrarily small change in the problem can lead to an arbitrarily large change in the answer. Such problems are said to be ill-posed. A properly posed problem is one in which bounded changes to the problem lead to bounded changes in the answer. A well-conditioned problem is one whose answers change only in a small way if the initial problem is changed in a small way. The equation

$$(x - 1.1)^4 = 0$$

has the answer $x = 1.1$ by inspection. When the expression on the left-hand side is multiplied out, the equation

$$x^4 - 4.4x^3 + 7.26x^2 - 5.324x + 1.4641 = 0 \quad (2)$$

is obtained. In this form it is ill-conditioned. If five-digit arithmetic is used, the coefficients in (2) can be represented exactly. On the other hand, if four-digit arithmetic is used, the last coefficient would be represented as 1.464, to get the equation

$$x^4 - 4.4x^3 + 7.26x^2 - 5.324x + 1.464 = 0, \quad (3)$$

which is the same as

$$x^4 - 4.4x^3 + 7.26x^2 - 5.324x + 1.4641 = 0.0001 = 10^{-4}. \quad (4)$$

In this particular case, the roots of the changed equation can be computed exactly because it has the form $(x - 1.1)^4 = 10^{-4}$, of which one root is given by $(x - 1.1) = 10^{-1}$ or $x = 1.2$. Thus, a change in the fifth decimal place, or 0.01 percent, in the original problem (2) to get (3) has caused a change in the second place, or 10 percent, in the answer. Because this problem is ill-conditioned, no numerical method can avoid the fact that a slight change to the problem can cause a large change in the answer. Because round-off errors in the early stages of the calculation are indistinguishable from changes in the original problem, such problems are susceptible to large errors in their numerical answers, and a simple error analysis shows these errors.

A direct analysis of the effect of the errors on the answers is called a forward error analysis because it analyzes the effects of the errors as they propagate forward through the steps of the calculation to the final result. A forward analysis leads to the statement "Round-off errors have caused this much error in the answer." As illustrated above, a small round-off can cause a large error in the answer of an ill-conditioned problem. Another useful measure of the computational error is the amount by which the computed answer fails to satisfy the problem. This is called the residual. For example, if the computed answer of 1.2 is substituted into equation (2), the left-hand side is $(1.2 - 1.1)^4 = 10^{-4}$. Although the error in the answer is 0.1, the residual is 10^{-4} . In this example and in many others, the size of the residual can be estimated by a backward error analysis. This leads to the statement "Round-off errors can change the answers so that they are the exact answers of a problem that is different from the original problem by this much." A backward error analysis applied to a good method for the problem discussed above might show that the method solved a problem whose coefficients were within 0.01 percent of those in (2), so that (3) could have been the problem solved. Although the answers to the changed problem may be very different from those of the original, they are as good as can be expected from an ill-conditioned problem. A good method is one that has small backward errors or residuals: for a well-conditioned problem, such a method always gives accurate answers because, by definition, in a well-conditioned problem the answer changes by only a small amount when the problem changes by a small amount.

Finite-dimension errors: truncation. The types of problems discussed in the previous section are finite dimensional because only a finite number of values are involved:

Ill-conditioned and ill-posed problems

Forward and backward error analysis

the values of the unknown, x , and the coefficients. In many problems an infinite amount of information is inherently present, and the problem cannot be solved exactly by numerical methods that deal with only a finite number of values. This circumstance introduces a fundamental concept, that of a finite approximation to an infinite-dimensional object, which is illustrated by the approximation of a smooth graph of a function by a series of straight lines (a piecewise-linear approximation).

A function, $f(x)$, is a prescription of a value corresponding to each value of its argument, x . For example, $f(x) = 2 - x + x^2$ is a function whose value is 2 when $x = 0$, 2 when $x = 1$, 4 when $x = 2$, etc. A description of a function by a mathematical formula defines the value of the function for all values of its argument. The mathematical definition of a function is that it is a (possibly infinite) set of pairs of values, (x_i, y_i) . A function of a single variable x can be represented graphically by placing a point at $[x, f(x)]$ for each value of x . If this is done for a few values of x , say five values, the set of points shown in Figure 1 is obtained. This graph can be described with just 10 numbers, $x_1, y_1, x_2, y_2, \dots, y_5$, where $y_i = f(x_i)$. The members of each pair (x_i, y_i) are the coordinates of one of the points. These five points, however, do not prescribe the value of the function for other than the five given values of x . More pairs of values (x_i, y_i) could be added, but they cannot specify the value of the function for every value of x unless there is an infinite number of pairs of values. Hence, this graph needs infinitely much information if it is to describe the function completely. Thus, a general function is an infinite-dimensional object because it requires infinitely much information to specify it. If the graph is "smooth," however, it is reasonable to approximate it by joining a small set of points with a continuous line. If consecutive points are joined by a sequence of straight lines, as shown in Figure 2, a piecewise-linear approximation is obtained. Such an approximation requires the values of only a finite number of values, the values of the end points of each of the straight-line segments shown in Figure 2. The piecewise-linear approximation is a finite-dimensional approximation to an infinite-dimensional object. This is critically important in numerical computation by hand or computer because computers and people can deal only with finite amounts of information. More closely spaced points can be used in a piecewise-linear approximation to get a more accurate approximation, as also shown in Figure 2, but the additional points mean that more information is used to approximate the function.

The error caused by replacing an infinite-dimensional object by a finite-dimensional approximation is called truncation error. A large part of numerical analysis is

Figure 1: Graph of values of the function $y = f(x) = 2 - x + x^2$ for $x = 0, 1, 2, 3$, and 4 .

Figure 2: Piecewise-linear approximations to a continuous function (see text).

concerned with the accuracy of finite-dimensional approximations, examining questions such as "What type of approximation can be used?", "How much information is needed for a given accuracy?", and "Will the approximation become more accurate as more information is used?". As more information is used in an approximation, more computation is required to evaluate it, so that it is natural to expect more accuracy. A method that can achieve arbitrarily much accuracy by using sufficient information is said to be convergent. Most methods have one or a few parameters that determine the amount of information used in the approximation. For example, if, in the piecewise-linear approximation discussed above, the points x_i are equally spaced, that is, if $x_{i+1} - x_i = h$ for all i , where h is the mesh spacing, then the number of points used over a fixed interval, say $(0, 1)$, is determined by the parameter h . As h is reduced, the amount of information used to approximate the function increases, and it is visually obvious from Figure 2 that the approximation becomes more accurate. How much more accurate it becomes is typical of the questions that numerical analysts investigate. In this case it is relatively easy to show with calculus that if h is halved, the error decreases by a factor of approximately 4, provided that the function $f(x)$ is smooth enough, that is, if it is continuous and has no sharp turns in it, or, mathematically, if it has a second derivative. The relationship between the error and the mesh size for the piecewise-linear approximation is that the error is no larger than h^2 times a constant times the second derivative of the function. This method is said to have second-order convergence. (If a method depends on a parameter h and its error is proportional to h^p , it is said to have p th-order convergence.) Numerical analysts look for methods that have high orders of convergence because, as more information is used, their accuracy increases more rapidly than lower-order methods. Straightforward methods for simple problems, such as the approximation of functions, are usually convergent, but much care must be exercised in the choice of methods for complex problems to get convergence. A significant part of the theoretical work in numerical analysis is concerned with proofs of the convergence of methods.

In practical calculation, round-off errors are also present. As the amount of information is increased to decrease truncation error, the size of each round-off error, which is determined by the number of digits used in the calculation, remains constant. Hence, no amount of additional infor-

Convergent
methods

mation can reduce the error below some minimum unless the precision of the calculation is increased. Furthermore, in methods for many problems the number of arithmetic operations in the calculation increases as the amount of information increases, so that the total error due to round-off increases because it is the combined effect of an increasing number of round-off errors. In these calculations, the error in the answer, which is the sum of the effects of truncation errors and round-off errors, initially decreases as the amount of information used increases and the truncation error decreases, but then increases as the round-off errors become dominant. This is illustrated in Figure 3.

APPROXIMATION OF FUNCTIONS

An approximation to a function may be needed for several reasons. In some cases, values of the function are known at only a finite number of points, where they have been previously obtained by measurement. In that case, a method of estimating the values of the function between those points is needed. The process of obtaining these values is called interpolation. In other cases, it is computationally expensive to calculate the function every time it is needed, but less expensive to compute an approximation, which requires fewer computational operations. In still other cases, it is not possible to compute the function exactly with the standard arithmetic operations of addition, multiplication, etc., even with exact arithmetic, so that an approximate formula must be used.

Many approximations to functions consist of polynomials. A polynomial is a function of the form

$$P(x) = a_0 + a_1x + a_2x^2 + \cdots + a_nx^n. \quad (5)$$

This polynomial has degree n . It can be evaluated using n multiplications and additions when written in the form

$$(\cdots((a_n \times x + a_{n-1}) \times x + a_{n-2}) \times x + \cdots + a_1) \times x + a_0.$$

A polynomial of degree n contains $n+1$ coefficients a_i , $i=0, 1, \dots, n$, so that it has $n+1$ degrees of freedom, or has dimension $n+1$. It is formed as a linear sum of multiples of the $n+1$ basis functions x^i , $i=0, 1, \dots, n$. These functions are independent, which means that no linear combination of them will be identically zero for all x . When an infinite-dimensional object has to be approximated by a finite-dimensional one, any set of independent functions can be used. If $\phi_i(x)$, $i=0, 1, \dots, n$, are a set of $n+1$ independent functions, they form a basis, and the approximation

$$f(x) \approx a_0\phi_0(x) + a_1\phi_1(x) + \cdots + a_n\phi_n(x)$$

can be used. If the $\{\phi_i(x)\}$, $i=0, 1, 2, \dots$, are an infinite set of independent basis functions that satisfy certain technical restrictions, they can be used to get arbitrarily accurate approximations by including enough of them. If the basis function $\phi_i(x)$ is a polynomial of degree i , these technical restrictions are satisfied. The approximations generally have better properties if the basis functions are as different from one another as possible. In this respect, the functions x^i are not very good because, for example, the functions x^2 and x^4 are not greatly different in overall shape, as can be seen by drawing them. An important class of basis functions are those that are mutually orthogonal,

Figure 3: The effect of the amount of information on error in numeric computations.

which is a mathematical prescription for requiring them to be as different as possible. (This use of orthogonal is related to its use in specifying directions that are at right angles, and thus very different, such as north and east.)

Polynomial interpolation. Interpolation is used to compute the approximate value of a function, given its values at a set of points. To approximate the function at a point whose value is not given, the value of a polynomial passing through a few neighbouring points is computed, as shown in Figure 4. Usually, the points with known values closest to the point of unknown value are chosen because the accuracy of interpolation is proportional to the distance of the unknown point from each of the known points. An important fact about polynomials is that a unique polynomial of degree n can be constructed to pass through any set of $n+1$ points; that is, if (x_i, y_i) , $i=0, 1, \dots, n$, are a set of points with all x_i different, there is a unique set of coefficients a_i such that $P(x)$ given by equation (5) satisfies $P(x_i) = y_i$ for $0 \leq i \leq n$. A different set of points, and hence a different polynomial, is used to interpolate for different regions of x values. For example, if a third-degree polynomial (a cubic) were to be used, four points would be needed. If the x_i are ordered, that is, if $x_0 < x_1 < x_2 < \dots$, and x lies between, say, x_7 and x_8 , the points x_6, x_7, x_8 , and x_9 would be used, whereas if x lies between x_{15} and x_{16} the points x_{14}, x_{15}, x_{16} , and x_{17} would be used to construct the interpolating polynomial. The coefficients of that polynomial could be calculated for each interval, and then the value of $P(x)$ could be calculated from the polynomial. However, computational schemes have been devised to compute the interpolated value directly without finding the coefficients of the underlying polynomial. The user of such schemes is interested in rapid calculation with a minimum susceptibility to round-off error. The Lagrange formula is an important form of polynomial interpolation. To interpolate an n th-degree polynomial that matches the $n+1$ points (x_i, y_i) , $i=0, 1, \dots, n$, this formula incorporates the set of $n+1$ polynomial basis functions, $\phi_i(x)$, each of degree n , which are such that $\phi_i(x)$ is zero at all of the $n+1$ points except at x_i , where its value is 1. The interpolating polynomial can be written as

$$P(x) = y_0\phi_0(x) + y_1\phi_1(x) + \cdots + y_n\phi_n(x).$$

This clearly satisfies the interpolation conditions: each of the basis functions is a polynomial of degree n , so their sum is also an n th-degree polynomial; when $x = x_i$, all of the terms in the sum vanish except for $y_i\phi_i(x_i)$, which is just y_i . Definition of the $\phi_i(x)$ is straightforward. On the basis of the function

$$\Pi(x) = (x - x_0)(x - x_1) \cdots (x - x_n),$$

which is an $(n+1)$ st-degree polynomial that is zero at $x = x_i$ for $0 \leq i \leq n$, a set of functions

$$\pi_i(x) = \Pi(x)/(x - x_i)$$

may be defined. These are n th-degree polynomials that are zero except at x_i . Division of each of them by $\pi_i(x_i)$ gives the functions

$$\phi_i(x) = \pi_i(x)/\pi_i(x_i),$$

each of which has the desired property that its value at x_i is 1. Although these formulas are simple, they are not the basis for computationally efficient methods. The importance of the Lagrange formula arises mainly from its use in the mathematical development of methods and proofs of their properties. Although there are many different polynomial interpolation formulas, all n th-degree polynomial interpolation formulas that are correct at $n+1$ points are equivalent except in the amount of computation and the effects of round-off.

The approximation of a function by a polynomial forms the basis of many other numerical calculations besides interpolation. If the integral or derivative of a function is needed and it is not possible to compute it directly, it can be approximated by computing the integral or derivative of a polynomial approximant since there are straightforward rules for evaluating the integral or derivative of a polynomial.

Lagrange formula

Figure 4: Polynomial interpolation.

The six points x_1, y_1 , etc., represent values of an unknown function. A third-degree polynomial has been constructed so that four of its values match four of the values of the unknown function. Other third-degree polynomials could be made to match other sets of four values of the unknown function, or a polynomial of higher degree could be found to match all six.

Difference calculus. Differences are the basis for the development of many methods of polynomial approximation. If the values of a function $f(x)$ are given at a set of equally spaced argument values x_0, x_1, x_2, \dots , where $x_n = x_0 + nh$, the forward difference of $f(x)$ at x_n , written as $\Delta f(x_n)$, is defined as $f(x_{n+1}) - f(x_n)$. Piecewise-linear interpolation between x_n and x_{n+1} is given by the formula

$$f(x) \approx f(x_n) + \frac{(x - x_n)}{(x_{n+1} - x_n)} \Delta f(x_n).$$

Since the spacing between the x_i 's is h , this can be written as

$$f(x) \approx f(x_n) + s \Delta f(x_n),$$

where $s = (x - x_n)/h$. Higher degree polynomials can be used by using higher order differences. The second difference, written $\Delta^2 f(x_n)$, is defined as $\Delta f(x_{n+1}) - \Delta f(x_n)$, which can be rewritten as $f(x_{n+2}) - 2f(x_{n+1}) + f(x_n)$. In general, the m th-order difference is given by

$$\Delta^m f(x_n) = \Delta^{m-1} f(x_{n+1}) - \Delta^{m-1} f(x_n).$$

The polynomial of degree m passing through the points $x_n, x_{n+1}, \dots, x_{n+m}$ can be written as

$$P(x) = f(x_n) + \frac{(x - x_n)}{(x_{n+1} - x_n)} \Delta f(x_n) + \frac{(x - x_{n+1})(x - x_n)}{(x_{n+2} - x_{n+1})(x_{n+2} - x_n)} \Delta^2 f(x_n) + \dots + \frac{(x - x_{n+m-1}) \cdots (x - x_n)}{(x_{n+m} - x_n) \cdots (x_{n+1} - x_n)} \Delta^m f(x_n).$$

This can be rewritten as

$$f(x) \approx f(x_n) + s \Delta f(x_n) + \frac{s(s-1)}{2} \Delta^2 f(x_n) + \dots + \frac{s(s-1) \cdots (s-m+1)}{m!} \Delta^m f(x_n).$$

If the function is smooth, its differences get smaller as their order increases until round-off errors cause them to increase again. The point at which they become smallest gives a direct indication of how many differences can be used to achieve the maximum accuracy possible. A list of the differences of various orders can be easily computed and used for interpolation. An important property of differences is that if the function is a polynomial of degree m in x , the differences of order higher than m are zero and $\Delta^m f(x_n)$ is independent of n , that is, is a constant.

Difference calculus is a formal manipulation scheme for developing useful approximations. It uses the operators Δ (already introduced as the forward difference operator); E , which is defined as the step operator so that $Ef(x_n) = f(x_{n+1})$; and others. Because of the relationship

$$f(x_{n+1}) = f(x_n) + \Delta f(x_n) = f(x_n) + \Delta f(x_n),$$

the formal relationship

$$E = 1 + \Delta$$

can be written. This can be squared to get

$$E^2 = (1 + \Delta)^2 = 1 + 2\Delta + \Delta^2.$$

This is the formal statement that

$$f(x_{n+2}) = f(x_n) + 2\Delta f(x_n) + \Delta^2 f(x_n),$$

whose truth can be verified by simple algebra. Since E^m is the equivalent of moving forward m values in the table, it seems reasonable that $E^{0.5}$ should be the equivalent of moving forward half a step in the table, that is, to interpolating for the value of $f(x)$ at $x_{n+0.5}$. Similarly, E^s should represent interpolation s steps forward for any s , whether integer or not. Formally, E^s can be rewritten as

$$E^s = (1 + \Delta)^s$$

and expanded according to the binomial expansion to get

$$E^s = 1 + s\Delta + \frac{s(s-1)}{2} \Delta^2 + \frac{s(s-1)(s-2)}{3!} \Delta^3 + \dots$$

When this is applied to $f(x_n)$ and the infinite series is terminated after $m+1$ terms, the previous interpolation formula is obtained. Thus, difference calculus has provided a formal verification of the formula stated earlier.

To illustrate how differences can be used for many other approximations, it is convenient to define the operator D as differentiation. Formally,

$$Df(x) = \frac{d}{dx} f(x).$$

The Taylor's series approximation to a function states that

$$f(x+a) = f(x) + a \frac{d}{dx} f(x) + \frac{a^2}{2} \frac{d^2}{dx^2} f(x) + \frac{a^3}{3!} \frac{d^3}{dx^3} f(x) + \dots$$

This can be written in operator form as

$$E^{ah} = 1 + aD + \frac{(aD)^2}{2} + \frac{(aD)^3}{3!} + \dots$$

The series on the right-hand side is the power-series expansion of the exponential function and is equal to e^{aD} . On the replacement $a = sh$ this relation becomes

$$E^s = e^{shD} = (e^{hD})^s.$$

This leads to $E = e^{hD}$, from which the relationship

$$hD = \log(E) = \log(1 + \Delta)$$

is obtained. Expansion of the logarithm then yields

$$hD = \Delta - \frac{\Delta^2}{2} + \frac{\Delta^3}{3} - \dots,$$

which gives a numerical approximation for the derivative of a function in terms of its differences. If this relation is terminated after $m+1$ terms, it is exactly equivalent to computing the derivative of a polynomial of degree m through $m+1$ values of the function. This fact follows from the fact that the differences of order higher than m of an m th-degree polynomial are zero.

Difference calculus operates on data tabulated at equidistant points. If the mesh points x_i are unequally spaced, different formulas must be used. In this case, divided differences are a valuable tool. The first divided difference of a function $f(x)$ is the slope of the line through two points on the function. It is written as

$$f[x_n, x_{n+1}] = \frac{f(x_{n+1}) - f(x_n)}{x_{n+1} - x_n}.$$

Its value depends on the two points, x_n and x_{n+1} , that are used, but not on their order. That is, $f[x_n, x_{n+1}] = f[x_{n+1}, x_n]$. The m th-order divided difference on $m+1$ points is defined as

$$f[x_n, x_{n+1}, \dots, x_{n+m}] = \frac{f[x_{n+1}, x_{n+2}, \dots, x_{n+m}] - f[x_n, x_{n+1}, \dots, x_{n+m-1}]}{[x_{n+m} - x_n]}.$$

If the points x_i are equally spaced with the distance between them equal to 1, then the m th-order divided difference is identical to the m th-order difference divided by $m!$. Polynomial interpolation by an m th-degree polynomial can be written as

$$f(x) \approx f(x_n) + (x - x_n)[x_n, x_{n+1}] + \dots + (x - x_n)(x - x_{n+1}) \dots (x - x_{n+m-1})[x_n, x_{n+1}, \dots, x_{n+m}].$$

Computation of elementary functions. Elementary functions are functions that occur very frequently in scientific and engineering calculations. They are usually the solution of simple relations that cannot be expressed directly in terms of other, simpler operations or functions. Examples include sine, cosine, and exponential. The solutions to many problems can be written explicitly in terms of elementary functions. Many elementary functions can be expressed as power series, which are like polynomials but which have infinitely many terms. For example, the exponential function has the power series expansion

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \frac{x^5}{5!} + \dots \quad (6)$$

This summation has the property that as more and more terms are included it converges; that is, its value comes closer and closer to the true value. If (6) is evaluated to seven-digit accuracy with $x = 0.1$ for a number of terms, the following results are obtained:

number of terms (n)	value of n th term	sum of n terms
1	1.000000	1.000000
2	0.100000	1.100000
3	0.005000	1.105000
4	0.000167	1.105167
5	0.000004	1.105171
6	0.000000	1.105171

Further terms would not change the seven-digit sum. The series provides a way of computing an approximation of e^x to any desired accuracy by adding enough terms. Many elementary functions are calculated in this way (although the minimax method described later can be used to reduce the amount of arithmetic and hence the time taken).

Spline approximation. In many applications the shape of an object is defined by the positions of a number of points on its surface, for example, the hull of a ship or the body of an automobile. The builder, to construct a smooth-surfaced object from this information, needs a mechanism for determining the position of any point on its surface. A simpler case of this problem is the construction of a smooth curve through a set of points—the problem solved by a drafter asked to draw a graph. The numerical problem is to approximate a function smoothly from the knowledge of a few of its points. Polynomial interpolation provides an interpolant, which is the approximating function, but it is not usually smooth because different polynomials are used between different pairs of points. Thus, a piecewise-linear interpolant has angles between the straight lines in adjacent regions, as shown in Figure 2.

A spline approximant is a piecewise polynomial interpolant with the property that it matches the function values at the given points, called the knots, and that it is smooth. The mathematical definition of a smooth function is that it has a certain number of continuous derivatives. The first derivative is the slope of the curve. If the slope is continuous, the curve has no angles, that is, no sudden changes in direction. The second derivative is related to the radius of curvature. In a surface such as that of an automobile body, the radius of curvature determines how reflections are magnified or reduced. A sudden change in the radius of curvature results in a surface that is not visually pleasing if it is supposed to be uniform—for example, the hood of an automobile might appear to have a crease in it. For this reason, curves and surfaces with continuous second derivatives are often desirable. A common spline approximation is a piecewise cubic with continuous second derivatives.

Least squares approximation. Interpolation approximates functions whose form is known approximately with

a polynomial (or other easily computable interpolant) that matches the function values assumed to be known exactly. In some situations the form of the function is known exactly (for example, it is known that it is a linear function), but the only other information known is the approximate value at a few points. This happens when, for example, the values are obtained from experimental measurements. In this situation it is desirable to compute a function of the known form that is the best fit to the given values. To make this definition precise, the meaning of “best” must be specified. The least-squares approximation is the one that minimizes the sum of the squares of the differences between the given values and the values of the function. For example, if it is known that the function is linear, that is, that $f(x) = ax + b$, and the three measurements $x_1, y_1; x_2, y_2; x_3, y_3$ are given, where $y_i \approx f(x_i)$, the three differences are $y_i - (ax_i + b)$, $i = 1, 2, 3$, and the least squares method chooses a and b such that

$$[y_1 - (ax_1 + b)]^2 + [y_2 - (ax_2 + b)]^2 + [y_3 - (ax_3 + b)]^2$$

is as small as possible. If at least two of the x_i are distinct, there is a unique set a and b that achieves a minimum of this expression. Formulas for the values of a and b can be derived by the use of calculus. The general linear least-squares problem, which is a least-squares problem in which the unknown parameters (a and b in the example) appear linearly in the original errors ($y_i - ax_i - b$ in the example), has the same properties: if there are n unknown parameters and there are at least n distinct points x_i , there is a unique minimum.

The calculation of the solution to a least-squares problem is a good example of the application of numerical analysis. Straightforward application of calculus to the problem of the least-squares n th-degree polynomial approximant leads to a system of linear equations whose solution is discussed below. For large n the system is very poorly conditioned, so that a poor numerical answer is obtained. This occurs when the polynomials x^i are used as a basis; the use of orthogonal polynomials as a basis leads to much better accuracy.

Minimax approximation. Minimax approximation is another example of choosing the best approximation from a set of possible approximations. A measure of the error in an approximation to a function is first defined as the size of the largest difference between the approximation and the function at any of the points of interest. The approximation that has the smallest error measure is the minimax approximant. For example, the minimax linear approximation to the three points (x_i, y_i) , $i = 1, 2$, and 3 , is the line shown in Figure 5. It is equidistant from each of the points, as shown. Minimax approximations are related to least-squares approximations in that both are best approximations; in both approximations, “best” is defined as the minimum of some measure of error, but the measure of the error is different. In least squares, it is the sum of the squares of the errors; in the minimax case, it is the size of the largest error. (Both methods can be viewed as special cases of general minimum-error approximations.)

Minimax approximations are most frequently used to approximate one known function by another function that is less difficult to compute. For example, the sine function might be approximated by a polynomial in a computer program that computes a numerical value of $\sin(x)$ by

Figure 5: Linear minimax approximation. The line has been drawn so that its vertical distance, e , is the same from each of the three points.

Power
series

Measures
of error

evaluation of the polynomial. In this approach, a polynomial that is the best approximation in the minimax sense is used. The minimax polynomial may require fewer terms to get a given accuracy than would be needed if the first few terms of the power series were used. Although it takes a large amount of computation to determine the minimax polynomial for a given accuracy, that computation can be carried out once, and then the resulting polynomial can be evaluated whenever an approximation to the function is needed.

The n th-degree minimax polynomial approximant to a function has the important property that the difference between the polynomial and the function (the error) reaches its maximum value at least $n+2$ times, and the sign of the error has alternate signs at each extremum. Figure 5 illustrates this in the case $n=1$. The Chebyshev orthogonal polynomials are a set of polynomials, $T_0(x)$, $T_1(x)$, $T_2(x)$, \dots , where $T_n(x)$ has degree n and is such that it has $n+1$ equal and opposite extrema. The values of the extrema alternate between $+1$ and -1 . These polynomials are effective as basis functions for the representation of minimax approximations.

SOLUTION OF EQUATIONS

An equation is a relation between two expressions, for example, $3z + 4 = (y - 2)^2$. The expressions may contain known values, such as the numbers in the example, and unknowns, such as z and y , for which values must be computed. An equation says that the values of the unknowns must be such that the values of the expressions on either side of the equal sign are the same. An unknown, say x , appears linearly in an expression if it appears only in the form ax , where a has a known value independent of x , after all terms in the expression have been multiplied out. Thus, z appears linearly in the above example, but y does not—because the right-hand side is $y^2 - 4y + 4$ and the term y^2 is nonlinear. A linear equation is one in which all unknowns appear linearly and each is multiplied only by a constant. Most phenomena that physicists and engineers model are nonlinear, so that the effective solution of nonlinear equations is important. Many of the models can be approximated by linear equations, however, so the efficient solution of linear equations is equally important. Indeed, the solution of nonlinear equations often involves the solution of linear equations within the process.

The first section below discusses the solution of linear equations. In addition to their importance in many problems, they also illustrate the problems of round-off errors, backward error analysis, and the difficulty of ill-conditioned problems. Linear equations have the property that they can be solved exactly using the usual arithmetic operations of addition, subtraction, etc., if no round-off is involved. Methods that solve a problem exactly in the absence of round-off are called direct methods because they lead directly to the solution. Nonlinear equations cannot be solved exactly; rather, their solution must be approximated. So-called iterative methods generate a sequence of closer and closer approximations called iterates.

Linear equations and direct methods. The standard linear-equation problem is a set of N linear equations in N unknown variables. An example of a simple system of two equations is

$$3x_1 + 6x_2 = 12 \quad (7)$$

$$5x_1 - 3x_2 = 7. \quad (8)$$

Gauss's
procedure

These can be solved by the process of elimination and back substitution originated by the 19th-century German mathematician Carl Friedrich Gauss. In this process one of the equations is solved for a variable in terms of the other variables, and this variable is eliminated from the remaining equations to get a system of one fewer equations in one fewer unknowns. In the simple example above, equation (7) is divided by the coefficient of x_1 , namely, 3, and rearranged to get

$$x_1 = 4 - 2x_2. \quad (9)$$

This is substituted into equation (8) to get

$$5(4 - 2x_2) - 3x_2 = 7, \quad (10)$$

which can be rearranged to get

$$-13x_2 = -13$$

or $x_2 = 1$. This result can now be substituted back into equation (9) to get $x_1 = 2$. The key idea is that, with each elimination step, the number of equations and number of unknowns involved is reduced by one. If there are initially N equations, $N-1$ elimination steps reduce the system to one equation in one unknown, which can be solved directly. A system of N equations in N unknowns is usually written as

$$A_{i1}x_1 + A_{i2}x_2 + \dots + A_{iN}x_N = b_i, \quad i = 1, \dots, N, \quad (11)$$

where the A_{ij} are the coefficients, the b_i are the right-hand side values, and the x_j are the unknowns to be computed. The first of these equations ($i=1$) can be solved for x_1 to get

$$x_1 = (b_1 - A_{12}x_2 - \dots - A_{1N}x_N)/A_{11} \quad (12)$$

and this value of x_1 can be substituted into the remaining $N-1$ equations, which will then involve only $N-1$ unknowns. The same process can be repeated until a set of equations, each like equation (12) and each specifying an x_i in terms of x_j for $j > i$, is obtained. The N th such equation specifies x_N directly. The value of x_N can then be substituted into the $(N-1)$ st equation to get x_{N-1} , and so on. This is an entirely mechanical process that can be programmed easily for a computer. It is called an algorithm, a specification of a computational process that will determine the answer to a problem in a finite number of steps. It should be noted that if exact arithmetic could be used in this algorithm and if the division in equation (12) and subsequent divisions were possible (that is, if A_{11} and subsequent A_{ii} were not zero), the solution of the linear equations could be computed exactly.

In a practical computation, arithmetic cannot be performed exactly, so round-off errors will affect the answers. Their effect can be seen by considering a graphic interpretation of an equation: an equation of the form (7) represents a straight line on a graph relating x_1 and x_2 , as in Figure 6. Any point on the line λ_1 shown has coordinates x_1 and x_2 that satisfy equation (7). Similarly, equation (8) represents another straight line shown as λ_2 in Figure 6. Any point on that line satisfies equation (8). Hence, the values of x_1 and x_2 that satisfy both (7) and (8) must lie on both lines, so that these values are the coordinates of the intersection of the two lines. If the lines are not parallel, they have a unique intersection, so that the equations have a unique solution.

Figure 6: Graphic solution of a pair of linear equations (see text).

Round-off errors in the computation have an effect similar to that of changing the coefficients of the equations. Hence, in the presence of round-off errors, a computer will work with a narrow region that can be thought of as a "thick line," as shown in Figure 7, rather than an ideal line. The coordinates of any point inside the shaded region satisfy the equation of the line within the accuracy of the errors introduced into the coefficients. A pair of equations represents two thick lines within the accuracy of their coefficients, and the solution determined by the pair of equations lies somewhere within the intersection of the two thick lines, as shown in Figure 8.

If the equations represent a pair of lines that are nearly parallel, the numerical problem represented by the pair

Figure 7: Effect of round-off errors on the graphic representation of a linear equation.

If the coefficients could be expressed exactly, the equation would be represented by an ideal line (having zero width), but because the coefficients can be expressed with limited accuracy, the line must be replaced by a band of finite width.

of thick lines in Figure 9 does not have an accurately determined answer because the region of intersection is large. The problem is said to be ill-conditioned. Any slight changes in the coefficients can cause large changes in the answer, so any round-off errors in the numerical procedure may cause large changes in the answer.

In the Gauss elimination-back substitution procedure described above, it was noted that it could always be completed unless one of the A_{ii} divisors was zero. If one of those divisors is very small, intermediate results may be very large, and the final answer may be obtained as the difference of two large numbers. This means that cancellation may occur so that there may be a large effect due to round-off. This effect can be seen in a graphic view of the process of Gaussian elimination. As described above, the equations represent a pair of lines. Dividing an equation by a number, as in dividing (7) by 3 to get (9), does not change the line the equation represents. Substituting one equation into another, as in substituting (9) into (8) to get (10), gives another equation that also represents a straight line, λ_4 . Since the solution of the original equations lies on the new line, this new line must pass through the intersection of the two original lines. It should be noted that equation (10) does not involve x_1 , so that line λ_4 is horizontal, as shown in Figure 10. The final step, the back substitution, evaluates x_2 from (10) and substitutes into (9)—which represents the same line as (7)—to get x_1 . Thus, the solution is determined from lines λ_1 and λ_4 . In Figure 6 they intersect nearly at right angles, as do λ_1 and λ_2 . Hence, both the original problem of finding the intersection of λ_1 and λ_2 , and the intermediate problem of finding the intersection of λ_1 and λ_4 , are well-conditioned. If the line λ_1 had been nearly horizontal and the line λ_2 had been nearly vertical, however, the result of the Gaussian elimination would have been a nearly horizontal line, λ_4 , to be used with the nearly horizontal line λ_1 to determine the solution. As described earlier, this is an ill-conditioned problem subject to large numerical changes in the answer. In this case, although the initial problem is well-conditioned (lines λ_1 and λ_2 intersect nearly at right angles), the intermediate problem given by lines λ_1 and λ_4 is ill-conditioned because of the poor choice of the numbering of the equations. The algorithmic solution to this

Figure 8: Graphic solution of two linear equations, showing the effect of round-off error. Instead of two ideal lines intersecting in a single point, two narrow bands intersect in a region of finite area.

is to reorder the equations during the elimination process to ensure that the A_{ii} elements are large. This is called partial pivoting. Even with partial pivoting, solution errors for ill-conditioned problems can be large. A formal error analysis provides a pessimistic bound of the errors that can occur even for a well-conditioned problem, especially as the number of equations increases. Before the introduction of electronic computers this situation did not present a difficulty because large problems could not be tackled. Around 1950 it was thought unlikely that computers could produce accurate solutions of large systems of linear equations. The English mathematician J.H. Wilkinson and other researchers, who had been solving problems by hand methods, showed that problems could frequently be solved much more accurately than the conventional analysis predicted. Finally, Wilkinson's backward error analysis showed that the Gaussian elimination process would solve a system of equations with a residual or backward error that did not increase too rapidly as the size of the problem increased. Experience has confirmed Wilkinson's theoretical result: the error does not increase very much with the size of the problem.

Partial
pivoting

Figure 9: Graphic solution of two linear equations for which the slopes of the lines are nearly the same. Because the region of intersection is large, the error in the solution is large.

Today it is common to solve sets of hundreds of thousands of linear equations on computers. There is major interest in ways in which such large problems can be solved rapidly. If the system is dense, which means that most of the coefficients, A_{ij} , are not zero, the Gaussian elimination process takes an amount of time equal to $aN^3 + bN^2 + cN + d$, where a, b, c , and d are constants that depend on the computer. As N gets large, the dominant term in the time is aN^3 , and subsequent doublings in the problem size result in eightfold increases in the solution time. The method is said to have a running time asymptotic to N^3 . The asymptotic behaviour of a method provides a measure of its speed for very large problems. For example, if a method has an asymptotic speed of $N^{2.5}$, it will execute more rapidly than one with asymptotic speed N^3 for very large N , although for small N it may not be faster. The asymptotically fastest method for linear equations is not known, and it is a question of considerable theoretical interest. It is known that they can be solved at asymptotic speeds close to $N^{2.5}$. For practical problems that will fit into computers, the Gaussian elimination technique remains the best method known for dense problems.

Many large problems are sparse; that is, most of the coefficients A_{ij} are zero (because each equation describes a small piece of the physical system being modeled, and each piece is influenced only by a few other pieces). In such cases, the numerical analyst is interested in methods that do not change many coefficients from zero to non-zero (called fill-in). Gaussian elimination can still be used, and the equations can be re-ordered to minimize fill-in. In many cases of large sparse problems, however, iterative methods (discussed below) are preferable.

Nonlinear equations and iterative methods. Most accurate models necessitate the solution of nonlinear equations. Only in a few cases is it possible to solve such equations explicitly. The example of the quadratic equation $ax^2 + bx + c = 0$ was used above. The roots of this can be written explicitly, but polynomial equations involving x^5 or higher powers cannot be solved explicitly. The general

Comparing
speeds of
computa-
tions

Figure 10: Graphic representation of the Gaussian elimination-back substitution procedure (see text).

problem is to find the value of x that gives a zero of a function $f(x)$, that is, to find a root of

$$f(x) = 0. \quad (13)$$

Generally, the computational solution of this problem is possible only by approximating the function by one for which a zero can be computed. If the approximation is good enough, the zero of the approximate function may be a sufficiently accurate approximation to the desired zero. If not, another approximation is used to get a more accurate answer. Each repetition of this process is called an iteration. Iteration is an extremely important approach to the solution of nonlinear equations, and it also has applications to linear equations.

An iterative method can be described as one in which knowledge about each succeeding approximate solution is used to compute a better solution. This knowledge is used to get a better approximation to the function. To illustrate the principle, the simplest of iterative methods is considered here, even though it is of value only in very limited applications. If x is added to both sides of equation (13), it becomes

$$x + f(x) = x, \quad (14)$$

an equation with the same roots as (13). It is now rewritten as

$$x = x - f(x). \quad (15)$$

Equation (15) is no easier to solve than (13), but the nonlinear right-hand side can be replaced with an approximation. In the first method, it is replaced by the constant value obtained by replacing x with a known value, say, c , to get

$$x = c - f(c). \quad (16)$$

This is certainly easy to solve for x since it is linear in x ; in fact, it is necessary only to evaluate the right-hand side. This process can be turned into an iterative algorithm by taking the value computed for x and using it for the value of c in a second application of the process, and so on. An initial guess for the root is obtained somehow. (The problem solver will probably have some knowledge of an approximate value of the solution from experience. If not, any reasonable value, for example, $x = 0$, is chosen.) This initial guess is called $x^{(0)}$, and each new approximation is named $x^{(i)}$, $i = 1, 2, \dots$. Then the relationship

$$x^{(n+1)} = x^{(n)} - f(x^{(n)}) \quad (17)$$

is obtained. The values $x^{(0)}, x^{(1)}, x^{(2)}, \dots$, form an infinite sequence. If they are such that $x^{(n+1)} = x^{(n)}$, it is clear that $x = x^{(n)} = x^{(n+1)}$ satisfies (15) and hence the original problem (13). This method is illustrated with the linear equation $f(x) = 0.9x - 1$ to keep the exposition simple (it is obvious that the zero of $0.9x - 1$ could be found directly with simple arithmetic). The iteration is

$$x^{(n+1)} = x^{(n)} - (0.9x^{(n)} - 1) = 1 + 0.1x^{(n)}. \quad (18)$$

If $x^{(0)} = 0$, the following sequence of values for $x^{(n)}$ is obtained:

n	$x^{(n)}$
1	1.
2	1.1
3	1.11
4	1.111
5	...

It is clear that $x^{(n+1)}$ will never equal $x^{(n)}$ mathematically because it will have one more digit, but each succeeding value is closer to the answer, $10/9 = 1.111 \dots$. Thus, $x^{(n)}$ converges to the correct solution as n gets larger, although it never gets there. As much accuracy as is needed can be obtained by performing enough iterations.

The iterative process described above (which is called functional iteration) can be described graphically as follows: Figure 11 shows a simple function $f(x)$ with a zero at x^* . The current guess, $x^{(n)}$, is also shown along with $f(x^{(n)})$. The right-hand side of (17) can be constructed by drawing a 45° right-angle triangle as shown to get $x - f(x^{(n)})$ on the x -axis. This is the next iterate. In Figure 11 the graph of $f(x)$ has been approximated by a 45° line. This view suggests that a better approximation to the curve could be used. This is the basis of many methods, of which two will be described, the chord method and Newton's method.

Figure 11: Functional iteration for successive approximations to x^* , the value of x for which $f(x)$ is zero (see text).

In the chord method, two different values of x , $x^{(0)}$, and $x^{(1)}$, are selected, and a straight line is drawn through them to approximate the curve. The next point, $x^{(2)}$, is given by the intersection of this line with the x -axis, as shown in Figure 12. The process is repeated using $x^{(1)}$ and $x^{(2)}$ to get $x^{(3)}$, and so on. It is not difficult to construct examples for which the chord method will not converge, so many variants of the method have been devised in attempts to improve its performance. A particular variant, the method of false position, always finds an answer if the initial guesses are such that the values of the function at the two initial points, $f(x^{(0)})$ and $f(x^{(1)})$, have opposite signs. The method computes $x^{(2)}$ exactly as in the chord method, and it then uses $x^{(2)}$ and one of $x^{(0)}$ and $x^{(1)}$ as the starting point for the next iteration so that they also satisfy the opposite-sign criterion.

Chord method

In Newton's method, the curve is approximated by the straight line tangent to the curve at the current point $x^{(n)}$, as shown in Figure 13. If s is the slope of the curve at the point x (s is the derivative $df(x)/dx$) and $s^{(n)}$ is its value at $x^{(n)}$, then the approximation is given by

Newton's method

Figure 12: Chord method of iteration, in which each successive approximation is based on two previous approximations (see text).

$$f(x) \approx f(x^{(n)}) + s^{(n)}(x - x^{(n)}).$$

The zero of the approximation is computed to get the Newton formula

$$x^{(n+1)} = x^{(n)} - \frac{f(x^{(n)})}{s^{(n)}}. \quad (19)$$

This is one of the fastest methods for finding zeros when the initial guess is fairly close to the answer, but $x^{(n)}$ may not converge to the root if the initial guess is far away.

Figure 13: Newton's method of iteration, in which each successive approximation is based on the preceding one and the slope of the tangent line (see text).

Newton's methods and other methods can be applied to systems of nonlinear equations in n unknowns of the form

$$f_i(x_1, x_2, \dots, x_n) = 0, \quad i = 1, 2, \dots, n, \quad (20)$$

by forming a linear approximation to the functions of many variables and using the techniques for solving linear equations discussed above.

The first example of the iterative solution was devoted to a linear equation. Iterative methods are an efficient way to solve large, sparse linear systems.

General nonlinear equations can be very difficult to solve computationally, in part because it is not possible to know where a solution may exist from local knowledge of the functions. (Local knowledge means information derived from the values of the function at a few points near a particular x .) Methods that use a local approximation to estimate the solution may compute an approximant that is in error by more than the current best approximant, so that the approximants diverge. For this reason, many iterative methods work only if the initial approximant is near the solution. Continuation methods are ones that construct a class of problems based on a parameter such that problems with nearby values of the parameter have solutions that are close. Hence, if the solution for one value of the parameter is known, it forms a good initial guess to the solution for a nearby value of the parameter. After the problem has been solved for the nearby parameter value, the process can be repeated. If the process starts with a value of the parameter for which the solution is known, the solution can be computed for a sequence of other values of the parameter until the original problem has been solved. For example, if the class of problems $f(x) = tf(x_0)$ is solved, where t is the parameter, a function $x(t)$ is defined. For $t = 1$ the solution is x_0 . For $t = 0$, the solution is the solution of the original problem, $f(x) = 0$. Thus, $x(t)$ is computed for a sequence of values $t_0 = 1$, $t_1 = 1 - h$, \dots , $t_n = 1 - nh$, \dots , until the solution for $t_n = 0$ has been computed. The step size, h , is chosen to be small enough such that $x(t_n)$ forms a close first approximation to $x(t_{n+1})$.

Differential equations. Models of systems that change involve differential equations. A derivative describes the rate of change, or slope, of a function, and a differential equation is a relation between the rate of change of variables and expressions involving those and other variables. For example, the equations of motion for a space rocket relate the rate of change of the velocity of the rocket (called its acceleration) and its mass, to the forces on the rocket due to the thrust from its engines, the drag due to

air resistance, and the force of gravity. This is Newton's second law, written as

$$a = \frac{dv}{dt} = \frac{\text{total force on body}}{\text{mass of body}},$$

where a is the acceleration, v the velocity, and t the time. This is called an ordinary differential equation: the unknowns (v , etc.) are functions of a single independent variable, t , only. The equations describing air flow around an airplane wing describe the rate of change, in time of the velocity of the air at every point in terms of the rates of change, with respect to spatial position, of pressure, density, and velocity of the air at that point. These are partial differential equations: the unknowns are functions of both space and time.

There are two different types of problems to be solved in differential equations, initial value problems and boundary value problems. The former type arises when the values of the unknowns are given at a particular point, for example, at a given time, and the values at future times are to be computed. For example, the position of the rocket before launch may be known, and future values of its position and velocity are to be computed. The latter type arises when the values of the unknowns are given on the boundary of a region and the values in the interior of the region are to be computed. For example, the flow of air a great distance from the airplane wing may be known to be uniform with a specified velocity and pressure, and the flow near the wing is to be computed. The methods used for these two types of problems are somewhat different, but they share the most important feature: a differential equation describes an infinite-dimensional object, a finite-dimensional object must be chosen to represent the solution, and the value of that approximation must be computed.

There are two main forms of approximation: finite differences and finite elements. In finite difference methods, the solution is represented by its values at a finite number of points, called mesh points. For example, if the velocity of the space rocket is to be computed, its velocities v_n at the set of times $t_n = nh$, $n = 0, 1, \dots, N$, where h is the mesh spacing, could be computed as an approximation. If a differential equation of the form

$$s = \frac{dy}{dt} = f(y, t)$$

is given, where s is the slope, or derivative, of the unknown function $y(t)$, s can be replaced with the slope of a polynomial through a few neighbouring points to get

$$\text{slope of polynomial through } \{y_{n+i}\} = f(y_n, t_n), \quad (21)$$

where y_n is the computed approximation to $y(t_n)$. For example, if a straight-line approximation through points y_n and y_{n+1} is used, the approximate equation becomes

$$\frac{y_{n+1} - y_n}{t_{n+1} - t_n} = f(y_n, t_n).$$

This method is called Euler's method. It is usually written $y_{n+1} = y_n + hf(y_n, t_n)$. If y_0 is given as an initial value, this formula can be used to compute successive values of y_1 , y_2 , etc. Euler's method is the simplest of all methods but is seldom the most efficient.

In the finite element method, the region over which the solution is to be computed is divided up into a number of small subregions called elements. The unknown solution is expressed as a sum of basis functions $\phi_i(x)$, which are polynomials in each of the elements, continuous across the boundaries of the elements (and possibly having continuous derivatives), and such that each is zero except in a very small number of elements. The simplest basis functions are the linear functions, which will be illustrated in one dimension. In this case, an interval (say, $[0, 1]$) of the real line is divided into a series of subintervals. These are called $[x_i, x_{i+1}]$ for $i = 0, 1, \dots, N$, where $x_0 = 0$, $x_i < x_{i+1}$, and $x_{N+1} = 1$. The i th basis function is as shown in Figure 14. It is zero except in the intervals from x_{i-1} to x_{i+1} , where it rises to 1 linearly and then falls back to zero. It is known

Initial-value and boundary-value problems

Finite difference methods

Finite element methods

as a hat function. (The zeroth hat function is 1 at x_0 and falls to zero at x_1 , while the $(N+1)$ st rises from zero at x_N to 1 at x_{N+1} .) The unknown y is expressed as

$$y = a_0\phi_0(x) + a_1\phi_1(x) + \cdots + a_{N+1}\phi_{N+1}(x). \quad (22)$$

This is a piecewise-linear function.

The next step in the finite element method is to use the differential equation to compute the unknown parameters a_i in (22). This function cannot satisfy the differential equation in general because the differential equation implies relations at all points in the interval. There are an infinite number of points, but there are only a finite number of parameters to be chosen. There are several ways to proceed. One is to apply the differential equation at a finite number of points only. This is called collocation and is applicable in some situations. Another way, valuable when the original problem satisfies a minimum-energy principle, is to seek the minimum-energy form of the approximation. This is an important method for many physical problems because they frequently satisfy a minimum-energy principle. For example, the shape assumed by a soap bubble is the one that has the least energy.

Figure 14: Example of a hat function used as a basis function in the finite-element method of finding approximate solutions of differential equations (see text).

As more points or elements are used, the mesh spacing diminishes, and the truncation error or residual in methods such as Euler's method becomes smaller. Methods for which these errors diminish as the mesh spacing is reduced are called consistent. Unfortunately, consistency alone is not enough to guarantee accuracy, because the number of mesh points or elements, and hence the number of equations such as (22), is increasing at the same time. Each of these approximate equations contributes a small error, and it is possible that the contribution of an increasingly large number of increasingly small errors could have a large effect. A critical property of methods is their stability. The technical definition of stability depends on the type of problem, but the essential idea is that as the number of mesh points (and approximate equations) increases, the effect of a single small error remains bounded. The so-called equivalency theorem for properly posed initial value problems in differential equations states that the consistency and stability of a method guarantee the convergence of the answer—that is, the errors in the answer shrink to zero as the mesh spacing is reduced.

APPLICATIONS AND IMPLEMENTATION

Methods for the numerical approximation and solution of equations are applied to complex problems that arise in the utilization of computers for a variety of tasks. The numerical solution of these problems requires their decomposition into sequences of subtasks that can be solved by standard methods. Many of these methods are made available to users through mathematical software that consists of programs organized to provide reliable solutions to large classes of problems on various types of computers. This section discusses two important applications and the implementation of methods in software for high-speed computation.

Numerical optimization. Many problems involve finding the best—in some defined respect—of many possible solutions. The best solution might be the one leading to

the lowest cost, the largest profit, or the shortest journey. Such problems are ones of optimization. Because of their economic importance, their efficient computational solution is extremely important. The mathematical problem is to find a set of values x_i such that $\phi(\{x_i\})$ is as small (or as large) as possible, where $\{x_i\}$ means the set of all x_i , $i = 1, 2, \dots, n$. The function ϕ represents the cost, the profit, or other value to be optimized. It is called the cost function, or objective function, and the problem is usually defined so that the cost is to be minimized. In many problems, the variables, x_i , are subject to constraints. These can be equality or inequality constraints, or both. They take the form $f_j(\{x_i\}) = 0$, $j = 1, 2, \dots, p$, for the equality constraints and $g_k(\{x_i\}) \geq 0$, $k = 1, 2, \dots, q$, for the inequality constraints. Either or both of p and q can be zero, meaning that there are no constraints in that class. The cost function and the constraints may be linear or nonlinear. If both are linear, the problem belongs to the specialty called linear programming. For a discussion of this topic, see the article OPTIMIZATION, THE MATHEMATICAL THEORY OF.

Linear programming

Linear programming problems can involve thousands of variables and require the solution of numerous linear equations at each step of an iterative process. Nonlinear optimization is an important problem that is computationally more difficult than linear programming. The simplest case is the minimization of a function of a single variable, $\phi(x)$. If the function is as shown in Figure 15, the problem is to find the point marked P. At that point the curve has a horizontal tangent; that is, its derivative is zero. One method is to solve the nonlinear equation $d\phi(x)/dx = 0$ using the methods discussed for nonlinear equations. This method, however, requires a technique for evaluating the derivative, which may not be convenient or possible in some applications. In such cases, the function $\phi(x)$ may be evaluated at a number of points and this information used to construct an approximation to the function locally, usually as a quadratic function that has a minimum. This approximation, however, is not a reliable indicator of the minimum, and it is normally used to indicate in which direction to look for a smaller value of the function. In the case of a function of several variables ($n > 1$), the derivative or the function approximation indicates a direction in which to move, that is, a line in the space of x_i variables. The users of most optimization algorithms, in effect, search along that line for a smaller value of the cost function.

Because of the nonlinearities, these problems are very difficult, and it is not possible to develop methods that always work. Even in the simple example shown in Figure 15, a method might find the local minimum at Q instead of the global minimum at P.

Figure 15: Nonlinear optimization.

In seeking the global minimum P, computational difficulties may lead the procedure to the local minimum Q (see text).

Inverse problems. An inverse problem takes the form: "Here is the answer, what was the question?" These problems arise when a person needs to determine some information, such as the density of different regions in the interior of a human head to check for medical problems, but it is not possible to gather all of the information needed by direct methods, as it clearly is not in this

Stability of methods

example. What the person can determine is information concerning the amount of X rays that can be transmitted along various line segments through the head. This information will give an estimate of the average density along the whole line but not at any specific interior point. The inverse problem in this example is to start with measurements along many different lines and with these data to calculate the density at all interior points.

Inverse problems are ill-posed because there are usually many different questions that could have yielded the same answer. This is simply illustrated in the interpolation and approximation problems discussed above. A function is infinite dimensional, so that if its values are given at a finite set of points, its values cannot be determined everywhere; in fact, there are infinitely many functions passing through any given set of points (as many different functions can be drawn as desired). In computing an approximation, assumptions are made concerning the nature of the function—for example, that it is a polynomial or has some other form. The same approach is taken to inverse problems: assumptions are made about the nature of the unknown function so that the finite amount of data in the observations is sufficient to determine that function. This is called regularization and converts the ill-posed problem into a properly posed one.

Large-scale scientific computation. The increasing speed of computers and advances in numerical methods have made it possible to solve most small problems rapidly by means of readily available software, and the attention of many numerical analysts has turned to the solution of problems so large that they require inordinate amounts of computer time. The use of the most efficient method has much greater importance in large problems than it does in small ones. In the latter the flexibility of human use of the program may be of much greater importance. One measure of the efficiency of a numerical method is the number of arithmetic operations needed to solve a problem. (Others include the amount of memory used and the order in which it is used, but these issues are more properly subjects of computer science.) Computational complexity is the study of the inherent computational cost (measured by number of operations) of solving a problem. The result of a complexity analysis is an estimate of how rapidly the solution time increases as the problem size increases. It can be used to analyze problems and assist in the design of algorithms for their solution.

Computational complexity

On a serial computer, which is one with a single processor capable of performing only one arithmetic operation at a time, the time needed to solve a problem is proportional to the number of operations, so that this is the number that the numerical analyst tries to reduce in algorithm design. Because parallel computers have more than one processor, they are capable of performing several arithmetic operations simultaneously. To make effective use of a parallel computer, an algorithm must have parallelism; that is, it must require the simultaneous performance of certain operations. For example, evaluation of the expression $a \times b + c$ requires two operations, but the multiplication must be completed before the addition can be started: they must be done serially. On the other hand, in evaluating the expression $w + x + y + z$, two of the additions can be performed in parallel, for example $w + x$ and $y + z$, and then their results can be added. In this case there are three arithmetic operations, but a suitably organized parallel computer can complete the sum in the time it takes to do two additions. In the design of numerical algorithms for parallel computers, one relevant criterion is the number of nonoverlapped operations needed.

Mathematical software. An important product of the numerical analyst's activity is mathematical software. It consists of computer programs designed to solve classes of numerical problems both automatically and reliably. Such software can be used by people with little knowledge of numerical techniques, and the programs themselves de-

termine, on the basis of evaluations of the mathematical expressions provided by the user, the best method to use and the parameters of that method. For example, in software for differential equations, the program might decide which of several methods to use and what mesh spacing to use for the method chosen. Since there are infinitely many problems and a program can evaluate a function only at a finite number of points, it is possible for such software to make mistakes (but so can people who try to solve problems). Robust software is software that is not only reliable but that also attempts to determine when it has encountered an intractable problem and informs the user that an answer cannot be found, rather than returning an incorrect one. The oft-heard statement that "any answer is better than none" is not true for most computational problems, as any passenger on an airplane—pondering the amount of numerical computation used in its safe and efficient design—realizes. The challenge to numerical analysts is to develop methods that compute accurate results efficiently or to recognize that they cannot do so.

Nutrition

Nutrition is the process by which an organism absorbs and utilizes food substances. The study of nutrition involves the identification of individual nutrients essential for growth and for the maintenance of individual organisms; it includes the determination of interrelationships among nutrients within individual organisms, as well as the evaluation of the quantitative requirements of organisms for specific nutrients under various environmental conditions. Treated in this article are

the identification and determination of the requirements of nutrients, the ways in which they vary from one organism to another, and the ways in which requirements for certain of them arose. Human nutritional requirements are then discussed, followed by a review of the diseases and disorders related to nutrition.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 421, 422, and 423.

This article is divided into the following sections:

General features of nutrients and nutrition	50	Inorganic elements	
Functions of food	50	Vitamins	
Nutritional patterns		Diet and diseases	63
Nutritional evolution of organisms		Sources of information	63
Methods of ingestion or penetration of nutrients		Animal experiments

General features of nutrients and nutrition

FUNCTIONS OF FOOD

Food serves three functions in most living organisms. First, it provides materials that are metabolized either by oxidative or by fermentative processes to supply the energy required for the absorption and translocation of nutrients, for the synthesis of cell materials, for motility and locomotion, for excretion of waste products, and for all other activities of the organism. Second, food supplies the electron donors (reducing agents) required for the formation of the reduced coenzymes (enzyme components) necessary for the synthetic processes that occur within the cell. Third, food provides the materials from which all of the structural and catalytic components of the living cell can be assembled by processes sometimes called anabolism. The three roles of food are not mutually exclusive; energy-yielding substances in many organisms may function in all three ways, and essential nutrients, if present in excess, may frequently be metabolized to supply energy.

The essential precursors (*i.e.*, the substances from which other substances are formed) of cell materials can be divided into two groups—nonessential nutrients, which can be synthesized by the cell from other materials, and essential nutrients, which, because they cannot be synthesized by the cell, must be supplied in foods. All of the inorganic materials required for growth, together with

an assortment of organic compounds whose number may vary from one to 30 or more, depending on the organism, fall into the latter category. Although organisms are able to synthesize nonessential nutrients, such nutrients are frequently utilized directly if present in food, thereby saving the organism the need to expend the energy required to synthesize them.

Nutritional patterns. One method of classifying living organisms on a nutritional basis centres on the way in which the functions of food are carried out. Thus, organisms such as green plants and some bacteria that need only inorganic compounds for growth are called autotrophic organisms; and organisms, including all animals, fungi, and most bacteria, that require both inorganic and organic compounds for growth are called heterotrophic. Although these general terms are widely employed, the classification has been broadened to describe various nutritional patterns that have been observed. In one scheme, organisms are classified according to the energy source they utilize. Phototrophic, or photosynthetic, organisms trap light energy and convert it to chemical energy in the form of an energy-rich compound, adenosine triphosphate (ATP); chemoautotrophic, or chemosynthetic, organisms utilize inorganic or organic compounds to supply their ATP requirements. An additional method of differentiation is based on the type of electron-donor material utilized to form the reduced coenzymes required for synthesis of cell

Auto-
trophic and
hetero-
trophic
organisms

Anabolism

constituents. If the electron-donor material consists of inorganic compounds, the organism is said to be lithotrophic; if organic, the organism is organotrophic. Combinations of these patterns may also be used to describe organisms; higher plants, for example, are photolithotrophic; *i.e.*, they utilize light energy, with the inorganic compound water serving as the ultimate electron donor. Certain photosynthetic bacteria that cannot utilize water as the electron donor and require organic compounds for this purpose are called photo-organotrophs. Animals, by this classification, are chemoorganotrophs; *i.e.*, they utilize chemical compounds to supply ATP and organic compounds as electron donors.

Despite wide variations in the nature of the external energy source utilized by various organisms, all organisms form from the external energy source the immediate intracellular source of energy, ATP, which is common to all cells. Through the breaking of the high-energy phosphate bonds of ATP and thus by its conversion to a less energy-rich compound, adenosine diphosphate (ADP), ATP provides the energy for the chemical and mechanical work required by an organism. The energy requirements of the organism can be measured in either joules or calories; the need for cell-precursor materials cannot be.

Chemo-
organo-
trophs

All animals, fungi, and most bacteria are chemoorganotrophs (*i.e.*, organic compounds supply both ATP and serve as electron donors). In these organisms the multiple roles played by foodstuffs are partially obscured because the carbon-containing compounds that serve as energy sources also serve as electron donors and provide intermediate compounds from which many cell materials are synthesized. Similarly, essential organic nutrients, when present in excess, may be utilized in part to provide the energy needs of the organisms.

Nutritional evolution of organisms. Little is known about the nutritional evolution of living organisms. Nucleic acids, proteins, carbohydrates, and fats, which are present in all living cells, are formed by specific reaction sequences from a limited number of smaller compounds, most of which are common to all living organisms and, according to current theories, were available on Earth before life arose. Since less complex metabolic organization and less energy are required to synthesize cellular proteins from preformed amino acids than from carbon dioxide and other precursors, it is assumed that the simplest early forms of life were heterotrophic organisms requiring many organic nutrients for growth and that they selected such nutrients from their surroundings. As the supply of these preformed substances was exhausted the organisms presumably developed the capacity to synthesize these preformed substances from simpler (precursor) materials present in the environment; in some organisms, this synthesizing capacity eventually evolved to the extent that carbon from carbon dioxide could be utilized to synthesize organic compounds.

At this point, autotrophy, as it now is known, became possible; autotrophy, in fact, may have evolved as a result of the exhaustion of the supply of preformed organic materials in the environment and the consequent necessity of organisms to synthesize the requirements themselves in order to survive. Implicit in this theory is the demonstrable assumption that autotrophic cells contain the most complex biosynthetic organization found in living things and that heterotrophic cells are simpler in that certain biosynthetic pathways do not occur. After the evolution of photosynthesis, a constantly renewable source of the organic compounds necessary for heterotrophic cell growth became available. It became feasible that those organisms whose environments provided a constantly available supply of a given compound could lose, through changes in their genetic material (mutations), the ability to synthesize that compound and still survive. Entire biosynthetic pathways may have been lost in this way; as long as such mutant organisms remained in an environment that supplied the necessary compound, the simplification in cellular organization and the energy saved by using preformed cell components would have given them a competitive advantage over the more complex parents from which they were derived and permitted stabilization of the mutation within

Effects of
mutation

the cell type. A theory that the requirements of modern organisms for essential organic nutrients arose through the loss of synthetic abilities present in more complex parent organisms was confirmed between 1940 and 1950 by the discovery that artificially produced mutant offspring of microorganisms can be readily obtained and may require the presence of one or more preformed organic compounds, which the parent microorganisms could synthesize.

Methods of ingestion or penetration of nutrients. Foodstuffs of chemoorganotrophs are composed chiefly of large molecules, such as nucleic acids, proteins, lipids, and carbohydrates, which are derived from other organisms. When these materials are eaten as food, they usually must be broken down into the low-molecular-weight substances from which they were formed (*e.g.*, purine and pyrimidine bases from nucleic acids, amino acids from proteins, fatty acids from fats, and simple sugars from carbohydrates) before they can be absorbed and utilized. The breakdown process is generally accomplished outside the cells (extracellularly) of both unicellular and multicellular organisms through hydrolysis (breakdown involving water), catalyzed by specific enzymes secreted for this purpose. Some unicellular organisms (*e.g.*, the protozoan genus *Amoeba*), however, engulf particulate matter and hydrolyze it intracellularly.

The organic products of digestion produced extracellularly, together with essential inorganic nutrients, must cross one or more cell membranes before they can be utilized for growth. When nutrient concentrations are high, some materials may diffuse through the cell membrane to enter the cell. Absorption of some materials can occur from an extracellular solution containing small quantities of the nutrients to an intracellular solution containing larger quantities (active transport) and is catalyzed within the cell membrane by systems that are specific for the type of compound being transported. Those catalysts best characterized involve either specific proteins with high affinity for the nutrient substance being transferred or enzymes that chemically modify the nutrient during its passage through the membrane or both.

Absorption
of nutrients

DETERMINATION OF ESSENTIAL REQUIREMENTS

It has been estimated that the approximate quantities of chemical elements in the human body (in percent of wet weight) are oxygen, 65; carbon, 18; hydrogen, 10; nitrogen, 3; calcium, 2; phosphorus, 1.1; sulfur, 0.25; potassium, 0.20; sodium, 0.15; chlorine, 0.15; magnesium, 0.05; iron, 0.004; copper, 0.00015; manganese, 0.00013; and iodine, 0.00004. Also present are traces of about 20 other elements—*e.g.*, zinc, cobalt, silicon, molybdenum, selenium, aluminum, arsenic, barium, boron, bromine, cadmium, chromium (Table 1). Analytical figures such as those for humans given above serve to distinguish between chemical elements that occur in relatively large amounts—oxygen, carbon, nitrogen, sulfur, and phosphorus—and the so-called trace elements, an obsolescent term applied to elements that are present in small amounts and that in the past could be detected in tissues but not analyzed accurately.

Trace
elements

The methods used to determine the pure substances necessary for growth are similar in principle for all organisms. Occasionally, crude diets lacking only one or a few nutrients result in some naturally occurring deficiency disease; the substance that cures such a condition can be determined directly by adding it to the diet. Certain vitamins were recognized in this way. In the absence of a deficiency condition, a crude nutrient medium (or diet) adequate for growth is selected for the organism to be studied, and attempts are then made to replace the various ingredients of the medium with purified materials and, finally, with substances of known composition. If replacement with substances of known composition permits growth, the added materials can be determined with relative ease; if the pure substances do not allow growth, however, chemical testing must be carried out to isolate and identify the substances in crude materials that permit growth. Detailed nutritional requirements of many organisms are known, and essentially all of the organic nutrients are available as pure compounds, so determination of the nutrient require-

ments of a previously unstudied organism is a comparatively easy task. Elucidation of trace-element requirements remains troublesome, however, because these substances occur commonly as contaminants in other materials.

ESSENTIAL INORGANIC NUTRIENTS

Table 1 is a list of inorganic elements (minerals) that are essential for the growth of living things, together with one or more examples of organisms that exhibit a requirement for them. The effects of certain mineral deficiencies on the development of higher plants and animals are illustrated by several photographs. Naturally occurring deficiencies of a number of different trace elements occur in various parts of the world in special types of soils and are therefore of tremendous economic and agricultural importance.

Specialized mineral requirements

Several examples of specialized mineral requirements are present in Table 1. Boron, for example, has been demonstrated to be required for the growth of many—perhaps all—higher plants but has not been implicated as an essential element in the nutrition of either microorganisms or animals. Trace amounts of fluorine (as fluoride) are certainly beneficial, and perhaps essential, for proper tooth formation in higher animals, but no essential role for fluorine in other organisms has been found. Similarly, iodine (as iodide) is required in animals for formation of thyroxine, the active component of an important regulatory hormone; it plays no known role in other organisms. Silicon (as silicate) is a prominent component of the outer skeletons of diatomaceous protozoans and similar organisms and is required in them for normal growth. In higher animals, the requirement for silicon is much smaller. A less obvious example of a specialized mineral requirement is provided by calcium, which is required by higher animals in comparatively large amounts because it plays a role in the formation of bone and eggshells (in birds); for other organisms, calcium is an essential nutrient but only as a trace element. Several additional examples of specialized requirements are evident from Table 1. Mineral elements in wide variety are present in trace amounts in almost all foodstuffs. It cannot be assumed that, because a given mineral element is nonessential, it plays no useful role in metabolism.

Antagonistic mineral nutrients

Important antagonistic relationships between certain mineral nutrients also are known. A large excess of rubidium, for example, interferes with the utilization of potassium in some lactic-acid bacteria; zinc can also interfere with manganese utilization in the same organism. In animal nutrition, excessive molybdenum or zinc (both of which are essential minerals) interferes with the utilization of copper, another essential mineral, and, in higher plants, excessive zinc can lead to a disorder that is known as iron chlorosis. Proper nutrient growth media for microorganisms and plants or diets for animals, therefore, require not only that the essential mineral elements be provided in sufficient amounts but also that they be used in the proper ratios to each other.

ESSENTIAL ORGANIC NUTRIENTS

Considered in this section is the nature of the essential organic nutrients, necessary building blocks of various cell components that certain organisms can no longer synthesize and therefore must be supplied to them preformed. These essential compounds include certain amino acids, which are the precursors of protein; purine and pyrimidine bases or their derivatives, which are the precursors of nucleic acids; fatty acids, which are precursors of fats and phospholipids; and, occasionally (in mutant organisms), simple sugars (e.g., glucose). Other essential organic nutrients include the vitamins, which are required in small amounts (relative to, for example, the amino acids), because of either the catalytic role or the regulatory role they play in metabolism.

Essential compounds

Amino acid requirements. Proteins usually contain about 20 different amino acids or their derivatives, and there are organisms that require none, several, or most of them for growth. Many yeasts and bacteria (e.g., *Escherichia coli*) are able to synthesize all of their amino acids from other compounds (glucose and ammonium salts). Animals may require up to nine or 10 different

Table 1: Essential Inorganic Nutrients for Living Organisms*		
element	utilizable ionic form	representative organisms exhibiting the requirement
Boron	B ₄ O ₇ ²⁻	certain vascular plants and algae; no evidence of an animal requirement
Calcium	Ca ²⁺	plants, animals, most microorganisms
Chlorine	Cl ⁻	higher animals; no evidence for requirement in plants
Chromium	Cr ³⁺	probably essential in higher animals
Cobalt	Co ²⁺	essential in ruminants; probably functions chiefly through microbial incorporation into vitamin B ₁₂
Copper	Cu ²⁺	plants, animals, most microorganisms
Fluorine	F ⁻	highly beneficial to bone and tooth formation in animals, including humans
Iodine	I ⁻	higher animals; no evidence for requirement in plants or microorganisms
Iron	Fe ²⁺	animals, higher plants, most microorganisms
Magnesium	Mg ²⁺	animals, plants, microorganisms
Manganese	Mn ²⁺	animals, plants, microorganisms
Molybdenum	MoO ₄ ²⁻	animals, plants, nitrogen-fixing bacteria
Nitrogen	NO ₃ ⁻ , NH ₄ ⁺	plants, microorganisms (animals derive nitrogen mostly from organic sources and utilize limited amounts of NH ₄ ⁺ , but not NO ₃ ⁻)
Phosphorus	PO ₄ ³⁻	animals, plants, microorganisms
Potassium	K ⁺	animals, plants, microorganisms
Selenium	SeO ₄ ²⁻	higher animals
Silicon	SiO ₄ ⁴⁻	certain Protozoa and Porifera
Sodium	Na ⁺	animals, some plants, some marine bacteria
Sulfur	SO ₄ ²⁻	plants, many bacteria (animals derive sulfur mostly from organic sources)
Vanadium	VO ₄ ²⁻	various tunicates and holothurian echinoderms; some algae; possibly higher animals
Zinc	Zn ²⁺	all animals, plants, most microorganisms

*Carbon dioxide (CO₂) and water (H₂O), although not formally tabulated, are important nutrients for all organisms; external sources of carbon dioxide, however, are required for only a few heterotrophic organisms since it is a prominent waste product of energy metabolism in these organisms.

amino acids in their diets. Species of lactic-acid bacteria have been identified as requiring none (*Streptococcus bovis*), a few (*Lactobacillus plantarum*), or as many as 17 amino acids (*Streptococcus equinus*).

Purine and pyrimidine bases and related compounds. A large number of species of microorganisms require one or more of these substances as precursors for the synthesis of nucleic acids. All higher animals examined have retained the capacity to synthesize purine and pyrimidine bases. Certain compounds (putrescine, spermidine, spermine) that are closely associated with nucleic acids in living cells, although synthesized by most organisms, are required preformed by certain bacteria; e.g., *Haemophilus parainfluenzae*, *Neisseria perflava*.

Lipids and related compounds. Phospholipids are essential components of all cell membranes. Those organisms that have lost the ability to synthesize certain lipids (since they are supplied in their diets), require them as essential nutrients. Essential fatty acids for rats (and most vertebrates) include linoleic and arachidonic acids and, perhaps, linolenic acid as well. For many bacteria (e.g., *Erysipelothrix rhusiopathiae*, several species of lactic-acid bacteria), oleic acid is essential for growth, although it can be replaced in most cases by linoleic acid and by an unusual fatty acid called lactobacillic acid.

Choline, a nitrogen-containing compound found in the phospholipid lecithin, is usually listed among the nutrients required by rats, although it can be synthesized by them if sufficient vitamin B₁₂ is present. Choline is also required for growth of certain pneumococcal bacteria. Inositol, another structural component of certain lipids, is an essential nutrient for many yeasts but appears to be synthesized by most animals. Finally, the steroid cholesterol is an essential nutrient for a wide variety of protozoans and for the bacteria-like organisms known as mycoplasmas. Higher animals are able to synthesize this important cell constituent; it is not present in most bacteria.

Choline, inositol, and cholesterol

Effects of mineral deficiencies on the development of higher plants and animals.

Para-
amino-
benzoic
acid

Vitamins. Vitamins may be defined as nutritionally essential organic substances that play a catalytic role within the cell, usually as components of coenzymes or other groups associated with enzymes. More than half of the water-soluble vitamins required by humans were discovered when they were found to be growth factors for microorganisms. Vitamin requirements are specific for each organism, and their deficiency may cause disease. Vitamin deficiencies in young animals usually result in growth failure, various symptoms whose nature depends on the vitamin, and eventual death. Certain vitamins (retinol, calciferol, tocopherol, and ascorbic acid) do not appear to play an essential role in unicellular organisms. Para-aminobenzoic acid is a vitamin for several bacteria only because it is an essential precursor of the vitamin folic acid, which, since it is unable to cross the bacterial cell membrane, must be synthesized from para-aminobenzoic acid. Heme and lipoic acid are typical vitamins for organ-

isms that cannot synthesize them, but they have a catalytic role in all organisms; they are synthesized by higher animals. A few bacteria have lost the ability to convert certain vitamins to their functional forms, the coenzymes; the preformed coenzymes (or intermediates in their synthesis) thus are vitamins for such organisms.

Interdependency of nutritional requirements. The effects of one mineral nutrient in reducing or increasing the requirement for another have been mentioned previously (see above *Essential inorganic nutrients*). Similar relationships occur among organic nutrients and originate for several reasons, the most common of which are discussed briefly below.

Competition for sites of absorption by the cell. Since absorption of nutrients frequently occurs by way of active transport within cell membranes, an excess of one nutrient (A) may inhibit absorption of a second nutrient (B), if they share the same absorption pathway. In such cases, the apparent requirement for nutrient B increases; B, however, can sometimes be supplied in an alternate form that is able to enter the cell by a different route. Many examples of amino acid antagonism, in which inhibition of growth by one amino acid is counteracted by another amino acid, are best explained by this mechanism. For example, under some conditions *Lactobacillus casei* requires both D- and L-alanine, which differ from each other only in the position of the amino, or NH_2 , group in the molecule, and the two forms of this amino acid share the same absorption pathway. Excess D-alanine inhibits growth of this species, but the inhibition can be alleviated either by supplying additional L-alanine or, more effectively, by supplying peptides of L-alanine. The peptides enter the cell by a pathway different from that of the two forms of alanine and, after they are in the cell, can be broken down to form L-alanine. Relationships of this type provide one explanation for the fact that peptides are frequently more effective than amino acids in promoting growth of bacteria.

Competition for sites of utilization within the cell. This phenomenon is similar to that regarding competition for absorption sites, but it occurs inside the cell and only between structurally similar nutrients (e.g., leucine and valine; serine and threonine).

Precursor-product relationships. The requirement of rats and humans for the essential amino acids phenylalanine and methionine is substantially reduced if tyrosine, which is formed from phenylalanine, or cysteine, which is formed from methionine, is added to the diet. These relationships are explained by the fact that tyrosine and cysteine are synthesized in animals from phenylalanine and methio-

Amino
acid
antagonism

nine, respectively. When the former (product) amino acids are supplied preformed, the latter (precursor) amino acids are required in smaller amounts. Several instances of the sparing of one nutrient by another because they have similar precursor-product relationships have been identified in other organisms.

Changes in metabolic pathways within the cell. Rats fed diets containing large amounts of fat require substantially less thiamine than do those fed diets high in carbohydrate. The utilization of carbohydrate as an energy source (*i.e.*, for ATP formation) is known to involve an important thiamine-dependent step, which is bypassed when fat is used as an energy source, and it is assumed that the lessened requirement for thiamine results from the change in metabolic pathways.

COMPARISON OF NUTRIENT REQUIREMENTS

Trace elements and vitamins are distinguished from other nutrients on the basis of the relatively smaller amounts required. For example, potassium, a mineral element present in comparatively large amounts in all organisms, is required by *Lactobacillus casei* in amounts more than 200 times greater than the requirement for manganese. The magnitude of the requirement for potassium is similar to that for the amino acid leucine. Nutrients such as manganese and the vitamins, which are required in small amounts, are sometimes referred to as micronutrients because of these quantitative relationships. For *Lactobacillus*, glucose is the energy source, and, to permit the amount of growth described, approximately 1,000 times more glucose is required than the nutrients potassium and leucine. These ratios are fairly representative of organoheterotrophs in general. Lactic-acid bacteria, however, form lactic acid from glucose; other organisms, which oxidize this substance to carbon dioxide and water, require only about 5 percent of the amount of glucose required by lactic-acid bacteria for equivalent ATP production and, hence, for equivalent growth.

SYNTROPHISM

Since the nutritional requirements and metabolic activities of organisms differ, it is clear that two or more different organisms growing relatedly may produce different overall changes in the environment. A rough example is provided by a balanced aquarium, in which aquatic plants utilize light and the waste products of animals—*e.g.*, carbon dioxide, water, ammonia—to synthesize cell materials and generate oxygen, which in turn provide the materials necessary for animal growth. Such relationships are common among microorganisms; *i.e.*, intermediate or end products of metabolism of one organism may provide essential nutrients for another. The mixed populations that result in nature provide examples of this phenomenon, which is called syntrophism; in some instances, the relationship may be so close as to constitute nutritional symbiosis, or mutualism. Several examples of this phenomenon have been found among thiamine-requiring yeasts and fungi, certain of which (group A) synthesized the thiazole component of thiamine molecule but require the pyrimidine portion preformed; for a second group (group B), the relationship is reversed. When group A and group B are grown together in a thiamine-free medium, both types of organisms survive, since each organism synthesizes the growth factor required by its partner; neither organism grows alone under these same conditions. Thus, two or more types of microorganisms frequently grow in situations in which only one species would not.

Such nutritional interrelationships may explain the fact that the nutritionally demanding lactic-acid bacteria are able to coexist with the nutritionally nondemanding coliform bacteria in the intestinal tracts of animals. It is known that the bacterial flora of the intestinal tract synthesize sufficient amounts of certain vitamins (*e.g.*, vitamin K, folic acid) so that detection of deficiency symptoms in rats requires special measures, and the role of rumen bacteria in ruminant animals (*e.g.*, cows, sheep) in rendering otherwise indigestible cellulose and other materials available to the host animal is well-known. These few examples indicate that syntrophic interrelationships are widespread

in nature and may contribute substantially to the nutrition of a wide variety of species. (E.E.Sn./A.S.T.)

Human nutrition and diet

The scope of human nutrition extends far beyond the classical study of the physiological and biochemical processes involved in nourishment; *i.e.*, how substances in food are converted into energy and body tissues. Human nutrition has come to involve all the effects on humans of any component found in food; these include most chronic degenerative diseases (dental decay, coronary heart disease, some cancers, etc.), which are now major targets of research activity. The scope of nutrition extends to the effects of food on human function; *e.g.*, mental function, athletic performance, resistance to infection, and fetal health and development. There is a growing interaction between nutritional science and genetics because of the diversity of human chemical make-up and because food components of which most people are unaware can have marked effects on some individuals. Last, nutrition also considers why people choose to eat the foods they do, even after they have been advised that doing so may be unhealthy. The study of food habits and people's attitudes, beliefs, likes, and dislikes overlaps with the social sciences of physiology, anthropology, sociology, and economics. Dietetics is the application of nutrition in the health sciences.

UTILIZATION OF FOOD BY THE BODY

The human body can be thought of as an engine that releases the energy present in the foods and utilizes it partly for the mechanical work performed by muscles and in secretory processes and partly for the work necessary to maintain its structure and functions. The performance of this work is associated with the production of heat; heat loss is controlled so as to keep body temperature within a narrow range. Unlike other engines, the human body is continually breaking down (catabolism) and building up (anabolism) its component parts. Certain foods supply nutrients essential to the manufacture of the new material and provide energy needed for the chemical reactions involved.

The supply of energy. The energy taken in food and that utilized in daily life can be measured. The measuring unit has been the kilocalorie (kcal), which is 1,000 gram calories; a gram calorie is the amount of heat required to raise one gram of water from 14.5° to 15.5° C at one atmosphere of pressure. Nutritionists are now coming into line with other branches of science and using joules as the unit of energy. One joule is the energy expended when one kilogram is moved one metre by a force of one newton. The amount of energy spent by the whole body and that present in foods are relatively large and are expressed as kilojoules (kJ = 10³ J) or megajoules (MJ = 10⁶ J). One kilocalorie is equivalent to 4.186 kilojoules.

The energy present in food can be determined directly by measuring the output of heat when the food is oxidized in a calorimeter. Heats of combustion of individual proteins, fats, and starches are about 5.4, 9.3, and 4.1 kilocalories (23, 39, and 17 kilojoules) per gram, respectively.

Not all of this energy is available to the body because some ingested material is not absorbed from the gut and is lost in the feces; further, the nitrogenous compounds are not completely combusted, and some of the energy in proteins is lost in the urine, mostly as urea. Corrections for these losses give physiological values for dietary protein, fat, and carbohydrate of approximately four, nine, and four kilocalories (17, 38, and 17 kilojoules) per gram, respectively. These are called the Atwater factors, after the American physiologist Wilbur Olin Atwater, who, between 1895 and 1905, calculated the quantitative aspects of energy exchanges. Tables of energy value and nutrient content of common foods provide background data for general dietetic advice (see Table 2).

Proteins, fats, and carbohydrates can, within wide limits, be interchanged as sources of energy. Among the members of prosperous communities most diets provide 12 percent of the energy as protein, about 40 percent as fat, and 48 percent as carbohydrate. In many poor agricultural soci-

Micro-nutrients

eties, for whom cereals provide most of the energy, the figures for the individuals' diets are 10 percent for protein, 10 percent for fat, and 80 percent for carbohydrate. Throughout most of the world, protein provides between 8 and 14 percent of the energy ingested. High-fat diets are associated with a high incidence of atherosclerosis (deposits of lipid material in the larger arteries). Wide variations in the proportions of fat and carbohydrate in the diet may, nevertheless, be compatible with good health, at least in the short term. Ethyl alcohol is another source of energy to the body. Only a small part of the alcohol intake, usually less than 5 percent, is excreted in the urine and expired air; most is oxidized in the liver, where it serves as a source of energy with a value of seven kilocalories (29 kilojoules) per gram (almost that of pure fat). Muscle cannot utilize alcohol, and alcohol intake reduces the use of fat and carbohydrate by the liver. In this way alcoholic drinks increase the energy value of a diet and often contribute to obesity and fat deposits in the liver.

Building and maintenance. The body of a young adult male weighing 65 kilograms (143 pounds) consists of some 11 kilograms of protein, nine of fat, one of carbohydrate, four of minerals, and 40 of water. During the first 20 years of life, an average of about 1.5 grams of protein and 150 milligrams of calcium must be retained from the diet every day in order to build soft tissues and skeleton. Tissues, however, are not static, and their components are being continually catabolized and replaced at varying rates. The inner epithelial lining of the gut is replaced every three or four days and red blood cells have a lifespan of only 120 days. On the other hand, collagen, a protein constituent of tendons, is turned over at intervals of a few years. Much of the material derived from the breakdown of tissues is reutilized, but new material is also required from food. Probably some 200 grams of tissue protein is replenished daily in an adult, but the minimal dietary requirement of protein is only about 40 grams per day.

Essential nutrients. The principal evidence that an organic compound is essential is that it consistently cures a specific deficiency disease. An inorganic element is essential if it regularly occurs in the body and is demonstrated to have a function (such as being an integral part of an enzyme). Humans require oxygen, water, food energy, protein, 14 other organic compounds (vitamins and essential fatty acids), and some 18 inorganic elements, as well as carbon, hydrogen, and nitrogen.

Protein. Growing children need more protein per kilogram of body weight than do adults. Protein requirement at all ages is increased by infections not only because there is an increased utilization of protein but also because illness usually impairs the appetite and thus reduces dietary intake of all substances, including protein. In many countries children are weaned on a diet of cereal paps with little or no supplement of milk or other protein-containing foods. Such a diet at the least retards growth and development. If a child on such a diet suffers from an

acute infection, notably measles or gastroenteritis, a severe illness, which may take several forms—known variously as protein-calorie malnutrition, kwashiorkor, or nutritional marasmus—may ensue. The death rate from protein-calorie malnutrition in many poverty-stricken communities is high. (See below *Energy (calories)*, under the heading *Deficiency diseases*.) Primary protein deficiency is not common among adults, for whom cereals in general satisfy the protein requirement.

Foods vary in the quantity of proteins they contain per 100 grams (or per typical serving). They also vary in the nutritional value, or quality, of their protein. This is because of differences in the pattern of essential amino acids that they contain (see Table 3). Eight amino acids are essential (*i.e.*, required, but not produced, by the body) for humans: isoleucine, leucine, lysine, methionine (which can be partly replaced by cystine), phenylalanine (which can be partly replaced by tyrosine), threonine, tryptophan, and valine. Histidine appears to be essential as well in some situations. These amino acids are not all required in the same amount each day; for example, leucine is required most, and tryptophan least. Vegetable food proteins usually have lower nutritive values because they have sub-optimal proportions of one or more essential amino acids, called the limiting amino acids; *e.g.*, lysine in wheat (see Table 3). When vegetable protein sources are combined, however, the amino acid pattern of the combination is usually improved.

Minerals. Iron is required for the synthesis of hemoglobin, the oxygen-binding pigment in red blood cells. Normally the iron liberated from old cells is retained and can be reutilized. When, however, there is chronic bleeding from wounds or there is severe and prolonged menstruation, the normal amount of dietary iron may be insufficient to replenish the body's supply. Losses of iron in the menses, the needs of a fetus, and the inevitable loss at labour and in the milk of a lactating woman increase the iron requirements of women during their reproductive life.

Most dietary iron is in a form that is poorly absorbed from the gut. Many diets contain about 12 milligrams of iron, of which less than 10 percent need be absorbed by a normal adult male. Absorption of iron in plant foods is usually less than 10 percent. The iron in meat is absorbed better and so is that in human milk. As body stores of iron become depleted, the efficiency of intestinal absorption is enhanced. If menstrual losses are large, iron-deficiency anemia follows unless the diet is supplemented with absorbable iron compounds.

Calcium is the most obvious and persistent of the mineral nutrients, yet it is more difficult to measure the adequacy of its intake than for other nutrients. More than 99 percent of the body's calcium is in the skeleton, where it not only provides structural support but also is a large reservoir for maintaining a constant calcium concentration in plasma. Several hormones, including parathormone, cal-

citonin, and a derivative of vitamin D, are all involved in this regulation. The amount of calcium in the bones is nearly 30 grams at birth and builds up to about 1,200 grams in an adult. Hence, an average of 180 milligrams of calcium must be retained in the body throughout childhood, and the individual daily amounts should reach 400 milligrams during the adolescent growth spurt. Absorption of calcium, like that of many other metallic elements, is inefficient. The diet must therefore supply more calcium than the amount theoretically retained for skeletal growth. Three major questions about calcium are as yet not fully answered by nutritional science: (1) whether generous intakes of calcium during childhood and adolescence will lead to taller adults or heavier bones, (2) whether a generous intake of calcium from about 45 years of age will delay the progress of osteoporosis (thinning of the bones), which occurs in older people and is more likely to cause symptoms in women after menopause, and (3) what mechanisms enable people in Africa, for example, who grow up on cereal diets low in calcium, to retain enough calcium to achieve a skeleton of similar height to those in northern countries where milk and cheese (both rich in calcium) are staples in the diet.

Sodium and potassium

Sodium is present only in small quantities in most natural foods, but salt is added, often in large amounts, in food processing and by cooks to enhance flavour. Sodium is the predominant ion in extracellular fluid; an excess can cause edema (an accumulation of extracellular fluid), especially in conditions such as congestive heart failure. A low sodium intake leads to a lowering of the blood pressure and brings about diuresis, ridding the body of the excess extracellular fluid. There is now much evidence that excess dietary salt may contribute to high blood pressure in some individuals, but other factors are also responsible.

Potassium, present in all natural foods, is the predominant intracellular ion. Deficiency of it does not occur as a result of a primary dietary lack, but it may arise when there is chronic diarrhea or from repeated diuresis. All wasting diseases are associated with loss of potassium from the tissues. Potassium deficiency disturbs the excitability of tissues and leads to paralysis of muscle, including cardiac muscle. Sodium and potassium are two of the most important ions in maintaining the homeostatic equilibrium of the body fluids.

Other elements required by humans are magnesium, iodine, zinc, phosphorus (in the form of phosphate), sulfur (usually in the forms of the amino acids methionine and cystine), and chlorine (in the form of chloride, often combined with sodium). Other elements required in trace amounts are copper, chromium, molybdenum, selenium, cobalt (in the form of vitamin B₁₂), probably fluorine (in the form of fluoride), and possibly vanadium.

Vitamins. For normal nutrition and metabolism the body requires certain organic substances, called vitamins, which it cannot make for itself, at least in sufficient quantities. Many of them function as components of enzyme systems. Because they are required in such small quantities, vitamins do not contribute significantly to the energy

needs of the body. In their absence, however, the carbohydrates, fats, and proteins required for energy production and tissue maintenance cannot be properly metabolized. Vitamins were originally identified by letters as each new one was discovered, but this method of nomenclature is being replaced as the vitamins become known by their chemical names (Table 4). For a detailed treatment of deficiency diseases, see below *Deficiency diseases: Vitamins*.

Vitamin deficiency diseases

The evidence that vitamins promote health in any way apart from preventing deficiency diseases is controversial and not established scientifically. The recommended intakes or allowances of vitamins (Table 5) carry a safety margin that allows for a wide range of individual needs, so there are usually no deficiency effects if the intake is only a small percentage below the recommended intake. High intakes are of no benefit and may be dangerous in the cases of the fat-soluble vitamins A and D and the water-soluble vitamin B₆.

CLASSES OF FOODS

The following set of 17 groups covers most of the nutritional differences between foods: (1) cereals and cereal products, (2) starchy roots, (3) legumes (pulses), (4) other vegetables, (5) fruits, (6) nuts and seeds, (7) sugars, syrups, sweets, and preserves, (8) meat, including poultry, and meat products, (9) seafood—finfish and shellfish, (10) eggs and roe, (11) milk, cream, and cheese, (12) fats and oils, (13) herbs and spices, (14) nonalcoholic, nondairy beverages, (15) alcoholic beverages, (16) dietetic preparations, (17) miscellaneous (e.g., salt and vinegar).

Grouping of food

Cereals. Of the present world population, half lives in Asia and three-quarters in developing countries. In these areas cereals play the leading dietary role. On the whole, the carbohydrate-rich cereals compare favourably with the protein-rich foods in energy value; in addition they are significantly less expensive to produce. Therefore most of the world's diets are arranged to meet main calorie re-

Table 4: Nomenclature of Vitamins		
name recommended by IUNS*	alternative name	usual pharmaceutical preparation
Vitamin A	Retinol	Retinol
Thiamin	Vitamin B ₁	Thiamine hydrochloride
Riboflavin	Vitamin B ₂	Riboflavin
Niacin	Nicotinic acid and nicotinamide	Nicotinamide
Vitamin B ₆	Pyridoxine	Pyridoxine hydrochloride
Pantothenic acid		Calcium pantothenate
Biotin		Biotin
Folate	Folacin	Folic acid
Vitamin B ₁₂	Cobalamin	Cyanocobalamin or hydroxocobalamin
Vitamin C	Ascorbic acid	Ascorbic acid
Vitamin D	Vitamins D ₂ and D ₃	(Ergo) calciferol
Vitamin E		α -Tocopherol
Vitamin K		Vitamin K ₁

quirements from the cheaper carbohydrate foods, and the protein-rich foods are used sparingly to provide essential amino acids. Cereal products generally contribute a large proportion of the dietary protein of vegetable origin, in addition to their carbohydrate content.

Forms of cereals

Cereals are largely consumed as bread and to a lesser extent as cakes, crackers, and breakfast cereals. They are also consumed in other forms in some countries; *e.g.*, boiled, crushed, or rolled, made into pasta, etc. There has been controversy as to the relative merits of white bread and bread made from whole wheat flour of much longer extraction, which is darker in colour. White flour consists of about 72 percent of the grain but contains little of the germ, or embryo, and of the outer coverings (bran). Since the B vitamins are concentrated mainly in the scutellum (covering of the germ), and to a lesser extent in the bran, the vitamin B content of white flour, unless artificially enriched, is much less than that of brown flour. The dietary fibre is mostly in the bran, and white flour contains only about one-third of that in whole wheat flour. White flour is routinely fortified with synthetic vitamins in a number of countries, including the United States and United Kingdom, so that the vitamin content is similar to that of the darker flours. In the United Kingdom white bread is also fortified with calcium carbonate.

Nutritional value

Table 6 shows the contribution of cereals to the intakes of a number of key nutrients in the United Kingdom. As a group they provide almost half the carbohydrate, one-quarter of the protein and calcium, more than one-third of the iron, and nearly half the thiamine. The protein of cereals does not have as high a nutritive value as that of many animal foods because of the low lysine content. It is possible to fortify bread with synthetic lysine. Corn has been altered to produce a higher lysine and tryptophan content than standard corn (see Table 3), but the yield is lower. The usual solution to the suboptimal amino acid pattern of cereals is to eat them mixed with other foods (legumes, animal foods) that have more than enough lysine. This is the traditional, intuitive way in which cereals have been eaten in settled communities in many different

cultures. The amino acids of mixed protein foods tend to complement one another and increase the percentage of the limiting amino acid. In less developed countries, the contribution of cereals to the intake of nutrients is greater than in the United Kingdom, which is an example of an industrial country in which the cereal consumed by humans is predominantly wheat.

Wheat and rice are the two major cereals for human consumption; wheat in Europe, North America, and northern India, and rice in East and Southeast Asia. The nutritional weakness of rice is its low thiamine and riboflavin content when it is milled to polished rice. Beriberi was formerly common in poor Asian communities in which a large proportion of the diet consisted of polished rice. Beriberi has almost completely disappeared from Asia with the advent of greater availability of other foods, of better ways of handling the rice (*e.g.*, parboiling), and, in some areas, of fortification with thiamine.

Corn differs from other cereals in that the yellow form contains carotenoids with provitamin A activity. Its other special feature is its low content of tryptophan. The niacin in corn is in a bound form that cannot be digested and absorbed by humans unless pretreated with lime (calcium hydroxide) or by roasting. Niacin is also formed in the body as a metabolite of the amino acid tryptophan, but this alternative source is not available when the tryptophan content is too low.

Niacin

Most cereals contain little fat, although oats contain 7 percent. Wheat contains a type of dietary fibre (arabinoxylan hemicellulose) that is particularly valuable for treatment and prevention of constipation. It increases the bulk of the feces and shortens the mouth-to-anus transit time. Bran is a concentrated source of the same dietary fibre.

(D.W.K.-J./A.S.T.)

Starchy roots. Potatoes, cassava, and yams are easily cultivated and are valuable as cheap sources of energy. Their nutritive value, in general, resembles that of cereals, but their protein content is lower. Protein deficiency may be common in tropical communities in which the staple food is cassava or yams. The potato, however, provides some protein—less than cereal does—but also contains some vitamin C, and sweet potatoes contain the pigment beta-carotene, convertible in the body into vitamin A. Although the quantity of protein in potatoes is only small (2 percent), its nutritive value appears to be high. Cassava contains half the protein of potatoes. There are toxic substances in, or adjacent to, some of the starchy root foods that have to be avoided or dealt with by careful preparation; *e.g.*, solanine in the green sprouts of potatoes and a cyanide compound in the leaves and outer parts of the roots of cassava.

Legumes (pulses). Peas and beans, the seeds of Fabaceae, resemble the cereals in nutritive value but have a higher protein content and, since they are not subject to milling, are a good source of B vitamins. They are thus a valuable supplement to a cereal diet, especially in tropical or subtropical countries; moreover, they, particularly the soybean, are also valued for their taste. The soybean is especially rich in protein (38 percent) and is a major commercial source of edible oil.

Table 6: Percentage of Several Major Nutrients Supplied by Food Groups in the United Kingdom*

	energy	protein	fat	carbo- hydrate	iron	cal- cium	thi- amine	vitamin C	vitamin A
Milk, cream, and cheese	14	22	19	7	3	59	12	7	13.5

Total vegetables	9	9.5	2	15	19	6	19	48	24
Total fruits	3	1	—	5	4	2	4	41	1
Total cereals (Breads)	29 (13.5)	24 (14)	10 (2)	48 (24)	37 (17)	24 (12)	42 (21)	— (—)	1 (—)

*From the Household Food Consumption Survey (1981). The figures for breads are in parentheses because they are part of the total for cereals.

Vegetables and fruits. Vegetables and fruits all have similar nutritive properties. Because 70 percent or more of their weight is water, they provide comparatively little energy or protein, but many contain vitamin C and carotene, two nutrients not found in cereals. Fresh fruits, particularly the citrus variety, and their juices are usually rich in vitamin C, but cooked vegetables are an uncertain source, as this vitamin is easily destroyed. Vegetables and fruits contain fibre, which adds bulk to the intestinal content and is useful in preventing constipation. Vegetables also provide calcium and iron but often in a form that is poorly absorbed.

Sugars, preserves, and syrups. In adults in the United States, the average intake of added sugars is 60 grams per day in males, or one pound per week. The sugars, mostly sucrose and high-fructose corn syrup, are added both in processing and at the table. Together sucrose and fructose provide 12 percent of the average total calories in adults and a little more in children. There are also naturally occurring sugars in foods (fructose, glucose, sucrose in fruits and some vegetables, and lactose in milk). The intake of these in the United States is about 8 percent of total caloric intake in adults and much more in young children (due to the lactose). Sugar, however, contains no protein, no minerals, and no vitamins and thus has been called a source of "empty calories."

Sugar is an excellent preservative because it adsorbs water and prevents the growth of microorganisms. Jams contain from 30 to 60 percent sugar, and honey and natural syrups (e.g., maple) are composed of more than 75 percent sugar.

Meat, fish, and eggs. Meats generally consist of about 20 percent protein, 20 percent fat, and 60 percent water; the amount of fat present in a particular portion of meat varies greatly, not only with the kind of meat—pork, beef, lamb, etc.—but also with its quality; the "energy value" varies in direct proportion with the fat content. Meat is valuable for its protein, which is of high biological value. Meat also is an excellent source of B vitamins, including thiamine, one of the most important. Pork is the best source of thiamine, liver is next, and skeletal muscle, from any meat source, is third. Meat is also a good source of niacin, vitamin B₆, vitamin B₁₂, other vitamins of the B group, and the mineral nutrients iron, zinc, phosphorus, potassium, and magnesium. Liver is the storage organ for, and very rich in, vitamins A and B₁₂. It is also an excellent source of riboflavin and of folic acid.

The muscular tissue of fishes consists of 13–20 percent protein; varying amounts of fat, ranging from less than 1 to more than 20 percent; and 60–82 percent water, varying inversely with fat content. Exact proportions vary among different species, and seasonal and feeding variations result in differences among individuals of the same species. The fatty acids in fish are largely polyunsaturated. One of the major fatty acids, eicosapentaenoic acid, in large amounts reduces the tendency to thrombosis.

Eggs have a deservedly high reputation as a food. The white is protein and the yolk is rich in both protein and vitamin A. Eggs also provide calcium and iron; egg yolk, however, has a high cholesterol content.

Milk and milk products. The milk of each species of animal is a complete food for its young. One pint of cow's summer milk contributes about 90 percent of the calcium, 30 to 40 percent of the riboflavin, 25 to 30 percent of the protein, 10 to 20 percent of the calories and vitamins A and B, and up to 10 percent of the iron and vitamin D needed by an adult. Although human milk supplies a higher proportion of the daily needs of a five-year-old child for calories, protein, vitamin A, thiamine, and riboflavin, the contribution of calcium is reduced to about 70 percent because of the higher calcium requirements of a child.

The milks of mammals contain all essential nutrients. Human milk (Table 7) is the perfect food for infants, provided it comes from a healthy, well-nourished mother and the infant is full-term. Breast milk contains important antibodies, white cells, and nutrients, and, in communities where hygiene is poor, breast-fed babies have fewer infections than formula-fed babies.

Cow's milk (Table 7) is good food for human adults, but the cream (i.e., fat) contains 52 percent saturated

fatty acids (longer than 10 carbon atoms in length) as compared to only 3 percent polyunsaturated fat. This fat raises the plasma cholesterol and is thought to be one of the dietary components that contributes to coronary heart disease, along with the same fat in concentrated forms (cream and butter). To circumvent this, the dairy industry has developed low-fat cow's milk (with 2 percent instead of almost 4 percent fat), very low-fat skim milk, or skim milk with extra nonfat milk solids (lactose, protein, and calcium), which gives more body to the milk.

Lactose, the characteristic sugar of milk, is a disaccharide made of the monosaccharides glucose and galactose. While these monosaccharides are easily absorbed, lactose is not. Lactose passes to the large intestine, where it is fermented by the resident bacteria to produce gas and sometimes diarrhea. Galactose is incorporated into the complex fatty substance ceramide, which is the major component of the myelin sheaths of nerves (the white matter of the central nervous system).

In the late 1960s it was discovered that the adults of many ethnic groups cannot break down the lactose of large quantities of milk into galactose and glucose; they lose most of their intestinal lactase enzyme activity as they grow up (lactose intolerance). It is now recognized that such individuals share this deficiency with adults throughout the world, such as in Asia and Africa, and with most of the animal kingdom. People originating in northern Europe are the exception from the global viewpoint: they usually retain full intestinal lactase activity into adult life. People who have little of the enzyme lactase in their bodies can still take large amounts of milk if it has been allowed to go sour, if lactobacilli have split most of the lactose into lactic acid, or if the lactose has been treated with commercially available lactase.

The vitamin C present in milk is destroyed by heating (pasteurization), which in many countries is required to prevent the milk from spreading bacterial and other infections.

Cheese making is an ancient art formerly used on farms to convert surplus milk into a food that could be stored without refrigeration. Cheese is rich in protein and calcium and is a good source of vitamin A and riboflavin. Most cheeses, however, contain about 25 to 30 percent fat (constituting about 70 percent of the calories of the cheese), which is mostly saturated, and they are usually high in salt (sodium).

Fats and oils. The animal fats used by humans are butter, suet from beef, lard from pork, and fish oils. Important vegetable oils include olive oil, peanut (groundnut) oil, coconut oil, cottonseed oil, sunflower seed oil, soybean oil, safflower oil, rape oil, sesame (gingelly) oil, mustard oil, red palm oil, and corn oil. All these are high in calories. Only butter (other than the previously mentioned fish-liver oils) contains any of the vitamins A and D, but red palm oil does contain carotene, which is converted to vitamin A in the body. Vitamins A and D in controlled amounts are added to margarines.

making

All natural fats and oils contain variable amounts of vitamin E, the fat-soluble vitamin antioxidant. They provide more calories per gram than any other food, and they contain no protein and few micronutrients.

Fatty acids

The predominant substances in fats and oils are triglycerides, chemical compounds containing any three fatty acids combined with a molecule of glycerol. The fatty acids consist of a chain of carbon atoms with a carboxylic acid group (–COOH) at one end. The number of carbon atoms ranges from four to more than 22, but the most common chain length is 16 or 18. Because they are synthesized in the body from two-carbon units (acetyl coenzyme A), chain lengths are nearly always even numbers. Each carbon has four valences, or potential sites for bonding—two valences for the adjacent carbons and one for each hydrogen.

Butyric acid is an example of a saturated fatty acid. The four valences of each carbon atom are attached to two hydrogen atoms and to the two adjacent carbons:

When adjacent carbon atoms are linked by a double bond, each has only one valence available for hydrogen:

When no double bonds are present, the fatty acid is said to be saturated; with the presence of one (monounsaturated) or more (polyunsaturated) double bonds, the fatty acid is said to be unsaturated.

Fats with a high percentage of saturated fatty acids tend to be solid at room temperature; e.g., butter and lard. Those with a high percentage of unsaturated fatty acids are usually liquid oils; e.g., sunflower, safflower, and corn oils. The names and shorthand numbers for the principal fatty acids in foods are shown in Table 8. In this shorthand notation, the number to the left of the colon is the number of carbon atoms, and the number to the right of the colon represents the number of double bonds; e.g., 4:0 has four carbon atoms and no double bonds (i.e., is saturated). This is the shorthand notation for butyric acid.

Essential fatty acids

A small group of fatty acids are essential in the diet. They occur in body structures, especially the different membranes inside and around cells, and cannot be synthesized in the body from other fats. Linoleic acid (18:2) is the most important of these fatty acids because it is convertible to the other essential fatty acids. Linoleic acid has two double bonds and is a polyunsaturated fatty acid. As well as being an essential fatty acid it tends to lower the plasma cholesterol. Linoleic acid occurs in moderate

to high proportions in many of the seed oils; e.g., corn, sunflower, cottonseed, and safflower oils. Some margarines (polyunsaturated margarines) use a blend of oils selected so that they have a moderately high linoleic acid content.

Edible fats and oils contain smaller amounts of other lipids as well as triglycerides (see below *Habitual dietary pattern and disease: Diet and coronary heart disease*).

Beverages. Although most adults drink one to two litres (about one to two quarts) of water a day, much of this is in the form of liquids such as coffee, tea, fruit juices, soft drinks, beer, wines, or spirits. In general, these are appreciated more for their taste or for their effects than for their nutritive value. Fruit juices are, of course, useful for their vitamin C content and good sources of potassium while low in sodium. Coffee and tea by themselves are of no nutritive value, except that coffee contains some niacin and tea contains fluoride and manganese, but they may be a vehicle for intakes of sugar, milk, or lemon. Beer contains 2 to 6 percent alcohol, natural wines 10–13 percent, and most spirits up to 40 percent. Since ethyl alcohol has an energy value of seven kilocalories per gram, very significant amounts of energy can be obtained from alcoholic drinks, and beer and wine contain natural sugars as well. With one or two exceptions, they contain no nutrients and are only a source of “empty calories.” The only vitamin present in significant amounts in beer from a brewery is riboflavin. Wines are devoid of vitamins but sometimes contain large amounts of iron, probably acquired from iron vessels used in preparation, especially of cheap wine. It is possible for excess iron to be absorbed and stored in the liver where it may contribute to toxic manifestations.

Ethyl alcohol and “empty calories”

RECOMMENDED INTAKES OF NUTRIENTS

Some forty countries now have their own recommended intakes of nutrients. In addition, international recommendations are published jointly by the Food and Agricultural Organization (FAO) and the World Health Organization (WHO). Several names are used to describe these dietary standards, but recommended dietary allowance (RDA) is the most common. In general, RDAs can be defined as the levels of intake of essential nutrients considered, in the judgment of the (national or international) committee on dietary allowances, to be adequate to meet the known nutritional needs of practically all healthy persons. This means that the RDA for each nutrient (except calories) is set at the top end of the frequency distribution of experimentally determined individual requirements (Figure 1A). For energy (calories), the RDA is different (Figure 1B)—it should be set in the middle of the frequency distribution of individual calorie requirements so that the value is too little for half the population and too much for the other half; i.e., it is the mean for the group.

The RDAs have a number of uses. The prescriptive and original use of RDAs is for planning diets of groups or individuals. The RDAs have been used as well for planning national or regional food supplies. International agencies compare the RDAs of countries to see which has the greater need for aid because they are the fairest basis for calculating rations during food shortages or disaster. The RDAs provide a standard reference so that, when the food intake of groups or individuals is assessed, the relative levels of different nutrients can be seen in perspective. Since the RDA of each nutrient is enough for almost all healthy people, an intake just below the RDA may be quite adequate for a particular individual. If the intake of a whole group is below the RDA, however, the probability is high that some individuals in the group are eating a diet inadequate in that nutrient. Finally, RDAs can be used as a denominator for nutrition labeling of foods. Thus, rather than indicating the amount of nutrient available (e.g., 0.35 milligram of thiamine), the percentage relative to the RDA may be cited (e.g., percent of the RDA of thiamine).

Uses of RDAs

The following information is required to work out the RDAs: (1) the level of nutrient intake at which a deficiency disease starts to occur in the community, (2) the least amount of nutrient required to cure clinical signs of deficiency, (3) the lowest intake of the nutrient that maintains chemical balance in the body over a long period, and

Figure 1: Theoretical frequency distribution of individual requirements (same sex and age group) for (A) a typical essential nutrient and (B) energy. (A) The recommended dietary allowance is set at the upper end of the distribution. For a few nutrients—for example, iron in women—the frequency distribution of requirement is not Gaussian but skewed. (B) The recommended allowance is in the centre of the distribution—the mean or median—so that half of the population need more and half need fewer calories per day than the recommended daily allowance (RDA).

(4) the minimum intake needed to give normal function tests for the nutrient or for tissue saturation (an index of adequacy for some of the vitamins).

Limitations

Most RDAs are for nutrients as eaten in foods after processing and cooking. They are for healthy people and do not allow for illnesses or major stresses in life, and they may be affected by a variety of medications, as well as smoking. The RDAs do not have to be reached every day, and a low intake on one day can be balanced by taking more than the recommendation the next day. They are more than enough for most people, and, although they should not be considered the upper limit, they do not (usually) indicate at what higher level toxic effects might start. The RDA assumes that enough of other major nutrients and energy are consumed. The RDAs are for standard body size (usually predefined) and for a usual range of exercise and assume a moderate or good nutritive quality, biological value, or availability of the nutrient to the body. They do not cover minor vitamins and minor trace elements and assume that adequate intakes of the main nutrients generally mean a mixed diet and an adequate intake of the minor nutrients. The RDAs cannot fully allow for the adaptation that can occur to high or low intake of some nutrients (e.g., iron and calcium) and they do not allow for interactions between some of the nutrients.

The RDAs of the United States have been regularly revised about every five years since they first appeared in 1941. During the 1980s a proposal was made to bring the RDAs for vitamins A and C into line with the RDAs of most other countries. The British RDAs cover only about 10 nutrients as well as calories. As an example of a modern set of RDAs, the Australian recommendations (1982–88) are reproduced in Table 9.

Energy. The body needs dietary energy in amounts equal to the energy expended in the external work of daily physical activities, in the internal work of tissue maintenance, for repair in the case of disease or injury, and, in the case of children, for growth.

The French chemist Antoine-Laurent Lavoisier initiated the quantitative study of energy exchange in animals using a small calorimeter, which allowed the rates of oxygen utilization and carbon dioxide release to be measured. Lavoisier also measured the rate of oxygen consumption in humans and showed that it rose with exercise. It was

not until the end of the 19th century, however, that a calorimeter chamber was constructed in which a person could live for three or four days. During this 72–96-hour period all the energy expenditure could be measured as heat and equated with the net energy intake (energy in food minus energy in feces and urine). In this way the law of conservation of energy in humans was demonstrated. There is no doubt that the human body operates within the limits imposed by the law of conservation of energy. Energy output is related to the rate of oxygen utilization, with one litre of oxygen equivalent to approximately 4.8 kilocalories of energy.

Measurements of the heat output of humans, direct calorimetry, are difficult. By contrast, measurements of oxygen consumption by indirect calorimetry are relatively easy and can be made on humans in their normal day-to-day environment, at home, and at work in offices, factories, fields, and mines, and during recreations, including most sports.

The rate at which energy is expended for maintenance at rest, known as the basal metabolic rate (BMR), amounts to about 1.25 kilocalories per minute for a man weighing 65 kilograms (one kilogram = 2.2 pounds) and 0.90 kilocalorie per minute for a woman weighing 55 kilograms. The basal metabolism, if expressed per unit of body weight or per unit of surface area, as has been the tradition for a long time, appears higher in men than in women. This is so because women have relatively more fat (adipose tissue) and less muscle than men and because men tend to be much more active.

The metabolic rate is raised by as much as 30 percent after a meal. This is the thermic effect of meals and is due in part to the work of secretion of the digestive juices and in part to chemical processes, mainly in the liver, involved in the metabolism of amino acids and other absorbed products of digestion.

The metabolism of a seated person usually is not raised by more than 50 percent above the basal level (i.e., $1.5 \times \text{BMR}$). The arms are light, and little physical work is involved in writing or sewing. Although the metabolism of the brain is high and accounts for 20 percent of resting energy expenditure, it is not raised significantly by mental activity.

Energy expenditure is increased fourfold, up to about five kilocalories per minute, by a brisk walk and is usually between two and four times the resting rate during the accomplishment of such light work as most assembly-line labour in industry, domestic activities, painting, and carpentry and in participation in recreations such as golf or bowling.

An increase of up to sixfold, or 7.5 kilocalories per minute, constitutes moderate work and is characteristic of most manual labour, gardening, tennis, and bicycling. Work involving energy expenditures above this is graded as heavy. Although many jobs in coal mining, lumbering, and the steel industry involve periods of strenuous work, relatively few persons in a modern industrial society do significant amounts of continuous heavy work. Cross-country skiing is the recreation with one of the greatest demands for energy and involves rates of 15 kilocalories per minute, or even more, for long periods.

Most individuals in urban societies have their days divided into three eight-hour portions. Normally, one period is spent in bed and asleep, one at work, and one in recreation or in other nonoccupational activities. The period in bed at approximately basal rates involves about 500 kilocalories of energy. A rough guide for occupational work is as follows: sedentary (about 900 kilocalories per eight-hour period), including office workers, drivers, teachers, and shop workers; and moderately active (about 1,200 kilocalories per eight-hour period), including virtually all engaged in light industry and assembly plants, postal workers, most farm labourers, and construction labourers.

A man's energy expenditure, however, is determined in an urban society more by how he uses his spare time than by the nature of his job. Nonoccupational activities may range from 800 to 1,800 kilocalories per eight-hour period. Energy requirements from food may vary from 2,200 kilocalories per day for sedentary activities to more than

Basal
metabolism

Average
daily
energy
expenditure

4,000 for the very active. These figures are generalities and cannot be applied to nonmechanized farming, still the way of life for the majority of the world's male population. There may be marked seasonal variations with men "very active" at seed and harvest time, and "sedentary" during some periods in between. Surveys in Africa and Asia indicate that a yearly average shows most farmers to be moderately active.

Corresponding figures for women show a total of about 2,200 kilocalories per day. The range of expenditure is not as wide as for men, and the great majority of women need food providing from 1,800 to 2,400 kilocalories per 24-hour period.

Much of the work done by humans consists in contracting muscles to move the body or its parts. Energy expenditure during exercise is directly related to body weight, and the basal metabolism is related to body size. In theory, then, large people should require more food than smaller people do. Activity level, however, is important, and some less physically active large men and women may have lower energy requirements than smaller persons. Exercise alone is not the most important factor in weight loss. The types and amounts of food consumed, as well as the balance of nutrients, play major roles as well. As age advances, physical activity is curtailed, lean body mass gradually declines, and the need for dietary energy is reduced.

(R.Pa./A.S.T.)

Protein. Protein constitutes the soft tissues of the lean body as well as the hundreds of enzymes involved in its activity. These proteins are continually broken down and replaced, some faster than others. In the process, proteins are converted to their constituent amino acids, some of which are deaminated in the liver and used up in energy production (e.g., in the citric acid cycle). The amino groups are concentrated in urea and excreted in the urine (Figure 2). Because of this turnover, some protein is required in the adult diet. Additional protein is required in the growth of new tissues in children and pregnant women and for the secretion of milk in lactating women. Protein requirements vary with lean body mass, and they are usually expressed as the amount per kilogram of body weight.

Since the League of Nations nutrition committee first recommended one gram of protein per kilogram of body weight for adults in 1938, pronouncements on protein requirements by successive international (FAO/WHO) committees in 1957, 1965, 1973, and 1985 have fluctuated between recommending 0.66 and 0.89 grams per kilogram of body weight. In 1985 the international recommendation was 0.75 grams of good-quality protein per kilogram of body weight for adults. This is 52.5 grams for a 70-kilogram man and 41 grams for a 55-kilogram woman. For children, the recommendation starts at 1.85 grams per kilogram of body weight in young infants and falls to one

gram per kilogram of body weight by the age of five years.

Proteins are made up of some 20 amino acids, at least eight of which are indispensable for humans. Their proportions vary from food to food (Table 3), and human requirements of individual amino acids range widely. The requirement for tryptophan is smallest. If tryptophan is taken as 1, the requirements for the others are approximately as follows: threonine, 2; valine, 3; isoleucine, 3; histidine, 3; lysine, 3.4; methionine + cystine (*i.e.*, total sulfur-containing amino acids), 3.7; leucine, 4; and phenylalanine + tyrosine, 4. (These requirement ratios are not related to molecular weights; they do not come closer if expressed in molar units.) Tryptophan has the highest molecular weight but the smallest requirement.

The reasons for the different requirements for individual amino acids are that they are present in different amounts in the major body tissues; *e.g.*, muscle (the most abundant tissue) contains about seven times as much leucine as tryptophan. There are differences as well in the rates of involvement of amino acids in different pathways of interconversion and metabolism.

If the diet is deficient in one of the essential amino acids, the protein requirement has to be adjusted upward. In practice, however, when protein foods are eaten together their amino acids complement one another. Mixtures of foods are less likely than single foods to have any individual amino acids far below the requirement.

Inorganic elements. Although requirements for nutrients are generally lower in women, who have lower lean body mass and eat less food, the RDA for iron is an exception. Women of reproductive age need about twice as much iron as men. Some degree of iron deficiency is a worldwide problem in women. In the Third World most of the iron in food is in vegetables, from which it is poorly absorbed. In affluent communities meat is available, but many women have low iron intakes because they restrict food consumption in order to lose weight. The RDA for iron in pregnant women (Table 9) may be considered very high, but it represents the upper end of the distribution of requirements, because some women who begin pregnancy with depleted body iron stores are likely to become anemic unless they take an iron supplement.

Requirements for calcium are difficult to determine because 99 percent of it in the body is in the bones. Any reduction of absorbed calcium is not evident in the plasma concentration because calcium loss increases the secretion of parathormone, which mobilizes some calcium from bones. In parts of the world without a dairy industry, adults appear to maintain strong bones on calcium intakes around 500 milligrams, while in industrial countries adults have been found to go into negative calcium balance on such low intakes.

The RDAs for zinc have only been considered and researched since the 1970s. Human zinc deficiency was not described until 1963, and it took an additional 10 years before it was confirmed and accepted that zinc is an important nutrient for humans. Although most reports agree with the RDA of 12–16 milligrams per day for adults in Table 9, more recent evidence suggests that the present RDAs are set too high.

Sodium levels are more than adequate in the great majority of human diets. Sodium chloride (common table salt) is added during processing to many foods, and smaller amounts of sodium bicarbonate and monosodium glutamate are also widely used as additives in food processing and preparation. The concern of nutritionists is not whether people are consuming enough sodium but whether they are consuming too much. This is why the Australian RDAs suggest an upper level of intake as well as a lower, but still generous, requirement.

Because it is the major cation inside all living cells, potassium is present in moderate amounts in most unrefined plant and animal foods (*e.g.*, meat, fruits, vegetables). Potassium presents a problem only in people with a variety of diseases in which potassium intake must be carefully monitored. Potassium intake may need to be supplemented in people with chronic diarrhea and in those with heart disease or high blood pressure who take regular diuretic tablets. On the other hand, those with im-

Relative requirements

paired kidney function (renal failure) may develop a blood potassium level that is too high, even while consuming an ordinary amount.

Magnesium and phosphorus (in the form of phosphate) are essential elements but few, if any, natural diets do not meet the requirements. Iodine deficiency is important in a number of underdeveloped inland and mountainous areas in the world. Intakes are adequate in nearly all the industrialized countries because foods come from a variety of places and so some at least have been grown in soils with adequate iodine. In addition, iodized salt is available and a few food additives contain iodine.

Vitamins. Table 4 shows the 13 vitamins essential for humans.

Vitamin A. A fat-soluble compound, vitamin A (retinol) is found in animal foods, especially in liver of land animals or fish, where it is stored and concentrated. Most of the world's population, however, derive most or all of their vitamin A from plant foods, many of which contain the yellow-orange pigment β -carotene. One molecule of β -carotene can be cleaved by an intestinal enzyme into two molecules of vitamin A. The pigment β -carotene occurs in fruits such as apricots, peaches, melons, mangoes, and pumpkins. It is also a companion of chlorophyll, the green pigment in leaves, so that green vegetables are good sources. Enough vitamin A is stored in the liver of a well-nourished adult to last about two years of deprivation. Vitamin A (not carotene) is one of the vitamins whose toxicity at doses 10 times the RDA or more is well established. It can lead to bone changes and fetal malformations and has been responsible for occasional fatalities.

Thiamine. Found in whole-grain cereals, meats, yeasts, and nuts, thiamine (a water-soluble vitamin) plays an indispensable role as cofactor for enzymes involved in the metabolism of carbohydrates, alcohol, and some amino acids. The requirement is therefore proportional to an individual's calorie intake from foods other than fats. There are hardly any stores of thiamine in the body, and it only takes about 30 days without thiamine intake before signs of deficiency appear, provided the calorie intake is maintained. Alcoholics are at special risk of thiamine deficiency because the more alcohol a person drinks, the less thiamine-containing food he consumes. Alcohol requires thiamine for its metabolism, and body stores of thiamine are smaller than for any other vitamin.

Riboflavin. Another of the water-soluble vitamins, riboflavin is unusual in that it has a fluorescent yellow-green colour. It too plays a vital role in intermediary metabolism, but deficiency disease is rare. In industrial countries this may be because milk is a good source.

Niacin. Niacin is a water-soluble vitamin that is also made in the human liver by the conversion of the amino acid tryptophan. If the protein intake is low, preformed niacin must be provided in the diet; if the protein intake is generous, niacin normally can be made by the body from

the tryptophan. Some animals (such as cats) do not have this ability. One form of niacin (nicotinic acid) in doses about 200 times the RDA is used in medicine as a drug that lowers the cholesterol level in the plasma. This is an example of a pharmacological action of a nutrient.

Vitamin B₆. Vitamin B₆ is a water-soluble vitamin of the B group. The five closely related substances with B₆ activity, of which the best-known is pyridoxine, act as cofactors for the many enzymes involved in amino acid metabolism. Vitamin B₆ requirements, therefore, are proportional to the protein intake. Primary deficiency is rare but several drugs (*e.g.*, isoniazid) can produce secondary vitamin B₆ deficiency. Pyridoxine in megadoses (100 and more times the RDA of around two milligrams per day) has been taken to ameliorate the effects of premenstrual syndrome (prescribed or self-medication), but its efficacy has not been established. It is known that prolonged dosage of 500 milligrams and above causes damage to peripheral nerves, with a loss of sensation in legs and hands.

Folic acid. A number of related water-soluble compounds have folic acid activity. Because the main function of folic acid is in the synthesis of DNA, in folic acid deficiency replication of DNA and cell division are slowed or stopped. Cells that rapidly turn over, such as blood cells and epithelial cells lining the intestine, are affected first. The requirement for folic acid is notably increased in pregnancy. The name comes from Latin *folia* ("leaf"), but this vitamin is found in animal organs and whole-grain cereals, as well as vegetables. It is sensitive to heat and is mostly destroyed when vegetables are overboiled. Folic acid deficiency is common in a number of conditions encountered in hospital patients.

Vitamin B₁₂. Vitamin B₁₂ was the last of the vitamins to be isolated (in 1948). It is water-soluble, has the highest molecular weight (1,355) of any vitamin, and is absorbed by a complex mechanism. Failure of absorption (pernicious anemia) is more common than dietary deficiency. Vitamin B₁₂ is found only in animal foods, so that vegans (pure vegetarians) are at risk of deficiency over the course of several years. The requirement of vitamin B₁₂ is (with vitamin D) the smallest of all the vitamins, only two micrograms per day, with liver stores usually enough to last for five years of deprivation. Vitamin B₁₂ participates with folic acid in DNA synthesis so its deficiency leads to a similar anemia. There is a separate effect of vitamin B₁₂ deficiency on the nervous system.

Vitamin C. Also water-soluble, vitamin C is the opposite of vitamin B₁₂ in that it is found in almost all plant foods but not in meat. It is a powerful antioxidant and is required for the formation of collagen; *i.e.*, in wound healing. The RDA of vitamin C in Table 9 is more than enough to prevent scurvy. It is not clear whether there is any advantage in larger intakes than 40 milligrams per day. Indirect epidemiological data suggest the possibility that generous intakes of salads and citrus fruits may re-

*Expressed as a mean daily intake. This table expresses the amounts of nutrients that should be available per head of population if the needs of practically all members of the population are to be met. All RDIs are based on estimates of requirements with a generous "safety factor" added. Recommendations for all nutrients were revised between 1982 and 1988. Recommendations for dietary intakes of Vitamin D were not considered necessary since the Vitamin D status of Australians is determined by exposure to sunlight. For people confined indoors, however, 10 μ g per day is recommended.

Source: National Health and Medical Research Council, Canberra.

Association
with
sunlight

duce the chance of developing cancer of the stomach. Megadoses, 100 to 250 times RDA, have been claimed to prevent colds, but most controlled trials have shown that it does not. Like folic acid, vitamin C is easily destroyed by cooking. Large doses of vitamin C are well tolerated but they may contribute to the formation of kidney stones in the urinary tract.

Vitamin D. Vitamin D is fat-soluble, and cholecalciferol is the major active substance. Its main function is to stimulate the absorption of calcium. The natural source of vitamin D is from the action of short-wave ultraviolet light from the Sun on a derivative of cholesterol in the skin. Vitamin D also occurs in some foods. It is only when people live in high latitudes, consistently wear concealing clothes, and spend nearly all their time indoors, and when the sky is usually cloudy and smoky, that there is insufficient skin exposure to ultraviolet light to make the required amount of vitamin D. Under these conditions dietary intake becomes critical and cholecalciferol assumes the role of a vitamin. Overdose of vitamin D leads to an increased blood calcium concentration and symptoms such as vomiting.

Vitamin E. Eight chemically similar substances have vitamin E activity: α -tocopherol is the most active of these and the most abundant in most foods. Vitamin E is fat-soluble and an antioxidant that is present in cell membranes. Its requirement is increased by high intakes of polyunsaturated fats. Vitamin E deficiency that produces signs and symptoms is rare; it can occur in premature infants and in older individuals with chronic defects of fat absorption. It is possible that generous intakes protect cell membranes from oxidation damage and consequent degenerative diseases, but this is speculation. No controlled trial has been carried out. Dosages of vitamin E up to 20 times the RDA appear to be well tolerated.

Vitamin K. Vitamin K is a fat-soluble vitamin involved in the processes of coagulation. Although the alphabetical letters for most vitamins are arbitrary, the letter *K* came from the German *Koagulationsvitamin*. This activity is found in several chemically different substances. One (vitamin K_1) occurs in some plant foods; others (the vitamin K_2 group) are formed by bacteria in the large intestine. Some of this is absorbed by the host. In newborn infants the latter source has not yet come into operation, and transfer of vitamin K from the mother's blood across the placenta is evidently unreliable. Vitamin K_1 is commonly given to newborn babies to prevent the possibility of hemorrhagic disease. Vitamin K deficiency in older individuals can occur when fat absorption is defective. Oral anticoagulants (warfarin, etc.) act by antagonizing the action of vitamin K.

Biotin and pantothenic acid. Biotin and pantothenic acid are the last two of the established vitamins for humans. Spontaneous deficiency of biotin is extremely rare and that of pantothenic acid is unknown. They are, however, required in infant formulas and in fluids for total parenteral (intravenous) nutrition.

The following compounds are not vitamins required for humans, or in infant formulas or fluids for total parenteral nutrition: bioflavonoids, carnitine, inositol, orotic acid, para-aminobenzoic acid (PABA), "pangamic acid" (vitamin B_{15}), laetrile (vitamin B_{17}), and vitamin P.

Diet and diseases

SOURCES OF INFORMATION

Animal experiments. The results of studies on animals provide suggestive associations to humans, but for each nutritional biochemical process some or many animals may not be suitable models for humans. For example, rats do not need vitamin C in their diet because they synthesize it in their bodies from glucose. For a model of human scurvy, therefore, rats cannot be used. Only a very small number of higher animals are similar to humans in that they lack the enzyme to complete the synthesis of vitamin C. In 1907 it was discovered in Norway that guinea pigs must have vitamin C in their diets; research on vitamin C made rapid progress after this.

Comparative and evolutionary studies. *Homo sapiens* and his predecessors have been on the Earth for at least 1,000,000 years. For 99 percent of this time they lived as hunter-gatherers; agriculture did not begin until 10,000 years ago. There has not been time for humans to evolve biochemical mechanisms to deal with the mixture of foods that has become usual in Western communities. Presumably human bodies are well adapted to the habits and diet of their hunter-gatherer forebears. There is some information about these diets (and a little about their effects) from archaeological records and some information from studies of the few isolated groups of hunter-gatherers remaining today.

Experiments of nature and travelers' tales. People in the United States and Britain cannot be persuaded to take an unfamiliar and unpleasant diet long-term in order to follow its effect on body functions. In other parts of the world, however, groups of people may be on restrictive diets due to reasons such as culture and the availability of food. Diets may consist of a lot of fatty fish, or of blood and sour milk, or of mostly starchy low-protein roots, or of food cooked in salt water. It may be no coincidence that many of the leading human nutritionists have worked in several different countries, returning with their experi-

Animal
models

ences (the so-called travelers' tales). The trouble with such experiences is that the data are not very reliable.

Epidemiological studies. Epidemiology is the study of the distribution of disease in different sections of the population. Modern epidemiology is a more important tool for studying human nutrition than is animal nutrition. It has been particularly useful in finding which diets are associated with each of the chronic degenerative diseases—dental caries, coronary heart disease, high blood pressure, diverticulosis, and various cancers. Association, however, does not prove cause and effect.

Prospective studies

Prospective (or cohort) studies are more reliable than retrospective or cross-sectional ones. In a prospective study a large group of several thousand people in one place (a town or large firm) at risk of later developing a common disease have their medical histories taken and are examined, including laboratory tests (blood biochemistry, etc.). Their health is then monitored for a period of time, usually five years or longer. If one of the variables at the initial examination is significantly associated with early development of disease X, this is considered evidence that a high value of the variable is a "risk factor" for disease X. If the same association should hold up in other prospective studies made in different places, the evidence becomes very strong.

Clinical records. Measurements of the food intake of patients with deficiency diseases are an important part of the classic evidence about these diseases. Precise information has come from experiences with patients fed entirely with solutions given by vein (total parenteral nutrition). Patients with extensive disease of the small intestine can be kept alive in this way. When patients rely on this route for all their nutrients for weeks, months, or years, the essentiality of trace elements becomes obvious. If a particular nutrient is not included in the fluid for total parenteral nutrition, the patient develops specific symptoms, which are then corrected when that nutrient is supplied. The role of diet in treatment of diseases such as diabetes mellitus or kidney failure is important. The dietary changes that will give the lowest blood glucose or blood urea, respectively, is explored by the nutritionist.

Food composition analysis. The independent variables in nutritional epidemiology and in dietary treatment of diseases are food constituents (protein, vitamin C, iron, etc.). Foods keep changing because of new methods of production, different formulations of ingredients, and changing consumption patterns. To facilitate international sharing of the available food composition data, Infoods (International Network of Food Data Systems) was set up in 1983, with its secretariat at the Massachusetts Institute of Technology in Cambridge.

Human experiments and trials. There are many different types of human experiments and trials. They range in duration from hours to years and in number of subjects from a handful to thousands. The variables measured can be clinical symptoms; biochemical substances in any available body fluid or accessible tissue, including expiratory air; body composition (estimates of size of the different compartments of the body); or the chemical transformations of radioactively labeled nutrients. Such studies are usually performed on healthy subjects. Some examples illustrate the scope.

Depletion diets

The first type of study involves the depletion of a single nutrient in human volunteers under experimental conditions (with all other essential nutrients provided, either in the food or as supplements). Ethical considerations are important, so that subjects often have been the scientists themselves and numbers usually have been very small. Such experiments, however, have provided important information. Some experiments have been continued (under close supervision) until the first clinical signs of deficiency appear; this takes three or four months for vitamin C and folic acid and much longer for vitamin A (because of large stores in the liver). Other experiments have used indexes such as low blood levels as measures and have stopped before any symptoms or signs.

A second type of study, involving absorption and uptake studies using test meals, takes only a few hours to carry out. Many are needed, however, because humans digest

and absorb nutrients in different amounts and at different rates, depending on the food. For example, measures of iron uptake vary considerably, and a number of tests have been done with radioactive isotopes of iron (short half-life) to find the effects of different foods on uptake of this nutrient element.

In a third type of trial, the metabolic study, the diet is usually changed in one way only, and the result is measured in a change in blood or excreta. One type of study is the balance experiment, where the intake of a nutrient is controlled and measured and its output (in urine, feces, etc.) is measured. Because of variability in defecation, measurements have to be made for a metabolic "period" of about a week. The amount of the nutrient measured can be changed (with time allowed for adjustment) and the effect of this on the balance determined. When, for example, the output of nitrogen exceeds intake, there is a negative nitrogen balance; when output is less than intake the balance is positive.

Another type of metabolic experiment measures the effect of a change of diet on plasma cholesterol. Such an effect takes 10 to 14 days to appear and requires control periods for comparison before and after the dietary change being examined. Whenever one component is added to, or removed from, a person's diet, another food must be removed or added to keep the calories and other important nutrients constant. That substitution may itself affect the variable under study.

In a fourth type of study, the double-blind trial, control groups receive identical-looking placebo tablets, and individuals are randomly allocated to experimental or control group by someone who is not going to assess the clinical results. The researchers also do not know who took which tablets. Controlled double-blind trials of vitamin C tablets during winter months to see if they prevent colds measured incidence, severity, duration, and type of respiratory symptoms. Most of the trials have shown no statistically significant reduction in the incidence of colds with the use of vitamin C.

Double-blind trials

A fifth type of trial, the prevention trial, measures the effects of one combination of foods versus another. It is not possible to achieve double-blind conditions, but the control group is kept separate from the experimental group and the emphasis is on objective rather than subjective changes, such as biochemical measurements on blood samples and electrocardiographic changes. For example, the effects of a low saturated-fat, increased polyunsaturated-fat diet were measured in half of 850 middle-aged male war veterans in Los Angeles. The other half (the control group) consumed their usual foods. Variables measured were blood lipids, tissue fatty acid patterns (reflecting compliance with the prescribed increase of polyunsaturated fat), electrocardiographic changes, and the incidences of coronary and other diseases.

Classification of nutritional disorders. *Undernutrition.* Undernutrition is a condition in which there is not enough food energy as measured in calories or kilojoules. Undernutrition usually means that not enough total food is consumed. The main characteristics are loss of body weight and wasting of body fat and later muscle. Severe forms are starvation in adults and marasmus in young children. Undernutrition may be due to a failure of the food supply or to deliberate fasting, or it may be secondary to prolonged disease. Epidemic failure of the food supply is called famine.

Malnutrition. Malnutrition covers at least 25 different deficiency diseases resulting from lack of one of the essential nutrients: protein, vitamins, essential fats, or nutrient elements. Kwashiorkor, rickets, and iron-deficiency anemia are examples of the results of malnutrition. Multiple deficiencies are more likely than single, though one type often predominates. The deficiency disorder may be subclinical (recognizable only by laboratory tests) and not show characteristic features.

Obesity. Obesity is an excess of fat in the body (subcutaneous or internal) that results from a prolonged net positive energy balance; *i.e.*, the energy (calories or joules) consumed has been greater than the energy expended. Obesity is the opposite of undernutrition. Any or all of the

Positive energy balance

proximate energy-yielding nutrients can be responsible: usually fat, carbohydrate, and/or alcohol.

Nutrient excess. Nutrient excess is due to too much of one nutrient. For many nutrients a very high intake in the short term or a high intake over a long period (chronic nutrient toxicity) can be harmful. The nutrient may be an essential one (e.g., as in vitamin D intoxication and iron overload), or it may be a nonessential nutrient (e.g., alcohol or saturated fat, resulting in raised blood cholesterol).

Effects of toxicants. Unless very refined, foods contain hundreds of substances other than the nutrients, most in tiny amounts. Some naturally occurring toxicants can cause illness if people rely too heavily on a single food-stuff—e.g., lathyrism, a paralysis of both legs (which occurs in India) from eating too much of the pulse *Lathyrus sativus* (grass pea). Potatoes contain alkaloids, including solanine, mostly in the green sprouts, and occasionally cases are reported of vomiting and other symptoms attributed to solanine poisoning. Other substances affect only a few individuals who are hypersensitive to them—e.g., celiac disease (from sensitivity to wheat gluten) and urticaria (from sensitivity to such substances as naturally occurring salicylates). (A.S.T.)

DEFICIENCY DISEASES

Deficiency diseases may best be considered under six main headings, according to the principal deficiency: water, energy (calories), proteins, vitamins, inorganic elements, and fats and carbohydrates. There is considerable overlap among these groups.

Dehydration and over-hydration

Water. Some 65 percent of a normal body consists of water distributed between three compartments: within the cells, between the cells, and within the circulatory system. A great variety of diseases disturb the water balance, but in healthy people dehydration and overhydration result from wrong intake of water. The prominent symptom of dehydration is thirst, which develops quickly when water is unavailable. Dehydration becomes rapidly worse, and death may ensue within two or three days. Water is lost from the body by evaporation from the lungs and skin, through the urine, and through the stools, a loss that can become serious in diarrhea. Lung and skin losses are increased by work that causes sweating, particularly in a hot, dry climate. The kidneys usually excrete between one and two litres of urine per day, but when dehydration threatens they can conserve water through concentration of the urine.

Overhydration from overdrinking is not a common occurrence in healthy people because the combined effects of excretion by the kidney and satiation, the opposite of thirst, are usually adequate even for the most enthusiastic drinker.

The distribution of water between the three compartments is largely determined by the ions sodium and potassium. The important positively charged ion, or cation, in the interstitial (between the cells) fluid is sodium. Mammals, which have acquired an energy-dependent mechanism for removing sodium from the individual cells, the sodium pump, have potassium as their principal cation within the cells. (The cell membrane is permeable to sodium ions, and the sodium concentration outside the cells is stronger than within, so that one would expect sodium to pass from the tissue fluids into the cells; its movement in the opposite direction requires energy. The process that involves this expenditure of energy is called the sodium pump.) Ion and fluid balance are both normally maintained by the regulatory power of the sodium pump and of the kidney tubules. Upset of the delicate ion and fluid balance may be aggravated by deficient or excess intake of water.

The most severe dehydration occurs from diarrhea, with or without vomiting, in undernourished infants in poor communities who develop gastroenteritis, and in adults with cholera. The most efficient lifesaving treatment is intravenous infusion of sterile water containing glucose, sodium chloride, and potassium chloride. Water is poorly absorbed when drunk, but a good first aid formula consists of sodium chloride, 3.5 grams; sodium bicarbonate, 2.5 grams; potassium chloride, 1.5 grams; glucose 20 grams (or sucrose 40 grams); and clean water up to one litre. The

glucose assists absorption of the sodium and vice versa, and as they are absorbed water is absorbed with them.

Energy (calories). Chemical energy in food, ultimately dependent on solar energy, occurs in carbohydrates, fats, and proteins (and alcohol). It is expended in mechanical work, in the work of the internal organs, in maintaining body temperature, and in growth. Undernutrition (calorie deficit) can result from (1) failure of the food supply, (2) loss of appetite, (3) fasting and anorexia nervosa, (4) persistent vomiting or inability to swallow, (5) incomplete absorption, comprising a group of diseases (malabsorption syndrome) in which digestion and intestinal absorption are impaired and there is excess loss of nutrients in the feces, (6) increased basal metabolic rate, as in prolonged fever, overactivity of the thyroid gland, or some cancers, and (7) loss of calories from the body; e.g., glucose in the urine in diabetes.

Calorie deficit

Cessation of growth is an early feature of undernutrition in children. There is otherwise little difference between starving adults and marasmic infants. Body tissues are used as energy reserves. Body fat (adipose tissue) is the largest and most concentrated energy store and it is used first and most. As energy deficit continues, the proteins in muscles are used as well. Typically there is a large loss (wasting) of subcutaneous fat and a smaller loss (wasting) of the muscles. Some compensatory changes reduce the rate of energy expenditure: reduced voluntary activity, thyroid secretion, basal metabolic rate, and heart rate.

Severity of undernutrition is usually graded by comparing actual weight to the standard weight for a certain height. In adults undernutrition is defined as mild when weight is 81 to 90 percent of standard weight for the height; moderate when weight is 71 to 80 percent of standard weight for the height; and severe when weight is 70 percent or less of standard weight for the height. During famine people with mild starvation are in no danger; those with moderate starvation need extra feeding; those severely underweight need hospital care. Table 10 gives moderate (80 percent of standard weights) and severe (70 percent of standard) underweights for adults of different heights, and it can be used for men or women.

Under-nutrition defined

Table 10: Underweights in Adults by Height

height		weight			
(m)	(in.)	80% of standard (kg)	(lb)	70% of standard (kg)	(lb)
1.45	57.1	38	84	33	73
1.48	58.3	39.5	87	34.5	76
1.50	59.1	40.5	89	35	77
1.52	59.8	41.5	91.5	36	79
1.54	60.6	42.5	94	37	82
1.56	61.4	44	97	38.5	85
1.58	62.2	45	99	39	86
1.60	63.0	46	101	40	88
1.62	63.8	47	104	41	90
1.64	64.6	48.5	107	42	93
1.66	65.4	49.5	109	43	95
1.68	66.1	50.5	111	44	97
1.70	66.9	52	115	45.5	100
1.72	67.7	53	117	47	104
1.74	68.5	54.5	120	48	106
1.76	69.3	56	123.5	49	108
1.78	70.1	57	126	50	110
1.80	70.9	58	128	51	112.5
1.82	71.7	60	132	52	115
1.84	72.4	61	134.5	53.5	118
1.86	73.2	62	137	54	119
1.88	74.0	63.5	140	55.5	122
1.90	74.8	65	143	57	126

Protein. Because children have higher protein requirements per calorie and are more at risk of being given a low-protein diet, protein deficiency is more prominent among them. In most malnourished children, calorie deficiency and protein deficiency are combined, and features of both are detectable. There is a spectrum that begins with marasmus at one end, showing severe wasting but no signs of protein deficiency, and kwashiorkor at the other end, showing edema, severe reduction of the major plasma protein (albumin), and usually little weight loss.

The most common severe form of protein-energy malnutrition, nutritional marasmus usually occurs in the first

Nutritional marasmus

year of life. The affected child is extremely underweight and has lost all subcutaneous fat. The body is wizened, the face gaunt, and the limbs like matchsticks. The cause is a diet very low in calories from all sources (including protein), often from early weaning to bottled formula diluted because of poverty. Poor hygiene leads to gastroenteritis and a vicious cycle of poor appetite and even more diluted formula. In turn further depletion leads to thinning of the inner lining of the intestine and reduction of its resistance to infection. In marasmus, the child's weight is 60 percent or less of standard weight for age (which is the median weight for healthy children in the United States). With such a large loss of tissue it takes about three months of good nutrition before the child's weight is normal, but the general condition is usually much improved after the first two weeks.

Kwashi-
iorkor

In its fullest form, kwashiorkor is less common than marasmus. It was first described in Ghana in the 1930s, and the word kwashiorkor comes from the Ga language of that country. There is edema, with puffy feet or face, and patches of excess skin pigmentation and peeling. There may be little wasting or loss of weight. The hair is pale and thinned; the child is miserable and apathetic and will not eat. The liver is infiltrated with fat and the concentration of albumin in blood plasma is about one-quarter of the normal. While all agree that marasmus results from not enough food, the classical hypothesis of the pathogenesis of kwashiorkor—insufficient protein with adequate starchy food and sugar—is not fully accepted by all researchers. A major reason is that the dietary histories of children with kwashiorkor are inaccurate.

Treatment
of mal-
nutrition

Treatment of protein-energy malnutrition is essentially the same whether it is marasmus or kwashiorkor. There are three phases to treatment. (1) Resuscitation is the correction of dehydration, deficiency of potassium, low blood sugar, and low body temperature and treatment of infections. (2) The cure is begun with mixed foods, usually including milk, providing increasing calories and protein per kilogram of body weight. Appetite may be poor and the child must be fed by hand. A multivitamin preparation and supplements of potassium, magnesium, and zinc are needed. (3) Rehabilitation takes place after about three weeks when the child usually has improved and has a good appetite, but is still underweight. It will take many weeks of good nutrition before catch-up growth is complete. If the home background is unfavourable because of poverty or social disorganization, the mother will need support as well as advice.

Other nutrients are often deficient in malnourished children: potassium, magnesium, zinc, folic acid, vitamin A, iron, and others that differ from one region (and staple diet) to another. Children malnourished for a long period in early childhood are likely to grow up to be short adults. A more serious and complex question is whether severe malnutrition impairs a child's mental ability. Malnourished children often come from an emotionally and educationally deprived home; however, the balance of evidence from psychological follow-up studies shows that children who have been malnourished have the potential to reach normal intellectual development, though they may not. The outcome is likely to be favourable if the child returns to an encouraging and stimulating home and unfavourable if the malnutrition was prolonged and occurred in the first year of life.

Mild mal-
nutrition

For every child in a developing country with marasmus, marasmic kwashiorkor, or kwashiorkor (the severe forms) there are likely to be about 10 with mild to moderate forms, the most useful sign of which is a low weight for age (between 61 and 80 percent of the normal standard). It has been estimated that around 2 percent of young children in Third World countries have severe malnutrition while about 20 percent show mild to moderate forms. Such children are not growing at their genetic potential, and they have an increased risk of severer attacks of the common infections of childhood (gastroenteritis, respiratory infections, measles, etc.). Two keys to recognizing mild to moderate protein-energy malnutrition are widespread inexpensive maternal and child health clinics, each with a weighing machine, and a clear and simple growth chart

Figure 3: Standard weights for children. The top line is the World Health Organization standard weight for age (the 50th percentile of the National Center for Health Statistics reference) and the bottom line is the 3rd percentile of the reference, close to 80 percent of the standard. In prosperous communities children's weights should be close to the top line. In poor communities they should not fall too far below the bottom line. By courtesy of the World Health Organization

(Figure 3). Another simple measurement is the mid-upper arm circumference: from 12 to 60 months of age a measurement of 13.5 centimetres (or above) is normal, which remains the same for these four years. A circumference of 12.5 to 13.5 centimetres suggests mild malnutrition and under 12.5 centimetres indicates definite malnutrition.

Vitamins. Each of the vitamin-deficiency diseases is commonly attributed to a deficiency of a single vitamin, and many have been produced in animals and in human volunteers by diets apparently complete except for the vitamin under trial. In human experience, these supposed single-vitamin diseases usually arise from unhealthy and unbalanced diets that are also deficient in other vitamins or in nonvitamin nutrients. In these complex nutrient-deficiency states, the nutrient whose deficiency plays the largest part in the causation of symptoms is often referred to as the most limiting nutrient; e.g., niacin is the most limiting nutrient in pellagra, but there are often deficiencies of other B vitamins, and protein deficiency is commonly present.

A good example of a single-nutrient disease is scurvy, the scourge of mariners in the days of long ocean voyages. In 1754 a Scottish naval surgeon, James Lind, established the concept of deficiency diseases by showing that scurvy can be both cured and prevented by the use of orange and lemon juice. Scurvy is an eminently preventable disease, and it is now seen mainly at the extremes of life and where there is disregard of the principles of nutrition. At an early stage scurvy results in swelling and bleeding of the gums and bleeding into the skin. Bleeding into the muscles and under the periosteum, the membrane that covers the bones, in small children may also occur. It is probable that in the classical epidemics among mariners and in prisons the diet was unsatisfactory in many ways and that other deficiency states contributed to the more serious complications and to death, but experiments on human volunteers fed diets lacking in vitamin C but otherwise satisfactory have shown that scurvy can be and often is a single-nutrient-deficiency disease.

The earliest manifestation of vitamin A deficiency is night blindness, because the retinal pigment rhodopsin (visual purple) in the retina of the eye requires retinol (vitamin A) for its functioning. Retinol deficiency manifests itself as inability of the eyes to adapt in dim light. Moreover, epithelial cells throughout the body—the various cells covering or lining the body and its organs—degenerate in vitamin A deficiency. In the eyes, the conjunctiva and cornea undergo changes (xerophthalmia) that can lead eventually to breakdown and complete blindness. Other epithelial cells, including the skin and the mucous lining of the respiratory and urinary tracts, degenerate, with characteristic results such as hardening and drying

Scurvy

Vitamin A deficiency

of the skin, respiratory infections, and kidney stones. (All of these changes can be simulated to more or less degree by diseases that have nothing to do with vitamin A deficiency.) (J.F.B./A.S.T.)

Xerophthalmia is a late manifestation of vitamin A deficiency. It has been estimated that there may be as many as 500,000 new cases of xerophthalmia each year, half of which lead to loss of vision. The highest incidence of xerophthalmia is found in East Asia—*e.g.*, Bangladesh, India, Indonesia, Philippines. It is virtually confined to infants and young children and usually is associated with protein malnutrition. In the early stages of xerophthalmia, the conjunctiva is dry, wrinkled, and thickened. If not treated with vitamin A at this stage the cornea becomes involved (keratomalacia). The result is a scar, but there is a danger the cornea will perforate, resulting in total blindness in the eye. Where xerophthalmia occurs in a community, other children may be found to have low plasma levels of vitamin A. Children with mild eye signs (night blindness or early xerophthalmia) have an increased risk of acquiring severe measles and respiratory infections. These children develop vitamin A deficiency first because the mother was undernourished, so that they are born with small liver stores of vitamin A and their mother's milk has a low vitamin A content; second because they are given little or no dietary preformed vitamin A or β -carotene; and third because absorption of vitamin A is impaired in protein malnutrition. The World Health Organization has made prevention of xerophthalmia one of its priorities in nutrition. In the short term, the incidence of the disease is being reduced by giving young children a high-dose vitamin A capsule (50 times the adult RDA) every six months. The long-term solution is education, so that mothers and babies regularly eat foods rich in β -carotene, such as dark green leafy vegetables or pumpkin, squash, mangoes, pawpaw, even sweet potatoes and yellow corn, which all provide β -carotene.

Vitamin D deficiencies

Vitamin D is involved in the absorption of calcium and, less important, phosphorus from the gastrointestinal tract. The process is affected by both the ratio of calcium to phosphorus and the amount of phytate in the diet. (Phytate, which is present in cereals, interferes with the availability of calcium.)

Whether formed in the skin from a derivative of cholesterol or taken from the diet (*e.g.*, in fatty fish and dairy products), vitamin D is changed in the liver to 25-hydroxyvitamin D. This is further changed in the kidney by an enzyme (regulated by parathormone) to 1,25-dihydroxyvitamin D (1,25-(OH)₂ vitamin D), the active form. The best-known action of activated vitamin D at the cellular level is to turn on synthesis of calcium transport protein in the cells lining the small intestine.

Vitamin D deficiency affects the bones. The signs and symptoms of rickets in growing children are different from those of osteomalacia in adults. Features of rickets vary with age, depending on which bones are growing fastest. In young infants there may be softening of the skull (craniotabes). At about one year the wrist bones are thickened and there is a line of beadlike bony nodules (the rachitic rosary) at the junctions of the ribs and the breastbone (sternum). When the child is walking, the growing bone ends (epiphyses) most affected are just above and just below the knee joints and there is either knock-knee or bowlegs. A complication of severe rickets in older children is a contracted pelvis, now rare, which later gives difficulty in childbirth. In adults with osteomalacia, in one or more of the large bones there are pain and tenderness, reduced bone density, and cracks.

Rickets and osteomalacia are rare in tropical countries unless infants or young women are by custom kept indoors or completely covered while outside. In the industrial countries these diseases have been eliminated largely by a combination of cleaner air, sunshine, fortification of some basic foods with vitamin D (margarine and infant formulas generally, milk for adults in North America and Sweden), and administration of cod-liver oil or low-dose vitamin D capsules prophylactically when required. Rickets remains a health problem in Asian people living in northern industrial cities in Britain, and osteomalacia is

a possibility in housebound and institutionalized elderly people unless they are given a vitamin D supplement or regularly sit in the sunshine.

Vitamin E deficiency is rare and only known in two situations: in premature infants and in some prolonged cases of defective absorption; *e.g.*, cystic fibrosis. In the former only the earliest manifestation is seen, a mild hemolytic anemia. In the latter, where the deficiency is more chronic, parts of the spinal cord may be affected, with loss of position sense in the legs. Pure dietary deficiency has only been seen under experimental conditions in adults who were given a diet low in vitamin E for over a year; the effect was a mild hemolytic anemia. Vitamin E, like other fat-soluble vitamins, is transported with difficulty across the placenta to the fetus. In adults vitamin E is stored primarily in adipose tissue, and generally enough is stored to last about a year.

Vitamin K is necessary for the formation of prothrombin and other clotting factors in the liver. Vitamin K deficiency causes hemorrhagic disease in which there is excessive bleeding from a wound as well as internal bleeding that can occur anywhere in the body even without injury. Vitamin K deficiency occurs in four situations: (1) in hemorrhagic disease of the newborn, for which many obstetricians routinely give vitamin K to infants at birth; (2) in disorders of fat absorption (*e.g.*, biliary obstruction) and extensive intestinal disease since vitamin K is fat-soluble; (3) in patients who combine a restricted diet, lacking vegetable foods, with one of the antibiotics that destroys the normal bacterial flora in the large intestine—thus producing a situation in which dietary vitamin K₁ and colonic vitamin K₂ are both lacking; and (4) in therapy with anticoagulant tablets (*e.g.*, warfarin), prescribed to reduce clotting in veins, which antagonizes (or competes with) vitamin K and can be counteracted by an injection of vitamin K₁.

Vitamin K deficiency

When thiamine is deficient, the two most prominent biochemical abnormalities are (1) the accumulation of pyruvic acid, because the enzyme that processes pyruvic acid for entry into the tricarboxylic acid cycle cannot function without thiamine, and (2) disturbances in areas of the nervous system, a system highly dependent on glucose as fuel and thus requiring thiamine as an essential coenzyme for three steps in glucose metabolism. Thiamine deficiency can lead to beriberi, Wernicke's encephalopathy in association with Korsakoff's syndrome, or a peripheral neuropathy (a disorder of the peripheral nervous system). Beriberi is a high-output cardiac failure associated with general dilatation of small blood vessels in response to accumulation of pyruvic and lactic acids. It was formerly common in rice-eating peoples of East Asia but is now rare. It is occasionally seen in Western alcoholics. In Wernicke's encephalopathy the abnormalities are in the central part of the brain. There is progressive mental deterioration, disorientation, and a characteristic paralysis of eye movements. It is mostly seen in alcoholics but was reported in Japanese prisoner of war camps in World War II. Like beriberi it responds dramatically to injection of thiamine, but unlike beriberi there may be a residual abnormality of memory. Thiamine deficiency is one of many causes of peripheral neuropathy, generally involving an impairment of the sensory, motor, and reflex functions of the limbs. But other B-vitamin deficiencies and a number of toxins can produce a similar effect. Response to nutrient therapy always takes weeks and it is advisable to treat the disease with multiple B vitamins.

Thiamine deficiency

Pellagra, before the 20th century, occurred in Italy (the name is Italian for "rough skin") and in the southern United States. It has now disappeared from Europe and North America but still occurs in Egypt and southern Africa. It affects poor people who subsist primarily on corn and little other food. In industrial countries it is occasionally seen in alcoholics. The principal nutritional deficiency in pellagra is of niacin. In corn the niacin is in bound form, not able to be broken down by humans unless prepared in a special way. In addition, unlike other cereals, corn is low in the amino acid tryptophan, a precursor of niacin. Pellagra is the disease of dermatosis, diarrhea, and dementia. The first clinical features of pellagra

Pellagra

are demarcated, symmetrical areas of pigmentation and thickening and cracking of the skin where it is exposed to sunlight. The collar area is usually affected and provides a useful diagnostic sign ("Casal's collar"). In severer cases there are mental disturbances such as fatigue, depression, and progressive confusion. Gastrointestinal effects include diarrhea. Other B vitamins, especially riboflavin and vitamin B₆, are usually deficient, and complete treatment calls for multiple B vitamins (in diet or tablets), not just niacin.

Folic acid and vitamin B₁₂ deficiencies

The major effect of deficiency of either folic acid or vitamin B₁₂ is the failure of cell division because one of the family of folic acid compounds (5, 10-methyltetrahydrofolate) is required for addition of a methyl group to uracil to form thymine, one of the four bases of DNA. An important function of vitamin B₁₂ involves interconversion of folic acid compounds. (When it is lacking, the methyltetrahydrofolate compound accumulates and the compound required for DNA synthesis is not made.)

Cells that turn over rapidly are most affected by deficiencies of folic acid and vitamin B: red blood cells, white blood cells, and platelets all decrease in number. Replacement of the lining cells of the intestine and formation of germ cells are also affected. In the bone marrow the red cell precursors are larger than normal, with an immature nucleus, called megaloblastic change. Thus folic acid deficiency and vitamin B₁₂ deficiency each causes megaloblastic anemia.

Vitamin B₁₂ plays another biochemical role, unrelated to folic acid, in the maintenance of myelin (the sheath that forms around a nerve fibre) in the nervous system. In vitamin B₁₂ deficiency, unusual odd-numbered fatty acids appear in myelin, apparently because of the accumulation of three-carbon compounds instead of the usual two-carbon raw material for fatty acid synthesis. The usual symptom is subacute degeneration of both sensory and motor tracts in the spinal cord.

Folic acid deficiency can occur in late pregnancy, when the requirement is double that in other adults. It is also fairly common in patients with diseases in which cell division is increased; e.g., in blood diseases or cancer. The most common cause of vitamin B₁₂ deficiency is pernicious anemia, in which absorption of the vitamin is defective because of the failure of the stomach to secrete a special protein (intrinsic factor) that assists absorption of vitamin B₁₂ in the lower intestine. Dietary deficiency occurs in vegans, who eat no animal food. It takes five or more years of such a diet before symptoms appear because the stores of vitamin B₁₂ in the liver, although only about 1.5 milligrams; are enough to last about five years with the daily requirement as small as one microgram.

Fats and carbohydrates. Most human diets contain between 10 and 15 percent of the total calories as protein. In poor communities this is mostly from vegetable foods; in rich communities it is more from animal foods. The rest of the dietary energy comes from carbohydrates, fats, and, in some people, alcohol. The proportion of calories from fats is only about 10 percent in poor communities, but it is 40 percent or even more in rich communities. Carbohydrates vary reciprocally: from 75 to 80 percent in poor communities to 45 percent in rich communities (Figure 4).

Humans are adaptable omnivores and survive on a greater variety of foods and metabolic fuels than many other animals. Adaptations occur to a low or high carbohydrate/fat ratio. Dietary carbohydrates can be considered for nutritional purposes in three groups: (1) metabolically available sugars, (2) starches, and (3) carbohydrates not absorbed in the small intestine (unavailable carbohydrates)—mostly cellulose, hemicelluloses, and pectin. These are the main types of dietary fibre. The minimum requirement for available carbohydrate is low, only about 50 grams for an adult. Below this intake ketosis occurs. In practice, few diets contain as few carbohydrates as this, except for discredited very-low-carbohydrate weight-loss diets.

Essential fatty acids

There is also a minimum requirement for fat—not for total fat, but only for a small group of fatty acids, of which linoleic acid is the most abundant and arachidonic acid and α -linolenic acid the only other important ones (see Table 8). The basic requirement for essential fatty acids to prevent deficiency is 1 to 2 percent of dietary energy;

Figure 4: Dietary energy derived from fats, carbohydrates, and proteins as a percentage of total energy, related to the income or gross domestic product of 85 countries at 1962 values of money on a logarithmic scale.

From J. Perisse, F. Sizaret, and P. Francois, *Nutrition Newsletter* (1969); Food and Agriculture Organization

i.e., two to six grams of linoleic acid. The characteristics of essential fatty acid deficiency include a scaly dermatitis, poor wound healing, anemia, reduced platelet count, and fatty infiltration of the liver. Deficiency of essential fatty acids as a result of an inadequate diet is rare. Even if people do not eat separated fats (butter, oils, etc.), they usually obtain enough linoleic acid from the cell membranes of plant foods and meats. With total parenteral nutrition, however, essential fatty acid deficiency is well described. It will occur if this form of feeding is prolonged unless a lipid emulsion rich in linoleic acid (e.g., Intralipid) is added to the administered fluids. There is good evidence that amounts of linoleic acid several times the basic requirement can contribute to reducing the risk of coronary heart disease by different mechanisms, such as lowering the plasma cholesterol and reducing the tendency to thrombosis.

Inorganic elements. Twenty-two of the 103 chemical elements are required as nutrients by humans. Another three or four might yet be shown to be needed in minute amounts. Carbon, nitrogen, hydrogen, and oxygen make up the organic nutrients, and the latter two are also consumed as water. Cobalt is only required as vitamin B₁₂ and sulfur as part of the essential amino acids methionine and cystine. Requirements for the rest range from 0.1 milligram or less for iodine, selenium, and chromium to up to one to five grams per day for sodium, chloride, and potassium. Elements required in minute amounts, usually present in food and body tissues in small amounts, were formerly called trace elements because analysts could only report presence of an amount too small to quantify. With modern methods, such as advanced atomic absorption spectrometry, extremely low concentrations can be accurately determined, and there is no reason to separate trace elements from minerals. Table 5 shows that there is no grouping of requirements for the inorganic elements.

Requirements

Sodium depletion occurs, usually with accompanying water loss, as a result of massive loss of fluids; e.g., diarrhea, vomiting, and excessive urination. Sodium is the major ion in the extracellular fluid, the total volume of which contracts as does the blood volume; the blood pressure falls and the heart rate increases. The patient is weak and exhausted. Sodium depletion occurs in a number of disease states, and chloride depletion usually accompanies it.

Sodium depletion

Potassium depletion occurs in similar situations and may become obvious if sodium and water, but not potassium, are replaced. Potassium loss is especially likely to occur with diarrhea or overuse of purgatives, with regular use of diuretic drugs, with corticosteroid treatment, and with wasting diseases. In potassium depletion the serum potassium level is low, there is weakness of voluntary muscles, intestinal peristalsis may stop, and an electrocardiograph shows low T waves.

Calcium depletion, unlike that of sodium and potassium, is difficult to recognize because 99 percent of the calcium in the body is in the bones. A 1 percent reduction of

bone calcium is impossible to detect, but it is quite a large amount of the element (10 to 12 grams). The major questions about calcium are: whether a generous intake during childhood and adolescence will contribute to taller adult height or heavier bones (less likely to fracture or become osteoporotic in old age), and whether a generous intake of calcium from about 45 years onward will delay the development of osteoporosis. Osteoporosis is reduced bone mass (*i.e.*, for a particular length or volume of bone, there is less mineral [calcium phosphate] and less bone protein). Osteoporosis is common in postmenopausal women in industrial societies. It causes bone pain and a tendency to fractures. It clearly has multiple causes, including lack of exercise as well as the possibility of insufficient dietary calcium.

Hemo-
globin
and
anemia

Iron deficiency is common throughout the world, much more so in women than in men. Bleeding depletes the body of iron because each millilitre of blood contains 0.5 milligram of iron and the body does not actively excrete iron, so that excretion cannot be shut down to adapt to a negative iron balance. There are stores in the bone marrow and other tissues that are drawn on, and absorption of iron, which is always inefficient, becomes more efficient. The main function of iron is in the formation of hemoglobin, the red pigment of the blood that carries oxygen from the lungs to other tissues. When iron stores are empty there is anemia (reduced red blood cell count) with small cells containing less hemoglobin than normal (microcytic, hypochromic anemia).

Iodine deficiency is now rare in the industrial countries but is an important handicap to development in those inland and mountainous areas with poor transport. Iodine is necessary for the synthesis of the hormones of the thyroid gland. In the absence of adequate iodine, the thyroid enlarges because of increased secretion of pituitary thyrotrophin. It has come to be realized that where the frequency of endemic goitre is high, not only are occasional babies born with cretinism (a cause of mental defect and dwarfism), but a large percentage of apparently normal people in the community have minor abnormalities such as learning disabilities, deafness, and a higher rate of stillbirths and malformed babies. The World Health Organization is giving priority to reducing these iodine-deficiency disorders. It has been estimated that 400,000-000 people may be affected to some degree. Iodized salt is effective only in developed communities. For remote, isolated communities the best method of prevention is an injection of two millilitres of iodized oil to all women of childbearing age.

Zinc deficiency has been described in its different manifestations since the late 1960s, although its frequency and importance have not been clearly defined. Zinc is often associated with protein in foods, and zinc status is low in protein-energy malnutrition. Zinc deficiency has been claimed in a number of circumstances; *e.g.*, among adolescents in the Middle East, Australian Aborigines, alcoholics, those affected by chronic renal failure and anorexia nervosa, and possibly pregnant women. It is difficult to interpret the significance of moderate reductions of plasma zinc below the usual concentration. Some cases of deficiency have been validated; *e.g.*, by the body's response to zinc supplementation. Some clear examples of zinc deficiency were encountered in patients given total parenteral nutrition before it became routine to include zinc in the regimen. Features of zinc deficiency in humans have been protean: various combinations of loss of taste, retarded growth, delayed wound healing, baldness, pustular skin lesions, impotence in males, infertility in females, and reduced immunity to infections.

Fluorida-
tion

Epidemiological studies in the United States in the 1930s and 1940s revealed an inverse relationship between the fluoride content of natural waters and the rate of dental caries. Fluoridation of water supplies at one part per million is safe, though it may be associated with mottled (not carious) teeth in hot, dry countries where large amounts of water are drunk. Wherever fluoridation has been introduced, the number of decayed, missing, and filled teeth in children has decreased, and where fluoridation has been subsequently stopped, the rate of caries has increased

again. Fluoride is concentrated in the dental enamel and in bones. It increases the resistance of the enamel to erosion by acid. The chronic toxic dose of fluoride starts at intakes of about five milligrams per day; the first sign is mottling of the teeth. Above 10 milligrams per day bony outgrowths may occur (skeletal fluorosis). The only foods that contain appreciable amounts of fluoride are tea and fish. In communities and countries where the drinking water is not fluoridated many obtain some fluoride from toothpastes, a few give fluoride tablets to children prophylactically, and dentists apply fluoride solution directly to their patients' teeth periodically. The incidence of dental caries has fallen remarkably in most countries since the 1960s.

Selenium deficiency appears to be responsible for heart muscle disease (cardiomyopathy) in children in K'o-shan Hsien, a part of northeastern China where the soil has the lowest selenium content in the world. Deficiencies of phosphate, magnesium, copper, molybdenum, manganese, and chromium are rare because the levels in foods cover requirements in most situations.

Dietary fibre. Fibre is not a true nutrient in the classical sense. Dietary fibre is the natural packing of plant foods. It can be defined as those parts of foods that are not digested by human enzymes in the small intestine. The principal chemical classes of dietary fibre are cellulose, hemicelluloses, pectins, gums, and lignins. They are all polysaccharides (*i.e.*, unavailable carbohydrates) except lignin, which occurs with cellulose in the structure of plants. Pectins and gums are not really fibrous; they are amorphous and viscous.

Some types of fibre, notably the hemicellulose of the outer layers of wheat, increase the water-holding capacity of the contents of the large intestine and so increase the bulk of the feces. This relieves simple constipation and probably reduces the likelihood of diverticula forming in the large intestine in older people. There is some evidence that fibre may reduce the chances of developing cancer of the large intestine. Other viscous, indigestible polysaccharides like pectin and guar gum, when isolated and in large doses, have more effect on the upper gastrointestinal tract. They tend to slow gastric emptying and contribute to satiety. They slow the rise of blood glucose after a carbohydrate meal, and they reduce the plasma cholesterol concentration.

Uses of
dietary
fibre

Dietary fibre is in fact partly digested in the large intestine. It is fermented by some of the resident bacterial flora (not by enzymes), resulting in the production of gas (hydrogen, methane, or carbon dioxide) in the form of flatus. A small quantity of volatile fatty acids (acetic, butyric, or propionic) is absorbed through the lining cells of the large intestine. Thus, some of the chemical energy in fibre does become available. Much of the pectins and hemicelluloses are metabolized by colonic fermentation and so is some of the cellulose. Lignin, however, resists even bacterial action. There are no official RDAs for dietary fibres because analyses for the different types in foods are not complete, but the average adult intake of about 15 to 20 grams per day in affluent countries is thought to be too low. Increased intake is likely to be most helpful in people confined to bed, in pregnant women, and in the elderly, three groups of people often troubled with constipation. The food sources of fibre are cereals (especially whole grain), vegetables, nuts, and fruits. A concentrated form of the fibrous type is found in wheat bran. (A.S.T.)

OBESITY AND OTHER DISORDERS OF THE DIET

Obesity. By far the most common effect of continued overconsumption of calories is obesity, a state of excess accumulation of fat in and on the body. It is often wrongly defined as a state in which weight is in excess of a 10 percent margin allowed over standard weight tables for age, height, sex, and race. Fat on the body is easily seen and measured. It is assumed that if there is excess fat in the subcutaneous tissue, there is probably also excess fat inside the body. More accurately, the amount of fat in the body can be calculated from the specific gravity of the total body, which in turn is measurable by comparison of weight underwater with weight in air. The more fat

Theories concerning causes of obesity

there is, the lower is the body specific gravity. To describe weight in excess of 10 percent above standard weight as obesity is misleading, because a small minority of persons who have inherited a large frame and bulky muscles may be 20 percent or more in excess of standard weight without being obese. Nevertheless, weight is a valuable screening measure for obesity.

Obesity is caused by consistent consumption of more calories than are required to meet energy expenditure. This simple explanation, however, conceals a great deal of difficult theory about causation. It is probably true that some persons put on fat more readily than others. This may have a simple double explanation: namely, that these people are more interested in food or that they expend less energy. This latter theory probably accounts for obesity in only a small minority. Overeating may be a habit culturally imposed by family custom, may be an occupational hazard (e.g., of cooks), may follow immobilization, can be stimulated by certain drugs, or may be an expression of boredom or emotional frustration. Underexpenditure of energy may be determined by cultural family environment, sedentary life, or temperament. It has been shown that obese adolescents at summer camps expend less energy than their leaner friends, even when engaged in active games.

Obesity, like underweight, is a condition with multiple causes. Some people have a metabolic rate that is lower than average (they may feel the cold sooner than others). Whenever energy intakes have been measured over a week in a standardized group, some members are found to eat consistently less than others. They presumably adjust their energy intake to their lower energy expenditure. These efficient metabolizers would have a better chance of survival under conditions of chronic undernutrition. Certain ethnic groups have been noted to have a predisposition to obesity when food is plentiful—e.g., the Pima American Indians, Micronesians (notably in Nauru), and probably Polynesians and Australian Aborigines. It is postulated that they have evolved as metabolically “thrifty genotypes” because their ancestors went through periods of starvation. In the few short-term studies of experimental overeating, some subjects have not put on as much weight as expected. It is suggested that this may be because they retain some brown adipose tissue, a specialized type of fat tissue present in newborns that is rich in mitochondria and which (when stimulated by norepinephrine) produces a large amount of heat and uses a large amount of energy. No solid evidence has been found for this in humans, however.

Brown adipose tissue

The effects of obesity can be stated with more certainty. Obese persons have a reduced life expectancy, and they suffer disproportionately from a number of diseases and disabilities. Diabetes of the middle-aged is strongly associated with obesity, and there is association of obesity in females with gallbladder disease. Contrary to general impression, coronary heart disease is not causally related to obesity, but in some communities it has been reported that those who put fat on their trunks are more likely to suffer coronary disease, while those who put fat on their hips or buttocks are not. Anyone with heart disease should maintain a standard weight because obesity increases the load on the heart. Obesity is a mechanical load on the lower spine and the major weight-bearing joints, the hips, knees, and ankles. Reduction of the weight of obese persons may mitigate the middle-aged tendency to degenerative diseases of the joints and muscular rheumatism. Obesity of the trunk may interfere seriously with breathing and may contribute to pulmonary heart disease. There is considerable association, both as cause and effect, between obesity and psycho-emotional disturbance. Many obese persons suffer a considerable sense of inferiority. Misdirected attempts at weight reduction may lead to deficiency disease and debility or, in a few persons, may go on to self-imposed starvation (anorexia nervosa). (J.F.B./A.S.T.)

The scientific principles of management of obesity stress prevention because prevention is easier than treatment of established obesity. The psychological aspects of weight management are more important than details of the diet, because, without the inner motivation to reduce weight, it is impossible to make it happen. Major aspects of the help

that doctors and dietitians can offer centre on building up the person’s self-esteem and guiding the person in avoiding situations in which it is difficult to stop eating. Habits are more important than diets. Crash diets do not work and may be dangerous. A loss of about one kilogram (two pounds) per week is as much as can be expected; half of this is acceptable and all that some people can manage.

Weight management should fit the grade of the obesity. People with gross obesity (Table 11) require special medical treatment, and special surgical procedures, such as jaw wiring or gastric stapling, are often investigated for such individuals. It is more appropriate to treat people with moderate obesity using behaviour modification and a reduced-calorie diet.

Importance of self-esteem

Partly based on Table I from Royal College of Physician’s report *Obesity*, 1983, and J.S. Garrow, *Treat Obesity Seriously*, 1981.
Source: A. Stewart Truswell et al., *ABC of Nutrition* (1986).

The nutritional principles of weight reduction and management are to eat less—two-thirds or one-half of the food previously eaten, which corresponds to about 1,500 kilocalories for a man and 1,000 kilocalories for a woman. The foods that should be cut from the diet are the “empty calorie” foods—fats, alcohol, and sugars (in order of priority), which provide nine, seven, and four kilocalories per gram, respectively. Meals should not be missed and a variety of foods, including meat or fish, milk or cheese, bread or cereals, and vegetables and fruits should be eaten each day. Fatty foods and fried foods as well as “tempting foods” must be avoided. Foods vary considerably in calories per usual serving (Table 12).

Some of the techniques of behaviour modification include using a shopping list, purchasing only nonfattening foods (see Table 12), avoiding shopping when hungry, eating only in one room, eating slowly, avoiding distracting activities (except conversation) like watching television, and avoiding eating unnecessarily. A variety of low-calorie foods, like raw vegetables, should always be available to use as snacks. Other people can be recruited to help by reinforcing the positive benefits of not overeating. Nonedible rewards should be given for remaining on the program. Steps should be taken to minimize hunger, loneliness, depression, boredom, anger, and fatigue, each of which can set off a bout of overeating. Finally, the amount of exercise taken each day should be increased.

Anorexia nervosa. Anorexia nervosa is the opposite of obesity. It seems to occur only in societies where adequate food is taken for granted and where people may feel anxiety about avoiding obesity. In affluent communities many teenage girls and young women diet to stay slim or become slim, though their attempts may not be successful. The young woman with anorexia nervosa, on the other hand, does not talk about dieting but succeeds in losing

Societal influence

Table 12: Representative Energy Values of Some Common Foods

food	kilocalories	food	kilocalories	food	kilocalories
Cucumber (2 oz)	5	Bread (1 slice, 1 oz)	65	Carbonated soft drink (12-oz can)	155
Lettuce (1 oz)	5	Potatoes (new, boiled, 4 oz)	85	Peanuts (1 oz)	160
Cauliflower (4 oz, raw)	15	Egg (medium, boiled)	90	Cake, sponge (2 oz)	170
Tomatoes (4 oz)	15	Banana (1 fruit)	90	Chicken (meat only, roast, 4 oz)	170
Carrot (3 oz)	20	Wine (4 oz)	90	Cheese, Cheddar (1 1/2 oz)	175
Grapefruit (1/2 fruit = 6 oz)	20	Beer (1/2 pint)	90	Avocado (1/2 fruit)	190
Milk (1 oz, in tea)	20	Butter (1/2 oz, for slice of bread)	105	Rice (2 oz before cooking)	205

the weight that the others talk about losing. She does have an appetite but it is strongly suppressed. By rigid control of her eating she avoids foods that she understands to be fattening. She has a phobia of being fat and often has a distorted body image, seeing herself in the mirror as fatter than she really is. Amenorrhea (cessation of menstruation) is an early characteristic. Before the loss of weight she was often a model of good behaviour, conformism, and achievement, though this probably concealed a sense of ineffectiveness and self-doubt. Up to one in 100 middle-class women from 15 to 25 years may be affected. Some women not only abstain; they have learned to induce vomiting or purging and may have eating binges in between. When habitual, this behaviour is called bulimia nervosa.

The physical effects of a young woman starving herself down to 90 pounds (45 kilograms) or less differ in several ways from those of famine. The young woman with anorexia nervosa usually eats adequate protein and micronutrients; she is restless and overactive. She denies that she is too thin or that she is not eating enough.

Treatment is easiest if the condition is recognized at an early stage. It is best managed by a specialized team, most often a psychiatrist with experience in anorexia nervosa, working with a dietitian. The principles of treatment are behavioral therapy, supervised eating, and supportive psychotherapy.

Nutrient excess. Ethyl alcohol is the only drug that provides calories, although meals of nonalcoholic foods have a gentle sedative effect. The acute effects of a large intake of alcohol are well known. Mental impairment starts when the blood concentration is about 0.05 percent. Levels of alcohol in the blood up to 0.15 percent are the maximum permitted for drivers in many countries. When ingested, alcohol is rapidly distributed throughout the entire body. A concentration of alcohol in the blood of 0.40 percent usually causes unconsciousness, and 0.50 percent can be fatal. The most dangerous effects of acute alcohol intoxication, however, are road accidents and violence. The many complications of chronically high intakes of alcohol include gastric ulcer, pancreatitis, cirrhosis of the liver, convulsions, delirium tremens, hypertension, several varieties of malnutrition, and fetal malformations. Malnutrition is avoided if a nutritious diet is consumed along with the alcohol, but this does not prevent the rise of blood pressure, which is seen from about four drinks per day. Cirrhosis of the liver takes years to develop. The lowest chronic intake of alcohol that can lead to cirrhosis is difficult to determine partly because heavy drinkers underestimate their consumption and partly because of the other causes of liver damage; *e.g.*, viral hepatitis may coexist in an alcoholic. Eight or more drinks per day over the course of many years is the typical pattern of an alcoholic. Women with smaller lean body mass are more susceptible to hepatic damage from alcohol. Fetal alcohol syndrome (a combination of malformations with characteristic facial appearance) has been reported with apparently quite low alcohol intakes in the first trimester of pregnancy. Delirium tremens is the withdrawal syndrome of tremor, agitation, and occasionally hallucinations that is seen when heavy chronic drinkers are removed from their supply.

In all biologic systems the dose of an added substance, including nutrients, determines the effect. Nutrients taken

in amounts above the RDA can be toxic. The level at which the nutrient may exert toxic effects varies, and for some nutrients, such as vitamins A and D, iron, fluoride, selenium, and iodine, the level is much lower than for others. Among the vitamins, the rule that fat-soluble vitamins can be toxic but water-soluble vitamins are not cannot be relied upon because vitamin B₆ (water-soluble) has been found to cause peripheral neuropathy in doses at least 200 times the RDA, while no consistent side effect of large intakes of fat-soluble vitamin E has been shown. The toxic effects of vitamins A and D and of fluoride are described above.

Iron toxicity may be acute or chronic. Acute toxicity occurs if a number of sugar-coated iron tablets are accidentally swallowed; it can be fatal. Chronic iron intoxication occurs in persons who regularly consume acidic alcoholic drinks brewed in unlined iron vessels. Iron is dissolved in the drink and absorbed and deposited in the liver. The condition, hemosiderosis, has been reported in blacks in southern Africa and in some drinkers in Europe who consume large amounts of wine. Selenium toxicity occurs in animals grazing on selenium-rich soils (*e.g.*, in South Dakota). In humans it has occurred occasionally from industrial exposure and, rarely, from the diet (in an area of China) and following unintentional overdose of selenium supplement tablets. The clinical features are loss of hair and nails, skin lesions, gastrointestinal disturbances, lassitude, and polyneuritis.

There are two types of vitamin tablets: multivitamins and single vitamins. Multivitamin tablets are, in theory, harmless, though usually unnecessary. Most multivitamin preparations do not contain all 13 true vitamins, and the doses of vitamins they do contain usually deviate far from their RDAs. Single-vitamin preparations are more difficult to justify because it has been found that people often take the wrong supplements. In pregnancy, for example, the special need is for extra iron, folic acid, and calcium. Megadoses of vitamins carry the risk of toxic effects, especially for vitamins A, D, and B₆, and possibly for some of the other vitamins.

FOOD SENSITIVITY

Some foods and drinks are more likely to provoke sensitivity than others and people exhibit varying sensitivities to foods. The most common reactions are gastrointestinal, in the form of indigestion, vomiting, or diarrhea; urticaria and angioneurotic edema; eczema; asthma; and migraine. Gastrointestinal effects are the result of sensitivity to the irritant effect of one of the ingredients in food. In sensitive people, these ingredients might relax the cardiac sphincter at the lower end of the esophagus so that acid regurgitates from the stomach; they might stimulate gastric acid secretion; or they might increase the motility of the intestine.

When the onset of eczema is related to food it is the result of a true allergic mechanism, an abnormal immunological reaction by immunoglobulin E to one of the proteins of the food. Urticaria and asthma sometimes can be truly allergic reactions but it seems likely that other mechanisms are more usual. Urticaria in some people is due to naturally occurring salicylates in plant foods. It is thought that they act by inhibiting the enzyme cyclo-oxygenase and allowing more arachidonic acid to be converted to

Toxicity of nutrients

Common sensitivity reactions

Alcohol

leukotrienes by the action of the enzyme lipoxygenase. Whether hyperactivity in children (usually boys) is aggravated by naturally occurring food salicylates or by some artificial food colours is controversial. There is little objective confirmation of this belief.

A minority of sufferers from migraine are able to incriminate particular foods as provoking agents. Cheese, chocolate, citrus fruits, and alcoholic drinks are the most likely agents, possibly via pressor amines like tyramine and histamine, which tend to raise blood pressure.

There are other more specific examples of food sensitivity, the most important of which is celiac disease, or gluten enteropathy. There is malabsorption, fat in the faeces (steatorrhea), weight loss, impaired growth in children, and other manifestations of malnutrition. Celiac disease is due to atrophy (flattening of the cells) of the inner lining of the small intestine. This condition was first described in 1888, but it was not until 1953 that doctors in The Netherlands discovered that a fraction of wheat, the gluten, acts as a toxin in these patients. When wheat is meticulously eliminated from the diet, patients recover. This is one therapeutic diet that is literally lifesaving.

When symptoms of food sensitivity are immediate, the individual himself makes the diagnosis. There are some people, for instance, whose lips swell the moment their mouth touches a peanut, and if by chance they should swallow some they will have several systemic symptoms—vomiting, urticaria, even asthma. When the symptoms are more delayed, diagnosis of the responsible food or food component requires more detective work. If the symptoms are chronic or recur frequently, they should disappear on an elimination diet, a diet of very few foods (lamb, rice, carrots, lettuce, refined seed oil, sugar, and water) that do not cause food sensitivity. Suspected foods then can be reintroduced one at a time. Skin tests are not very reliable.

Not all people who believe they are sensitive to a particular food really are. They may in fact dislike the food, or they may have eaten it coincidentally with the onset of an illness, or they may have been told by an unorthodox practitioner that their symptoms are due to a particular food.

HABITUAL DIETARY PATTERNS AND DISEASE

A major preoccupation of nutrition research and a theme of the public debate over nutrition in North America, Europe, and Australasia is the relationship between the usual diet and the chances of developing (prematurely) one of the prevalent chronic degenerative diseases—coronary heart disease, high blood pressure, cancer, diabetes mellitus, dental caries, gallstones, urinary tract stones, colonic diverticulosis, cirrhosis of the liver, etc. Only the first five of these will be discussed below.

The causation of each of these degenerative diseases is multifactorial; there are several factors that act over a long period of time and interact with one another. There are protective factors as well as pathogenic factors; there are genetic, dietary, and non-dietary factors. Even in the diet there often appear to be multiple factors operating in different ways. The evidence for each disease comes from a variety of sources and several disciplines; from descriptive epidemiology—cross-sectional and retrospective; from prospective (cohort) epidemiological studies; from basic science (biochemistry, microbiology, pathology); from animal models; from human metabolic studies; and from prevention trials (primary or secondary).

Diet and coronary heart disease. In a prospective study, a large group of people at moderate risk of developing coronary heart disease (usually middle-aged Caucasian men) is examined and blood tests performed. The group is then followed up for five to 20 years, during which time some develop one of the manifestations of coronary heart disease, while most do not. Coronary heart disease may or may not show signs and symptoms of disease. When symptoms are present there are four possible manifestations: sudden cardiac death, myocardial infarction (the typical heart attack, requiring hospitalization and a period of time off of work), angina pectoris (heart pain on exertion), and cardiac failure with an electrocardiogram indicating that the cause is coronary artery insufficiency. Those who develop clinical coronary heart disease are

compared against the battery of findings at the initial examination to see which characteristics are “risk factors”; *i.e.*, strongly associated with the disease and appearing to be predictive. Over 20 prospective studies have been made on thousands of people in 14 countries. They have all found that the three biggest risk factors for coronary heart disease are a high plasma total cholesterol, cigarette smoking, and high blood pressure (hypertension).

Being lipid and nonpolar, cholesterol is totally insoluble in an aqueous solution. All cholesterol in blood plasma, therefore, is carried on lipoproteins. Low-density lipoprotein (LDL) cholesterol, which normally carries about three-fourths of the total cholesterol, is the risk factor; it can, in some situations, carry cholesterol into the inner lining of artery walls. High density lipoprotein (HDL) cholesterol, on the contrary, tends to act as a protective factor; it may be able to clear some of the cholesterol deposited in the periphery and carry it to the liver, where it can be excreted with the bile. Deposition of cholesterol on the inner aspect of the walls of arteries is part of the process of formation of atherosclerosis, the pathological basis of coronary heart disease. Plasma HDL cholesterol only makes up about one-quarter of normal total cholesterol concentration, and its level is higher in women than in men, but never very high. A total cholesterol that is high nearly always results from elevation of LDL cholesterol; when very high it is always due to raised LDL cholesterol. It is a little simpler and cheaper to measure total cholesterol than LDL cholesterol. When discussing elevation of cholesterol and its treatment the two terms are almost synonymous. A change of plasma total cholesterol means the same sort of change in LDL cholesterol.

Plasma (total or LDL) cholesterol may be raised as the inherited condition familial hypercholesterolemia, a condition with a tendency toward premature coronary heart disease. Plasma cholesterol is also raised secondary to certain diseases; *e.g.*, hypothyroidism, some types of kidney disease, bile duct obstruction, and diabetes mellitus. Finally, it is moderately raised by a diet rich in saturated fat and cholesterol, a phenomenon first demonstrated in rabbits just before World War I. From a global viewpoint such countries as Great Britain, Finland, Ireland, New Zealand, Czechoslovakia, Australia, Hungary, and the United States are high plasma cholesterol countries, consuming high-fat diets and experiencing high incidences of coronary heart disease. In residents of these countries plasma cholesterol (total and LDL) can be consistently reduced by combining the following dietary changes (listed in order of effectiveness): (1) reduce saturated fat as much as possible, (2) reduce energy intake if overweight, (3) increase consumption of vegetables, legumes, fruits, and cereals (preferably whole grain), (4) partly replace the reduced saturated fat with moderate increase of polyunsaturated and some monounsaturated oils, and (5) reduce dietary cholesterol. In practical dietetics these translate to avoiding butter, hydrogenated margarine, lard and suet, full-cream milk, cream, meat fat, frying, chocolate, and sausages; to restricting egg yolks, most cheeses, cakes, pastries, and cookies; and to eating more vegetables, legumes, fruits, bread, rice, pasta, breakfast cereals, polyunsaturated oils (*e.g.*, sunflower seed, safflower, corn oils), and skim or low-fat milk.

Plasma total (and LDL) cholesterol is related to the risk of coronary heart disease in a continuous gradient. The higher the plasma cholesterol above about 4.9 millimoles per litre (190 milligrams per 100 millilitres) the greater the chances of subsequent coronary heart disease (Figure 5). Trials in people starting with moderately elevated plasma cholesterol have shown that the amount of coronary heart disease is less in subsequent years in those given a cholesterol-lowering drug compared with untreated controls. A World Health Organization expert committee concluded in 1982 that there is a causal relationship between plasma total cholesterol and coronary heart disease. In high-incidence countries, the committee recommended lowering the whole population's plasma cholesterol distribution by progressive changes in eating patterns toward the sort of diet described in the preceding paragraph. Department of Health, as well as heart associations or foundations in other countries, have reached essentially the same conclusions and recommendations. Several countries, notably the United States, Australia, New Zealand, Belgium, and Finland have seen important reductions in mortality from coronary heart disease since the mid-1960s. There, the amount of cigarette smoking is decreasing in men, hypertension is being treated, and there have been some dietary changes. Total fat intake has not come down in general but polyunsaturated fat intake has gone up and with it the ratio of polyunsaturated to saturated fats. In the same period, mortality from coronary heart disease has been increasing in the Soviet Union and other countries of eastern Europe. The incidence of coronary heart disease remains very low in Japan.

Figure 5: Relation between serum (total) cholesterol and subsequent death rate from coronary heart disease in a prospective study of more than 361,000 men screened.

Coronary atherosclerosis takes years to develop. What determines the onset of coronary heart disease in a middle-aged person with moderately narrowed coronary arteries appears to be the acute superimposition of thrombosis. Thrombosis is initiated when platelets adhere to the vessel wall and to one another. Four of the polyunsaturated fatty acids in Table 8 appear to reduce the tendency of platelets to stick together. Linoleic and linolenic acids are found in plant seed oils like safflower and sunflower seed oils; eicosapentaenoic (EPA) and docosahexaenoic acids (DHA) are found in fatty fish. Both EPA and DHA are probably more active inhibitors weight-for-weight, but it is easier to obtain more linoleic acid from the diet. A fish oil concentrate containing 30 percent EPA and DHA is available in capsules at pharmacies. It does not lower plasma cholesterol. Its effect on platelet aggregation is probably due to the fact that EPA is the parent substance for an unusual series of prostaglandins.

Diet and blood pressure. Arterial hypertension affects 10 to 15 percent of older adults in most countries. It can lead to strokes, heart failure, kidney disease, and aneurysms and contributes to coronary heart disease. It is usually treated with drugs, but these often have side effects. There are, however, some seven dietary factors now known to influence blood pressure. If several are changed in the appropriate directions their effects may enable mild hypertensives to cease using drugs and moderate hypertensives to reduce the number or dosage of drugs. The seven dietary factors are: (1) Blood pressure tends to be higher in obese people and to fall if they successfully lose weight. (2) Blood pressure is increased in people who regularly take more than three alcoholic drinks per day. (3) The great majority of people in developed and many developing countries eat much more sodium, in the form of table salt (NaCl) than is necessary. In the few isolated communities that do not have salt, hypertension is rare.

When people with hypertension reduce their intake of table salt, blood pressure falls, although in some people the salt intake must fall so low that the diet must be radically changed. There is, however, little correlation between salt intake and blood pressure among individuals. It would seem that either only some people are sensitive to salt (perhaps genetically determined) or high salt intake only affects blood pressure over a long time. (4) Vegetarians tend to have lower blood pressures. (5) Potassium is a natural antagonist of sodium, and in some trials potassium tablets have produced significant lowering of blood pressure. (6) A change of the dietary fat from mostly saturated to mostly polyunsaturated has usually resulted in a small reduction of blood pressure. (7) Calcium is being investigated for its postulated blood-pressure-lowering action. In some trials calcium tablets have lowered blood pressure but not in others.

Diet and cancer. First, the best indication that habitual diet is one of the multiple risk factors for some types of cancer is the large differences recorded in age-standardized incidence (or mortality) tables of different types of cancer between human populations. Genetic concentration cannot explain most of these large differences; they must be environmental, and there is patchy evidence of association between diet and certain types of cancer. Second, in experimental animals (mostly small rodents), induction of some types of tumours is influenced by the nature of the animals' rations. Third, almost all foreign substances that are able to enter the human body must do so via the alimentary canal; *i.e.*, in food or drink. Substances that affect the pathogenesis of cancer work in one of two broad ways. They may initiate malignant change by gene toxicity, altering some of the DNA in the nucleus of a particular cell type: occasionally, one of these mutations results in unchecked growth of the cell. Alternatively, once tumour growth has started a substance may promote its growth or protect against its development.

There are three ways in which a person's usual diet may lead to cancer: (1) A carcinogenic (cancer-producing) substance in food (or drink) can come in contact with the epithelium (inner lining) of mouth, throat, esophagus, stomach, or, usually in chemically altered form, with the intestines, liver, or urinary bladder. Most such substances in food are only weakly carcinogenic and would have no effect taken once or twice, but they might lead to cancer if taken repeatedly over a long time. (2) The plane of nutrition (*i.e.*, whether a person is a little overfed or a little underfed) may influence the incidence of endocrine-dependent cancers by altering hormone secretion or metabolism. Cancers thought to be in this category are those of the breast, uterus, or prostate. (3) Some nutrients may influence susceptibility to carcinogenesis at other sites. A major question about diet and cancer is whether intakes of some nutrients could act as protective factors at intakes above the RDA and below the start of toxic levels. According to the "free radical hypothesis," free oxygen radicals sometimes arise from chemical processes in cells and may produce damage to DNA. This increases the chance of a carcinogenic mutation. Generous intake of one or more of the nutrients with antioxidant properties—vitamin A, vitamin C, vitamin E, selenium—might reduce this risk. This hypothesis is theoretical; evidence supporting it is small and circumstantial at present.

In 1981 Sir Richard Doll estimated the proportions of deaths from cancer in the United States that could be attributed to environmental factors. Potentially, cancer mortality could be reduced by these estimated proportions if specific environmental factors were identified and avoided. The diet group of factors (not food additives) was thought to be more important than any other group, responsible for around 38 percent of cancer deaths. While there is strong but indirect epidemiological evidence that most of the common cancers could be made less common by suitable modifications of food habits, there is still no precise and reliable evidence as to exactly what dietary changes would be of major importance. There are many different types of cancer, and knowledge of the relation between diet and even the most common types is many years behind the body of knowledge about diet and coro-

Carcinogenic substances

Environmental factors

Dietary factors

nary heart disease. Three major types illustrate that dietary factors differ for cancer in different sites.

Stomach cancer. Dietary factors associated with gastric cancer include dried salted fish, pickled foods, cured meats, high salt intake, and lack of domestic refrigerators. Foods that appear from surveys to be protective include salads and citrus fruits. The best-fitting hypothesis is that nitrates (in salts) form nitrites, which combine with secondary amines (derived from bacterial action on meat proteins) in the stomach to produce small amounts of potentially carcinogenic nitrosamines. In people who secrete subnormal amounts of gastric acid (achlorhydria), bacteria can live in the stomach and produce more nitrites. Refrigeration reduces secondary amine production in protein-rich foods; vitamin C (in salads and citrus) tends to inhibit formation of nitrosamine. The incidence of gastric cancer is declining spontaneously in all industrial countries.

Large intestinal cancer. Several studies both within and between countries suggest a pathogenic association between total fat intake and cancer of the colon or rectum and that both wheat fibre and brassica vegetables may protect against it. Meat consumption is usually correlated with fat but is less consistently related to cancer of the large intestine. Some types of beer have been associated with cancer of the rectum (the lower end of the large intestine). There have, however, been variations and inconsistencies in all the epidemiological studies. Most cancers of the large intestine appear to originate in polyps (precancerous adenomas), which are often multiple.

Breast cancer. The range between countries with the lowest and those with the highest mortalities from breast cancer is only sevenfold, so the environmental influence must be smaller than with some other cancers. Two sets of data have suggested a relationship of breast cancer with dietary fat: it is seen in between-country correlations and in experimental mammary tumours in mice and rats. In several case-control and two prospective studies, however, the association with dietary fat has been unimpressive or absent. In animal experiments it now seems that the effect originally attributed to fat could have been due, at least in part, to increased calorie intake.

Diabetes. In terms of diabetes, there are two questions about habitual diet: (1) whether diet predisposes a person to the development of diabetes, and, if so, which diet, and (2) which diet is best for the treatment of patients who have established diabetes.

There are two basic types of diabetes: insulin-dependent and non-insulin-dependent. Insulin-dependent diabetes usually starts in younger people; their islets of Langerhans secrete little or no insulin and they must receive one or more injections of insulin each day to control their blood glucose. Development of this type of diabetes is not related to diet. It occurs throughout the world and is probably the result of a viral infection or autoimmune (self-imposed by the body's own cells) damage to the islets of Langerhans.

Non-insulin-dependent (NID) diabetes is the more common type in developed communities. In NID, which usually starts in middle age, the patient's islets of Langerhans secrete normal amounts of insulin, but the tissues are resistant to insulin so that the response of blood glucose to insulin is subnormal. The NID type of diabetes is closely linked to obesity. Comparisons between countries suggest that a diet high in fat is likely to lead to diabetes. Findings of a decrease in the incidence of diabetes in periods of shortages (e.g., wartime) support this.

There is clearly a genetic predisposition to NID diabetes in those who become overweight or obese. This is seen most clearly in the Pima American Indians in Arizona and the Micronesians on the island of Nauru. When these people are obese the incidence of diabetes (in later life) is over 50 percent.

The proportions of carbohydrate in the therapeutic diet prescribed for diabetes have changed greatly from that used before and shortly after the introduction of insulin in 1921. At that time patients were expected to take diets with as little as five percent total carbohydrate. This meant that they were eating a very high-fat diet. Modern dietary prescriptions emphasize weight reduction for obese patients and a generous carbohydrate intake be-

cause: (1) Western diabetics are now more likely to die of atherosclerotic diseases like coronary heart disease than of uncontrolled diabetes; a high-fat diet would be harmful because it would raise their plasma cholesterol. (2) In Asian countries, diabetics can manage relatively well and have fewer complications on high-carbohydrate (e.g., rice) diets. It has been found that blood glucose is not as high after the ingestion of legumes, pasta, and many fruits and dairy products as after other carbohydrate foods like bread and potatoes.

Dental caries. Dental caries, or a hole in the enamel outer layer of the teeth, occurs all over the world. Ancient skeletons show that it has plagued humans for a long time. Its incidence is mostly in the first 25 years of life. Dental enamel is the hardest material in the body. Its weakness is that, because it is a form of calcium phosphate, it can be dissolved by acid. Three factors contribute to dental caries: the presence of a specific bacteria, sugars that these bacteria metabolize to lactic acid, and resistance of the enamel to bacterial colonization and carious attack.

A species of bacteria, *Streptococcus mutans*, is necessary for dental caries to occur. It is part of the bacterial population of most people's mouths, but some people harbour more than others. This organism not only metabolizes sucrose, glucose, fructose, or lactose to lactic acid, but it also converts them to sticky polymers (plaque) in which the bacteria are shielded from saliva and the tongue. Starches too, if they stay in the mouth, are split (depolymerized) by the amylase enzyme in saliva to glucose, which the streptococci can also use as substrate. Consumption of sugary or starchy foods between meals, especially if they are sticky, favours the development of caries.

In the teeth the most susceptible surfaces are in the fissures and between the teeth, where plaque is least disturbed by saliva, chewing, the tongue, or toothbrush. A fluoride intake of one to three milligrams per day—as with fluoridated drinking water—increases the enamel's resistance to acid attack, especially if the fluoride is taken while the tooth's enamel is being formed in the jaws before the permanent teeth erupt.

DIETARY GUIDELINES

Dietary goals, or guidelines, are a more recent tool for nutritional advice than RDAs. They aim not to provide enough of the essential nutrients but to reduce the chances of developing chronic degenerative diseases. While there has never been more than one RDA committee and report in a country, there can be several sets of dietary guidelines.

Dietary guidelines start not from zero intake (as for RDAs) but from the present estimated national average diet. They deal not with energy requirements but with optimal proportions of the energy-yielding dietary components—how much carbohydrate and fat and what type. Dietary guidelines are not usually expressed as weight of nutrient per day but as percentage change of food components from the present average intake. They are targets for the community to aim for, not what people have to eat that week. The first set of dietary guidelines in the world appeared in 1968 in Scandinavia. The following is a summary of the dietary guidelines for Americans suggested by the United States Department of Agriculture and the United States Department of Health and Human Services.

The daily diet should contain a variety of foods in adequate amounts, including selections from the food groups discussed above. Ideally, an infant should be breast-fed unless there are special problems, and other foods should be delayed until a baby is four to six months old; salt or sugar should not be added to the food. A healthy weight should be maintained. Excessive amounts of fat and fatty foods, sugar and sweets, and alcoholic beverages should be avoided; pregnant women are advised to refrain from the use of alcohol. Physical activity should be increased.

Excess fat, saturated fat, and cholesterol should be avoided; instead lean meat, fish, poultry, and dry beans and peas should be used as protein sources. Skim or low-fat milk and milk products should be used. Egg yolks, organ meats, fats and oils (especially those high in saturated fat, such as butter, cream, lard, heavily hydrogenated fats, shortenings, and foods containing palm and coconut

Pathogens

Plaque

Types of diabetes

Goals of the guidelines

Changes in diet

oils) should be avoided. Foods should be broiled (grilled), baked, or boiled rather than fried.

Foods with adequate starch and fibre should be part of the diet. The use of large amounts of sugars and foods containing large amounts of sugars should be avoided, as should large amounts of sodium. Food should be flavoured with herbs, spices, and lemon juice instead of salt.

Dietary guidelines will have to be amended, developed, and added to as knowledge of the relationship between habitual diet and disease grows by research. They should be modified based on age and sex, as well as for individuals who appear to be more or less sensitive to sodium, dietary cholesterol, and so on. They are, however, a valuable statement of consensus among a country's orthodox scientific nutritionists of the direction in which ordinary healthy people are advised to move their dietary habits to improve their chances of better health in the future—not to guarantee it.

BIBLIOGRAPHY

General works: Major journals covering general human and animal nutrition include *The Journal of Nutrition* (monthly); *The British Journal of Nutrition* (bimonthly); *Nutrition Abstracts and Reviews: Series A. Human and Experimental* (monthly); *Nutrition Abstracts and Reviews: Series B. Livestock Feeds and Feeding* (monthly); *The American Journal of Clinical Nutrition* (monthly); *European Journal of Clinical Nutrition* (monthly); *Journal of the American Dietetic Association* (monthly); *Nutrition Reviews* (monthly); and *Annual Review of Nutrition*.

Requirements for nutrients and nutrition: The nutritional requirements of microorganisms are detailed in BEVERLY M. GUIRARD and ESMOND E. SNELL, "Biochemical Factors in Growth," ch. 7, pp. 79–111, in PHILIPP GERHARDT (ed.), *Manual of Methods for General Bacteriology* (1981). Good sources on animal nutrition in general with information on particular animals, such as ruminants, include P. McDONALD, R.A. EDWARDS, and J.F.D. GREENHALGH, *Animal Nutrition*, 4th ed. (1988); and D.C. CHURCH, *Digestive Physiology and Nutrition of Ruminants*, 2nd ed., vol. 2, "Nutrition" (1979). Most common (and some uncommon) animals are covered in "Nutrient Requirements of Domestic Animals," a multivolume series by the National Research Council (U.S.); as well as in "The Nutrient Requirements of Farm Livestock," a series by the British Agricultural Research Council. See also E.J. UNDERWOOD, *The Mineral Nutrition of Livestock*, 2nd ed. (1981); and WALTER MERTZ (ed.), *Trace Elements in Human and Animal Nutrition*, 5th ed., 2 vol. (1986–87), a classic text on inorganic micronutrients.

Human metabolism and nutrition: General comprehensive information is presented in GREAT BRITAIN. MINISTRY OF AGRICULTURE, FISHERIES, AND FOOD, *Manual of Nutrition*, 8th ed. (1976); ETHEL AUSTIN MARTIN and ARDATH ANDERS COOLIDGE, *Nutrition in Action*, 4th ed. (1978); and A. STEWART TRUSWELL et al., *ABC of Nutrition* (1986), a collection of articles from the *British Medical Journal. Nutrition Reviews: Present Knowledge in Nutrition*, 5th ed. (1984), is a major text providing broad coverage; as is *Davidson and Passmore Human Nutri-*

tion and Dietetics, 8th ed., rev. by R. PASSMORE and M.A. EASTWOOD (1986). Special topics in human nutrition are studied in RICHARD B. LEE and IRVEN DEVORE (eds.), *Man the Hunter* (1969), and *Kalahari Hunter-Gatherers: Studies of the !Kung San and Their Neighbors* (1976), in which see especially A. STEWART TRUSWELL and J.D.L. HANSEN, "Medical Research Among the !Kung." See also M. ISABEL IRWIN et al., *Nutritional Requirements of Man: A Conspectus of Research* (1980); SAMUEL J. FOMON, *Infant Nutrition*, 2nd ed. (1974); DERRICK B. JELLIFFE and E.F. PATRICE JELLIFFE, *Human Milk in the Modern World: Psychosocial, Nutritional, and Economic Significance* (1978); and MARTHA L. HUTCHINSON and HAMISH N. MUNRO (eds.), *Nutrition and Aging* (1986).

Foods: The composition and nutritional value of foods, in tabular form, are presented in McCance and Widdowson's *The Composition of Foods*, 4th rev. ed., edited by A.A. PAUL and D.A.T. SOUTHGATE (1978); and in many issues of the *Agriculture Handbook* (irregular), published by the United States Department of Agriculture.

Nutrition recommendations: Recommended dietary allowances are studied in WORLD HEALTH ORGANIZATION, *Energy and Protein Requirements: Report* (1985); A. SHILS and VERNON R. YOUNG (eds.), *Modern Nutrition in Health and Disease*, 7th ed. (1988); GREAT BRITAIN. PANEL ON DIET IN RELATION TO CARDIOVASCULAR DISEASE, *Diet and Cardiovascular Disease: Report* (1984); WORLD HEALTH ORGANIZATION, *Prevention of Coronary Heart Disease: Report* (1982); and NATIONAL RESEARCH COUNCIL (U.S.), *Diet, Nutrition, and Cancer* (1982).

(A.S.T.)

Occultism

Occultism encompasses a wide range of theories and practices involving a belief in and knowledge or use of supernatural forces or beings. Such beliefs and practices—principally magical or divinatory—have occurred in all human societies throughout recorded history, with considerable variations both in their nature and in the attitude of societies toward them. In the West the term occultism has acquired intellectually and morally pejorative overtones that do not obtain in other societies where the practices and beliefs concerned do not run counter to the prevailing worldview.

Occult practices centre on the presumed ability of the practitioner to manipulate natural laws for his own or his client's benefit; such practices tend to be regarded as evil only when they also involve the breaking of moral laws. Some anthropologists have argued that it is not possible to make a clear-cut distinction between magic—a principal component of occultism—and religion, and this may well be true of the religious systems of some nonliterate societies. The argument does not hold, however, for any of the major religions, which regard both natural and moral law as immutable.

Those aspects of occultism that appear to be common to all human societies—divination, magic, witchcraft, and alchemy—are treated in depth below. Features that are unique to Western cultures, and the history of their development, are treated only briefly.

The Western tradition of occultism, as popularly conceived, is of an ancient "secret philosophy" underlying all occult practices. This secret philosophy derives ultimately from Hellenistic magic and alchemy on the one hand and from Jewish mysticism on the other. The principal Hellenistic source is the *Corpus Hermeticum*, the texts associated with Hermes Trismegistos, which are concerned with astrology and other occult sciences and with spiritual regeneration.

The Jewish element is supplied by the Kabbala (the doctrine of a secret, mystical interpretation of the Torah), which had been familiar to scholars in Europe since the Middle Ages, and which was linked with the Hermetic texts during the Renaissance. The resulting Hermetic-

Kabbalistic tradition, known as Hermetism, incorporated both theory and magical practice, with the latter presented as natural, and thus good, magic, in contrast to the evil magic of sorcery or witchcraft.

Alchemy was also absorbed into the body of Hermetism, and this link was strengthened in the early 17th century with the appearance of Rosicrucianism, an alleged secret brotherhood that utilized alchemical symbolism and taught secret wisdom to its followers, creating a spiritual alchemy that survived the rise of empirical science and enabled Hermetism to pass unscathed into the period of the Enlightenment.

During the 18th century the tradition was taken up by esoterically inclined Freemasons who could not find an occult philosophy within Freemasonry. These enthusiasts persisted, both as individual students of Hermetism and, in continental Europe, as groups of occult practitioners, into the 19th century, when the growth of religious skepticism led to an increased rejection of orthodox religion by the educated and a consequent search for salvation by other means—including occultism.

But those interested turned to new forms of occultism rather than to the Hermetic tradition: on the one hand to Spiritualism—the practice of alleged regular communication between the living and the spirits of the dead through a living "medium"—and on the other to Theosophy—a blend of Western occultism and Eastern mysticism that proved to be a most effective propagator of occultism but whose influence has declined markedly over the last 50 years.

Indeed, despite the 19th-century revival, occult ideas have failed to gain acceptance in academic circles, although they have occasionally influenced the work of major artists, such as the poet William Butler Yeats and the painter Wassily Kandinsky, and occultism in Europe and North America seems destined to remain the province of popular culture. Relation-
ship of
alchemy
and
astrology

Alchemy

Alchemy was the name given, in Latin Europe, from the 12th century, to an aspect of thought that corresponds to astrology, which is apparently an older tradition. Both represent attempts to discover the relationship of man to the cosmos and to exploit that relationship to his benefit. The first of these objectives may be called scientific, the second technological. Astrology (see below) is concerned with man's relationship to "the stars" (including the members of the solar system); alchemy, with terrestrial nature. But the distinction is far from absolute, since both are interested in the influence of the stars on terrestrial events. Moreover, both have always been pursued in the belief that the processes human beings witness in heaven and on earth manifest the will of the Creator and, if correctly understood, will yield the key to the Creator's intentions.

NATURE AND SIGNIFICANCE

That both astrology and alchemy may be regarded as fundamental aspects of thought is indicated by their apparent universality. It is notable, however, that the evidence is not equally substantial in all times and places. Evidence from ancient Middle America (Aztecs, Mayans) is still almost nonexistent; evidence from India is tenuous and from ancient China, Greece, and Islāmic lands is only relatively more plentiful. A single manuscript of some 80,000 words is the principal source for the history of Greek alchemy. Chinese alchemy is largely recorded in about 100 "books" that are part of the Taoist canon. Neither Indian nor Islāmic alchemy has ever been collected, and scholars are thus dependent for their knowledge of the subject on occasional allusions in works of natural philosophy and medicine, plus a few specifically alchemical works.

Nor is it really clear what alchemy was (or is). The word is a European one, derived from Arabic, but the origin of the root word, *chem*, is uncertain. Words similar to it have been found in most ancient languages, with different meanings, but conceivably somehow related to alchemy. In fact, the Greeks, Chinese, and Indians usually referred to what Westerners call alchemy as "The Art," or by terms denoting change or transmutation.

The chemistry of alchemy. Superficially, the chemistry involved in alchemy appears a hopelessly complicated succession of heatings of multiple mixtures of obscurely named materials, but it seems likely that a relative simplicity underlies this complexity. The metals gold, silver, copper, lead, iron, and tin were all known before the rise of alchemy. Mercury, the liquid metal, certainly known before 300 BC, when it appears in both Eastern and Western sources, was crucial to alchemy. Sulfur, "the stone that burns," was also crucial. It was known from prehistoric times in native deposits and was also given off in metallurgic processes (the "roasting" of sulfide ores). Mercury united with most of the other metals, and the amalgam formed coloured powders (the sulfides) when treated with sulfur. Mercury itself occurs in nature in a red sulfide, cinnabar, which can also be made artificially. All of these, except possibly the last, were operations known to the metallurgist and were adopted by the alchemist.

The alchemist added the action on metals of a number of corrosive salts, mainly the vitriols (copper and iron sulfates), alums (the aluminum sulfates of potassium and ammonium), and the chlorides of sodium and ammonium. And he made much of arsenic's property of colouring metals. All of these materials, except the chloride of ammonia, were known in ancient times. Known as *sal ammoniac* in the West, *nao sha* in China, *nao sadar* in India, and *mushādir* in Persia and Arabic lands, the chloride of ammonia first became known to the West in the *Chou-i ts'an t'ung ch'i*, a Chinese treatise of the 2nd century AD. It was to be crucial to alchemy, for on sublimation it dissociates into antagonistic corrosive materials, ammonia and hydrochloric acid, which readily attack the metals. Until the 9th century it seems to have come from a single source, the Flame Mountain (Huo-yen Shan) near T'u-lu-p'an (Turfan), in Central Asia.

Finally, the manipulation of these materials was to lead to the discovery of the mineral acids, the history of

which began in Europe in the 13th century. The first was probably nitric acid, made by distilling together saltpetre (potassium nitrate) and vitriol or alum. More difficult to discover was sulfuric acid, which was distilled from vitriol or alum alone but required apparatus resistant to corrosion and heat. And most difficult was hydrochloric acid, distilled from common salt or *sal ammoniac* and vitriol or alum, for the vapours of this acid cannot be simply condensed but must be dissolved in water.

Goals. "Transmutation" is the key word characterizing alchemy, and it may be understood in several ways: in the changes that are called chemical, in physiological changes such as passing from sickness to health, in a hoped-for transformation from old age to youth, or even in passing from an earthly to a supernatural existence. Alchemical changes seem always to have been positive, never involving degradation except as an intermediate stage in a process having a "happy ending." Alchemy aimed at the great human "goods": wealth, longevity, and immortality.

Alchemy was not original in seeking these goals, for it had been preceded by religion, medicine, and metallurgy. The first chemists were metallurgists, who were perhaps the most successful practitioners of the arts in antiquity. Their theories seem to have come not from science but from folklore and religion. The miner and metallurgist, like the agriculturalist, in this view, accelerate the normal maturation of the fruits of the earth, in a magico-religious relationship with nature. In primitive societies the metallurgist is often a member of an occult religious society.

But the first ventures into natural philosophy, the beginnings of what is called the scientific view, also preceded alchemy. Systems of five almost identical basic elements were postulated in China, India, and Greece, according to a view in which nature comprised antagonistic, opposite forces—hot and cold, positive and negative, and male and female; *i.e.*, primitive versions of the modern conception of energy. Drawing on a similar astrological heritage, philosophers found correspondences among the elements, planets, and metals. In short, both the chemical arts and the theories of the philosophers of nature had become complex before alchemy appeared.

REGIONAL VARIATIONS

Chinese alchemy. Neither in China nor in the West can scholars approach with certitude the origins of alchemy, but the evidences in China appear to be slightly older. Indeed, Chinese alchemy was connected with an enterprise older than metallurgy—*i.e.*, medicine. Belief in physical immortality among the Chinese seems to go back to the 8th century BC, and belief in the possibility of attaining it through drugs to the 4th century BC. The magical drug, namely the "elixir of life" (elixir is the European word), is mentioned about that time, and that most potent elixir, "drinkable gold," which was a solution (usually imaginary) of this corrosion-resistant metal, as early as the 1st century BC—many centuries before it is heard of in the West.

Although non-Chinese influences (especially Indian) are possible, the genesis of alchemy in China may have been a purely domestic affair. It emerged during a period of political turmoil, the Warring States Period (from the 5th to the 3rd century BC), and it came to be associated with Taoism—a mystical religion founded by the 6th-century-BC sage Lao-tzu—and its sacred book, the *Tao-te Ching* ("Classic of the Way of Power"). The Taoists were a miscellaneous collection of "outsiders"—in relation to the prevailing Confucians—and such mystical doctrines as alchemy were soon grafted onto the Taoist canon. What is known of Chinese alchemy is mainly owing to that graft, and especially to a collection known as *Yün chi ch'i ch'ien* ("Seven Tablets in a Cloudy Satchel"), which is dated 1023. Thus, sources on alchemy in China (as elsewhere) are compilations of much earlier writings.

The oldest known Chinese alchemical treatise is the *Chou-i ts'an t'ung ch'i* ("Commentary on the *I Ching*"). In the main it is an apocryphal interpretation of the *I Ching* ("Classic of Changes"), an ancient classic especially esteemed by the Confucians, relating alchemy to the mystical mathematics of the 64 hexagrams (six-line figures used for divination). Its relationship to chemical practice

Wealth,
longevity,
and im-
mortality

is tenuous, but it mentions materials (including sal ammoniac) and implies chemical operations. The first Chinese alchemist who is reasonably well known was Ko Hung (AD 283–343), whose book *Pao-p'u-tzu* (pseudonym of Ko Hung) contains two chapters with obscure recipes for elixirs, mostly based on mercury or arsenic compounds. The most famous Chinese alchemical book is the *Tan chin yao chüeh* (“Great Secrets of Alchemy”), probably by Sun Ssu-miao (AD 581–after 673). It is a practical treatise on creating elixirs (mercury, sulfur, and the salts of mercury and arsenic are prominent) for the attainment of immortality, plus a few for specific cures for disease and such other purposes as the fabrication of precious stones.

Objective
of Chinese
alchemy

Altogether, the similarities between the materials used and the elixirs made in China, India, and the West are more remarkable than are their differences. Nonetheless, Chinese alchemy differed from that of the West in its objective. Whereas in the West the objective seems to have evolved from gold to elixirs of immortality to simply superior medicines, neither the first nor the last of these objectives seems ever to have been very important in China.

Chinese alchemy was consistent from first to last, and there was relatively little controversy among its practitioners, who seem to have varied only in their prescriptions for the elixir of immortality or perhaps only over their names for it, of which one Sinologist has counted about 1,000. In the West there were conflicts between advocates of herbal and “chemical” (i.e., mineral) pharmacy, but in China mineral remedies were always accepted. There were, in Europe, conflicts between alchemists who favoured gold making and those who thought medicine the proper goal, but the Chinese always favoured the latter. Since alchemy rarely achieved any of these goals, it was an advantage to the Western alchemist to have the situation obscured, and the art survived in Europe long after Chinese alchemy had simply faded away.

Chinese alchemy followed its own path. Whereas the Western world, with its numerous religious promises of immortality, never seriously expected alchemy to fulfill that goal, the deficiencies of Chinese religions in respect to promises of immortality left that goal open to the alchemist. A serious reliance on medical elixirs that were in varying degrees poisonous led the alchemist into permanent exertions to moderate those poisons, either through variation of the ingredients or through chemical manipulations. The fact that immortality was so desirable and the alchemist correspondingly valued enabled the British historian of science Joseph Needham to tabulate a series of Chinese emperors who probably died of elixir poisoning. Ultimately a succession of royal deaths made alchemists and emperors alike more cautious, and Chinese alchemy vanished (probably as the Chinese adopted Buddhism, which offered other, less dangerous avenues to immortality), leaving its literary manifestations embedded in the Taoist canons.

Indian alchemy. The oldest Indian writings, the Vedas (Hindu sacred scriptures), contain the same hints of alchemy that are found in evidence from ancient China, namely vague references to a connection between gold and long life. Mercury, which was so vital to alchemy everywhere, is first mentioned in the 4th- to 3rd-century-BC *Artha-shāstra*, about the same time it is encountered in China and in the West. Evidence of the idea of transmuting base metals to gold appears in 2nd- to 5th-century-AD Buddhist texts, about the same time as in the West. Since Alexander the Great had invaded India in 325 BC, leaving a Greek state (Gandhāra) that long endured, the possibility exists that the Indians acquired the idea from the Greeks, but it could have been the other way around.

Medical
and
religious
concerns
of Indian
alchemy

It is also possible that the alchemy of medicine and immortality came to India from China, or vice versa; in any case, gold making appears to have been a minor concern, and medicine the major concern, of both cultures. But the elixir of immortality was of little importance in India (which had other avenues to immortality). The Indian elixirs were mineral remedies for specific diseases or, at the most, to promote long life.

As in China and the West, alchemy in India came to be associated with religious mysticism, but much later—not

until the rise of Tantrism (an esoteric, occultic, meditative system), AD 1100–1300. To Tantrism are owed writings that are clearly alchemical (such as the 12th-century *Rasārṇava*, or “Treatise on Metallic Preparations”).

From the earliest records of Indian natural philosophy, which date from the 5th–3rd centuries BC, theories of nature were based on conceptions of material elements (fire, wind, water, earth, and space), vitalism (“animated atoms”), and dualisms of love and hate or action and reaction. The alchemist coloured metals and on occasion “made” gold, but he gave little importance to that. His six metals (gold, silver, tin, iron, lead, and copper), each further subdivided (five kinds of gold, etc.), were “killed” (i.e., corroded) but not “resurrected,” as was the custom of Western alchemy. Rather, they were killed to make medicines. Although “the secrets of mercurial lore” became part of the Tantric rite, mercury seems to have been much less important than in China. The Indians exploited metal reactions more widely, but, although they possessed from an early date not only vitriol and sal ammoniac but also saltpetre, they nevertheless failed to discover the mineral acids. This is the more remarkable because India was long the principal source of saltpetre, which occurs as an efflorescence on the soil, especially in populous tropical countries. But it lacks the high degree of corrosivity of metals possessed by the vitriols and chlorides and played a small part in early alchemy. Saltpetre appears particularly in 9th- to 11th-century-AD Indian and Chinese recipes for fireworks, one of which—a mixture of saltpetre, sulfur, and charcoal—is gunpowder. Saltpetre first appears in Europe in the 13th century, along with the modern formula for gunpowder and the recipe for nitric acid.

Hellenistic alchemy. Western alchemy may go back to the beginnings of the Hellenistic period (c. 300 BC–c. AD 300), although the earliest alchemist whom authorities have regarded as authentic is Zosimos of Panopolis (Egypt), who lived near the end of the period. He is one of about 40 authors represented in a compendium of alchemical writings that was probably put together in Byzantium (Constantinople) in the 7th or 8th century AD and that exists in manuscripts in Venice and Paris. Synesius, the latest author represented, lived in Byzantium in the 4th century. The earliest is the author designated Democritus but identified by scholars with Bolos of Mende, a Hellenized Egyptian who lived in the Nile Delta about 200 BC. He is represented by a treatise called *Physica et mystica* (“Natural and Mystical Things”), a kind of recipe book for dyeing and colouring but principally for the making of gold and silver. The recipes are stated obscurely and are justified with references to the Greek theory of elements and to astrological theory. Most end with the phrase “One nature rejoices in another nature; one nature triumphs over another nature; one nature masters another nature,” which authorities variously trace to the Magi (Zoroastrian priests), Stoic pantheism (a Greek philosophy concerned with nature), or to the 4th-century-BC Greek philosopher Aristotle. It was the first of a number of such aphorisms over which alchemists were to speculate for many centuries.

The importance
of the
*Physica
et mystica*

In 1828 a group of ancient papyrus manuscripts written in Greek was purchased in Thebes (Egypt), and about a half-century later it was noticed that among them, divided between libraries in Leyden (The Netherlands) and Stockholm, was a tract very like the *Physica et mystica*. It differed, however, in that it lacked the former’s theoretical embellishments and stated in some recipes that only fraudulent imitation of gold and silver was intended. Scholars believe that this kind of work was the ancestor both of the *Physica et mystica* and of the ordinary artist’s recipe book. The techniques were ancient. Archaeology has revealed metal objects inlaid with colours obtained by grinding metals with sulfur, and Homer’s description (8th century BC) of the shield of Achilles gives the impression that the artist in his time was virtually able to paint in metal.

Democritus is praised by most of the other authors in the Venice–Paris manuscript, and he is much commented upon. But only Zosimos shows what had become of alchemy after Bolos of Mende. His theory is luxuriant in imagery, beginning with a discussion of “the composition

of waters, movement, growth, embodying and disembodying, drawing the spirits from bodies and binding the spirits within bodies" and continuing in the same vein. The "base" metals are to be "ennobled" (to gold) by killing and resurrecting them, but his practice is full of distillation and sublimation, and he is obsessed with "spirits." Theory and practice are joined in the concept that success depends upon the production of a series of colours, usually black, white, yellow, and purple, and that the colours are to be obtained through *Theion hydōr* (divine or sulfur water—it could mean either).

Zosimos credits these innovations mainly to Maria (sometimes called "the Jewess"), who invented the apparatus, and to Agathodaimon, probably a pseudonym. Neither is represented (beyond Zosimos' references) in the Venice-Paris manuscript, but a tract attributed to Agathodaimon, published in 1953, shows him to be preoccupied with the colour sequence and complicating it by using arsenic instead of sulfur. Thus, the colour-producing potentialities of chemistry were considerable by the time of Zosimos.

Zosimos also shows that alchemical theory came to focus on the idea that there exists a substance that can bring about the desired transformation instantly, magically, or, as a modern chemist might say, catalytically. He called it "the tincture," and had several. It was also sometimes called "the powder" (*xērion*), which was to pass through Arabic into Latin as elixir and finally (signifying its inorganic nature) as the "philosopher's stone," "a stone which is not a stone," as the alchemists were wont to say. It was sometimes called a medicine for the rectification of "base" or "sick" metals, and from this it was a short step to view it as a drug for the rectification of human maladies. Zosimos notes the possibility, in passing. When the objective of alchemy became human salvation, the material constitution of the elixir became less important than the incantations that accompanied its production. Synesius, the last author in the Venice-Paris manuscript, already defined alchemy as a mental operation, independent of the science of matter.

Thus, Greek alchemy came to resemble, in both theory and practice, that of China and India. But its objectives included gold making; thus it remained fundamentally different.

Arabic alchemy. Arabic alchemy is as mysterious as Greek in its origins, and the two seem to have been significantly different. The respect in which *Physica et mystica* was held by the Greek alchemists was bestowed by the Arabs on a different work, the *Emerald Tablet* of Hermes Trismegistos, the reputed Hellenistic author of various alchemical, occultic, and theological works. Beginning "That which is above is like to that which is below, and that which is below is like to that which is above," it is brief, theoretical, and astrological. Hermes "the thrice great" (Trismegistos) was a Greek version of the Egyptian god Thoth and the supposed founder of an astrological philosophy that is first noted in 150 BC. The *Emerald Tablet*, however, comes from a larger work called *Book of the Secret of Creation*, which exists in Latin and Arabic manuscripts and was thought by the Muslim alchemist ar-Rāzī to have been written during the reign of Caliph al-Ma'mūn (AD 813–833), though it has been attributed to the 1st-century-AD pagan mystic Apollonius of Tyana.

Some scholars have suggested that Arabic alchemy descended from a western Asiatic school and that Greek alchemy was derived from an Egyptian school. As far as is known, the Asiatic school was not Chinese or Indian. What is known is that Arabic alchemy was associated with a specific city in Syria, Harran, which seems to have been a fountainhead of alchemical notions. And it is possible that the distillation ideology and its spokeswoman, Maria—as well as Agathodaimon—represented the alchemy of Harran, which presumably migrated to Alexandria and was incorporated into the alchemy of Zosimos.

The existing versions of the *Book of the Secret of Creation* have been carried back only to the 7th or 6th century but are believed by some to represent much earlier writings, although not necessarily those of Apollonius himself. He is the subject of an ancient biography that says nothing about alchemy, but neither does the *Emerald Tablet* nor

the rest of the *Book of the Secret of Creation*. On the other hand, their theories of nature have an alchemical ring, and the *Book* mentions the characteristic materials of alchemy, including, for the first time in the West, sal ammoniac. It was clearly an important book to the Arabs, most of whose eminent philosophers mentioned alchemy, although sometimes disapprovingly. Those who practiced it were even more interested in literal gold making than had been the Greeks. The most well-attested and probably the greatest Arabic alchemist was ar-Rāzī (c. 850–923/924), a Persian physician who lived in Baghdad. The most famous was Jābir ibn Ḥayyān, now believed to be a name applied to a collection of "underground writings" produced in Baghdad after the theological reaction against science. In any case, the Jābirian writings are very similar to those of ar-Rāzī.

Ar-Rāzī classified the materials used by the alchemist into "bodies" (the metals), stones, vitriols, boraxes, salts, and "spirits," putting into the latter those vital (and sublimable) materials, mercury, sulfur, orpiment and realgar (the arsenic sulfides), and sal ammoniac. Much is made of sal ammoniac, the reactive powers of which seem to have given Western alchemy a new lease on life. Ar-Rāzī and the Jābirian writers were really trying to make gold, through the catalytic action of the elixir. Both wrote much on the compounding of "strong waters," an enterprise that was ultimately to lead to the discovery of the mineral acids, but students have been no more able to find evidence of this discovery in the writings of the Arabic alchemists than in those of China and India. The Arabic strong waters were merely corrosive salt solutions.

Ar-Rāzī's writing represents the apogee of Arabic alchemy, so much so that students of alchemy have little evidence of its later reorientation toward mystical or quasi-religious objectives. Nor does it seem to have turned to medicine, which remained independent. But there was a tendency in Arabic medicine to give greater emphasis to mineral remedies and less to the herbs that had been the chief medicines of the earlier Greek and Arabic physicians. The result was a pharmacopoeia not of elixirs but of specific remedies that are inorganic in origin and not very different from the elixirs of ar-Rāzī. This new pharmacopoeia was taken to Europe by Constantine of Africa, a Baghdad-educated Muslim who died in 1087 as a Christian monk at Monte Cassino (Italy). The pharmacopoeia also appeared in Spain in the 11th century and passed from there to Latin Europe, along with the Arabic alchemical writings, which were translated into Latin in the 12th century.

Latin alchemy. In the 12th century the Christian West began to shed its habit of indifference or hostility to the secular literature of ancient and alien civilizations. Christian scholars were particularly attracted to Muslim Spain and Sicily and there made translations from both Arabic and Greek works, many of which were in some degree familiar, but some of which, including the literature of alchemy, were new.

The Greek alchemy of the Venice-Paris manuscript had much less impact than the work of ar-Rāzī and other Arabs, which emerged among the voluminous translations made in Spain about 1150 by Gerard of Cremona. By 1250 alchemy was familiar enough to enable such encyclopaedists as Vincent of Beauvais to discuss it fairly intelligibly, and before 1300 the subject was under discussion by the English philosopher and scientist Roger Bacon and the German philosopher, scientist, and theologian Albertus Magnus. To learn about alchemy was to learn about chemistry, for Europe had no independent word to describe the science of matter. It had been touched upon in works concerned with other forms of change—e.g., the motion of projectiles, the aging of man, and similar Aristotelian concepts. On the practical side there were also artists' recipe books; but for the first time in the works of Bacon and Albertus Magnus change was discussed in a truly chemical sense, with Bacon treating the newly translated alchemy as a general science of matter for which he had great hopes.

But the more familiar alchemy became, the more clearly it was understood that gold making was the almost exclusive objective of alchemy, and Europeans proved no more

The dissemination of the pharmacopoeia

The objective of European alchemy

The significance of Hermetic literature

resistant to the lure of this objective than their Arabic predecessors. By 1350, alchemical tracts were pouring out of the scriptoria (monastic copying rooms), and the Europeans had even taken over the tradition of anonymity and false attribution. One authority wrote at length about supposed disagreements between two Arabs, Iahiae Abindinon and Geber Abinbaen, who were probably two versions of the name of Jābir ibn Ḥayyān. The most famous Jābirian work in Europe, *The Sum of Perfection*, is now thought to have been an original European composition. At about this time personal reminiscences of alchemists began to appear. Most famous was the Paris notary Nicolas Flamel (1330–1418), who claimed that he dreamed of an occult book, subsequently found it, and succeeded in deciphering it with the aid of a Jewish scholar learned in the mystic Hebrew writings known as the Kabbala. In 1382 Flamel claimed to have succeeded in the “Great Work” (gold making); certainly he became rich and made donations to churches.

By 1300 alchemists had begun the discovery of the mineral acids, a discovery that occupied about three centuries between the first evidence of the new strong water (aqua fortis—i.e., nitric acid) and the clear differentiation of the acids into three kinds: nitric, hydrochloric, and sulfuric. These three centuries saw prodigious efforts in European alchemy, for these spontaneously reactive and highly corrosive substances opened a whole new world of research. And yet, it was of little profit to chemistry, for the experiments were inhibited by the old objectives of separating the base metals into their “elements,” concocting elixirs, and other traditional procedures.

The “water of life” (aqua vitae; i.e., alcohol) was probably discovered a little earlier than nitric acid, and some physicians and a few alchemists turned to the elixir of life as an objective. John of Rupescissa, a Catalan monk who wrote c. 1350, prescribed virtually the same elixirs for metal ennoblement and for the preservation of health. His successors multiplied elixirs, which lost their uniqueness and finally simply became new medicines, often for specific ailments. Medical chemistry may have been conceived under Islām, but it was born in Europe. It only awaited christening by its great publicist, Paracelsus (1493–1541), who was the sworn enemy of the malpractices of 16th-century medicine and a vigorous advocate of “folk” and “chemical” remedies. By the end of the 16th century, medicine was divided into warring camps of Paracelsians and anti-Paracelsians, and the alchemists began to move en masse into pharmacy.

Paracelsian pharmacy was to lead, by a devious path, to modern chemistry, but gold making still persisted, though methods sometimes differed. Salomon Trismosin, purported author of the *Splendor solis*, or “Splendour of the Sun” (published 1598), engaged in extensive visits to alchemical adepts (a common practice) and claimed success through “kabbalistic and magical books in the Egyptian language.” The impression given is that many had the secret of gold making but that most of them had acquired it from someone else and not from personal experimentation. Illustrations, often heavily symbolic, became particularly important, those of *Splendor solis* being far more complex than the text but clearly exercising a greater appeal, even to modern students.

MODERN ALCHEMY

The possibility of chemical gold making was not conclusively disproved by scientific evidence until the 19th century. As rational a scientist as Sir Isaac Newton (1643–1727) had thought it worthwhile to experiment with it. The official attitude toward alchemy in the 16th to 18th century was ambivalent. On the one hand, The Art posed a threat to the control of precious metal and was often outlawed; on the other hand, there were obvious advantages to any sovereign who could control gold making. In “the metropolis of alchemy,” Prague, the Holy Roman emperors Maximilian II (reigned 1564–76) and Rudolf II (reigned 1576–1612) proved ever-hopeful sponsors and entertained most of the leading alchemists of Europe.

This was not altogether to the alchemist’s advantage. In 1595 Edward Kelley, an English alchemist and companion

of the famous astrologer, alchemist, and mathematician John Dee, lost his life in an attempt to escape after imprisonment by Rudolf II, and in 1603 the elector of Saxony, Christian II, imprisoned and tortured the Scotsman Alexander Seton, who had been traveling about Europe performing well-publicized transmutations. The situation was complicated by the fact that some alchemists were turning from gold making not to medicine but to a quasi-religious alchemy reminiscent of the Greek Synesius. Rudolf II made the German alchemist Michael Maier a count and his private secretary, although Maier’s mystical and allegorical writings were, in the words of a modern authority, “distinguished for the extraordinary obscurity of his style” and made no claim to gold making. Neither did the German alchemist Heinrich Khunrath (c. 1560–1601), whose works have long been esteemed for their illustrations, make such a claim.

Conventional attempts at gold making were not dead, but by the 18th century alchemy had turned conclusively to religious aims. The rise of modern chemistry engendered not only general skepticism as to the possibility of making gold but also widespread dissatisfaction with the objectives of modern science, which were viewed as too limited. Unlike the scientists of the Middle Ages and Renaissance, the successors of Newton and the great 18th-century French chemist Antoine-Laurent Lavoisier limited their objectives in a way that amounted to a renunciation of what many had considered the most important question of science, the relation of man to the cosmos. Those who persisted in asking these questions came to feel an affinity with the alchemists and sought their answers in the texts of “esoteric,” or spiritual, alchemy (as distinct from the “exoteric” alchemy of the gold makers), with its roots in Synesius and other late Greek alchemists of the Venice-Paris manuscript.

This spiritual alchemy, or Hermetism, as its practitioners often prefer to call it, was popularly associated with the supposititious Rosicrucian brotherhood, whose so-called *Manifestoes* (author unknown; popularly ascribed to the German theologian Johann Valentin Andreae) had appeared in Germany in the early 17th century and had attracted the favourable attention not only of such reform-

Saturn, or *Mercurius senex*, being cooked in the bath until the spirit or white dove (*pneuma*) ascends. From Salomon Trismosin's *Splendor solis*, 1598. In the British Museum (MS, Harley 3469).

Association of alchemy with chemistry

ing alchemists as Michael Maier but also of many prominent philosophers who were disquieted by the mechanistic character of the new science. In modern times alchemy has become a focal point for various kinds of mysticism. The old alchemical literature continues to be scrutinized for evidence, because alchemical doctrine is claimed to have on more than one occasion come into the possession of man but always again been lost. Nor is its association with chemistry considered accidental. In the words of the famous 19th-century English spiritual alchemist Mary Anne Atwood,

Alchemy is an universal art of vital chemistry which by fermenting the human spirit purifies and finally dissolves it. . . . Alchemy is philosophy; it is the philosophy, the finding of the Sophia in the mind.

ASSESSMENTS OF ALCHEMY

Accomplishments. The most persistent goals of alchemy have been the prolongation of life and the transmutation of base metals into gold. It appears that neither was accomplished, unless one credits alchemy with the consequences of modern chemotherapy and the cyclotron.

It has been said that alchemy can be credited with the development of the science of chemistry, a keystone of modern science. During the alchemical period the repertoire of known substances was enlarged (*e.g.*, by the addition of sal ammoniac and saltpetre), alcohol and the mineral acids were discovered, and the basis was laid from which modern chemistry was to rise. Historians of chemistry have been tempted to credit alchemy with laying this base while at the same time regarding alchemy as mostly "wrong." It is far from clear, however, that the basis of chemistry was in fact laid by alchemy rather than medicine. During the crucial period of Arabic and early Latin alchemy, it appears that innovation owed more to nascent medical chemistry than to alchemy.

But those who explore the history of the science of matter, where matter is considered on a wider basis than the modern chemist understands the term, may find alchemy more rewarding. Numerous Hermetic writers of previous centuries claimed that the aims of their art could yet be achieved—indeed, that the true knowledge had been repeatedly found and repeatedly lost. This is a matter of judgment, but it can certainly be said that the modern chemist has not attained the goal sought by the alchemist. For those who are wedded to scientific chemistry, alchemy can have no further interest. For those who seek the wider goal, which was also that of the natural philosopher before the advent of "mechanical," "Newtonian," or "modern" science, the search is still on.

Interpretations. Charlatanism was a prominent feature of European alchemy during the 16th century, and such monarchs as Rudolf II—even if they had mainly themselves to blame—were not entirely without reason in incarcerating some of their resident adepts. The picturesqueness of this era, which also saw the birth of the modern science of chemistry, has led many historians of chemistry to view alchemy in general as a fraud.

Other historians of chemistry have attempted to differentiate the good from the bad in alchemy, citing as good the discovery of new substances and processes and the invention of new apparatus. Some of this was certainly accomplished by alchemists (*e.g.*, Maria), but most of it is more justifiably ascribed to early pharmacists.

Modern Hermetic and psychological views

Scholars generally agree that alchemy had something to do with chemistry, but the modern Hermetic holds that chemistry was the handmaiden of alchemy, not the reverse. From this point of view the development of modern chemistry involved the abandonment of the true goal of the art.

Finally, a new interpretation was offered in the 1920s by the Swiss psychoanalyst Carl Jung, who, following the earlier work of the Austrian psychologist Herbert Silberer, judged alchemical literature to be explicable in psychological terms. Noticing the similarities between alchemical literature, particularly in its reliance on bizarre symbolic illustrations, and the dreams and fantasies of his patients, Jung viewed them as manifestations of a "collective unconscious" (inherited disposition). Jung's theory, still

largely undeveloped, remains a challenge rather than an explanation. (R.P.M./R.A.Gi.)

Divination: astrology

Divination, the alleged art or science of foretelling the future by various natural, psychological, and other techniques, is a phenomenon found in all civilizations, both ancient and modern. In the context of ancient Latin language and belief, divination was concerned with discovering the will of the gods. Today, however, scholars no longer restrict the word to that earlier root meaning. Divinatory practices and the beliefs undergirding them are greater in scope than the ancient methods of discerning the will of the gods and the fatalistic view of the human condition that inspired so much of early Mediterranean religious thought. In some societies, in fact, divination is a practice to which many persons frequently resort, but never in terms of discovering the will of the gods. The idea of a godly providence controlling human affairs, in such societies, is unusual, although humbler spirits are often thought to intervene in troublesome ways. (G.K.P.)

The most significant form of divination is astrology, defined as the science, or pseudoscience, of forecasting earthly and human events by means of observing and interpreting the fixed stars, the Sun, the Moon, and the planets. As a science, astrology has been used to predict or affect the destinies of individuals, groups, or nations by an assumed understanding of the influence of the planets and stars on earthly affairs. As a pseudoscience, astrology is considered to be diametrically opposed to the findings and theories of modern Western science.

NATURE AND SIGNIFICANCE

Astrology is a method of predicting mundane events based upon the assumption that the celestial bodies—particularly the planets and the stars considered in their arbitrary combinations or configurations (called constellations)—in some way either determine or indicate changes in the sublunar world. The theoretical basis for this assumption lies historically in Hellenistic philosophy and radically distinguishes astrology from the celestial *omina* ("omens") that were first categorized and cataloged in ancient Mesopotamia. Originally, astrologers presupposed a geocentric universe in which the "planets" (including the Sun and Moon) revolve in orbits whose centres are at or near the centre of the Earth, and in which the stars are fixed upon a sphere with a finite radius whose centre is also the centre of the Earth. Later, the principles of Aristotelian physics were adopted, according to which there is an absolute division between the eternal, circular motions of the heavenly element and the limited, linear motions of the four sublunar elements: fire, air, water, earth.

Special relations were believed to exist between particular celestial bodies and their varied motions, configurations with each other, and the processes of generation and decay apparent in the world of fire, air, water, and earth. These relations were sometimes regarded as so complex that no human mind could completely grasp them; thus, the astrologer might be readily excused for any errors. A similar set of special relations was also assumed by those whose physics was more akin to that of the Greek philosopher Plato. For the Platonic astrologers, the element of fire was believed to extend throughout the celestial spheres, and they were more likely than the Aristotelians to believe in the possibility of divine intervention in the natural processes through celestial influences upon the Earth, since they believed in the deity's creation of the celestial bodies themselves.

The role of the divine in astrological theory varies considerably. In its most rigorous aspect, astrology postulates a totally mechanistic universe, denying to the deity the possibility of intervention and to man that of free will; as such it was vigorously attacked by orthodox Christianity and Islam. For some, however, astrology is not an exact science like astronomy but merely indicates trends and directions that can be altered either by divine or by human will. In the interpretation of Bardesanes, a Syrian Christian scholar (154–c. 222)—who has often been identified as a

The role of the divine will

Gnostic (a believer in esoteric salvatory knowledge and the view that matter is evil and spirit good)—the motions of the stars govern only the elemental world, leaving the soul free to choose between the good and the evil. Man's ultimate goal is to attain emancipation from an astrologically dominated material world. Some astrologers, such as the Harranians (from the ancient Mesopotamian city of Harran) and the Hindus, regard the planets themselves as potent deities whose decrees can be changed through supplication and liturgy or through theurgy, the science of persuading the gods or other supernatural powers. In still other interpretations—e.g., that of the Christian Priscillianists (followers of Priscillian, a Spanish ascetic of the 4th century who apparently held dualistic views)—the stars merely make manifest the will of God to those trained in astrological symbolism.

Significance of astral omens. The view that the stars make manifest the divine will is closest to the concept that lies behind the ancient Mesopotamian collections of celestial omens. Their primary purpose was to inform the royal court of impending disaster or success. These might take the forms of meteorological or epidemic phenomena affecting entire human, animal, or plant populations. Frequently, however, they involved the military affairs of the state or the personal lives of the ruler and his family. Since the celestial *omina* were regarded not as deterministic but rather as indicative—as a kind of symbolic language in which the gods communicated with men about the future and as only a part of a vast array of ominous events—it was believed that their unpleasant forebodings might be mitigated or nullified by ritual means or by contrary omens. The *bāru* (the official prognosticator), who observed and interpreted the celestial *omina*, was thus in a position to advise his royal employer on the means of avoiding misfortunes; the omens provided a basis for intelligent action rather than an indication of an inexorable fate.

Purposes of astrology. The original purpose of astrology, on the other hand, was to inform the individual of the course of his life on the basis of the positions of the planets and of the zodiacal signs (the 12 astrological constellations) at the moment of his birth or conception. From this science, called genethliology (casting nativities), were developed the fundamental techniques of astrology. The main subdivisions of astrology that developed after genethliology are general, catarchic, and interrogatory.

General astrology studies the relationship of the significant celestial moments (e.g., the times of vernal equinoxes, eclipses, or planetary conjunctions) to social groups, nations, or all humanity. It answers, by astrological means, questions formerly posed in Mesopotamia to the *bāru*.

Catarchic (pertaining to beginnings or sources) astrology determines whether or not a chosen moment is astrologically conducive to the success of a course of action begun in it. Basically in conflict with a rigorous interpretation of genethliology, it allows the individual (or corporate body) to act at astrologically favourable times and, thereby, to escape any failures predictable from his (or its) nativity.

Interrogatory astrology provides answers to a client's queries based on the situation of the heavens at the moment of his posing the questions. This astrological consulting service is even more remote from determinism than is catarchic astrology; it is thereby closer to divination by omens and insists upon the ritual purification and preparation of the astrologer.

Other forms of astrology, such as iatromathematics (application of astrology to medicine) and military astrology are variants on one or another of the above.

HISTORICAL DEVELOPMENT

Astral omens in the ancient Middle East. The astral omens employed in Mesopotamian divination were later commingled with what came to be known as astrology in the strict sense of the term and constituted within astrology a branch described as natural astrology. Though lunar eclipses apparently were regarded as ominous at a somewhat earlier period, the period of the 1st dynasty of Babylon (18th to 16th centuries BC) was the time when the cuneiform text *Enūma Anu Enlil*, devoted to celestial *omina*, was initiated. The final collection and codification

of this series, however, was not accomplished before the beginning of the 1st millennium BC. But the tablets that have survived—mainly from the Assyrian library of King Ashurbanipal (7th century BC)—indicate that a standard version never existed. Each copy had its own characteristic contents and organization designed to facilitate its owner's consultation of the omens.

The common categories into which the omens of *Enūma Anu Enlil* were considered to fall were four, named after the chief gods involved in the ominous communication: Sin, Shamash, Adad, and Ishtar. Sin (the Moon) contains omens involving such lunar phenomena as first crescents, eclipses, halos, and conjunctions with various fixed stars; Shamash (the Sun) deals with omens involving such solar phenomena as eclipses, simultaneous observations of two suns, and perihelia (additional suns); Adad (the weather god) is concerned with omens involving meteorological phenomena, such as thunder, lightning, and cloud formations, as well as earthquakes; and Ishtar (Venus) contains omens involving planetary phenomena such as first and last visibilities, stations (the points at which the planets appear to stand still), acronychal risings (rising of the planet in the east when the Sun sets in the west), and conjunctions with the fixed stars.

Though these omens are often cited in the reports of a network of observers established throughout the Assyrian Empire in the 7th century BC, they seem to have lost their popularity late in the period of the Persian domination of Mesopotamia (ending in the 4th century BC). During the later period new efforts were made, in a large number of works called *Diaries*, to find the correct correlations between celestial phenomena and terrestrial events. Before this development, however, portions of the older omen series were transmitted to Egypt, Greece, and India as a direct result of the Achaemenid domination (a dynasty ruling in Persia 559–330 BC) of these cultural areas or of their border regions.

Astral omens in Egypt, Greece, India, China, and Islām.

The evidence for a transmission of lunar omens to Egypt in the Achaemenid period lies primarily in a demotic papyrus based on an original of about 500 BC. A more extensive use of Mesopotamian celestial omens is attested by the fragments of a book written in Greek in the 2nd century BC and claimed as a work addressed to a King Nectepso by the priest Petosiris. From this source, among others, the contents of *Enūma Anu Enlil* were included in the second book of the *Apotelesmatika*, or "Work on Astrology" (commonly called the *Tetrabiblos*, or "Four Books"), by Ptolemy, a Greek astronomer of the 2nd century AD; the first book of an astrological compendium, by Hephaestion of Thebes, a Greco-Egyptian astrologer of the 5th century AD; and the *On Signs* of John Lydus, a Byzantine bureaucrat of the 6th century. Yet another channel of transmission to the Greeks was through the Magusaeans of Asia Minor, a group of Iranian settlers influenced by Babylonian ideas. Their teachings are preserved in several classical works on natural history, primarily that of Pliny the Elder (c. AD 23–79), and the *Geoponica* (a late collection of agricultural lore).

In various Middle Eastern languages there also exist many texts dealing with celestial omens, though their sources and the question as to whether they are directly descended from a Mesopotamian tradition or are derived from Greek or Indian intermediaries is yet to be investigated. Of these texts the most important are those ascribed to Hermes Trismegistos by the Harranians and now preserved in Arabic, the *Book of the Zodiac* of the Mandaeans (a Gnostic sect still existing in Iraq and Khuzistan), the *Apocalypse*, attributed to the Old Testament prophet Daniel (extant in Greek, Syriac, and Arabic versions), and *The Book of the Bee* in Syriac.

The transmission of Mesopotamian omen literature to India, including the material in *Enūma Anu Enlil*, apparently took place in the 5th century BC during the Achaemenid occupation of the Indus Valley. The first traces are found in Buddhist texts of this period, and Buddhist missionaries were instrumental in carrying this material to Central Asia, China, Tibet, Japan, and Southeast Asia. But the most important of the works of this In-

Introduction of Mesopotamian literature to India

dian tradition and the oldest extant one in Sanskrit is the earliest version of the as yet unpublished *Gargasamhitā* ("Compositions of Garga") of about the 1st century AD. The original Mesopotamian material was modified so as to fit into the Indian conception of society, including the system of the four castes and the duty of the upper castes to perform the *saṃskāras* (sanctifying ceremonies).

There are numerous later compilations of omens in Sanskrit—of which the most notable are the *Brhatsamhitā*, or "Great Composition," of Varāhamihira (c. 550), the Jaina *Bhadrabāhu-samhitā*, or "Composition of Bhadrabāhu" (c. 10th century), and the *Pariśiṣṭas* ("Supplements") of the Atharvaveda (perhaps 10th or 11th century)—though these add little to the tradition. But in the works of the 13th century and later, entitled *Tājika*, there is a massive infusion of the Arabic adaptations of the originally Mesopotamian celestial omens as transmitted through Persian (*Tājika*) translations. In *Tājika* the omens are closely connected with general astrology; in the earlier Sanskrit texts their connections with astrology had been primarily in the fields of military and catarchic astrology.

Astrology in the Hellenistic period (3rd century BC to 3rd century AD). In the 3rd century BC and perhaps somewhat earlier, Babylonian diviners began—for the purpose of predicting the course of an individual's life—to utilize some planetary omens: positions relative to the horizon, latitudes, retrogressions, and other positions at the moment of birth or of computed conception. This method was still far from astrology, but its evolution was more or less contemporary and parallel with the development of the science of genethliology in Hellenistic Egypt.

Equally obscure are those individuals who, living in Egypt under the Ptolemies (a Greek dynasty ruling 305–30 BC), mathematicized the concept of a correspondence between the macrocosm (larger order, or universe) and the microcosm (smaller order, or man) as interpreted in terms of Platonic or Aristotelian theories concerning the Earth as the centre of the planetary system. They conceived of the ecliptic (the apparent orbital circle of the Sun) as being divided into 12 equal parts, or zodiacal signs, each of which consists of 30°; in this they followed the Babylonians. They further regarded each of these 12 signs as the domicile (or house) of a planet and subdivided each into various parts—decans of 10° each, *finēs* ("bounds") of varying lengths, and *dōdecatēmoría* of 2°30' each—each of which is also dominated by a planet. Scattered at various points throughout the ecliptic are the planets' degrees of exaltation (high influence), opposite to which are their degrees of dejection (low influence). Various arcs of the zodiac, then, are either primarily or secondarily subject to each planet, whose strength and influence in a geniture (nativity) depend partially on its position relative to these arcs and to those of its friends and enemies.

Furthermore, each zodiacal sign has a special relation with a part of the human body. The 12 signs are further divided into four triplicities, each of which governs one of the four elements. Numerous pairs of opposites (male-female, diurnal-nocturnal, hot-cold, and others), based on the speculations of the followers of Pythagoras, a Greek mystical philosopher of the 6th century BC, are connected with consecutive pairs of signs. Finally, a wide variety of substances in the elemental world and attributes of human character are more or less arbitrarily associated with the different signs. These lists of interrelationships provide the rationale for many of the astrologer's predictions.

The individual planet's influences are related both to its general indications when regarded as ominous in Mesopotamian texts and to the traits of its presiding deity in Greek mythology. But on them are also superimposed the system of the four elements and their four qualities, the Pythagorean opposites, and lists of sublunar substances. Furthermore, as in the omens, the modes of the planetary motions are carefully considered, since their strengths are partially determined by their phases with respect to the Sun. Also, they exert a mutual influence both by occupying each other's houses and by means of conjunction and aspects—opposition (to the seventh) and quartile (to the fourth or 10th) being generally considered bad, trine (to the fifth or ninth) and sextile (to the third or 11th) good.

Moreover, as the planetary orbits revolve from west to east, the zodiac rotates daily about the Earth in the opposite sense. From a given spot on the Earth's surface this latter motion—if the ecliptic were a visible circle—would appear as a succession of signs rising one after the other above the eastern horizon. The astrologers regard the one that is momentarily in the ascendant as the first place, the one to follow it as the second, and so on, with the one that rose immediately prior to the ascendant being the 12th. In genethliology each place in this *dōdecatropos* determines an aspect of the life of the native (one born under a particular sign); in other forms of astrology the place determines some appropriate aspect of the sublunar world.

The astrologer, then, casts a horoscope by first determining for the given moment and locality the boundaries of the 12 places and the longitudes and latitudes of the seven planets. He reads this horoscope by examining the intricate geometric interrelationships of the signs and their parts and of the planets of varying computed strengths with the places and each other and by associating with each element in the horoscope its list of sublunar correspondences. Any horoscopic diagram, of course, will yield a vast number of predictions, including many that are contradictory or extravagant. The astrologer thus must rely on his knowledge of his client's social, ethnic, and economic background and on his own experience to guide him in avoiding error and attaining credibility.

Since about 100 BC the above method has been the essential procedure of astrology, though various refinements and additional devices occasionally have been introduced, including those associated with the Hermetic tradition of Hermes Trismegistos and with Dorotheus of Sidon, an influential astrological poet of the third quarter of the 1st century AD. One is the system of lots, which are influential points as distant from some specified points in the horoscopic diagram as two planets are from each other. A second is the prorogator, a point on the ecliptic that, traveling at the rate of one degree of oblique ascension a year toward either the descendant or ascendant, determines a person's length of life. Another is the method of continuous horoscopy, under which anniversary diagrams are compared with the base nativity to provide annual readings. And, finally, certain periods of life are appor-

tioned to their governing planets in a fixed sequence; these period governors in turn share their authority with the other planets by granting them subperiods. All of these complications serve, among other purposes, to provide the astrologer with convenient excuses for his inevitable errors.

Astrology after the Hellenistic period. *In India.* Greek astrology was transmitted to India in the 2nd and 3rd centuries AD by means of several Sanskrit translations, of which the one best known is that made in AD 149/150 by Yavaneśvara and verified as the *Yavanajātaka* by Sphujidhvaja in AD 269/270. The techniques of Indian astrology are thus not surprisingly similar to those of its Hellenistic counterpart. But the techniques were transmitted without their philosophical underpinnings (for which the Indians substituted divine revelation), and the Indians modified the predictions, originally intended to be applied to Greek and Roman society, so that they would be meaningful to them. In particular, they took into account the caste system, the doctrine of metempsychosis (transmigration of souls), the Indian theory of five elements (earth, water, air, fire, and space), and the Indian systems of values.

The Indians also found it useful to make more elaborate the already complex methodology of Hellenistic astrology. They added as significant elements: the *nakṣatras* (or lunar mansions); an elaborate system of three categories of *yogas* (or planetary combinations); dozens of different varieties of *daśās* (periods of the planets) and *antardaśās* (subperiods); and a complex theory of *aṣṭakavarga* based on continuous horoscopy. The number of subdivisions of the zodiacal signs was increased by the addition of the *horās* (15° each), the *saptāṃśās* (4²/₇° each), and the *navāṃśās* (3°20' each); the number of planets was increased by the addition of the nodes of the Moon (the points of intersection of the lunar orbit with the ecliptic), and of a series of *upagrahas*, or imaginary planets. Several elements of Hellenistic astrology and its Sāsānian offshoot (see below *In Sāsānian Iran*), however—including the lots, the prorogator, the Lord of the Year, the triplicities, and astrological history—were introduced into India only in the 13th century through the *Tājika* texts. Besides genethliology, the Indians particularly cultivated military astrology and a form of catarchic astrology termed *muhūrta-śāstra* and, to a lesser extent, iatromathematics and interrogatory astrology.

In Sāsānian Iran. Shortly after Ardashīr I founded the Sāsānian Empire in AD 226, a substantial transmission of both Greek and Indian astrology to Iran took place. There were Pahlavi (Iranian language) translations of Dorotheus of Sidon, Vettius Valens, Hermes, and an Indian called (in the Arabic sources) Farmaṣp. Since the Pahlavi originals are all lost, these translations provided the only knowledge of the Sāsānian science. Genethliology in Iran was essentially an imitation of the Hellenistic (though without any philosophy), onto which were grafted some Indian features, such as the *navāṃśās* and a Śaivite interpretation of illustrations of the Greco-Egyptian deities of the decans. The most influential and characteristic innovation of the Sāsānian astrologers was the development of the theory of

astrological history—that is, the writing of history, both past and future, on the basis of extensions of the techniques of the prorogator, the Lord of the Year, the planetary periods, and the continuous horoscopy employed in Hellenistic genethliology. This was done in conjunction with Zoroastrian millenarianism (the division of the finite duration of the material creation into 12 millennia).

In Islām. Astrology entered Islāmic civilization in the 8th and 9th centuries in three simultaneous streams—Hellenistic, Indian, and Sāsānian. Arabic translations from the Greek and Syriac represented the Hellenistic science, from Sanskrit the Indian version, and from Pahlavi the Sāsānian combination of the two. But to these influences Islāmic astrology, through the work of Abū Ma'shar, an astrologer of the 9th century, added the Harranian adaptation of the Neoplatonic definition of the mode of astral influences in terms of Aristotelian physics. Abū Ma'shar further elaborated Sāsānian astrological history and greatly expanded the number of lots that an astrologer had to take into consideration. Much attention was paid by the Muslims to catarchic and interrogatory astrology, but, under attack by the theologians for denying divine intervention in the world and man's free will, astrology rapidly declined in its appeal to Muslim intellectuals after the Mongol invasions of the 13th century, though not before its influence had spread in India, the Latin West, and Byzantium.

In Byzantium. During the last upsurge of paganism in the 5th and 6th centuries AD, Byzantium (the Eastern Roman Empire) boasted a host of astrologers: Hephæstion, Julian of Laodicea, "Proclus," Rhetorius, and John Lydus. Though their works are singularly unoriginal compilations, they remain the major sources for an understanding of earlier Hellenistic astrology. By the end of the 6th century, however, the general decline of the Byzantine Empire's intellectual life and the strong opposition of the church had combined to virtually obliterate astrology, though some practice of reading celestial omens survived in Byzantium as it did in western Europe. The science was revived only in the late 8th century and the 9th century under the impact of translations from Syriac and Arabic. The period from about 800 to 1200 was the most propitious for Byzantine astrology, though nothing was essentially added to astrological theories or techniques. This period was rivaled only by a last flowering of astrology in the late 14th century, when John Abramius and his students revised the older astrological treatises in Greek to provide the Renaissance with vulgate texts.

In western Europe. The astrological texts of the Roman Empire were written almost universally in Greek rather than in Latin; the only surviving exceptions are the poem *Astronomica* of Manilius (c. AD 15–20), the *Matheseos libri* ("Books on Astrology") of Firmicus Maternus (c. 335), and the anonymous *Liber Hermetis* ("Book of Hermes") from the 6th century. In the absence of astronomical tables in Latin, however, none of these was of any use, and astrology for all practical purposes disappeared with the knowledge of Greek in western Europe. It was revived only with the numerous translations of Arabic astrological and astronomical treatises executed in Spain and Sicily in the 12th and 13th centuries, supplemented by a few translations directly from the Greek. But the new astrology in the Latin-reading world remained essentially an offshoot of Islāmic astrology, gaining an adequate representation of its Hellenistic originals only in the 15th and 16th centuries. These two centuries also witnessed the fullest flowering of astrology in western Europe, frequently in conjunction with Neoplatonism and Hermetism. By the 17th century, however—with the displacement of the Earth from the centre of the universe in the new astronomy of Copernicus (1473–1543), Galileo (1564–1642), and Johannes Kepler (1571–1630), and with the rise of the new mechanistic physics of Descartes (1596–1650) and Newton (1643–1727)—astrology lost its intellectual viability and became increasingly recognized as scientifically untenable. Though Kepler attempted to devise a new method of computing astrological influences in the heliocentric (Sun-centred) universe, he did not succeed.

Astrology in modern times. In the West, Newtonian physics largely eradicated a belief in astrology among the

Significance of Arabic astrology

Effect of modern science on astrology

educated, and the practice of what now degenerated into a pseudoscience became increasingly the province of the fraudulent fortune-teller. In countries such as India, however, where only a small intellectual elite has been trained in Western physics, it manages to retain here and there its position among the sciences. Some Indian universities offer advanced degrees in astrology.

Recently in the West, however, astrology has gained a large popular following, and there have been attempts to reestablish a firm theoretical basis for it, notably by the French psychologist Michel Gauquelin, although with results that are at best inconclusive. The divisions of the year governed by the 12 zodiacal signs (which are derived from Hellenistic astrology) as depicted in newspapers, manuals, and almanacs are as follows:

Aries, the Ram, March 21–April 19	Libra, the Balance, September 23–October 23
Taurus, the Bull, April 20–May 20	Scorpio, the Scorpion, October 24–November 21
Gemini, the Twins, May 21–June 21	Sagittarius, the Archer, November 22–December 21
Cancer, the Crab, June 22–July 22	Capricorn, the Goat, December 22–January 19
Leo, the Lion, July 23–August 22	Aquarius, the Water Carrier, January 20–February 18
Virgo, the Virgin, August 23–September 22	Pisces, the Fish, February 19–March 20

Attempts have been made to incorporate into the general astrological scheme the planets discovered since the Renaissance and to find some sort of statistical relation between planetary positions and human lives. None of these attempts appears to be at all convincing, however, and no serious explanation seems to exist regarding the alleged spheres of influence of the planets, the alleged nature of their influences, or the manner in which they are received. Nor has any modern astrologer proved that arbitrary arcs (houses or zodiacal signs) on a nonexistent circle (the ecliptic) are endowed with existence and with attributes, much less with the power to affect human lives. Moreover, since the phenomena of this world are now largely explicable by the hypotheses of modern science, it is difficult to understand how astrological influences can also be responsible for them. In short, modern Western astrology, though of great interest sociologically and popularly, generally is regarded as devoid of intellectual value.

(D.E.P./R.A.Gi.)

Divination: other forms

While divination is most commonly practiced in the modern Western world in the form of horoscopic astrology, other forms of divination were and are of equal importance for other cultures, both ancient and contemporary.

NATURE AND SIGNIFICANCE

Concerns
of
divination

Divination is universally concerned with practical problems, private or public, and seeks information upon which practical decisions can be made; but the source of such information is not conceived as mundane, and the technique of getting it is necessarily fanciful. The mantic (divinatory) arts are many, and a broad understanding can only emerge from a survey of actual practices in various cultural settings. A short definition, however, may be offered as a preliminary guide: divination is the effort to gain information of a mundane sort by means conceived of as transcending the mundane.

Though the act of divination is attended by respect and the attitude of the participants in the divinatory act may be religious, the subject matter of divination (like that of magic) is ephemeral—e.g., an illness, a worrisome portent, a lost object. Divination is a consultative institution, and the matter posed to a diviner may range from a query about a few lost coins to high questions of state. The casual or solemn nature of the matter is normally matched by that of the diviner in terms of attitude, technique, and style. Where the diviner is a private practitioner, the elaborateness of the procedure may be reflected in the fee. In contrast to the worldly motives of some diviners, the calling of diviner-priest was seen by the ancient Etruscans in Italy and the Maya in Mexico as sacred; his concern

Barotse basket diviner. The diviner shakes various objects in the winnowing basket and by interpreting their final juxtaposition seeks to predict the outcome of an illness and to name the sorcerer responsible.

By courtesy of the Livingstone Museum, Republic of Zambia

was for the very destiny of his people. Divination has many rationales, and it is difficult to describe the diviner as a distinctive social type. He may be a shaman (private curer employing psychic techniques), a priest, a peddler of sorcery medicines, or a holy man who speaks almost with the voice of prophecy. To appreciate the significance of the diviner's art in any culture or era, one must be familiar with prevailing beliefs about man and the world. In Christian times Europe has moved from a horror of necromancy (conceived not as consultation with a ghost but as a literal "raising of the dead") to an amused tolerance (among the educated) of spiritualism as a sort of parlour game. To assert that European beliefs about God and man have remained the same throughout the Christian Era would be to ignore the impact of modern science and secularization. On the other hand, to suppose that divination has been doomed by science and secularism would be to ignore the abiding popularity of horoscopic astrology and recurrent fashions for other mantic disciplines—and perhaps to misjudge the security of "modern" beliefs.

THE STRUCTURE OF DIVINATION

The extent to which a practice such as divination should be called a corollary of the beliefs entailed and the extent to which the opposite might be true (*i.e.*, the beliefs deriving from the practice as an after-the-fact explanation) is difficult to ascertain. Among the great cultures, the Chinese tradition has given the broadest scope to divination; yet there is no single Chinese religious cosmology, or theory on the ordering of the world, comparable to those of the Maya, Sanskritic (Hindu), or Judeo-Christian traditions, from which the variety of popular practice can be seen to derive. Sometimes, as with the flourishing business of astrology in Christian countries since the Renaissance, the metaphysical (transcendent) presuppositions of mantic practice may have been muted in order to minimize conflict with official religious and scientific doctrines. Generally, however, the philosophical underpinnings of divination need not be deep or well worked out, but, where they are, they will afford clues to fundamental beliefs about man and about visible or invisible nature. Some traditions of divination—such as astrology, geomancy (divination by means of figures or lines), or the Chinese divinatory disciplines—are so old and established that it is virtually impossible to discover their original contexts. Over the centuries such practices have survived many changes and have become perennial attempts to answer recurring questions about the human condition.

Established long ago in the hieratic (priestly) discipline of primitive theocracies, such a tradition still bears the marks of the specialists who worked out its systematic techniques. Since the practice is now observed only as

Importance
of world-views and philosophical underpinnings for divination

a folk or popular tradition, however, it would be rash to suppose that any legitimate philosophical tradition undergirding divination survives. Only in the case of the *I Ching*, the Chinese "Classic of Changes," have scholarly commentaries of any great intellectual substance accumulated over the millennia. Systematic studies of geomancy are recent, and the literature of astrology is as perishable as it is massive. Babylonian astrology, from which later forms are derived, arose in an agrarian Mesopotamian civilization concerned the vicissitudes of nature and the affairs of state. The mercantile, seafaring, and individualistic Greeks absorbed the mantic system of the collectivistic floodplain civilization of Mesopotamia, elaborated on it by adding the horoscopic discipline, and transmitted it, through Hellenistic, Egyptian, and Islamic science, to Europe. In the course of this transformation, a two-way relationship between a society's view of the world and its system may be seen. Various priests and scholars have made their contributions to the system; yet there also is a clear correspondence between the general character of a culture and the uses it finds for divination. That is, the worldview implicit in the divination system itself may reflect the historical rather than the current context of use. It requires only practical understanding to consult a ouija board or use a forked stick to decide where to drill for water. Hence, men of very different beliefs may adopt the same practices, and a full correspondence between practice and belief can only be expected where both have developed in the same cultural context. Where much of the popularity of the mantic art derives from its "exotic" flavour, its symbolism may be little understood. By its very nature, however, divination tends to develop as a discipline, becoming the tradition of an organized body of specialists. This is because the means to which the diviner must resort are conceived as setting him apart. That is the case even among such peoples as the Azande (adjective and singular noun form Zande) of the Nile-Congo divide in Africa, where the resort to divination is frequent, and the most common techniques utilized are recognized to be within the competence of ordinary men. There, on a sensitive or contentious issue, an extraordinary credibility is desired, and the ultimate reliability of an oracle reflects the political standing of its owner—the king's oracle, for example, is viewed as the final authority, and the royal court is scrupulously organized to guard this vessel of power (divinatory and other) from contamination. Few societies are as enthusiastically given to divination as the Azande, who routinely employ it to explore their thoughts and who will not consider any important undertakings without oracular confirmation in advance. Among the Azande, the ordinary man could be considered a divinatory specialist. Elsewhere, men are content to reserve divination for special crises, and consultation must be with a recognized expert in order to distinguish an authentic answer from a spurious one.

Types of divination. As schools of dramatic art range from those relying on explicit technique to those teaching intuitive identification with a role, mantic skills range from the mechanical to the inspirational but most often combine both skills in a unique, dramatically coherent format. The comparative study of divinatory practices is at least as old as the 1st-century-BC Roman orator and politician Cicero's treatise *De divinatione* (*Concerning Divination*), and the convenient distinction there drawn between inductive and intuitive forms designates the range. An intermediate class, interpretive divination, allows a less rigid classification, since many divinatory disciplines do not rely strongly either upon inductive rigour or upon trance and possession.

Inductive divination presupposes a determinative procedure, apparently free from mundane control, yielding unambiguous decisions or predictions. The reading of the "eight characters" of a Chinese boy and girl before proceeding to arrange a marriage—the year, month, day, and hour of birth of the two persons to be betrothed—illustrates this class of procedures. The "characters" are all predetermined by the accidents of birth date and hour, and it is supposed that all proper diviners would come to the same conclusions about them.

Interpretive divination requires the combination of correct procedure with the special gift of insight that sets a diviner apart from his fellows. The contemporary Maya diviner of Guatemala, seeking to diagnose an illness, will carefully pass a number of eggs over the patient's body in order to draw into them an essence of the affliction. The intact contents are then collected in water, and the diviner withdraws into a darkened corner to bend over the receptacle and read the signs of the eggs. His recitation then interprets the origin and nature of the disease.

Intuitive divination presupposes extraordinary gifts of insight or ability to communicate with beings in an extramundane sphere. The "Shaking Tent" rite of the Algonkian Indians of Canada illustrates the use of uncanny phenomena to lend credence to a mediumistic performance. The diviner, bound and cloaked, is no sooner placed in his barrel-like tent than the tent begins to shake with astonishing vigour and to fill the air with monstrous noises; and this continues with great effect until, all of a sudden, the communicating spirit makes his presence known from within the tent and undertakes to answer questions. It is difficult to explain away the phenomena of spirit possession as products of deliberate instruction.

The cosmological and psychological conditioning that affects divinatory practices within a cultural tradition will influence in a similar fashion all of its religious practices. The Greeks tended to the intuitive or "oracular" style, and the Etruscans, in contrast, elaborated upon the more systematic but less versatile inductive practice of Mesopotamia—developing an authoritative state religion in which the positions were monopolized by the ruling class. Greek divination was eccentric in that sanctuaries were located apart from the centres of political power; the Etruscan system, on the other hand, was concentric, focused at the summit itself. Rome eclectically incorporated both Greek and Etruscan elements, the ecstatic cult and the expert "reading" of livers—i.e., haruspimancy. Rome, however, never allowed divination to become the central preoccupation of society as it had been for Etruria, nor did it become an autonomous force in society as it had been for the Greeks. In this, Rome represented a balance that is more congenial to modern Western thought. Throughout the ancient Mediterranean world, the notable exception being Egypt, divination was tied to expiation and sacrifice: fate was perceived as dire but not quite implacable, and the function of divination was to foresee calamity in order to forestall it. In trans-Saharan Africa, religion centres on expiation and sacrifice, and divination is a pivotal institution, but the Mediterranean notion of fate is not developed. Instead, the trouble of a person is attributed to witchcraft, sorcery, or ancestral vexation—all of which are believed to be arbitrary and morally undeserved. Divination is employed to discover the source of trouble in order to remove it, whether by sacrifice, countersorcery, or accusation and ordeal. The mind is turned to past events or hidden motives of the present time, however, and not to the future—that would be to borrow trouble.

The function of divination. The function of divination needs to be understood in its motivational context. It is not enough to say that information won from the diviner serves to allay uncertainty, locate blame, or overcome misfortune. Divination is motivated by the fact that information, whether spurious or true, will please a client. Unless one assumes that the information is usually accurate, one would expect clients to be displeased and subsequently skeptical. A careful assessment of the kinds of information that divinatory systems are required to yield is thus in order. The two main kinds are general information about the future and specific information about the past as it bears upon the future.

The first kind of information is yielded by horoscopic divination. It is usually so general that it cannot be properly tested. If such information were really specific, the prediction could interfere with its own fulfillment, acting as a warning or breeding overconfidence. The other kind of information demanded from diviners is specific enough to be tested and often is; but testing a particular diviner's competence is seldom seen as putting the institution to the test. Indeed, it is common in trans-Saharan societies

Cosmological and psychological conditioning

Inductive, intuitive, and interpretive forms of divination

Occa-
sions of
divinatory
consulta-
tion

for a troubled client to consult a series of diviners until he finds one who is convincing. Again, many systems of divination have a double check built into them: the question is posed first in the positive and then in the negative, and the oracle must (obviously without manipulation) answer consistently. The chances are actually even that any oracle will fail to do so, yet the credibility of such oracles seems not to be lost. Technically, this means that false information can be obtained by a client without weakening his belief in the source. Early students of divinatory practice concluded that clients must be gullible, superstitious, illogical, or even "prelogical"; *i.e.*, culturally immature. Ethnographic studies do not confirm this, suggesting rather that what a client seeks from the diviner is information upon which he can confidently act. He is seeking, in so doing, public credibility for his own course of action. Consistent with this motive, he should set aside any finding that he thinks would lead him into doubtful action and continue his consultations until they suggest a course that he can take with confidence. The diviner's findings are judged pragmatically.

Clients seek out a diviner when they are unsure how to behave—when there is illness, drought, death, or the fear of death; when there is suspicion of malevolence, theft, or breach of faith; when dreams or other symptoms are disturbing or the signs of the time seem bad. Divination serves the purpose of circumscription, of marking out and delimiting the area of concern: the nature of the crisis is defined, the source of anxiety is named. Concern becomes allegation, bafflement decision. The diviner may function as a stage manager, speeding up the action, rejecting false moves in advance, or indicating the secret fear or the hidden motive. Where divinatory practice is a recognized resource, a man who ignores it is considered arbitrary, and one who heeds it needs no further justification for his actions. In this sense, the ultimate function of divination is the legitimation of problematic decisions.

VARIETIES OF DIVINATION

Because dramatic effect is important, divination takes many forms and employs a wealth of devices. In a general way, it may be said that inductive divination employs nonhuman phenomena, either artificial or natural, as signs that can be unambiguously read. The prime condition is that the signs appear to be genuine, not manipulated. Interpretive divination commonly combines the use of nonhuman phenomena with human action, employing devices so complex, subtle, or fluid that the special gifts of the diviner seem required if the meaning is to be known. It is here that divination takes its most characteristically dramatic forms. Intuitive divination usually places little reliance upon artificial trappings, except for dramatic effect. The impressive performer may exhibit gifts like those that in a different context would have made him an effective actor, writer, or political leader. Where the diviner can produce voices other than his own, the impression is that the gods or spirits are speaking.

Inductive divination. To speculate that inductive divination from natural phenomena must be very old—*i.e.*, that it arose from early man's intimate acquaintance with nature—is tempting. In fact, however, evidence of an awareness of nature as a system among preliterate peoples is spotty, and this is particularly true in respect to astral observation. Divination from the skies is concerned preeminently with the future but presupposes a concern with cycles of time and history. Quite distinctive attitudes were taken toward the celestial clock by the ancient Maya astronomers and those of Mesopotamia; and distinct but related forms of astrology were developed in the Western, Indian, and Chinese civilizations. But the relation between astrology and scientific astronomy is quite apparent, and the two "sciences" were inseparable in the West until early modern times.

Associated with the observation of the heavens is the reading of signs in the weather and the movement of birds. The interpretation of lightning as a decipherable message from the gods—not simply as an outburst of divine anger—was brought to the level of a pseudoscience by the Etruscans. Winds and clouds, being suited to less

exact observation, invited interpretive rather than inductive divination. Weather phenomena were also conceived of as in a special status relative to man, in that rain, drought, and natural disasters are forces that man seeks not simply to read but to control. Nonetheless, Hindu scripture discusses the art of interpreting "castles in the air"—celestial cities seen in towering clouds.

Augury, the art of interpreting omens, is the attempt to discover divine will in phenomena of animate nature. In Mesopotamia, augury was associated with sacrifice and perhaps developed from it. As the priests watched the rising smoke to divine the answer to a ritual query, they observed the movement of birds as auspicious or inauspicious. As a further augury the viscera of the sacrificial victim were examined, particularly the liver, which (rather than the heart) was conceived as the vital centre. The discipline of augury mapped cosmic space with the sacrificial altar at the centre, and each sector was assigned a definite meaning. Every event in the heavens could thus be charted and pondered. Similarly, haruspicy, the study

Forms of
inductive
divination

of the liver, was developed by mapping it as a microcosm and reading it as one may read the palm.

Inductive divination from nature is associated with the reading of artificially contrived events, such as the movement of sacrificial smoke, the fall of an arrow shot upward, or the cast of dice or lots. A much-used natural-artificial technique consists in the braising of bone or shell to produce a system of signs. Scapulimancy—divination from a fire-cracked shoulder blade—was widespread in North America and Eurasia. The related but more elaborate Chinese technique of tortoiseshell divination was inspired by the idea of equating the carapace (back) and ventral (lower) shell with their view of a rounded sky over flat earth. Only the “earth” was inscribed and heated to produce signs. In general, however, artificial systems of signs are likely to be manipulatory, as they will be used in an artful way by the professional diviner—and in such cases interpretive techniques have to be taken into account.

Interpretive divination. Interpretive divination involves, in the main, the reading of portents, omens, or prodigies. To the scientifically minded, no event is without a cause. Yet, the apparently arbitrary event does occur in an ordered world and thus is subject to various interpretations. Manipulated events are an element of interpretive divination, but the less active forms depend upon projection, introjection, and free association—thus being associated, to some degree, with intuitive techniques.

Pyromancy, divination by fire, may be highly dramatic in a society dependent on fire for light and safety at night. In some trans-Saharan societies the diviner may test an accusation at a seance around the fire, which will suddenly explode upon the “guilty” one. Elsewhere, objects may be overtly cast into the fire and signs read in the reaction. Hydromancy, divination by water, is usually less dramatic, ranging from the reading of reflections in a shallow surface, in the manner of the crystal gazer, to construing the movements of floating objects, as in the reading of tea leaves.

A range of related mantic practices may be grouped under the terms cleromancy, divination by lots, and geomancy, which may involve the casting of objects upon a map or a figure drawn on the ground. Cleromantic practices in trans-Saharan Africa may rely on the supposedly magical—or indeed horrifying—qualities of objects in the diviner’s bag or basket. When they are thrown, the proximity of one piece to another—for example, a dried bit of intestine from a murdered child and a man-eating animal’s tooth—may be regarded as having meaning; or the position of a particular piece at the centre or apart from the others may be picked out. Often, the diviner must first prove his ability by discovering the client’s problem, through a line of patter accompanying the throws—suggesting this, questioning that, leaping from one matter to another until the reactions of the client betray his interest. Here the diviner may be said to introject ideas and attitudes, while the lots act for the diviner and client alike as a projective device, the meaning of which is only half-formed in the objective pattern cast. A far more elaborate practice is the geomancy of West Africa, in which elegant equipment is combined with impressive erudition to produce a seance in which lots are used to select verses, wherein the client is expected to find his answers. The nature of the lots employed, the number lore on which the selection of verses is based, and the verses themselves are entirely distinct from their counterparts in the Chinese yarrow (an herb with finely dissected leaves) tradition embodied in the *I Ching*, but the general equivalence of the two elaborations is noteworthy. The parallel has perhaps been obscured by the use of “geomancy” in China to signify only a specialized art by which propitious locations are selected.

Sometimes a diviner can be said to interpret signs so characteristic of his client that the practice falls between interpretive and intuitive arts. Somatomancy, body divination, is clearly interpretive in most forms, whether in China or the West, though the system of signs employed comprises private attributes of the client’s physique. Examples are phrenology, employing features of the head that are normally unnoticed; and the reading of moles, where the body is treated as a microcosm bearing astrological

signs. But oneiromancy, dream interpretation, employs explicitly psychic phenomena; and here the diviner may be said to assist the intuition of meaning by his client as often as he can be said to introject. The Ojibwa and Bella Coola Indians of North America were characteristically preoccupied with the meanings of their dreams.

Intuitive divination. The prototype of the intuitive diviner is the occasional shaman or curer who uses trance states. These are achieved idiopathically (*i.e.*, arising from the self spontaneously) or induced by drugs or by autokinetic (self-energized) techniques, such as hand trembling among the Navajo, a large North American Indian tribe. As a mantic art, trance is associated with oracular utterance and spirit possession. An impressive performance will be taken to represent the actual voice of a god or spirit addressing the client directly; and divination in this mode is known from diverse religious traditions, including Christianity. The idea that the gods may be importuned to speak on a matter of temporal human concern seems to be very ancient. In early Egypt incubation was practiced—*i.e.*, sleeping in the temple in the hope of being inspired by the resident god. The idea behind Maya maiden sacrifice was the same: a number of maidens were cast into a sacred cenote or deep well, and those who survived after some hours were brought back to recite the messages received during their ordeal—a virtual enactment of the journey into the underworld. As oracular utterance became regular, special techniques or contraptions were developed for making the god’s image show assent or denial or for amplifying the sound of an unseen priest’s voice. In nomadic societies today, however, the diviner may still achieve personal authority by passing into a trance before his fellows, trembling and speaking “as if possessed”—that is, as if his own spirit had ceased to inhabit his body and had been replaced by another.

Related to possession is the conviction that malevolent persons are essentially unlike innocent ones, though not in outward appearance. When a test is devised for discovering malevolence, commonly conceived of as witchcraft or as a nonhuman force disguising itself in human form, the test takes the form of an ordeal. This may be a demonstration of invulnerability to harm, the presence of blessed qualities being viewed as inconsistent with malevolence; among the many types of ordeal are walking on coals and retrieving an object from boiling liquid. The ordeal may even involve death: in the ordeal by water, a witch was expected to float and so be spared for burning, but an innocent person would be accepted by the water and drown. In trans-Saharan poison ordeals the innocent person is expected to survive.

Intuitive divination may also be a wholly private affair. A Roman might hear a warning from the gods in a piece of conversation; the Aztec might discern a portent in an animal’s howl. The North American Indian who sought a private vision through isolation, self-mutilation, and fasting would preserve the memory of that vision throughout life, turning to it as his unique guardian spirit.

Divination today. The immense popularity of horoscopes in the urban West today illustrates the almost exclusive concern with individual fortune-telling that characterizes divination in a mobile and competitive mass society. Chiromancy, Tarot (fortune-telling) cards, and crystal gazing represent respectively body divination, sortilege (divination by lots), and trancelike performance in styles suitable for what might be called a half-serious attempt to learn one’s fate. Necromancy, in its modern spiritualist form, represents a slightly more serious and sustained effort to establish contact with extramundane beings. But astrology, in its various popular forms, is the form of divination best suited to mass consumption, since it is based on a well-articulated body of lore, touches matters of high destiny as well as individual fortune, and “personalizes” its introjective advice without the client’s having to be interviewed. On the other hand, the more esoteric mantic arts have the appeal of discipline—an individual may enter into the lore deeply until it becomes a part of his own worldview. Study of the *I Ching* for divinatory purposes can involve this sort of commitment.

Magic

In the occult, magic comprises a wide range of phenomena, from the elaborate ritual beliefs and practices that are at the core of many religious systems, to acts of conjuring and sleight of hand for entertainment. Used in the former sense magic is a social and cultural phenomenon found in all places and at all periods, with varying degrees of importance.

NATURE AND SIGNIFICANCE

The term magic essentially refers to a ritual performance or activity that is thought to lead to the influencing of human or natural events by an external and impersonal mystical force beyond the ordinary human sphere. The performance involves the use of special objects or the recitation of spells (words with an innate power or essence) or both by the magician. The nature of magic is frequently misunderstood because of uncertainty as to its definition, its relationship to other religious behaviour and institutions, and its social and psychological functions. This uncertainty is largely a consequence of 19th-century views on cultural and historical evolution that set magic apart from other religious phenomena as being especially prevalent in archaic and primitive societies and as merely a form of superstition without cultural or theological significance. This view has led to magic's being considered as different and distinct from other religious rites and beliefs and the overlooking of its essential similarity and connection with them, since both magical and non-magical rites and beliefs are concerned with the effects on human existence of outside mystical forces. The frequently held view that magical acts lack the intrinsically spiritual nature of religious acts, comprising external manipulation rather than supplication or inner grace, and that they are therefore of a simpler and lower kind in theological terms, has compounded the misunderstanding. The definition given above recognizes a main point of distinction between magic and other religious phenomena, in that the latter are concerned with a direct relationship between men and spiritual forces, whereas magic is regarded as rather an impersonal or technical act in which the personal link is not so important or is absent, even though the ultimate force behind both religious and magical acts is believed to be the same. The distinction made by Émile Durkheim (1858–1917), a seminal French sociologist of religion (see below), that a religious practitioner has a congregation whereas a magician has a clientele, is also a meaningful one. The difficulty in defining magic and distinguishing it from religion is due largely to Western ethnocentric views. In Judeo-Christian belief it has been distinguished from other religious acts, but this distinction is not always found in other religious systems and in fact would appear to be unusual. Many writers have referred to "magico-religious" phenomena, a convenient blanket term.

Magic is often confused with witchcraft, especially in the history of European religions. Modern anthropologists, however, make the useful distinction between magic as the manipulation of an external power by mechanical or behavioral means to affect others, and witchcraft as an inherent personal quality motivated to the same ends. In this classification, the word sorcery is used for magic that aims to harm other people; that is, sorcery is "black" magic, whereas magic used for beneficent ends is "white" magic. This distinction does not always hold for specific societies but is a useful one in analysis. Divination, the skill of understanding mystical agents that affect people and events, should be distinguished from magic in that its purpose is not to influence events but rather to understand them. The ultimate mystical power of diviners, however, may be thought to be the same as that behind the forces of magic. In some societies, magicians act as diviners, but the two skills should be distinguished. Magicians are often confused with priests, shamans, and prophets, mainly because many of these practitioners' activities include acts that are traditionally defined as "magical"; *i.e.*, while essentially they are regarded as intermediaries between men and gods or spirits, in the sense of acting in a direct personal relationship, some of their acts are also imper-

sonal or "magical." It is often, perhaps usually, impossible clearly to distinguish between priests and magicians; any distinction lies in the kind of actions they perform in particular situations rather than in any true distinction between the kinds of practitioners themselves.

HISTORY AND DISTRIBUTION

Magic in one form or other appears to be a part of all known religious systems, at all levels of historical development, although the degree of importance given to it varies considerably. The term has been used loosely by many writers, especially when discussing European magic. Also the ethnographic accounts of small-scale preliterate societies vary in the degree to which they contain detailed descriptions even when magic is important in a particular culture. Thus the analyses of magic in its total cultural setting are remarkably few.

Knowledge of magic in prehistory is limited by lack of reliable data. Many cave paintings and engravings, from all parts of the world, have been claimed to represent figures practicing hunting magic and sorcery, but this is only conjecture. More certain information about magical phenomena is available for the ancient Middle Eastern and Greco-Roman cultures, Christian Europe, and contemporary preliterate societies.

Magic in the ancient world. There are many recorded texts of what appear to be magic spells and formulas from ancient Mesopotamia and Egypt. Most accounts of these cultures class almost all records of ritual as forms of magic and as examples of magical or mythopoeic ways of thought. This is usually because the writers themselves assumed that these cultures were examples of "prelogical" thought (as compared with the thought of civilized man), and so took any religious record as evidence of this. The pharaohs of Egypt, for example, were what are usually called "divine kings," and as such were believed to have the power to control nature and fertility. Many writers refer to their powers as magical, but the evidence is rather that they were expressions of royal omnipotence and contingent on their divine status. Examples of true magical spells and formulas are recorded from both Mesopotamia and Egypt; *e.g.*, spells to ward off witches and sorcerers. Spells addressed to gods, to fire, to salt, and to grain are recorded from Mesopotamia and Egypt, as are spells uttered by sorcerers and including necromancy or invocation of the spirits of the dead, who were referred to as a last resort against evil magic. Excellent examples of spells are recorded from the earliest times, and especially in Greco-Egyptian papyri of the 1st to the 4th century AD. They include both magical recipes involving animals and animal substances, and also instructions for the ritual preparations and purification necessary to ensure the efficacy of the spells.

In ancient Roman culture much importance was given to sorcery and counter-sorcery. These seem to have been associated with the development of new urban classes whose members had to rely on their own efforts in both material and magical terms to defeat their rivals and attain success. Spells are recorded to ensure victory in love as well as in business, games, and oratory. Along with these are counter-spells to defeat rival sorcerers.

Magic in Christian Europe. For the European Middle Ages and later periods there is a vast corpus of written records. As is known from recent anthropological and historical work on witchcraft, magic, and religious syncretism, magic is specially prevalent during periods of rapid social change and mobility, when new personal relations and conflicts assume greater importance than the traditional kin and family relations more typical of times of social stability. Europe appears to have been no exception, particularly when the church, struggling to assert or maintain hegemony, leveled accusations of magic against its opponents. There are three main aspects to the history of European magic, much of which is ill-described and almost always without adequate accounts of the full cultural setting. One is that of magic and sorcery in everyday relationships at the community level from the end of the classical world until recently, when beliefs in magic have in general become weakened. In most cases these beliefs

Magic and
religion

Magic in
Egypt and
Mesopotamia

were part of the culture of lowly rural people and records are scant. An exception was sorcery used by wealthier and urban people, especially in Italy and Spain from the 14th century onward, a concomitant of increased social mobility and growth of class hierarchies. A second aspect is the better known but frequently misunderstood belief in magic defined by the church as the heretical practice of making pacts with the devil and evil spirits. St. Augustine and other early Christian writers had considered magic to be a relic of paganism and removable by conversion and education. After a papal bull in 1320, magic, regarded as synonymous with witchcraft, came to be defined as heresy, and the Inquisition's records began to mention the Witches' Sabbath (midnight assembly in fealty to the devil) and the Black Mass (a travesty of the Christian mass) as forms of magic and witchcraft. They were defined as magic because of the supposed use of material objects, philtres, spells, and poisons. The spells included the perverted use of prayers and the use of sacred writings and objects for diabolical ends. This aspect of European magic has persisted into recent times in the activities of self-styled satanists.

"White"
magic

Whereas these forms of magic were regarded as evil and tantamount to heresy, the third aspect has usually been considered as good, or "white," in intent. This is the use of magic as part of the Hermetic tradition. Followers of this tradition, who often practiced alchemy rather than magic, were sometimes considered to be evil magicians, acquiring their knowledge by a pact with the devil (as in the Faust legends), but most of them were tolerated in society because their practices, however strange, were perceived as being within the main Judaic and Christian Hermetic tradition. When their magical activities proved, or appeared, to be antisocial, the results were more often put down to simple trickery—as in the case of the 18th-century charlatan Alessandro, conte di Cagliostro (Giuseppe Balsamo)—than to supernatural agency.

Magic in nonliterate societies. Most knowledge of magic in its social setting is derived from anthropological accounts of people of the non-Western world who today believe in magic. The importance of firsthand anthropological accounts, even though many anthropologists tend to make use of the ethnocentric distinction between religion and magic, is that they show how the people themselves actually regard magic and what they actually do with it and against it, rather than relying on the records of inquisitors and missionaries whose aim it was to stamp out magic. Detailed descriptions of magic come mostly from accounts of societies in Oceania and Africa; magic is also frequently reported from many Muslim societies where pre-Islamic beliefs still exist, as in Malaysia and Indonesia. A difficulty in this respect is that accounts only rarely distinguish magic from witchcraft and divination, both of which are found in virtually every known Oriental society.

STRUCTURE AND FUNCTIONS

Structure. A general point to be made is that the frequent tales of peoples living in fear of evil magicians and black magic are merely fanciful travelers' stories. Magic is normally regarded as an everyday aspect of religion used to explain certain kinds of events and to help bring about desired eventualities. Like most religious phenomena, magic may be regarded with some sense of awe and mystery, but this is more often a sign of the importance given to it than of fear or terror. Typically people perform magical acts themselves or they go to a magician, an expert who knows how to observe the necessary ritual precautions and taboos, and who may be a professional consulted for a fee. Depending upon the beliefs of the particular culture, the skill may be transmitted by inheritance or bought from other magicians, or may be invented by the magician for himself. Magicians may be consulted for nefarious purposes, to protect a client from the evil magic of others, or for purely benevolent reasons. It seems universal that magic is morally neutral, although the emphasis in any particular society may be on either its good or its evil use.

In some religions, especially those of small-scale nonliterate societies, magic may be considered as important and

even central to religious belief; whereas in others, especially in the main world religions, it may be unimportant, and often regarded as a mere superstition that is not acceptable to official dogma. It has often been maintained that magic is important in societies that possess a particular worldview or cosmology, in which a scientifically or empirically correct cause-effect relationship between human and natural phenomena is seen as a symbolic one. This view, which is associated particularly with the British anthropologist Sir James Frazer (1854–1941), is now viewed as being based on a misunderstanding of patterns of thought in prescientific cultures. It is true that these cultures may lack the scientifically accurate knowledge of Western industrial societies; they may use magical techniques (for example, rainmaking), whereas in an industrial society it is known that such techniques are instrumentally ineffective. But magic is also performed for expressive purposes; *i.e.*, stating and maintaining the formal culture and organization of the society, so that rainmaking magic has also the function of stressing the importance of rain and the farming activities associated with it.

There are usually considered to be three main elements in magic: the spell, the rite itself, and the ritual condition of the performer. This was first stated by the anthropologist Bronisław Malinowski (1884–1942) in his study of the Trobriand Islanders of Melanesia. With the spell may be included the use of material objects or "medicines."

The spell. The importance of the spell or incantation is now thought to have been somewhat exaggerated by the influence of Malinowski's work. Among the Trobriand Islanders this aspect is extremely important: using the right words in the right way is regarded as essential to the efficacy of the rite. Among the Maori of New Zealand this element is thought so important that a mistake in the recitation of a spell would lead to the magician's own death. Frequently spells have an archaic or esoteric vocabulary that adds to the respect in which the rite is held. But in many societies the spell is of minimal importance, the magician using his own words and regarding the content as more significant.

Material objects or "medicines." Equally widespread—perhaps more so than the use of spells—is the use of material objects, often known in the literature as "medicines" (hence the popular use of the term medicine man for magician). The nature of the medicines varies greatly. In some cases, medicines intended to cause harm are genuine poisons (some African peoples place poisons in rivers to stun and catch fish, but regard them as they do any other, less genuinely efficacious medicines). More usually the medicines do not empirically bring about the effect but in some way represent it; for example, it is common practice for a magician to try to harm another person by destroying something from his body (*e.g.*, hair or nail parings), or something that has been in contact with him (*e.g.*, a piece of clothing or other personal possession). Another kind of symbolism is exemplified by the Trobriand use of light vegetable leaves in rites to ensure a canoe's speed, symbolizing the ease with which it will glide over the water; the Azande of The Sudan place a stone in a tree fork to postpone the setting of the Sun; many Balkan peoples used to swallow gold to cure jaundice.

The rite. The significance of the magical rite itself is often overlooked by those who hold the view that magic is something apart from religion. But it seems universal that magic is practiced only in formal and carefully defined ritual situations. The rite itself may be symbolic, as with the sprinkling of water on the ground to make rain or the destruction of a waxen image to harm a victim.

Condition of the performer. The ritual nature of magical performances may also be seen in a third element, that of the condition of the performer. Even though regarded as an everyday and "natural" phenomenon, magic is nonetheless considered as potentially dangerous and polluting, as is any sacred or religious object or activity. Both the magician and the rite itself are typically surrounded by the observance of taboos, by the purification of the participants, and so on. The magician may observe restrictions on certain foods or on sexual activity, and he may be regarded as polluting to other people at these times.

The
magical
view

Taboos,
purifica-
tions, and
precautions

There are two obvious reasons: failure to observe such precautions nullifies the magic, and taking precautions indicates to the participants and others the importance of the rite itself and the ends desired. The precautions mark off the rite from ordinary and profane activities and invest it with sanctity.

Functions. The functions of magic are several, but there are two main aspects, the instrumental and the expressive. A basic feature of magical rites and beliefs is that the practitioners believe that these are instrumental; *i.e.*, they are designed to achieve certain ends in nature or in the behaviour of other people. This is usually the aspect most important for the people concerned as well as for past writers on the subject. The symbolic or expressive aspect is always present, however; it is because of its symbolic content that magic may best be understood as a part of a religious system.

Instrumental functions. Malinowski and his followers have distinguished three main instrumental functions: the productive, the protective, and the destructive. Productive magic is used to ensure a successful outcome to some creative or productive activity in terms of both human labour and natural bounty, such as a good harvest or hunt. Malinowski showed clearly how it may foster confidence where technology is weak or uncertain; his example of the Trobriand Islanders making magic when fishing in the open sea but not doing so when fishing in a calm and protected lagoon makes the point clearly. In addition, productive magic may also assist the efficient organization of labour and give greater incentive to those who feel confident of success. Protective magic aims to prevent or remove danger, to cure sickness, and to protect an individual or community from the vagaries of nature and the evil acts of others. Again, it may give people confidence to continue their normal activities. Destructive magic is sorcery, directed specifically to harm other people. The fear of this form of magic may reduce individual initiative since a successful or wealthy person in an egalitarian society may fear the sorcery of the envious. On the other hand, the use of counter-magic against sorcery rids a community of its internal fears and tensions.

Expressive functions. The expressive functions of magic are symbolic and usually latent in the sense that the performers may not themselves be immediately aware of them. They have largely to do with the effects of individual acts upon society at large. It is there that the part played by magic in a total system of religion may be seen.

MAGIC, RELIGION, AND SCIENCE

Magic and religion. The relationship of magic to other religious activities depends on three main considerations. The first is the nature of the power toward which the rites are directed. The eminent British anthropologist Sir Edward Burnett Tylor (1832–1917) and his successors distinguished a personal, conscious, and omnipotent spiritual being as the object of religious ritual; magical performances have no power in themselves but are usually thought by believers to be an expression of an external, impersonal force in nature, for which the Melanesian–Polynesian term *mana* has typically been used. A second consideration is the participants: the magician and those who go to him. As noted above, Durkheim pointed out that a priest has a congregation whereas the magician has a clientele. A religious ritual has as its principal function (in sociological terms) the maintenance of a sense of cohesion among the members of the church, whereas the magical rite lacks this function. This view has been influential in the past and has by now become part of general anthropological thinking, although some of its details have been rejected by recent researchers.

The third consideration is that of the function of magic and of other religious activities. The magician may see the overt function of his action as instrumental, as geared to a specific end; the external observer may accept this but also see a latent function. Malinowski, for example, maintained that much of Trobriand magic was performed as an extension of human ability, as a power beyond the normal or understood. It had as its most important function the instillation of confidence in situations where

human knowledge and competence cease. In addition, the rite helps to throw the importance of a given activity and the cooperation needed for it into relief and thus helps maintain the high social value of cooperation in a small community beset by disruptive jealousies and competition over scarce and difficult resources. A.R. Radcliffe-Brown (1881–1955) pointed out in his work on the Andaman Islanders that their magical rites and precautions at child-birth and death may comfort those concerned, although they are also irksome, but that their main function is to highlight the social importance of birth and death and to bring to public notice the changes in patterns of local and kinship organization that follow them. Some of the hypotheses of Malinowski and Radcliffe-Brown are today regarded as questionable, but they have influenced subsequent studies in that they were concerned not only with the individual's belief in magic but also with the function of magic in the total social system.

In brief, it may be said that religious rites are ways of acting out beliefs about the relationships of man to God, man to man, and man to nature. In contrast, magic is a way of achieving certain ends beyond the knowledge and competence of ordinary people, especially in technologically limited societies, and of expressing their desires symbolically. Certain functions are common to both: the provision of explanation for the otherwise inexplicable; a means of coping with the unusual and mysterious; the enhancement of the social values of certain activities and situations and the coordination of socially valuable activities.

Magic, technology, and science. The problem of the relationship of magic to technical and scientific knowledge has concerned most writers on the subject. Magical rites have at least superficial similarities to nonmagical technical activities. In each the actor performs an action that he expects will have a certain consequence. The distinction between the two processes made by Tylor and Frazer (see below) was that the magician assumes a direct cause-effect relationship between the action and the subsequent event, whereas in empirical fact the relationship is one of the association of ideas only. Many writers have pointed out that magic is used when technical knowledge is missing or uncertain. This is not to say that magic is a substitute for technical knowledge but that its performance gives confidence to people aware of their technical limitations. The magician does not regard his magic as being the same kind of activity as weeding a field or sharpening a knife; the magical rite is of a different order, dealing with external and mystical forces.

To the scientific mind it is puzzling that people continue to believe in magic when it seems clear that there is empirically no cause-effect relationship between a magical rite and the desired consequence. The main purpose of magic, however, is not so much to achieve a certain technical end as to perform an act that has symbolic or psychological value. It is thus pointless to test it, in the same sense that a Christian does not test the efficacy of prayer. The problem was discussed by Tylor, who produced reasons why the failure of magic was not easily apparent to believers. The idiom of magic pervades all in contact with it and cannot be tested scientifically in its own terms, so that tests as to the magic's efficacy are not in fact tests at all but rational statements about commonsense experience.

THE MAIN THEORIES OF MAGIC

There is a voluminous literature on magic. The earliest studies were those of Judaic and Christian scholars concerned with the relationship of magic to their faiths, both as relics of paganism and as heresy. During the latter part of the 19th century, anthropologists entered the field with the aim of analyzing magic and its part in the evolution of the world's religions.

Anthropological. The first important figure in the anthropological consideration of the subject was Tylor, who, in his *Primitive Culture* (1871), regarded magic as a "pseudo-science" in which the "savage" incorrectly postulated a direct cause-effect relationship between the magical act and the desired event. Although Tylor regarded magic as "one of the most pernicious delusions that ever vexed mankind," he studied it not as a superstition or heresy

but as a phenomenon based on the "symbolic principle of magic," a logical scheme of thought founded on a quite rational process of analogy. He also faced the question of why the believer in magic did not realize its inefficacy. His reasons included the frequent association of magic with empirical behaviour, nature often performing what the magician tries to do; the attribution of failure to the breaking of taboos or to hostile magic forces; the plasticity of the notions of success and failure; and the weight of cultural belief and authority behind the magician. He also realized that magic and religion are parts of a total system of thought; they are not alternatives but complementary, and thus not stages in the evolutionary development of mankind—although he considered that magic and animistic beliefs decreased in the later stages of history.

Frazer's
theory

In *The Golden Bough* (1890) Frazer refined Tylor's views on magical thought, discussed the relationship of magic to religion and science, and placed them all in a grandiose evolutionary scheme. He accepted Tylor's theory about the false cause-effect relationship between magical and natural events, calling magic a "spurious system of natural law," and analyzed the principles behind the false relationship. According to Frazer the principles were that "like produces like, or that an effect resembles its cause" (the Law of Similarity) and that things once in physical contact with each other later continue to act on each other at a distance (the Law of Contact or Contagion). Magic based on the former he called homeopathic magic, that based on the latter he called contagious magic. He added the notion of taboo as negative magic, acting on the same principles of association.

Frazer also developed an evolutionary scheme for magic and religion. He saw magic and religion as belonging to different stages in the development of human thought. Magic was prior because it seemed to him to be logically more simple, because he assumed (erroneously, as was shown later) that the Australian Aborigines, examples of an archaic people, believed in magic but not in religion, and because magic forms a substratum of superstition even in advanced societies. According to Frazer, individuals in the earliest cultures must have come to realize the inefficacy of magic and the powerlessness of men to control nature; from this they postulated the existence of omnipotent spiritual beings who required supplication in order to direct nature as men wanted. Thus there came into existence religion. The final stage in this schema began with the recognition of the existence of empirical natural laws, aided by the discoveries of alchemy and then of science proper. With this final development religion joined magic as superstition.

These writers, and their followers such as R. Ranulph Marett (1866–1943), regarded magic as essentially an individual and intellectual matter, one of the ways in which individuals think about the world. Another line of writers widened the discussion by regarding the problem as essentially one of the social function of magic. The first such writers of note were the French sociologists Marcel Mauss (1872–1950) and Émile Durkheim. Durkheim, in *The Elementary Forms of the Religious Life* (Eng. trans. 1915), considered that magical rites comprised the manipulation of sacred objects by the magician on behalf of individual clients; the socially cohesive significance of religious rites proper, by the priests, was therefore largely lacking. His views were followed by Radcliffe-Brown (*The Andaman Islanders*, 1922) and to a lesser extent by Malinowski (*Argonauts of the Western Pacific*, 1922, and various papers brought together as *Magic, Science and Religion*, 1925), the latter influenced more by Frazer and the early psychoanalysts. Radcliffe-Brown's main hypothesis has been mentioned above: the social function of magic was to express the social importance of the desired or protected event. Malinowski, on the other hand, regarded magic as being opposed to religion, and as directly and essentially concerned with the psychological needs of the individual. It acted to extend his normal knowledge and competence; to provide confidence in situations of technical uncertainty by "ritualizing optimism"; to express desires that are otherwise unrealizable in a small and technically limited community; and, as counter-magic, to explain failure. Ma-

linowski's influence has been marked, due largely to the fact that his was the first detailed and firsthand account of the actual working of an ongoing system of magic. Other writers, notably Marett in England and Robert Lowie and Alexander Goldenweiser in the United States, differed from Tylor and Frazer in voicing the opinion that the distinction between magic and religion reflects an ethnocentric distinction between the "natural" and the "supernatural" that is largely untenable.

More recently there have been many reports of the working of systems of magic, especially from Africa and Oceania. On the whole they have followed Malinowski and Radcliffe-Brown and have been based on the single most important work on the topic that has appeared since theirs, *Witchcraft, Oracles and Magic Among the Azande* (1937), by Sir Edward Evans-Pritchard (1902–73). Evans-Pritchard shows concisely how magic is an integral part of religion and culture, being used to explain events the normal understanding and control of which are beyond the technical competence of this southern Sudan people. The Azande accept magic, together with witchcraft and oracles, as a normal part of nature and society. These various phenomena form a closed logical system, each part of which buttresses the other and provides a rational system of causation for both natural order and social order as well as for disorder or coincidence.

Psychological. These various anthropological approaches to magic have had the advantage of regarding it as a social phenomenon rather than one of individual psychology. The views of Tylor and Frazer, however, are ultimately psychological, since they are based on their notions of individual ways of thought. Their work was based to a considerable extent on that of Herbert Spencer and Wilhelm Wundt and was followed by anthropologists with views on the psychological origins of magic and religion, such as Lowie, Paul Radin, and Goldenweiser, all of whom were concerned with the problem of the individual psychological status of believers. Much of Malinowski's work depends on providing psychological reasons for belief in magic. Sigmund Freud (*Totem and Taboo*, 1918) had at one time considerable influence with his view that magic, the earliest phase in the development of religious thought (following Frazer), was similar in its essential processes to the thought of children and neurotics. This view was based on his theory of the "Omnipotence of Thought," by which savages, children, and neurotics all assumed that wish or intention led automatically to the fulfillment of the desired end. This view has long been abandoned, due not so much to its inherent misunderstanding of the expressive nature of magical ritual as to the general recognition that the assumption of the similarity between primitive, infantile, and neurotic modes of thought is false; it arose largely from the ignorance about primitive culture that prevailed before the development of modern anthropological field researches.

Conclusion. The study of magic as a distinct cultural phenomenon has a long history in anthropological and historical studies. Although some distinctions between it and other religious activities may often be useful, it cannot be studied in isolation as was once the fashion. It is essentially an aspect or reflection of the worldview held by a particular people at a particular stage of development in scientific and technical knowledge. It is thus a part, although to the people concerned often a very important part, of their total system of religion and cosmology.

(J.F.M./R.A.Gi.)

Witchcraft

The term witchcraft commonly has referred to the supposed use of supernatural means for harmful or evil ends. In traditional and popular English usage it is practically synonymous with sorcery. Many anthropologists, however, distinguish between witchcraft, as involving an inherent mysterious power of certain weird, aberrant individuals, and sorcery, as the work of ordinary persons using deliberate techniques and external means familiar to other adult members of the community. Practitioners of both types aim to do harm to others, but, while the witch appears to

Witchcraft
and
sorcery

Theories of
Malinow-
ski,
Radcliffe-
Brown, and
Evans-
Pritchard

move through an obscure compulsion or spirit possession, the sorcerer seems to be moved by simple ill will. Although this distinction was originally discerned among the Azande people of Central Africa, it has been found applicable to many other tribal peoples in nonliterate cultures and also to some early modern European societies. On the other hand, students of such phenomena in Oceania use the term sorcery for all forms of destructive magic, whether for socially approved purposes (*e.g.*, to protect property) or not. To add to the complexity of terms and meanings, in some societies (*e.g.*, in medieval Europe) witches were believed occasionally to pursue beneficial aims, such as healing the sick—so-called white witchcraft.

In any case, belief in witchcraft, in its anthropological sense, has been widely distributed in human society. Records of such beliefs go back to the dawn of history and, if certain interpretations of rock paintings and other archaeological evidence are accepted, probably to the prehistoric period as well. Nevertheless, there are some peoples (*e.g.*, the Kalahari San and Andaman Islanders) among whom a belief in witchcraft does not exist; others (*e.g.*, the Javanese) believe in sorcery but not witchcraft in the technical sense above; and still others (*e.g.*, in Arab-Muslim cultures) believe in the Evil Eye, but do not believe in witchcraft.

NATURE AND SIGNIFICANCE

Witchcraft and magic. The term magic, as treated above, refers to human actions that are believed to influence human or natural events through supernatural power. For anthropologists it is a neutral term, though the actions involved may be classified as productive, protective, or destructive. Sorcery belongs to the category of destructive magic but does not encompass all of it, since certain socially approved forms of destructive magic (*e.g.*, to protect property or to prevent adultery) are not considered sorcery. Sorcery is destructive magic that is regarded as antisocial and illicit, the resort of misguided persons who should instead have used arbitration or litigation for settling the issues that have aroused their anger, envy, or malice. Thus, the practice of sorcery is destructive magic illicitly applied.

All magic, whether productive, protective, or destructive, licit or illicit, has four recurring elements: performance of rituals or prescribed formal symbolic gestures, use of material substances and objects that have symbolic significance, utterance of a closely prescribed spell or of a less formal address, and a prescribed condition of the performer (see above *Magic*).

Magic and witchcraft need to be considered together. Sorcery, the illicit form of destructive magic, is closely akin to witchcraft in the special sense, since the same moral status is accorded those who are believed to practice or to be involved in it. Beliefs in both sorcery and witchcraft involve magical methods of identifying the supposed sorcerer or witch; and it is permissible to apply destructive counter-magic against either sorcerers or witches. Moreover, both beliefs derive from the same worldview, or cosmology, one that has been described as the closed predicament (*i.e.*, one in which any alternatives to traditional beliefs are unthinkable) as opposed to the open one that is considered to prevail in more enlightened modern societies. The third of these similarities has made the study of witchcraft and sorcery relevant to the philosophy of science (see below *A coherent explanatory system*).

Structure and function. Beliefs in witchcraft in the generic sense are conspicuous in most small-scale communities (*e.g.*, in preliterate cultures), where interaction is based upon personal relationships that tend to be life-long and difficult to break. In such societies belief in witches makes it possible for misfortunes to be explained in terms of disturbed social relationships; and the threat either of being accused of witchcraft or of being attacked by witches may well be a source of social control, making people more circumspect about their conduct toward others. Witches who are blamed for misfortunes, while often near kinsmen and neighbours, are conceived of as inhuman and beyond the pale of decent society. They are, thus, convenient scapegoats who are blamed for events

"Linda Maestra," by Francisco de Goya, showing a young witch being instructed by an experienced hag.

otherwise inexplicable in terms of the limited empirical knowledge prevailing in a society with a poorly developed technology—*e.g.*, events such as sudden death or persistent illness or even accidents.

This explanatory function of witchcraft is widespread. So too are some of the details of the witch's supposed habits and techniques, such as operating at night; flying through the air on broomsticks (in Europe) or saucer-shaped winnowing baskets (in Central Africa); employing animal familiars (assistants or agents), such as cats, dogs, and weasels in Europe, dogs and foxes in Japan, or hyenas, owls, and baboons in Africa; stealing or destroying property; and injuring people in a variety of ways, eating them while they are still alive (an African explanation for tropical ulcers), or killing them first and exhuming their corpses for ghoulish feasts.

Beliefs in witchcraft provide the mystical medium in which deep-lying structural conflicts, especially those not susceptible to rational adjustment by social intervention and arbitration, may be expressed and in some measure discharged. The inherent disharmonies in the social system are thus cloaked under an insistence that there is harmony in the values of the society, and the surface disturbances that they cause are attributed to the wickedness of individuals. This is why the witch and sorcerer become the villains of the society's morality plays (as personified vices), the ones to whom the most inhuman crimes and characteristics are attributed. So numerous and so revolting are the practices ascribed to witches that to accuse anyone of witchcraft is a condensed way of charging him with a long list of the foulest crimes—and much the same may be said of sorcery, except that the alleged sorcerer might find some room for defense in the ambiguity as to when the use of destructive magic is legitimate and when it is to be regarded as sorcery.

Because accusations of witchcraft, if they are successful, are devastating attacks on reputation, they punctuate the micropolitical processes relating to many forms of competition for some scarce status, power, resource, or personal affiliation. For example, among the matrilineal Ceŵa of east central Africa the generally accepted succession rule states that a headman's office should pass to his younger brothers in turn, followed by the eldest son of their eldest sister. In practice, however, the Ceŵa take personal qualifications into account and would not permit the succession of the rightful heir if his competence as a headman were seriously challenged by a convincing accusation of sorcery. The supposed victim of witchcraft or sorcery may also sometimes be regarded as getting his just deserts if he has, by tactless folly, incurred the wrath of powerful persons in the community.

Because in such belief systems the transgressors of a society's ideals are depicted with dramatic disapproval, witchcraft and sorcery are usually powerful brakes upon

Common details of witches' habits and techniques

Witchcraft and sorcery as inhibitors or accelerators of social change

social change. In many preliterate societies in modern times it is often those who have progressed economically and educationally who are most obsessed by fears of attack by witches and sorcerers or of accusation of employing witchcraft or sorcery. This is because they find themselves either out of line in social orders that economically at least are equalitarian or with a new-found status that lacks a niche in the traditional hierarchy; and their fears of the consequences of their eccentricity are expressed in beliefs that witches and sorcerers in the community will take their revenge or that they themselves will be accused of advancing their interests through mystical means at the cost of their kinsmen and neighbours.

On the other hand, belief in witchcraft may, under certain circumstances, have the effect of accelerating social change; e.g., by facilitating the rupture of close relationships that have become redundant but are difficult to break off. In such a situation an accusation of witchcraft has the effect of making a public issue out of what started as a private quarrel.

Characteristics of the witch or sorcerer. There is no single description of the witch or the sorcerer that may be taken as an authoritative picture fitting all societies. In most the witch is characteristically depicted as female, but in many either sex may be conceived of as witches. In a single society the sex ratio may vary according to whether the accusations consist of broad, general statements, leading to the impression that most witches are women, or specific explanations of misfortune, which may designate most witches as men, since men are often more socially involved in a small-scale community.

In regard to other characteristics, the stereotype of the witch varies from one society to another. In Europe witches are pictured as thin and gaunt, whereas in Central Africa they are described as fat from eating human flesh, while their eyes may be bloodshot from pursuing in sleeping hours evil practices of which their everyday waking selves may not be aware. Witches' familiars or imps may be conceived of as simply aiding them in their nefarious practices or as personifying their addiction by relentlessly driving them on in their evil ways. In most societies in which belief in them occurs, witches are assumed to be members of the same local community as their accusers and supposed victims. Among the peoples of the Himalayan foothills and the Navajo of the U.S. Southwest, however, witches are believed to attack people outside their own community. This is also commonly reported of sorcerers in Oceania, who, however, may be considered as legitimately employing destructive magic against an outside enemy rather than practicing sorcery in the antisocial sense of the term.

Distinctive traits of witches and sorcerers

In many societies witches are believed to be slaves of aberration and addiction. Thus considered, they are weird, sometimes tragic, characters in the human drama. Sorcerers, on the other hand, are regarded as ordinary people driven by understandable, even if deplorable, urges, such as malice, envy, or revenge, which are a part of everyone's experience. The propensity to be a witch is usually attributed to heredity or at least is considered constitutional in the sense of having been implanted at an early age through one's mother's milk or, as among the Cewa of east central Africa, through a child's having been magically inoculated by an adult, such as his grandparent, against the skin rash believed to result from eating human flesh, an activity attributed to Cewa witches. Sorcery, on the other hand, usually demands no special personal attributes and is believed to be practiced by anyone who can acquire the necessary magical substances (especially in Africa) or the appropriate magical spells (especially in Oceania).

Occasions of witchcraft. The envisioned relationships between the alleged witch and his believed victim, as well as the observable ones between him and his accuser (who may be the victim himself or a close relative or friend), are conceived of as tense because of the problems of close living or because of competition between them for social honour and prestige. In most instances people are believed to resort to witchcraft when the tension they feel toward those with whom they have quarreled or competed is not subject to arbitration by the society's normal

machinery of tension management, such as courts and similar assemblies.

Although the members of small-scale societies, both contemporary ones described by anthropologists and past ones reconstructed by historians, have tended to attribute a large proportion of their misfortunes to the evil actions of sorcerers and witches in their own communities, this does not necessarily mean that people in such societies are continuously involved in the rituals of sorcery or are frequently preoccupied with the possibility that they are exerting the mysterious, evil influences of witchcraft; nor does it mean that those who believe themselves to be the victims of sorcery or witchcraft are continuously obsessed by fears of them. People seem to learn to live with the threat of witchcraft and sorcery just as members of modern societies learn to live with the threat of automobile or airplane accidents.

A coherent explanatory system. Perhaps the most interesting feature of systems of belief involving witchcraft, sorcery, and divination is the consistency and harmony with which they bring together their constituent elements. This is the main message of the classic study *Witchcraft, Oracles and Magic Among the Azande*, by Sir Edward Evans-Pritchard. The Azande are shown to attribute virtually all their misfortunes to witchcraft and sorcery, and their conceptions of these entirely or largely imagined activities—along with beliefs in the general efficacy of their divinatory techniques—provide them with an explanatory frame of reference. Such a frame of reference removes uncertainties and prescribes steps for the management of tensions, steps that, though to the modern Western mind unrelated to the causes of their misfortunes, are nevertheless of psychological value to the believer and tend to reinforce and harmonize the circular belief system. For example, someone falls ill or has an accident; the poison oracle points to the witch responsible and is confirmed by superior oracles; the alleged witch is induced to withdraw his witchcraft; the patient gets better—as most patients do anyway. If he should not, however, the predictive failure of the oracle is easily explained away by the secondary elaborations that tend to develop as supports to the basic belief in divination; for example, the oracle poison used was of the wrong kind, or stale, or the oracle was upset by someone's use of witchcraft.

Michael Polanyi, a contemporary Hungarian-British philosopher, has analyzed Zande beliefs relating to witchcraft and found them to be characterized by the circularity just illustrated, by what he calls "epicyclical elaboration" (i.e., secondary beliefs that explain away predictive failure), and by what he terms "suppressed nucleation" (i.e., objections to the theory that explains misfortunes in terms of witchcraft are met and explained away one by one, so that they can never cluster into a rival explanatory system that can displace the belief in witchcraft). These three features, circularity, epicyclical elaboration, and suppressed nucleation, Polanyi maintains, are also characteristic—at least in the short run—of modern scientific theories, assuring their maintenance against contradictory experience and data. Another contemporary thinker, Thomas S. Kuhn, contends that scientific paradigms (i.e., prevailing theoretical systems) tend to outlast the observed anomalies that, logically speaking, should destroy them; and that they are abandoned less often by a change of heart on the part of the scientific establishment than by the entry into the field of a new generation of scientists uncommitted to the prevailing paradigm.

Theories of witchcraft. Various theories have been put forward to account for the existence of witch beliefs. Among those advanced to account for their occurrence in early modern Europe is that of Margaret Murray, a British Egyptologist, who considered the witches of western Europe to be the lingering adherents of a once general pagan religion displaced by Christianity. Most contemporary scholars in witchcraft reject this theory as unfounded historically. A more recent theory relating to the so-called European witch mania lasting from the mid-15th to the mid-18th century is that of the British historian Hugh R. Trevor-Roper. He views witchcraft as an outgrowth of the systematic "demonology" that the medieval

Systematic consistency of witchcraft, sorcery, and divination

Analogue with scientific explanations

Diffusionist, psychological, and sociological theories

church constructed out of the scattered folklore of peasant superstitions and that acquired a momentum of its own in the centuries of political and religious strife that transformed Europe from the so-called Dark Ages to the modern period.

Theories of more general applicability include the diffusionist, psychological, and sociological theories of various anthropologists and historians. Diffusionist theories are concerned with accounting for the distribution, either at present or in historical times, of beliefs and practices relating to witchcraft; e.g., viewing Pueblo witch beliefs as an amalgam of Spanish and Indian influences. Psychological theories stem ultimately from Freud's doctrine of the displacement of affect (that emotions repressed in one situation find an outlet in another), as exemplified in the theory of Malinowski, who regarded magic (including sorcery) as institutionalized "substitute activity" resorted to when urges for survival or for revenge are blocked by the inadequacies of technology or (following Clyde K.M. Kluckhohn's development of the theory) are limited by the closeness of social relationships that can be ended only with great difficulty.

Sociological theories of witchcraft stem from Evans-Pritchard's work among the Azande and illuminate two fields, the sociology of knowledge (the social conditions of knowledge and explanation) and the study of the micro-political processes, already noted above. Although Evans-Pritchard's book was a study in the sociology of knowledge in a particular society, it contained several acute insights into the links between social structure and belief that led other investigators to consider applying them in their studies of other societies. As a result there has emerged a body of theory that takes the relative frequency of accusations or supposed instances of witchcraft or sorcery to be social strain gauges that reveal which roles and relationships in a social system are especially subject to tensions—tensions for which articulation and periodic discharge must be provided if the structure is to survive.

WITCHCRAFT IN HISTORICAL CULTURES

Ancient Middle East and Europe. Belief in magical practices was apparently widespread in the cultures of the ancient Middle East. Magical power to heal sickness and other acts of white witchcraft or sorcery are ascribed to gods, heroes, and men in the extant literature of ancient Mesopotamia, Egypt, and Canaan. There was also a fear of malevolent magic or sorcery, especially in Mesopotamia, and a search for counteraction. According to the biblical record, the ancient Hebrews, as well as their pagan neighbours, were conversant with these practices, fears, and avoidances. It is disputable whether any of the Hebrew terms rendered "witch" or "sorcerer" in various translations refer to witchcraft in the special modern sense. Very often they have to do with mediums and necromancers applying certain techniques of divination. The so-called witch of Endor used by King Saul, according to the story in the First Book of Samuel, is a good example of this; actually the King James Version calls her "a woman that hath a familiar spirit," and the Revised Standard Version, "a medium." On the other hand, a passage in the Book of Ezekiel referring to certain women who, through the use of "magic bands" and veils, control the souls of other persons seems clearly to refer to sorcery. Such women are castigated as vainly going against God and his power. Sorcerers and magicians in general are denounced frequently in the Old Testament as antisocial as well as anti-God, and their offenses are punishable by death. The vehemence and frequency of the denunciations indicate that some such practices were prevalent; the New Testament writers also denounced them as immoral and idolatrous.

Witchcraft in ancient Greece and Rome

In ancient Greece and Rome only magical practices intended to do harm were condemned and punished; beneficent sorcery was approved and even official. It was believed that certain persons could do harm to others in their economic, political, athletic, and amorous endeavours and even cause their death. Such activities were often ascribed to the gods themselves, who, unlike the Judeo-Christian God, were not purely good and were, moreover, subject to the same impulses as human beings (and also

to human sorcery). Certain goddesses—e.g., Diana, Selene, or Hecate—were associated with the performance of malevolent magic that took place at night and according to a fixed ritual, with various paraphernalia and spells. A story recounted by Apuleius in *The Golden Ass* (2nd century), probably reflecting popular belief, centres on the alleged tendency of the witches of Thessaly (a region notorious for its witches) to gnaw off bits of a dead man's face and their power to assume various animal forms to carry out their ghoulish purpose.

Among the Germanic peoples, who spread throughout Europe during the decline and fall of the Roman Empire, fear of witches was widespread. Here, too, the gods were sponsors and practitioners of sorcery, as well as subject to its power, while kings practiced and suffered from malevolent magic. Types of witchcraft were assigned to whole social classes or families. As in the Greco-Roman world, such powers were especially attributed to women, and the old-woman witch type that was to become central in later European witch scares was a frequent figure in literature. Similar themes appear in the literature of the ancient Slavic peoples.

Western Christendom. Laws, both civil and ecclesiastical, against witchcraft practices and beliefs were enacted quite early in ancient Spain and Gaul in the early Christian Era. Charlemagne and other Frankish rulers condemned such practices and beliefs as evil and superstitious and passed severe laws against them, involving the death penalty. Church councils and leaders sometimes inveighed against belief in witchcraft as mere superstition and illusion, a contemptible relic of paganism; at other times they declared its practice was an actual evil that must be suppressed.

On the whole, though, with a few notable exceptions, such as Augustine and Thomas Aquinas, the ancient and medieval church attempted to wean its adherents from folk beliefs in witchcraft and magic. This skepticism, maintained by such influential figures as St. Boniface and St. Agobard, was officially embodied in canon law, which was comparatively moderate and lenient in its measures against witches and witchcraft.

Between the 12th and 15th centuries a decisive transformation occurred in the church's attitude. Contact with Arabic culture in the 12th century introduced studies such as alchemy and astrology that evoked a new interest in what has been called "natural magic," which, quite apart from the weapon it provided against heresy, could no longer be dismissed as peasant superstition. It was, however, agitation against heretics that finally caused a change in official church policy. In 1484 two Dominican friars, Heinrich Kraemer and Johann Sprenger, induced Pope Innocent VIII to issue a bull authorizing them to extirpate witchcraft in Germany; and two years later these two men published the *Malleus maleficarum* (*The Witches' Ham-*

The church's attack on witchcraft

mer), a work that became the authoritative encyclopaedia of demonology throughout Christendom. It was a synthesis of folk beliefs that had hitherto been manifested in local outbursts of witchfinding. Its authority lasted for nearly three centuries, during the time of the European witch mania.

The demonology that the *Malleus* enshrined became an established and systematized theory attributing witches' powers to their special links with the devil, especially their sexual relationships with him as incubus (embodiment in masculine form) if they were women or as succubus (embodiment in feminine form) if they were men. Though witches in other societies personify evil in general, in European history they became specifically identified as the earthly representatives of the Prince of Evil.

The campaign against the devil's earthly representatives was waged long and unrelentingly. The biblical injunction "You shall not permit a sorceress to live" was observed repeatedly. The fomenting of the witch mania cannot be attributed exclusively to either Roman Catholic or Protestant leaders. Although launched by Roman Catholic evangelists, it was revived and extended by their Protestant counterparts and further cultivated during the Counter-Reformation. Although throughout the centuries of its sway there were skeptics who opposed its fundamental tenets, the mania did not decline until the whole medieval cosmology was displaced by that of the less theocratic and more secular frame of reference of the modern world. A.D.J. Macfarlane, a modern British historian of witchcraft during the Tudor and Stuart eras in England, has used the insights of modern Africanist anthropology to demonstrate the link between the witch mania and the broader social changes in which it was set. This he has done by reviewing more than 1,200 cases gleaned from court records and contemporary pamphlets relating to the English county of Essex in the 120 years following 1560. The most frequent kind of accusation of witchcraft was the one in which someone who had repudiated a neighbour, usually an old woman seeking a favour, subsequently attributed some misfortune befalling him to her anger at being refused and thus to her witchcraft. Macfarlane links

this typical instance with the wider changes taking place from a neighbourly, highly integrated, mutually dependent village society to a more individualistic one of the kind now prevalent. In this general setting, the belief in witchcraft provided a means, though not necessarily one consciously employed, of sundering a close but redundant relationship.

The famous Salem witch trials of 1692 may be regarded as one of the last fitful flares of the witch mania. They have been studied anew by Chadwick Hansen, an American historian, who concluded that witchcraft was practiced in Salem, that it did harm to persons claimed to be victims, and that it posed a real threat to the community. The indiscriminate accusations that resulted in the execution of innocent people were the result of a general public panic in response to the psychosocial situation, not to the exhortations of clerical bigots. This fear sprang from a system of beliefs held by most Westerners at the time and also accounted for the harm done to the "afflicted" persons. Witchcraft worked in Salem because the persons involved believed in it.

The modern, secular world. During the following centuries cultural, social, economic, and technological developments resulted in the modern secular worldview in which belief in witchcraft has no place but instead appears as sheer superstition. Yet modern societies, too, have been beset by mass obsessions that in many respects resemble the witch manias of earlier times; the equivalent of satanic power and evil is sometimes ascribed to political and social deviants who are publicly accused, condemned, and suppressed. Moreover, reports of witchcraft practices and beliefs in the traditional sense still occur today in Western societies.

The term witchcraft is currently applied to two types of phenomena in modern societies, correctly to one but erroneously to the other. The authentic use of the term refers to cases in which persons believed to have harmed others by witchcraft are physically attacked or perhaps even lynched. Such cases usually occur in peasant communities in which old traditions are preserved and in which social mobility is slight; hence they resemble instances of witchcraft in nonliterate societies. In such communities people are living in close association with kinsmen and neighbours and cannot easily escape from the social networks that hold them; consequently, interpersonal tensions build up until the flash point of an accusation is reached.

The incorrect use of the term refers to persons claiming to be witches and reported to belong to covens, who assemble on appropriate calendrical occasions for sabbaths at which they perform rituals according to a tradition that the coven leaders claim descends from earlier witches. This kind of "witchcraft," judging by the way in which its participants freely acknowledge their adherence, seems highly respectable compared with the activities of the despised and hated miscreants of earlier periods in our own society or of contemporary nonliterate or peasant communities. These so-called witches claim to be adherents of an ancient religion, the one to which Christianity is regarded as a counter-religion, and in this way they seek to secure public recognition of their eccentric activities by appealing to the cherished modern value of religious toleration.

These practitioners usually turn out to be entirely sincere but misguided people who have been directly or indirectly influenced by Margaret Murray's article "Witchcraft," published in the 14th edition of *Encyclopaedia Britannica* (1929), which put forth in its most popular form her theory that the witches of western Europe were the lingering adherents of a once general pagan religion that has been displaced, though not completely, by Christianity. This highly imaginative but now discredited theory gave a new respectability to witchcraft and, along with the more practical influence of such modern practitioners as Aleister Crowley and Gerald Gardner, contributed to the emergence of self-styled witches that are sometimes featured in the sensationalist press.

WITCHCRAFT IN NONLITERATE SOCIETIES

Knowledge of the nature and functions of witchcraft has probably been advanced most by anthropological studies

Witchcraft today—authentic and inauthentic

Studies by
Gamitto,
Spencer
and Gillen,
Warner,
Fortune,
and
Kluckhohn

of nonliterate societies, as in the classic study by Evans-Pritchard of the Azande, already noted.

In 1831–32 A.C.P. Gamitto, a young Portuguese army officer, on an expedition to the interior of the African continent, made some remarkably full and objective notes on the witch beliefs of the Maravi and Ceŵa peoples on the plateau between the Zambezi River and its tributary, the Luangwa. His notes describe the measures taken against persons who were suspected of witchcraft, such as the poison ordeal—according to which innocence was believed to result in the vomiting of the poison and guilt was believed to result in its retention with consequent purging or death—and the execution of a witch by burning.

In their monumental works, published at the turn of this century, on the peoples of central Australia, Sir Baldwin Spencer and F.J. Gillen made frequent references to the Aborigines' belief in the power of sorcerers, who, by pointing with a charmed bone or stick, were believed to kill their enemies at a distance. According to the later studies (1937) of W. Lloyd Warner, the Murngin people of northern Australia believe that sorcerers by performing operations on their victims cause them to die later without knowing what has befallen them.

Reo Fortune's study (published in 1932) of Tewara, an island in the western Pacific near Dobu, revealed a small community riven by tension, hostility, and anxiety, one in which misfortunes and failures were constantly attributed to the sorcery of men and the witchcraft of women. To elucidate the tangled social relationships ultimately blamed for their frustrations and disappointments, the Dobuans resort to elaborate forms of divining, including water gazing, crystal gazing, and bending the supposed victim's middle finger and noting whether the tip of it flushes.

Clyde Kluckhohn's study of the Navajo, published in 1946, included a systematic examination of the occasions on which Navajo believe witchcraft to be employed, the various forms it is believed to take, and the measures taken to detect and combat it. Kluckhohn interprets Navajo witchcraft as providing a psychological safety valve for the tensions that develop from living in small groups at close quarters with kinsmen with whom one must cooperate in order to survive. He sees witch beliefs as important means of social control in that they check wide divergences from economic and social norms. J.D. and E.J. Krige, working among the Lovedu of South Africa, adopted a psychological approach similar to that of Kluckhohn. Among their conclusions are (1) that "witchcraft and sorcery provide avenues of vicarious achievement to those who, because of their aggressive temperaments or disharmonious conditioning, find it impossible or extremely irksome to conform [to the Lovedu society's ideal] pattern of co-operativeness and reciprocity" and (2) that "witchcraft is a reflection, not of tensions as such, whether open or repressed, but of tensions within the framework of cultural mechanisms for avoiding their being projected as witchcraft."

The study of witchcraft and sorcery as a means of elucidating micropolitical processes is a field to which several anthropologists working in Africa have contributed. Monica Wilson and S.F. Nadel have each made comparative studies of witch beliefs, showing how they are related to the social structures of the societies in which they occur. Clyde Mitchell among the Yao and Victor Turner among the Ndembu, in 1956 and 1957, respectively, have shown how accusations of witchcraft punctuate the periodic crises in the development of the social relationships enmeshing a village community. Max Marwick has shown how accusations of sorcery among the Ceŵa precipitate the periodic divisions of local village communities as they grow in size beyond the limits of administrative convenience and of local resources. Other writers have noted the changes in beliefs accompanying urbanization and similar modern developments. For instance, Clyde Mitchell and Marc Swartz have observed a decline among urban Africans in the tendency to explain misfortunes in terms of witchcraft. They attribute this to the fact that, because in modern towns there is a preponderance of strangers not linked intimately or emotionally, it is often possible for tensions resulting from the normal frustrations of living to be expressed openly rather than supernaturally and that, when

tension between intimate associates develops, it is easier for them to break off their relationship than it would be were they living in a small-scale rural community. These developments observed in African cities since the mid-20th century may well parallel those that finally emancipated the Western world from a universal belief in witchcraft.

Among the numerous accounts that have been published on modern movements in Africa, concerned with the extirpation of witchcraft, Roy Willis' study (1968) of the Kamcape movement among the Fipa of southwestern Tanzania broke new theoretical ground, for it showed that the movement had quasi-revolutionary overtones. The witch beliefs and the community's epidemic reaction to them facilitated a redistribution of power between generations, a kind of change the analysis of which is likely to increase understanding of the politics of developing countries. Willis pointed to the importance in the theory of social change of what he referred to as "proto-institutions," such as anti-witch cults, in which a general discontent with the strains of culture contact takes the form of organized rejection of traditional belief systems.

Occupational Diseases and Disorders

Occupational diseases and disorders are those associated with a particular occupation or industry. They result from a variety of biological, chemical, physical, and psychological factors that are present in the work environment or are otherwise encountered in the course of employment. Occupational medicine is concerned with the effect of all kinds of work on health and the effect of health on a worker's ability and efficiency.

Occupational diseases are essentially preventable and can be ascribed to faulty working conditions. The control of occupational health hazards decreases the incidence of work-related diseases and accidents and improves the health and morale of the work force, leading to decreased

absenteeism and increased worker efficiency. In most cases the moral and economic benefits far outweigh the costs of eliminating occupational hazards.

This article discusses general occupational health hazards and the disorders they cause, as well as the role of occupational health services. More detailed information about specific disorders can be found in the articles dealing with human diseases and the structures of the human body, such as **CANCER; INFECTIOUS DISEASES; and RESPIRATION AND RESPIRATORY SYSTEMS.**

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 424.

HISTORICAL OVERVIEW

The preindustrial era. The first recorded observation of an occupational disease may be a case of severe lead colic suffered by a worker who extracted metals. It is described in the third book of *Epidemics*, attributed to Hippocrates, the Greek physician of the 4th century BC. Other early writers also recognized the association between certain disorders and occupations. The Roman scholar Pliny, in the 1st century AD, described mercury poisoning as a disease of slaves because mines contaminated by mercury vapour were considered too unhealthy for Roman citizens and thus were worked only by slaves. In general, however, physicians of antiquity were not concerned with the health of workers.

During the Middle Ages the rise of metalliferous mining in central Europe inspired the German mineralogist Georgius Agricola to make a detailed study of gold- and silver-mining operations. In his *De Re Metallica*, published posthumously in 1556, Agricola described the primitive methods of ventilation and personal protection in use, common mining accidents and disasters, and such miners' occupational diseases as the "difficulty in breathing and destruction of the lungs" caused by the harmful effects of dust inhalation.

A more comprehensive account of occupational disorders was written by Bernardino Ramazzini, a professor of medicine first at the University of Modena and later at the University of Padua. His *De Morbis Artificum Diatriba* (1700; *Diseases of Workers*) contains descriptions of the diseases associated with 54 different occupations, from the mercury poisoning of Venetian mirror makers to the diseases afflicting learned men. Ramazzini believed that a physician must determine the patient's occupation in order to discover the cause of the patient's disorder. He is generally regarded as the father of occupational medicine.

The industrial era. The Industrial Revolution of the 18th century had a profound impact on occupational diseases. Rapid technological progress and industrial growth had led to crowded, unsanitary working and living conditions, with a corresponding rise in the number of accidents and deaths caused by the new machinery and exposure to

toxic materials. In 1775 Percivall Pott, a London surgeon, linked the frequent occurrence of scrotal cancer among chimney sweeps to the soot ingrained into their skin by prolonged exposure to flue dusts. Charles Turner Thackeray, a Leeds physician, further advanced the study of occupational medicine in Britain with his *The Effects of the Principal Arts, Trades and Professions . . . on Health and Longevity . . .* (1831), which described lung diseases caused by dust that commonly afflicted miners and metal grinders. In 1895 Britain introduced a statutory notification system that required medical personnel to report all occurrences of certain diseases to the chief inspector of factories. Other industrial nations followed Britain's lead, and legal provisions for the health of the worker continued to be instituted throughout the 19th and 20th centuries.

The 20th century. Although such classic occupational diseases as lead poisoning and anthrax have declined in incidence in industrialized countries, none have been eradicated. Furthermore, new diseases continue to develop as a result of advances in technology. X rays were discovered in 1895, and 20 years later nearly 100 radiologists were estimated to have died as a result of occupational exposures. Asbestos-related disease was first reported in the first half of the 20th century, and in 1974 hemangiosarcoma, a rare malignant tumour of the liver, was discovered among workers involved in the polymerization of vinyl chloride monomer. Other occupational diseases related to the introduction of industrial processes and materials may well be recognized in the future.

Paralleling the development of new technology and occupational hazards has been the development of occupational health services. No longer concerned primarily with the prevention of industrial accidents and diseases among manual workers, industrial medicine now aims to protect and improve the health of all classes and kinds of workers. In 1950 a joint committee of the International Labour Organisation and the World Health Organization (ILO/WHO) defined the concerns of occupational health as:

the promotion and maintenance of the highest degree of physical, mental and social well-being of workers in all occupations; the prevention among workers of departures from

The ILO/WHO definition of occupational health

The father of occupational medicine

health caused by their working conditions; the protection of workers in their employment from risks resulting from factors adverse to health; the placing and maintenance of the worker in an occupational environment adapted to his physiological equipment and, to summarise, the adaptation of work to man and of each man to his job.

In most countries in the West the responsibility for health and safety at work is placed on the employer, although the government may establish safety standards. Occupational health services are provided as benefits by employers and generally are separate from other community health services. In the Soviet Union and other eastern European countries, occupational health and hygiene are given high priority and are fully integrated in the general medical care system. In the developing and Third World countries, many of which are undergoing rapid industrialization, the importance of occupational health is increasingly realized. The problems of exposure to occupational hazards, however, are frequently compounded by preexisting malnutrition and a high incidence of infectious disease. Occupational health services in these countries are often most practical and cost-effective, therefore, when combined with primary health care delivery.

AIMS AND FUNCTIONS OF OCCUPATIONAL HEALTH SERVICES

The primary concerns of occupational health services remain those specified by the ILO/WHO in 1950, although work-related diseases are now considered as well as purely occupational diseases. The actual services offered are essentially preventive in nature and are summarized below.

Job placement. People with certain preexisting medical conditions may be at a disadvantage in some jobs. A pre-employment health questionnaire or medical examination can be of great value in such cases by determining job unsuitability before training time and expense have been incurred. Job suitability may also need to be regularly monitored in order to assure employee health and ability. Airline pilots, for example, undergo regular medical checkups because a pilot with failing vision or one who suffers from an undetected heart condition that can lead to a heart attack could endanger many lives. The health service can also give valuable advice with regard to alternative employment when a worker is found to be unfit for a particular job.

Safety training. An occupational health service has a responsibility to keep all employees informed about hazards in the workplace. The measures taken to protect employee health should be thoroughly explained so that workers understand the necessity of complying with such irksome or unpleasant restrictions as the wearing of protective clothing and face masks. First aid facilities should be organized and employees instructed about first aid procedures in case of accidental injuries or other emergencies.

Supervision of high-risk groups. Exposure levels considered safe for a young male worker may be hazardous for a pregnant woman (the fetus, especially during the first three months of development, is particularly sensitive to environmental toxic agents). Pregnant women, as well as such other vulnerable groups as the very young, the elderly, and the disabled, therefore require appropriate medical surveillance and advice about specific precautionary measures they can take.

Control of recognized hazards. A complex system of environmental and biological monitoring has been developed for the control of known hazards at work. Occupational health practice is concerned with monitoring the concentration of toxic substances in the environment, determining safe exposure levels, suggesting procedures to limit worker exposure, and monitoring workers for signs of overexposure. Occupational health specialists can also contribute to the prevention of health risks by assisting in the planning and design of new equipment and factories.

Identification of unrecognized hazards. Occupational health services can play a major role in the detection of new health hazards of all types. Clinical observation and study may reveal a causal relationship between patterns of sickness or mortality in groups of workers and their occupational exposure. Examples of hazards identified in this manner include lung and nasal cancer among nickel

workers, lung cancer in asbestos workers, and coronary heart disease among workers exposed to carbon disulfide (used in the manufacture of rayon).

Treatment. Quick, on-site treatment of work injuries and poisonings can prevent complications and aid recovery. Such treatment can also be economically beneficial by saving traveling and waiting time. Furthermore, physicians and nurses who are unfamiliar with their patients' working conditions may keep workers with minor injuries away from work longer than necessary. An occupational treatment service offers opportunities for specialized counseling and health education.

General health education and surveillance. Occupational health services may have to provide general medical care for workers and their families in developing countries with inadequate community health services. Even when general health care is provided elsewhere, an occupational health service can offer an effective and often economically advantageous program of health education and counseling. By advising employees on such topics as smoking, alcohol or drug abuse, exercise, and diet, the occupational health service can improve worker health and efficiency and reduce illness and absenteeism. The health service is also in a position to organize employee health surveillance programs for the early diagnosis of disease.

DISORDERS DUE TO CHEMICAL AGENTS

Hazardous chemicals can act directly on the skin, resulting in local irritation or an allergic reaction, or they may be absorbed through the skin, ingested, or inhaled. In the workplace ingestion of toxic chemicals is usually accidental and most commonly results from handling contaminated food, drink, or cigarettes. Substances that occur as gases, vapours, aerosols, and dusts are the most difficult to control, and most hazardous chemicals are therefore absorbed through the respiratory tract. If inhaled, airborne contaminants act as irritants to the respiratory tract or as systemic poisons. Toxicity in such cases depends on the contaminant's concentration, particle size, and physicochemical properties, particularly its solubility in body fluids. An individual's reaction to any hazard depends primarily on the length, pattern, and concentration of exposure but is also affected by such factors as age, sex, ethnic group, genetic background, nutritional status, coexistent disease, concomitant exposure to other toxic agents, life-style, and history of previous exposure to the agent in question. The wide range of both naturally occurring and synthetic chemical compounds that can give rise to adverse health effects can be roughly organized into four major categories: gases, metals, organic compounds, and dusts.

Gases. Gases may act as local irritants to inflame mucous surfaces. Examples include sulfur dioxide, chlorine, and fluorine, which have pungent odours and can severely irritate the eyes and the respiratory tract. Some gases, such as nitrogen oxides and phosgene, are more insidious. Victims may be unaware of the danger of exposure because the immediate effects of these gases may be mild and overlooked. Several hours after exposure, however, breathlessness and fatal cardiorespiratory failure due to pulmonary edema (collection of fluid in the lungs) may develop.

Gases that interfere with oxygen supply to the tissues are known as asphyxiants and are of two principal types. Simple asphyxiants are physiologically inert gases that act by diluting atmospheric oxygen. If the concentration of such gases is high enough, hypoxia (deficiency of oxygen reaching the tissues of the body) results. Victims of mild hypoxia may appear to be intoxicated and may even resist rescue attempts. Common examples of simple asphyxiants are methane and carbon dioxide.

In contrast to simple asphyxiants, chemical asphyxiants, such as carbon monoxide and hydrogen sulfide, are highly reactive. They cause a chemical action that either prevents the blood from transporting oxygen to the tissues or interferes with oxygenation in the tissues. For example, carbon monoxide, a frequently encountered gas produced by incomplete combustion, combines with hemoglobin in the blood and reduces its oxygen-carrying capacity. In low concentration carbon monoxide poisoning can cause symptoms of fatigue, headache, nausea, and vomiting, but

Exposure
to
hazardous
chemicals

Asphyxi-
ants

heavy exposure leads to coma and death. It is especially dangerous because it is both colourless and odourless. Hydrogen sulfide, however, can be recognized by its characteristic smell, suggestive of rotten eggs. It is produced when sulfur compounds decompose and acts by inhibiting the respiratory enzyme cytochrome oxidase, thus giving rise to severe tissue hypoxia. In addition to its asphyxiant properties, hydrogen sulfide also acts as an irritant to the eyes and mucous membranes.

Preventing gas poisoning involves preventing exposure. Workers should never enter enclosed spaces that have suspect atmospheres alone; workplaces should provide adequate ventilation, and air should be regularly tested for contamination. If exposure does occur, treatment involves the removal of the victim from the contaminated atmosphere, artificial respiration, and administration of oxygen or recommended antidotes. Victims exposed to gases with insidious delayed effects should be kept under medical observation for an appropriate period.

Metals. Metals and their compounds are among the poisons most commonly encountered in the home and workplace. Even metals essential for life can be toxic if they are present in excessive amounts. Iron, for example, is an essential element and is sometimes given therapeutically; if taken in overdose, however, it can be lethal.

Mercury poisoning

Mercury poisoning, one of the classic occupational diseases, is a representative example of metal poisoning. Exposure to mercury can occur in many situations, including the manufacture of thermometers, explosives, fungicides, drugs, paints, batteries, and various electrical products. The disorders it can cause vary depending on the type of mercury compound and the method of exposure.

Ingestion of mercury salts such as mercuric chloride (corrosive sublimate) leads to nausea, vomiting, and bloody diarrhea. Kidney damage resulting in death may follow in extreme cases. Inhalation or absorption through the skin of mercury vapour causes salivation, loosening of the teeth, and tremor; it also affects the higher centres of the brain, resulting in irritability, loss of memory, depression, anxiety, and other personality changes. This mental deterioration, known as erethism, led to the well-known saying "mad as a hatter," because, in the past, hatters commonly became ill when they used mercury salts to make felt out of rabbit fur. Poisoning with organic mercury compounds (used in fungicides and pesticides) results in permanent neurological damage and can be fatal.

Other hazardous metals commonly encountered in industry include arsenic, beryllium, cadmium, chromium, lead, manganese, nickel, and thallium. Some have been shown to be carcinogenic, including certain compounds of nickel (linked to lung and nasal cancer), chromium (lung cancer), and arsenic (lung and skin cancer).

Organic compounds. The organic compounds that pose the greatest occupational hazards are various aromatic, aliphatic, and halogenated hydrocarbons and the organophosphates, carbamates, organochlorine compounds, and bipyridylum compounds used as pesticides.

Pesticides

Pesticides are used the world over; and, even though precautionary measures (such as using protective clothing and respirators, monitoring contamination of equipment and clothing, keeping workers out of recently sprayed areas, and requiring workers to wash thoroughly after exposure) can be instituted, poisoning not infrequently occurs in agricultural communities. The organophosphates and the generally less toxic carbamates exert their effects by inhibiting cholinesterase, an enzyme that prevents stimulation from becoming too intense or prolonged by destroying the acetylcholine involved in the transmission of impulses in the autonomic nervous system. Cholinesterase inhibitors allow the accumulation of acetylcholine, causing symptoms related to parasympathetic overactivity, such as chest tightness, wheezing, blurring of vision, vomiting, diarrhea, abdominal pain, and in severe cases respiratory paralysis. Atropine and certain oximes counteract their effects.

Paraquat and diquat, the bipyridylum compounds, are deadly if ingested. Skin contact or inhalation of a concentrate of paraquat can cause fatal lung damage. Because no specific antidote is known, treatment consists of minimizing the body's absorption of the poison.

The organochlorine compounds, such as DDT, are being progressively phased out of use. Because they are fat-soluble and very stable, they accumulate and remain in the fatty tissues of the body for prolonged periods. Symptoms of poisoning include nausea, irritability, weakness, muscle tremors, and convulsions. There is no specific antidote.

Other groups of pesticides that are used less frequently or are less hazardous include the organomercury compounds (see above *Metals*); the dinitro and arsenic compounds; and nicotine.

Hydrocarbons are used industrially in the derivation of other compounds and in solvents, degreasing agents, refrigerants, fire extinguishers, dry cleaning agents, paint removers, and other products. Many are volatile and can be absorbed by inhalation; some are fat-soluble and can be readily absorbed following spills on the skin.

Hydrocarbons

Gasoline, fuel oils, and other petroleum products are common examples of aliphatic hydrocarbons. If they are ingested or inhaled, dizziness, weakness, nausea, or irritation of the lungs may follow. In very severe cases victims may become unconscious or experience convulsions. Direct contact causes skin irritation and dryness. Prolonged exposure to certain petroleum oils may result in skin cancer.

The aromatic hydrocarbon benzene provides the basis for the synthesis of many other organic compounds. It is rapidly absorbed following inhalation or skin contact. Symptoms from mild exposure include dizziness, headache, euphoria, confusion, and nausea. Long-term exposure may be followed by bone marrow depression, anemia, spontaneous bleeding, and leukemia. Several aromatic hydrocarbons are known to be carcinogens. Particularly hazardous are naphthylamine, benzidine, and 4-amino diphenyl, which cause bladder cancer. Previously used in the synthetic dye, synthetic rubber, cable-making, and chemical industries, they have been banned in a number of countries.

When aliphatic and aromatic hydrocarbons have hydrogen atoms in their structure replaced by halogens (often chlorine), they are known as halogenated hydrocarbons. In general, increasing the chlorination of aliphatic hydrocarbons increases their toxicity, while the reverse is true of the aromatic series. Many chlorinated hydrocarbons, including chloroform and trichloroethylene, act as depressants on the central nervous system, producing anesthetic or narcotic effects that may be abused. Occupational exposure to many solvents may act synergistically with alcohol, resulting in more damage than either agent could produce on its own. Some halogenated hydrocarbons cause extensive disorders in addition to their common narcotic effect. Inhaling or ingesting the solvent carbon tetrachloride, for example, leads to liver damage; and exposure to vinyl chloride causes Raynaud's phenomenon (spasms in the small arteries that cause the extremities to become pale and cold, as well as painful), necrosis of the small bones of the hand, liver damage, and a rare, highly malignant tumour of the liver.

Workers exposed to hydrocarbons should wear protective clothing or masks when appropriate, moderate alcohol consumption, and verify that work areas are well ventilated and that recommended exposure levels are not exceeded.

Dusts. The inhalation of a variety of dusts is responsible for a number of lung and respiratory disorders, whose symptoms and severity depend on the composition and size of the dust particle, the amount of dust inhaled, and the length of exposure. The lung diseases known as the pneumoconioses result when certain inhaled mineral dusts are deposited in the lungs, where they cause a chronic fibrotic reaction that leads to decreasing capacity for exercise and increasing breathlessness, cough, and respiratory difficulty. No specific treatment is known, but as with all respiratory disorders patients are urged to quit smoking, which aggravates the condition. Suggested measures for limiting exposure include using water and exhaust ventilation to lower dust levels and requiring workers to wear respirators or protective clothing, but such procedures are not always feasible. Coal worker's pneumoconiosis, silicosis, and asbestosis are the most common pneumoconioses.

Pneumoconioses

As its name suggests, coal worker's pneumoconiosis (also

known as black lung) occurs most frequently among coal miners and workers involved in the transporting or processing of coal. It is generally benign in its early stages, but after a variable number of years of exposure to coal dust, progressive massive fibrosis may develop, ending in cardiorespiratory failure. Miners and quarry workers are the people most likely to suffer from silicosis. Because silica is found in many rocks and is used in a variety of industries, workers involved in stonecutting, grinding, drilling, foundry work, sandblasting, pottery making, and the manufacture of abrasives are also at risk. Silicosis is an aggressive form of pulmonary fibrosis that speeds the progress of tuberculosis. Routine chest X rays can aid early diagnosis by revealing abnormal shadowing. Asbestosis is more difficult to detect in the early stages because chest X rays usually reveal little until the disease is advanced. From onset asbestosis progresses more rapidly than the other pneumoconioses and can result from relatively low exposure. Asbestos is the general term for a number of fibrous silicates that are used primarily in various fireproofing, insulation, and cement products. In addition to pulmonary fibrosis, inhaling asbestos fibres has also been shown to cause lung and other cancers.

Asthma

Prolonged exposure to certain plant and animal dusts can cause asthma, even in people without a predisposition for allergies. Specific hazards include dusts from flour, grains, and wood and wood products. Cotton workers and others handling hemp or flax may develop a condition known as byssinosis, similar to asthma. The group of diseases known as farmer's lung, malt worker's lung, bird fancier's lung, and so forth are caused by an allergic inflammatory reaction to the fungal spores present in moldy hay or barley, bird droppings, feathers, and a variety of other organic materials. Symptoms initially resemble those of influenza or pneumonia, but repeated episodes eventually lead to pulmonary fibrosis with chronic respiratory impairment. The only treatment for these disorders is avoiding exposure to the dusts.

DISORDERS DUE TO PHYSICAL AGENTS

Temperature. When working in a hot environment, humans maintain normal body temperature by perspiring and by increasing the blood flow to the surface of the body. The large amounts of water and salt lost in perspiration then need to be replaced. In the past, miners who perspired profusely and drank water to relieve their thirst experienced intense muscular pain—a condition known as miner's cramps—as a result of restoring their water but not their salt balance. When salt in the requisite amount was added to their drinks, workers no longer developed miner's cramps. Heat exhaustion is characterized by thirst, fatigue, giddiness, and often muscle cramps; fainting can also occur. Heatstroke, a more serious and sometimes lethal condition, results when prolonged exposure to heat and high humidity prevents efficient perspiration (by preventing evaporation of sweat), causing the body temperature to rise above 106° F (41° C) and the skin to feel hot and dry. If victims are not quickly cooled down, coma, convulsions, and death can follow. To prevent heat exhaustion or heatstroke, workers unaccustomed to high temperatures should allow adequate time (ranging from days to weeks) for their bodies to become acclimatized before performing strenuous physical tasks.

Work in cold environments may also have serious adverse effects. Tissue damage that does not involve freezing can cause inflammatory swelling known as chilblains. Frostbite, or the freezing of tissue, can lead to gangrene and the loss of fingers or toes. If exposure is prolonged and conditions (such as wet or tight clothing) encourage heat loss, hypothermia, a critical fall in body temperature, may result. When body temperature falls below 95° F (35° C), physiological processes are slowed, consciousness is impaired, and coma, cardiorespiratory failure, and death may ensue. Workers exposed to extreme cold require carefully designed protective clothing to minimize heat loss, even though a degree of acclimatization occurs with time.

Atmospheric pressure. Decompression sickness (caisson disease) can result from exposure to high or low atmospheric pressure. Under increased atmospheric pres-

sure (such as that experienced by deep-sea divers or tunnel workers), fat-soluble nitrogen gas dissolves in the body fluids and tissues. During decompression the gas comes out of solution and, if decompression is rapid, forms bubbles in the tissues. These bubbles cause pains in the limbs (known as the bends), breathlessness, angina, headache, dizziness, collapse, coma, and in some cases death. Similarly, the gases in solution in the body tissues under normal atmospheric pressure form bubbles when pressure rapidly decreases, as when aviators in unpressurized aircraft ascend to high altitudes too quickly. Emergency treatment of decompression sickness consists of rapid recompression in a compression chamber with gradual subsequent decompression. The condition can be prevented by allowing sufficient decompression time for the excess nitrogen gas to be expelled naturally.

Noise. Exposure to excessive noise can be unpleasant and can impair working efficiency. Temporary or permanent hearing loss may also occur, depending on the loudness or intensity of the noise, its pitch or frequency, the length and pattern of exposure, and the vulnerability of the individual. Prolonged exposure to sound energy of intensity above 80 to 90 decibels is likely to result in noise-induced hearing loss, developing first for high frequencies and progressing downward. The condition can be prevented by enclosing noisy machinery and by providing effective ear protection. Routine audiometry gives an indication of the effectiveness of preventive measures.

Vibration. Whole-body vibration is experienced in surface and air transport, with motion sickness its most familiar effect. A more serious disorder, known as Raynaud's syndrome or vibration white finger (VWF), can result from the extensive use of vibratory hand tools, especially in cold weather. The condition is seen most frequently among workers who handle chain saws, grinders, pneumatic drills, hammers, and chisels. Forestry workers in cold climates are particularly at risk. Initial signs of VWF are tingling and numbness of the fingers, followed by intermittent blanching; redness and pain occur in the recovery stage. In a minority of cases the tissues, bones, and joints affected by the vibration may develop abnormalities; even gangrene may develop. VWF can be prevented by using properly designed tools, avoiding prolonged use of vibrating tools, and keeping the hands warm in cold weather.

Other mechanical stresses. Muscle cramps often afflict workers engaged in heavy manual labour as well as typists, pianists, and others who frequently use rapid, repetitive movements of the hand or forearm. Tenosynovitis, a condition in which the sheath enclosing a tendon to the wrist or to one of the fingers becomes inflamed, causing pain and temporary disability, can also result from prolonged repetitive movement. When the movement involves the rotation of the forearm, the extensor tendon attached to the point of the elbow becomes inflamed, a condition commonly known as tennis elbow.

Ionizing radiation. Ionizing radiation damages or destroys body tissues by breaking down the molecules in the tissues into positively or negatively charged particles called ions. Radiation that is capable of causing ionization may be electromagnetic (X rays and gamma rays) or particulate (radiation of electrons, protons, neutrons, alpha particles, and other subatomic particles) and has many uses in industry, medicine, and scientific research.

Ionizing radiation injury is in general dose-dependent. Whole-body exposure to doses in excess of 1,000 rads results in acute radiation syndrome and is usually fatal. Doses in excess of 3,000 rads produce cerebral edema (brain swelling) within a matter of minutes, and death within days. Lesser doses cause acute gastrointestinal symptoms, such as severe vomiting and diarrhea, followed by a week or so of apparent well-being before the development of the third toxic phase, which is characterized by fever, further gastrointestinal symptoms, ulceration of the mouth and throat, hemorrhages, and hair loss. There is an immediate drop in the white-cell elements of the blood, affecting the lymphocytes first and then the granulocytes and platelets, with a slower decline in the red cells. If death does not occur, these symptoms may last for many months before slow recovery begins.

Decompression sickness

Carcinogenic effects of exposure to radiation

Delayed effects of exposure to radiation include the development of leukemia and other cancers. Examples include the skin cancers that killed many of the pioneering scientists who worked with X rays and radioactive elements; the lung cancer common among miners of radioactive ores; and the bone cancer and aplastic anemia that women who painted clock dials with a luminous mixture containing radium and mesothorium developed as a result of ingesting small amounts of paint when they licked their paintbrushes to form a point.

Nonionizing radiation. Nonionizing forms of radiation include electromagnetic radiation in the radio frequency, infrared, visible light, and ultraviolet ranges. Exposure to radiation in the radio frequency range occurs in the telecommunications industry and in the use of microwaves. Microwaves produce localized heating of tissues that may be intense and dangerous. Various other disorders, mainly of a subjective nature, have been reported in workers exposed to this frequency range. Infrared radiation can be felt as heat and is commonly used in industry in drying or baking processes. Prolonged exposure to the radiation can result in severe damage to the skin and especially to the lens of the eye, where cataracts may be produced. Working under poor lighting conditions can adversely affect worker efficiency and well-being and may even cause temporary physical disorders, such as headache or dizziness. Proper lighting should provide adequate, uniform illumination and appropriate contrast and colour, without any flickering or glare. Exposure to ultraviolet radiation from the Sun or such industrial operations as welding or glassblowing causes erythema of the skin (a condition familiarly known as sunburn), skin cancer, and inflammation of the conjunctiva and cornea. Pigmentation offers natural protection against sunburn, and clothing and glass can also be used as effective shields against ultraviolet radiation. Lasers emit intense infrared, visible, or ultraviolet radiation of a single frequency that is used in surgery, for scientific research, and for cutting, welding, and drilling in industry. Exposure to these beams can burn the skin and cause severe damage to the eye.

DISORDERS DUE TO INFECTIOUS AGENTS

A large number of infectious diseases are transmitted to humans by animals. Many such diseases have been largely eliminated, but some still pose hazards. Anthrax, for example, can be acquired by workers handling the unsterilized hair, hide, and bone of infected animals; and slaughterhouse workers, farmers, veterinarians, and others in contact with infected animals, milk, and milk products still frequently contract brucellosis.

Contact with contaminated water is another common method of acquiring infectious diseases. Many workers are infected by organisms that thrive in the puddles or stagnant water found in sewers, canals, paddies, slaughterhouses, irrigation projects, and mines.

Laboratory workers, nurses, surgeons, and other health care workers may contract infectious diseases such as tuberculosis in the course of their work. To help prevent infection, these workers should wear appropriate protective clothing and exercise care when handling contaminated needles or other equipment. Contaminated material should be appropriately bagged, labeled, and disposed.

DISORDERS DUE TO PSYCHOLOGICAL FACTORS

Psychological factors are important determinants of worker health, well-being, and productivity. Studies have shown

the benefits to workers who feel satisfied and stimulated by their jobs, who maintain good relationships with their employers or supervisors and with other employees, and who do not feel overworked. Such workers have lower rates of absenteeism and job turnover and higher rates of output than average.

The two psychological hazards commonly encountered at work are boredom and mental stress. Workers who perform simple, repetitious tasks for prolonged periods are subject to boredom, as are people who work in bland, colourless environments. Boredom can cause frustration, unhappiness, inattentiveness, and other detriments to mental well-being. More practically, boredom decreases worker output and increases the chances of error and accident. Providing refreshment and relaxation breaks or other outside stimulus can help relieve boredom.

Mental stress often results from overwork, although nonoccupational factors, such as personal relationships, life-style, and state of physical health, can play a major role. Job dissatisfaction, increased responsibility, disinterest, competition, feelings of inadequacy, and bad working relationships can also contribute to mental stress. Stress affects both mental and physical health, causing anger, irritation, fatigue, aches, nausea, ulcers, migraine, asthma, colitis, or even breakdown and coronary heart disease. Moderate exercise, meditation, relaxation, and therapy can help workers to cope with stress.

Boredom and mental stress

Oceanic Arts

The term Oceania has been variously used to refer to the land areas of the central and southern Pacific. For the purposes of this article, it is understood to include the island continent of Australia and the island groups of Melanesia, Polynesia, and Micronesia. The largest island in Melanesia, and the second largest island in the world, is New Guinea. New Guinea lies north of Australia and is on the western edge of Oceania. It is divided into the independent country of Papua New Guinea on the east and the Indonesian province of Irian Jaya on the west. Northeast and east of New Guinea lies the arc of islands that constitutes the rest of Melanesia. Included in this group are the Admiralty Islands, New Britain, and New Ireland (all in the Bismarck Archipelago and administratively part of Papua New Guinea), the Solomon Islands, Vanuatu (formerly the New Hebrides), New Caledonia, and Fiji. The small islands of Micronesia lie north of Melanesia and form a parallel arc that extends from Palau (Belau) and the Mariana Islands in the northwest through the Caroline and the Marshall islands to Kiribati (formerly the Gilbert Islands) in the southeast. East of both Melanesia and Micronesia is Polynesia, a vast triangular area formed by New Zealand in the southwest, Easter Island in the southeast, and Hawaii in the north. Within this triangle lie, roughly from west to east, Fiji (which serves as a transitional territory between Melanesia and Polynesia), Tuvalu (formerly the Ellice Islands), Tonga, Samoa, the Cook Islands, and French Polynesia (including the Society, the Austral [Tubuai], and the Marquesas [Marquises] islands).

The variety of Oceania's cultures has always been a matter for wonder. A small number of people, no more than three to four million at the time of first contact with Westerners, practiced a wide range of economies based largely on the ecological niches in which they lived. In the broad expanses of Australia, the tribal communities lived largely as hunting-and-gathering nomads. In New Guinea they ranged from nomadism to large-scale horticulture, with some coastal groups dependent mainly on fishing. The other Melanesian islanders were predominantly horticulturalists. With certain exceptions, Melanesian societies were acephalous, with men of energy and ambition com-

peting for status that lasted only for their lifetimes. Polynesian and Micronesian societies, on the other hand, were hierarchical; in the most formalized, dynastic rulers, of reputedly divine descent, dominated several lower classes, the most inferior being prisoners and slaves.

Religion was everywhere a paramount concern, and throughout Oceania the supernatural and the activities associated with it were the inspiration for the greater achievements of the arts. These were not limited to the dances, chants, figures, masks, and architectural sculptures connected with actual ritual; so pervasive was belief that it infused with symbolism the creation of what might seem mundane and secular objects. In Australia and Melanesia, male domination of women largely excluded the latter from religious cults and thus from many types of artistic endeavour. In fact, in much of Melanesia, religion and art centred on segregated male meetinghouses, dance grounds, secret societies, and initiation ceremonies. In Polynesia and eastern Micronesia, however, religious ceremonies were often held at open-air sacred enclosures. Thus, although architecture was well-developed, only a few areas had buildings as artistically significant as the men's houses in Melanesia. But, whatever the type, almost every example of art produced in Oceania, whether for ritual or functional use, reflects its creator's sense of the spiritual world.

This article discusses the visual art, music, dance, and literature of the traditional peoples of Oceania. Although it includes the effects of Western colonization and the adaptation of traditional forms to modern technology, it does not treat the postcolonial adoption of wholly Western styles and forms. The literatures of Australia and New Zealand, for example, are derived from and strongly influenced by the English literary tradition; they are therefore discussed separately in the article AUSTRALIA AND NEW ZEALAND, LITERATURES OF. Information on the geographic, economic, and historical background of Oceanic arts can be found in the article PACIFIC ISLANDS.

For coverage of related topics in the *Macropædia* and the *Micropædia*, see the *Propædia*, sections 613, 621-622, and 624-629, and the *Index*.

GENERAL CHARACTERISTICS

Materials and techniques. Until the 16th and 17th centuries, when European cultures appeared upon the scene, Oceanian cultures maintained various forms of Neolithic technology. The only exception was in the northwest of New Guinea, where the people living around Geelvink Bay (Teluk Cenderawasih) imported very small quantities of metal from the Indonesians of the Moluccas (Maluku). The technique of forging was jealously guarded, virtually as a cult secret; some tools were traded but only in quantities far too small to have made much impact on normal working conditions.

Throughout the rest of Melanesia and in Polynesia and Micronesia, the basic tool remained the stone blade, which

was hafted as an adz or an ax and sometimes interchangeably as both. Tridacna shell was sometimes used for blades in parts of Oceania where stone was in short supply, including Micronesia and the Solomon Islands. When obsidian was available, it was chipped into blades for use as both weapons and tools. Other working materials included bamboo and bivalve shells, which take extremely sharp edges. Some fine cutting and engraving was done with unhafted boar tusks or with hafted shark and rodent teeth. Animal bones served as gouges, awls, and needles. All these tools were employed in working wood, which with rare exceptions was the main medium used throughout Oceania.

Clay was also employed, mainly for sculptures, for some small musical instruments (whistles), and for pottery in Melanesia and New Guinea. The making of clay vessels

was almost exclusively women's work, except in a few small areas in New Guinea and the northern Solomons. The usual method involved spiral coiling of rolls of clay. The decorating of the pot was the work of men.

Some working of shell and turtle shell was done with simple drilling and abrading equipment. The carving of stone, although obviously presenting far more arduous and time-consuming problems than wood, was undertaken remarkably often and occurred throughout the Pacific Islands; hammering, pecking, and polishing were the main methods. Even so resistant a material as jade was mastered by grinding with abrasives.

Paint and painting animate sculpture—often literally, in religious symbolic terms, as paint was considered to have magical, vivifying powers. Paints were generally ochres, with some vegetable-derived pigments. Water was the usual medium, occasionally supplemented with sap. Brushes were the fibrous ends of chewed or frayed sticks, small feather bundles, pieces of wood, and sometimes the most elementary applicator of all, the finger. Apart from sculpture, the surfaces used for painting were rock faces, bark, and tapa (cloth made from pounded bark). Rock painting was most common in Australia, where panels of bark were also used. In Melanesia, paintings were made mainly on sago-palm spathes and sheets of tapa cloth. In Polynesia the women manufactured great quantities of tapa, which they then decorated with abstract designs using vegetable dyes. The techniques they employed included painting, stenciling with leaf templates, rubbing over relief-design tables, stamping, and printing with carved bamboo rollers.

The only areas where weaving was practiced were the Caroline Islands, the Polynesian outliers east of the Solomon Islands, some of the Santa Cruz Islands, parts of Vanuatu, the Saint Matthias Group (northwest of New Ireland), and a few places on the northern coast of Irian Jaya. Spinning was unknown; instead of yarn or thread, strips of banana fibre were used on a simple backstrap loom. Weaving was a woman's craft in the Caroline and Saint Matthias islands but was practiced by men elsewhere. A form of "finger weaving," as in net making, was used by Maori women in creating textiles from flax fibres.

The architecture of the Pacific Islands was varied and sometimes large in scale. Buildings reflected the structure and preoccupations of the societies that constructed them, with considerable symbolic detail. Technically, most buildings in Oceania were no more than simple assemblages of poles held together with cane lashings; only in the Caroline Islands were complex methods of joining and pegging known.

Oceanic artists' quest for media was consummately opportunistic; they regarded almost anything from the lavish natural world that surrounded them as potentially usable. The marine world yielded shells of all kinds, especially conus, cowrie, and nassa shells. Birds gave down, beaks, and plumes (those of the birds of paradise were especially prized); animals provided teeth, tusks, and skins; insects supplied their brilliant wing cases. The vegetable realm was drawn upon for flowers, leaves, and fibres. The assembly of such materials into single objects was rare in Polynesia and Micronesia, but the practice was typical of Australian and Melanesian styles and contributed brilliantly to their more spectacular effects. The most basic medium of all was the human body, which received both removable and permanent decorations, including scarification, enhanced by treatment to raise keloid welts, in New Guinea and tattooing with needles and pigments elsewhere.

Artist and society. In societies whose members are largely self-reliant, some degree of craft skill is practically universal. Men make their own canoes, build their own houses, and carve simple household equipment such as hooks and stools; individuals are responsible for decorating their own belongings, including their bodies. In the case of body decoration, however, which can be culturally prescribed in form, highly skilled in execution, and dense in symbolism, the more lavish displays usually entail more than the wearer's sole efforts. Tattooing and scarification, usually tokens of ritual or hierarchical status, were the work of esteemed specialists.

To progress beyond simple skills, a craftsman not only required the will to excel but sometimes was subject, in theory at least, to socially defined restrictions. There seems to have been an inclination to regard artistic talent as passing from father to son, or from mother to daughter when appropriate; but, in cases in which this was true, society's concept of the role of the artist probably played a bigger role than heredity.

In many societies the artist was—and still is today—expected to begin his career as an apprentice to a known master, often working on preparatory tasks or the less-demanding details of a project. In some parts of Melanesia, among the Kilege of New Britain, for example, or in the Solomons, artistic progress is recognized as covering several stages. The apprentice grows into an independent worker with limited skills and eventually, if he has talent and ambition, becomes a master in his turn. In the Solomons the aspirant is actually expected to produce test pieces for approval by his peers and mentors. Elsewhere the process is apparently less formal and, particularly for grandiose projects, less individualistic. Large-scale projects are often an affair of communal effort under specialized supervision. In Papua New Guinea several men at a time may work on a single large architectural carving among the Kwoma, and a whole team may paint one of the huge gables of the Abelam. Individuals, however, may carve major sacred objects when they are inspired by dreams or induced visions. These interventions by the supernatural world can be quite common: if work goes badly, the failure is attributed less to the workers' incompetence than to the displeasure of the spirits concerned.

In Polynesia, with its more sharply graded societies, the role of artist was more closely related to the religious expert (for instance, the Maori *tohunga*) than it was in Melanesia. Indeed, in Hawaii and elsewhere carvers formed a special priestly class, and their work was accompanied at every stage with rituals and prayers. The New Zealand Maori considered carving a sacred activity, surrounded by spiritual and physical dangers. Myths of the origins of carving connected it directly to the gods, and its subjects linked it intimately to the ancestors. Carving was one of eight proverbial attainments of a chief, and young Maori of

Remuneration of artists

high rank were trained in the formal schools of learning. There were cases of chiefs being captured and enslaved for their talents and, conversely, of slaves celebrated as artists.

The material rewards were not great. While the carver and painter was preoccupied with his work, it was the business of his employer to keep him well fed. On completion, the artist received agreed amounts of valuables, but he might well give away some of them (among the Kilenge at least) to those who praised him. Praise and esteem were in fact the main rewards and were steps toward the making of a "Big Man" of power and influence in Melanesian communities; in Polynesia *mana*—personal prestige and moral authority—was achieved in the same way. Equal or even greater credit often went to the man who commissioned the work, for he was regarded as its true author. His achievement in seeing that the work was first instigated and then carried through to a successful conclusion earned him fame and prestige.

Aesthetics. Pacific languages seem to be deficient in terms to express appreciation of or reactions to art, apart from a few that designate the mastery of individual specialists. Little is understood, moreover, about the islanders' aesthetic concepts. Reactions to works of art seem to range from the pragmatic and rational in the secular realm to the violently emotional in the religious. At a fairly simple level, aesthetic appreciation is expressed as approval of the manner in which a work has been accomplished, of its compliance with possibly unformulated but nevertheless well-understood standards. Craftsmanship and suitability to function are highly valued.

In general, innovation does not seem to have been highly prized. Nevertheless, changes have certainly taken place in the arts over the long period of Pacific history, even though, in the absence of more than a scattering of archaeological examples, such changes are difficult to document. One technique used by artists to attain success was to copy models of recognized excellence and symbolic soundness; old works were often retained precisely for this purpose. The inevitable introduction of variations in these situations, as a result of variations in individual talent, was largely ignored, and the intention of identity between old and new objects was accepted as always having been achieved. The ideal of the local tradition was thus maintained, even though actual stylistic fluctuations must have occurred over time.

In some areas the exotic was deeply admired and therefore copied: in parts of New Guinea, for instance, certain items captured in warfare are known to have been duplicated. Such cases were probably comparatively rare, however. More often works displaying special craft techniques (such as work in ivory imported by Fijians from Tonga) were treasured because it was accepted by the importers that the imports were beyond their skills to manufacture for themselves.

The Maori of New Zealand developed the most precise aesthetic terminology of Oceania, describing both the innate properties of a work and its effect on the viewer. A masterpiece possesses *ihi* (power), emanates *wana* (authority), and inspires *wehi* (awe and fear). The belief that art and religion overlap is widespread in the Pacific, and religious objects are often works of visual art (though not invariably). These objects are not considered sacred in themselves, however; they are humanly worked things into which supernatural beings can be induced for human purposes. These supernaturals are always powerful, unpredictable, and thus dangerous. In New Guinea their destructive power may turn against the object itself, causing a carving to rot, self-consumed; or an object may become so loaded with accumulated power that it has to be buried or otherwise eliminated. It is possible that the practice of abandoning elaborate and painstakingly made carvings after ritual use—as in New Ireland and among the Asmat of Irian Jaya—was inspired by such beliefs. In many societies an uninitiated person who glimpsed the sacred objects would be executed, but it is likely that the offended spirits were considered the killers, not the men who acted for them and performed the execution. Among the Maori, ancestral heirlooms were not to be touched without ritual purification, and mistakes in ritual, espe-

cially in the building of meetinghouses, with their powerful ancestral associations, could be fatal. Awe and fear are understandable emotions in such circumstances.

In areas where religion depends more on ritual dances or oratory than on objects, expression of the visual arts may be channeled (as in Samoa and much of Micronesia) into an exquisite refinement of craftsmanship, often in the making of utilitarian objects. In these circumstances, the quality of an object often becomes a symbolic reference to social status.

Oceanic visual art, then, although rarely baldly pictorial in a Western manner, is replete with references to both religious and social values. It may even, it has been suggested, be a material means by which values are transmitted nonverbally to those qualified to understand the messages involved, thus becoming a mode of communication that reinforces and is vital to society.

EARLY STYLES

The history of Oceanic art falls into two major phases, corresponding to the periods before and after Western contact. This is due not so much to the changes ensuing from contact—decisive as they have been—as to the preservation of otherwise ephemeral material by Western collectors and researchers. The total loss of early works and the paucity of archaeological discoveries renders the comprehension of ancient Oceanic art fitful and incomplete. In fact, there is not enough known about early Micronesian art to warrant discussion here. Nevertheless, what has survived elsewhere hints at the antiquity of art traditions in Oceania and sometimes illuminates the origins of more recent styles.

Australia. The Australian continent is liberally dotted with thousands of rock-art sites. They include rock shelters, outcrops of rock, and surface sheets of rock and are decorated with painted, pecked, or engraved figurative and nonfigurative forms in a wealth of styles. These are the main testimonials to the prehistoric art of the Aborigines; the only portable works from early periods that have been discovered are some elaborate items used for personal decoration. Long necklaces and chaplets made of animal teeth and lizard vertebrae, bone beads, and stone pendants have been found in burials and elsewhere dating from 15,000 BP (before the present) and later. Long bone pins indicate the existence of garments, probably cloaks made of animal skins.

The early use of colour for various purposes is attested by the inclusion of red ochre in burials at Lake Mungo in New South Wales, dated 32,000 BP. While this is not necessarily evidence of any specifically artistic activity, it shows the ritual value of the colour and of the material, which was imported from sources many miles away. Paintings for which human blood was the medium have been found and proved to be more than 20,000 years old.

The chronology of the rock-art styles is established largely

Holle Bildarchiv, Baden-Baden, Ger.

Role of religion in art

Rock-art styles

by the classic method of tracing the superposition of works in one style over works in another; but current theories are also based on such factors as known climatic and geologic events, the presence or absence in the paintings of certain animals or equipment that are now extinct or obsolete, and the degree to which modern Aborigines are familiar with the sites and the meanings of the art. One factor that decisively marks the end of the early period is the representation of European or (in the north of the continent) Indonesian cultural elements, such as ships and introduced animals.

One of the earliest known styles is the Panaramittee. It was widespread, mainly through southern Australia, central Australia, and Tasmania, and dates from about 30,000 BP onward. It is characterized by small pecked designs, both figurative and nonfigurative, on rock surfaces. The nonfigurative designs include circles, crescents, and radiating lines; the figurative are almost all of footprints and bird and animal tracks.

Another early style, dated to 20,000 BC, is represented in Koonalda Cave under the Nullarbor Plain in South Australia. Certain areas of the cave walls, which are composed of a soft rock, are densely covered with engraved or finger-marked geometric designs. Most of the designs consist of no more than parallel lines or herringbone patterns, but they cover several thousand square feet. It is possible that their significance lies as much in their placement at specific points in the cave as in their now undiscoverable symbolism.

Both rock engravings and paintings in the Simple Figurative style are widely found at sites in the north, east, and west of Australia but rarely in the interior. The style apparently followed the Panaramittee, but it cannot be dated precisely. It is characterized by somewhat loose silhouettes of human and animal forms and has remained influential until recent times.

In northwestern Australia, in both coastal and hinterland areas, there are at least two sequences of painting styles. In Arnhem Land, rock painting has been divided into a sequence of four styles, partly on the basis of apparent references to environmental changes. The earliest, the Mimi (a clan of spirit beings) or Dynamic style, is notable for linear human stick figures that wear ornaments, carry spears and boomerangs, and are occasionally endowed with animal heads. They are associated with paintings of now-extinct animals, such as the Tasmanian wolf (thylacine). The style is presumed to date from 18,000 BP to pre-9000 BP. It is followed by the Estuarine style, which developed during a period when saltwater conditions prevailed: a situation reflected in the use of crocodiles as subjects in paintings in the X-ray style (in which the internal organs are shown). A subsequent Freshwater phase is characterized by representations of ceremonial fans made from feathers of marsh birds. Finally, there are paintings from a "contact" period, which began with the arrival of Indonesian fishers of trepang (sea cucumber) at the end of the 18th century and continued, after 1880, with the arrival of Australian drovers on horseback. The visits of both are pictured in the rock art.

A parallel sequence has been traced in paintings from the Kimberly region, to the west. An early period is manifested by the Bradshaw style of small human figures, mostly in red, perhaps dating from before 3000 BC. The Bradshaw style is succeeded by the Wandjina style, which takes its name from the ancestor spirits depicted in the paintings. The large white spirit figures are outlined in black and have mouthless, circular faces that are framed in red, rayed halos. This style has persisted to the present.

Melanesia. The first indication of the existence of any form of art in Melanesia is shown by the use of pigments, probably for personal decoration, in the eastern Highlands of Papua New Guinea by 15,000 BC. Other examples of early art in New Guinea include the stone carvings, including pestles, animal and human figures, and mortars, that have been found in the central Highlands, where most seem to have been made. Some were exported to eastern Papua New Guinea. The carvings are as yet undated, although it is known that plain stone bowls were in use about 2000 BC. Much of the sculptures' imagery

Figure 3: Stone figure, igneous rock. From the Ambum River valley, Papua New Guinea. In the Australian National Gallery, Canberra. Height 20 cm.

Collection: Australian National Gallery, Canberra

has been repeated in the recent art styles of the Sepik area and elsewhere. Rock art, in the form of paintings and petroglyphs, is abundant in Papua New Guinea but also remains undated.

The most important evidence of art in the early western Pacific is the ceramic style called Lapita, after a site in New Caledonia. It is the most prominent material aspect of a culture that flourished from approximately 1900 BC to the beginning of the modern era and that achieved an astonishingly wide distribution. Lapita sites, or other evidences of Lapita influence, are found from the northern coast of Papua New Guinea throughout the major island groups of Melanesia to Fiji, Tonga, and Samoa in the east. The Lapita culture complex involved intensive exchange of ceramics, stone tools, and other goods over long distances. Obsidian for tools, in particular, was traded from the Admiralty Islands and New Britain as far as New Caledonia.

Lapita art

The Lapita ceramics include a range of handsome vessel forms: flat-bottomed dishes, shallow and deep bowls, and small-mouthed, carinated vessels. It is their decoration, applied with toothed stamps, that makes them so distinctive. Much of it is applied in stacked horizontal zones; most of the design units are constructed from simple arcs or right angles, but some are intricate interlocking patterns. There are also some complex curvilinear designs incorporating faces that are the earliest dated human representations in the Pacific Islands. The early western ceramics are the most elaborate; designs become increasingly simple to the east until, after about 500 BC, vessels made in the Fiji-Tonga-Samoa area retain some Lapita shapes but lack decoration. Little else remains of this elegant artistic tradition. Wood carving was practiced, judging by the remains of suitable tools, but no examples have survived.

By courtesy of R.C. Green

Figure 4: Lapita pottery, reconstructed two-dimensional anthropomorphic design (c. 1000 BC).

It is possible that Lapita art was fundamental to the later development of art in the Pacific. Some Lapita design motifs, especially the more complex, can be shown to have survived in Melanesia until the present day, as have Lapita principles of design layout. Lapita art was also in all probability ancestral to early phases of much Polynesian art and even to the tattooing and tapa decoration styles of recent times.

No other surviving early art from Melanesia approaches the accomplishment of Lapita, but a few contemporary and subsequent prehistoric ceramic traditions deserve mention. Some, as at Sohano on Bougainville Island in the northern Solomons (c. 500 BC) and Yule Island off the southern coast of Papua New Guinea (c. 1000–2000 BP), have incised designs that may derive from Lapita. A more elaborate and impressive style is that of the Mangaasi culture of Vanuatu, which dates from 700 BC to AD 1200. Early Mangaasi ceramics include spherical pots and are decorated with bold triangles outlined with applied fillets, within which are further arrangements of incised triangles. Handles were modeled in bird and animal forms.

The apparently early New Guinea tradition of stone carving has parallels in other parts of Melanesia. Stone bowls have been found in New Britain, and stone flared ax heads with flanges shaped like birds' and animals' heads have been found in the northern Solomons.

Polynesia. In the prehistoric cultures of Polynesia, two conspicuous themes figure largely: the ceremonial ground (the marae/ahu complex, known by varying local terms) and personal ornaments. The ceremonial ground was a place of worship. It usually took the form of an enclosure (marae), which was raised or walled or in some other way delineated, with a raised platform (ahu) across one end. A row of upright stone slabs along the ahu were backrests for the gods, while other stones indicated the places of human officiants. The grounds went through various phases of development in the island groups and were the Polynesians' most conspicuous architectural achievements.

Early Polynesian cultures shared a number of traits deriving from a common tradition. Types of adzes, fish-hooks, and certain ornaments recur, including reel-shaped necklace units and pendants of whale teeth, unshaped or shaped by carving a sliver from the lower end. Shaped whale-tooth pendants are found in the earliest phase of Marquesan culture (AD 300–600), as are small perforated shell disks that might have been attached to the coronets typical of later periods. A few simple stone figures belong to a "developmental" phase (AD 600–1300); one closely

resembles small stone figures from Necker Island, the most northerly of the Hawaiian group. These are posed frontally, have circular faces with clumsily delineated features, and may date from about the 10th century. They would seem to be representative of an ancestral Polynesian carving style and are the earliest sculpture from Hawaii. Monumental stone figures of gods, in a style that persisted into the 19th century, were being carved and installed on marae in the Marquesas about 1500.

Easter Island, remote and isolated, is the site of the most famous monuments of the Pacific. Among the monuments are some 300 stone platforms, some of which were used for burials and some of which supported the island's spectacular colossi. Work on the statues, which were carved from a soft volcanic stone, seems to have begun about AD 900. The first figures were relatively small, about 2 metres high; later statues were as much as 12 metres high. The statues' heads and torsos are in an extremely rigid frontal style, with the slender arms and elongated hands carved down the sides and across the belly. Necks are barely indicated; the faces have deep-set eyes, long pointed noses, and massive chins. The statues originally had barrel-shaped topknots of red stone and eyes of white shell and black stone. The Easter Island tradition of statue carving came to an end by about 1600, probably as a result of a serious breakdown of the culture caused by internecine wars.

The earliest New Zealand Maori culture had strong relationships to the contemporary art of eastern Polynesia, whence the Maori migrated about the 9th century. The use of tapa cloth was presumably common, and tattooing was practiced. Fishing lures (some carved as fish), fish-hooks, and adzes follow Polynesian types, and the *patu* type of club in whalebone existed in both areas. In this early phase, the whale-tooth pendants and reel-shaped ornaments of Polynesia became in New Zealand massive stone versions, which were used as pendants or strung as necklaces. Other stone pendants were divided spheres and plaques with stylized fish or zoomorphs carved in relief. Wood carving has not survived, although suitable stone chisels have been found.

The following phase shows the inception of specifically Maori styles. One indication is an increasing complexity exemplified by the elaboration of whale-tooth pendants. The original simple forms of central Polynesia became, by the 14th century, the so-called chevron pendants, which were probably worn in symmetrical pairs. They retain the tooth form but are flat and bordered with series of chevrons representing human limbs. A few small wood carvings from this period exist, as well as one major piece, the decoration for the roof of a house from Kaitaia. Although the roof decoration shows some Polynesian influence, it also powerfully states a major theme of Maori art: a human figure flanked by figures in profile, prototypes of the later *manaia* monsters. It is identical in composition to the lintel panels of later Maori art. Among other surviving carvings are a remarkable 16th-century stern piece and a canoe prow cover, both from the North Island; the bow cover is the oldest known work to be decorated with pecked spirals—the most dominant feature of later Maori art.

A series of combs found in a sacred deposit at Kauri Point Swamp on New Zealand's North Island illuminates the development of forms in the 16th to 18th centuries; the combs progress from square panels with engraved geometric designs to rounded forms with near-figurative decoration. Some of the later engraved features have spurs projecting from edges of parallel lines and are highly reminiscent of the carving on a canoe prow and stern post from Doubtless Bay and a relief panel from Awanui, both sites in the far north of North Island. In general, all these objects show a move away from the simple forms and plain surfaces of the earliest Maori art to more complex forms that are variegated with small areas of intensive bas-relief. This trend reached a culmination in a series of chests, for the bones of high-ranking people, carved in human form.

Following this, a highly vigorous revolution of Maori art took place. Cloaks, the primary garments, were still given geometric patterns on their borders, but otherwise there

was a new emphasis on flowing, curvilinear designs and a wealth of surface decoration. Pendants of whale teeth persisted, but only with minimal carving of a human face at the tip; and jade, from the mountains and streambeds of the South Island, became the most prestigious material for blades, weapons, and a wide range of ornaments.

EFFECTS OF EUROPEAN CONTACT

Interests
of early
Western
explorers

The earliest Westerners to explore the Pacific Ocean undertook their dangerous voyages with firm determination to discover wealth in one form or another. Except in rare cases, they had no lively curiosity about the islanders. Neither their interests nor their skills were engaged in recording island life; indeed, their visits were often too brief to leave time for observations. Tense and even hostile encounters were frequent and must have further distorted the mutual views of those involved. The few comments and drawings to be found in the records of the expeditions of Álvaro Mendaña de Neira (1567–68, 1595), Pedro Fernández de Quirós (1605–06), Luis Váez de Torres (1606), and Don Diego de Prado (1606), all in the service of Spain, Jakob Le Maire (1616) and Abel Janszoon Tasman (1642–43) of the Netherlands, and others are thus all the more telling. They reveal that in general the material culture they witnessed was approximately the same as was recorded and collected by the late 18th-century explorers and their successors.

Thus it seems that, in many parts of the Pacific, material culture had reached a settled state by the 16th century and remained conservative for two more centuries. Then, in the 18th century, contact with European collectors began to stimulate changes in some areas of Oceania, including the outright faking of antiquities and the adaptation of traditional forms to European fancy. The islanders also began the manufacture for sale of favourite collectibles, such as stone adzes and weapons. Such adaptation of production has continued and remains in practice today.

AUSTRALIAN VISUAL ART

The art styles of the Australian Aborigines fall into three groups, which follow to some extent the ecological zones of the continent. The first group is identified with the heart of Australia; this region, which covers most of the continent's landmass, is arid desert surrounded by a belt of savanna. The second zone extends from the central desert region to the southeastern coast and includes sections of open eucalyptus forest and belts of tropical jungle. The third zone is similar to the southeastern zone, but it extends to the northeastern and northern coasts (including Arnhem Land and Cape York). It is thought that, at the time of European contact, the Aboriginal population (about 300,000 people) roughly corresponded with these divisions, the north-northeast region having the greatest numbers and the desert the least.

The material culture of all three groups was limited in types of objects but versatile and highly efficient in its adaptation to the peoples' hunting-and-gathering economy. All material objects were necessarily portable and often served more than one purpose. For example, wooden bowls were used as both food carriers and cradles; and boomerangs, which were used primarily for fighting and hunting, could also be used, in conjunction with shields, to make fires. The most consistently decorated objects were shields, spears, spear-throwers, clubs, and boomerangs of various forms.

The central desert. The art of the central desert area features arrangements of primarily curvilinear and rectilinear designs engraved on flat surfaces. Stylized depictions of birds, snakes, and human figures occur infrequently. Paint was used sparingly and was usually restricted to red and white.

Curvilinear designs mostly appeared in the eastern and central parts of the area in the form of concentric circles, arcs, semi-ovals, and wavelike patterns. Probably the most striking examples are found on the engraved churingas of the Aranda tribe. These oval or disk-shaped sacred boards were made of wood or stone and painted with red ochre. Each design element refers to a specific object or situation; but the application of the reference in its context of the

general design, and its relation to myth, is known only to its clan proprietors. It is this relationship that is revealed, in whole or in part, at initiation rituals.

The most elaborate design creations in the central desert area were the settings devised for totemic rituals. The ground was painted with large designs featuring the characteristic circles and serpents, in red or black on an ochre field with white dots. Arrangements of decorated poles and symbolic structures completed the settings. The participants had their bodies painted and then were covered with bird down adhered with the wearer's blood. In the northern central desert, headpieces, worn transversely or vertically, were constructed of spears sheathed in red and white bird down and represented totemic fauna and flora. In the south and the west, the totemic emblems were smaller panels of string and down worked on stick frames.

Objects made for daily rather than ritual use, such as spear-throwers and boomerangs, were typically engraved. The engraved designs are characteristically curvilinear in the central area, but the engraving of the west and north-west tends to consist of angular grooved key or diamond patterns against a background of parallel grooves (which were sometimes painted alternately red and white). Similar key patterns were engraved onto mother-of-pearl shells by tribes living along the coastal waters of the northwest. Highly prized as ornaments, the shells were traded far into the interior.

The southeast. Living in the immediate path of European colonization, the Aborigines of the southeast were the first to suffer from its effects; their culture was extinguished with some rapidity, and the area was practically depopulated. Their culture had been relatively rich. The temperate climate and the natural resources of the great Murray and Darling river systems stimulated a number of regional variations in art and material culture. In response to the cool winters, the Aborigines built fairly substantial wood shelters, covered with bark sheets and animal skins. They made large cloaks by sewing together opossum pelts incised with decorative patterns on the inner sides. For transport and fishing on the rivers, they built simple bark canoes.

Throughout the area, the basic designs were geometric. Objects were frequently engraved with dense patterns of solid or dotted zigzags and parallel lines. The rich texture thus created served as a background for other carved geometric designs, such as squares or diamonds, as well as for painted elements. Local variations in style are best seen in shields, of which there were four main types. From roughly north to south, the first type was an elongated oval with a convex surface. The second, used for parrying, was extremely narrow and was triangular in section. In the Murray River area, shields were thin, flat, broad ovals with a projecting tab at each end. The fourth type of shield, found east of the Murray River, was a narrow elongated oval pointed at both ends. Other weapons included long spear-throwers and a remarkable range of club types, with spatulate, hooked, or knobbed heads. In areas where the second and third types of shields were made, decorated boomerangs were also used for fighting, but they were engraved with uncharacteristic designs.

The ritual art of the northern area included abstract and representational designs channeled into the ground and large-scale earth effigies. Bark effigies and paintings on bark are recorded but have not survived. In the northwest, a unique form of monument was created: the dendroglyph, an engraving on a living tree trunk. Carved in the usual geometric style, dendroglyphs featured clan designs or made references to local myths. They were used to mark the graves of notable men or to indicate the perimeters of ceremonial grounds.

The north. From the rain-forest country of northeastern Queensland comes an unusual type of shield, a large flat oval with somewhat asymmetrically curved sides. Most have a raised central boss. Designs above and below the boss radiate away from it and are outlined in black and infilled with red, white, and yellow. As usual, they refer to mythological beings and episodes. Paddles and cross-shaped boomerangs were painted in the same manner for ceremonial use.

The lavish use of colour on these objects is indicative of the emphasis placed on painting among the areas to the north, especially around the Gulf of Carpentaria and on its islands, in Cape York and Arnhem Land, and on Melville and Bathurst islands and Groote Eylandt. In Arnhem Land, paintings on bark sheets included both figurative images and the geometric designs typically used in sacred contexts. Paintings from western Arnhem Land and some adjacent islands were often in the X-ray style, in which

animals are painted on dark monochrome backgrounds with their internal organs showing. In paintings of north-eastern Arnhem Land the field was completely filled with both representational and geometric images depicted in fine-line cross-hatching. These images referred to ancestral myths and are programmatic, even narrative, in content.

Unlike the rest of Australia, the northern zone is rich in three-dimensional wood sculpture. The Tiwi people of Melville and Bathurst islands created tall poles in abstract forms by carving, removing, or leaving in their original dimensions alternate sections of a tree trunk. Each pole was then painted in flat areas of colour interspersed with bands of cross-hatching. Such poles were planted in clusters as grave markers in elaborate funerary ceremonies, and boldly painted bark containers for offerings were placed on the poles. Throughout the northern region, small carvings of birds, animals, and plants were typical sacred emblems; but in northeastern Arnhem Land, as nowhere else in Australia, large figures of human beings also were used in ritual and sometimes as grave markers. This use of human figures has been attributed to the influence of Indonesian fishermen who visited the area for shell and sea cucumber, but it is also possible that it resulted from contact with the Torres Strait islanders to the north.

MELANESIAN VISUAL ART

The Torres Strait. The small islands of the Torres Strait, between northern Australia and southern Papua New Guinea, were inhabited by groups of people who, generally speaking, shared a common basic culture. Religious life revolved largely around male initiation cults of various creative and peregrinatory heroes, fertility cults, and funerary ceremonies. Stage settings and decorated masks were used for all of these rites. The settings were typically screens before which dancers appeared in reenactments of myths.

On the southern islands the chief material of major works of art was tortoiseshell, which was perhaps nowhere else in the world used on a comparable scale for masks and effigies. The tradition was evidently an old one, having been observed by the Spanish explorers Torres and Prado in 1606. The masks and effigies were built up of small plates of shell lashed together. Masks were painted red, with white details; some sparse decorative engraved detail was filled in with white, and carved wooden accessories, seed rattles, and feathers were added. The masks are of three types. Two, used for the hero cults, were to be worn horizontally on the top of the head and represent fish or combinations of creatures, such as the head of a crocodile or hawk with a fish's tail. Sometimes a subsidiary human face was added on top of the head. The masks for funerary ceremonies were more naturalistic with somewhat elongated faces and slightly elongated earlobes, embellished with wigs and beards of human hair. On the western islands, large shield-shaped human masks may have been worn and were certainly employed as shrines with trophy skulls attached to them. Large effigies of human beings, crocodiles, and sharks—some as large as life-size—were constructed for initiations and kept in sacred fenced enclosures. Only on Saibai Island, off the southern New Guinea coast, were masks consistently carved in wood. They are extremely elongated, with long pierced ears and crescent-shaped, toothed mouths, and were worn in harvest times. Wood sculpture was otherwise restricted to representations of human heads, which were attached to canoe prows, and to small figures of humans, turtles, dugongs (sea cows), and other animals used for sexual and fertility magic. Magic for rainmaking involved small stone figures.

New Guinea. The visual arts of New Guinea are rich and highly complex. Fortunately, the great number of styles that exist can in many cases be subsumed into larger groupings corresponding to geographic areas. Moving clockwise from the extreme northwest of the island, the primary style areas are Geelvink Bay; Humboldt Bay (Teluk Yos Sudarso) and Lake Sentani; the prolific Sepik River region, which is subdivided into numerous smaller groups; Astrolabe Bay; the Huon Gulf; the Massim area; the Gulf of Papua; Fly River; the Marind-anim region; and the southwestern coast. The central Highland ranges of the island also constitute a major style area.

The *korwar* style

Geelvink Bay. The Geelvink Bay area, including several offshore islands, is located at the northwestern end of New Guinea in the Indonesian province of Irian Jaya. Its style of sculpture seems closely related to those of such eastern Indonesian islands as Tanimbar and Leti, probably as a result of relatively recent influences. The most famous works from the area are the *korwar* figures, small statues embodying the spirits of ancestors; they were used by shamans to divine the outcome of important ventures, illnesses, and other critical situations. They generally depict standing or seated males with disproportionately large heads, befitting their function as either representations of or actual containers for skulls. The heads are as a rule strongly rectangular, with sharply cut brows, small round eyes, and long anchor-shaped noses. The figures usually incorporate local features, such as subsidiary figures, headgear, figures of snakes, or openwork shields.

The carved designs of scrolls and spirals found on the *korwar* shields were also frequently used to decorate the vertical panels forming the prow ornaments of canoes and a multitude of small objects, including headrests and bamboo tobacco containers.

Humboldt Bay and Lake Sentani. The area around Humboldt Bay and Lake Sentani is one of intensive stylistic interaction. A striking example of this interaction can be seen in the diffusion, in the early 19th century, of a pyramidal type of ceremonial house from the eastern coast to Humboldt Bay and subsequently inland to Lake Sentani. The houses had human-shaped finials roughly carved of fern wood and, projecting from their walls, long poles terminating in bird and fish figures. Variations existed, of course, and in general the Sentani ceremonial houses were less elaborate, but the houses of chiefs were equipped with figures standing on short posts protruding up through the floor. The central posts supporting the ridgepole were also carved in human form.

The western edge of the area is best known for its small carvings of human figures and for its carved canoe ornaments. The figures are squat, even bulbous in limb and body; they have neckless, globular heads, with long projecting, sharply pointed noses. The canoe carvings basically consisted of two horizontal rectangular panels united in a point at the front, on which stood a carving of a human head, sometimes with a bird perched on it. Tied behind the head was a separate carving: a vertical rod with crosspieces terminating in either human heads or bird figures. Relief or incised details were picked out in colour.

To the east, closer to Humboldt Bay, the prow carvings

were S-shaped and depicted the body, neck, and head of a long-billed bird; subsidiary figures of fish and other creatures were arranged on the bird's body. Carved human figures were columnar, with the arms and shoulders in low relief and displaced forward almost to cover the chest. The figures had ovoid heads with down-slanted brows, circular eyes, and toothy crescent-shaped mouths.

Painting on tapa was common throughout the Humboldt-Sentani area, largely for women's skirts. At Lake Sentani the style was somewhat linear, using double spirals (also a common carving motif) and fish or bird forms with exaggerated V-shaped tails. Humboldt Bay tapas were denser in design, with the entire field covered with larger and bolder forms.

The Sepik River regions. Roughly 200 separate groups speaking distinct languages live around the Sepik River. As might be expected, the variety of artistic styles found among these groups is bewildering, but three visual elements seem to be basic to nearly all the styles in varying degrees: (1) designs in which two triangular forms are connected at their bases or apexes, often with further design elements in the angles so formed, (2) sculpture based on vertical series of hooklike forms that can be either unidirectional or in opposed groups, and (3) naturalistic representation of natural objects. The interplay of these three elements in various styles suggests that the first two elements preceded the third. The Sepik areas treated in this discussion are, moving clockwise, the northwestern coast, the central coast, the eastern coast, the southern tributaries, the South Sepik Hills, and the upper Sepik.

The styles of the northwestern Sepik area are closely related to those of its western neighbour, the Humboldt-Sentani area. Forked-tailed zoomorphs, used on canoe prows and paddles, and pyramidal houses are common in both regions. The art of the northwestern Sepik groups, however, is based predominantly on the triangular design described above. Sculpted figures are rare in the area. The most conspicuous works are shields, which show many variants of the triangular design. Among the Olo tribe, for example, the triangles are formed from a group of scrolls.

The northwestern Sepik area

Triangular designs can also be found painted on bark sheets used by various groups for initiations and on huge conical masks used by several groups in healing rituals. The Telefomin carved the designs onto tall boards used as house entrances. Similar boards were used to create whole facades by neighbouring tribes. Some tribes used the triangular motif in conjunction with an S-shaped double-spiral design on tobacco pipes, hand drums, and bark paintings.

The north-central section of the Sepik region stretches from the coast to Lake Chambri just south of the Sepik River. The major groups in the area are the Boiken, the Abelam, and the Sawos and the Iatmul.

The Boiken styles, which appear to have been numerous, are relatively little known. Their most conspicuous monuments are the ceremonial houses, which follow on a smaller scale the pattern of Abelam houses to the west. Masks of the coastal Boiken were in a long-nosed style; others were made in basketry. Basketry was also used for a variety of small masks, bird figures, and abstract forms that were attached to large turbo shells used as valuables. Figure sculpture was rare, but the Boiken had rich traditions of pottery making. Food and cooking pots were elaborately decorated with engraved designs and were widely distributed, especially to the river people.

The art of the Abelam tribe, which lived in the Prince Alexander Mountains, was tied to a vigorous ceremonial life. It thus presents a far more spectacular scene. Their pyramidal ceremonial houses, centres for cults of yam growing and initiation, were built on the grandest scale known in New Guinea. They featured vast painted gables and lintels, to which carvings of hornbills, parrots, and lizards were attached. The carvings were in every instance augmented by paint, which indeed the Abelam considered magical in itself.

There are three basic styles of Abelam sculpture. The figure sculpture of the north consists of simple, bulbous forms in massive but sketchy conformations, with detail largely supplied by painting in yellow, black, and white over a predominantly red ground. The eastern style is now similar to that of the north, although somewhat less

dependent on polychromy. At an earlier period, the eastern sculptures were elongated, with a human head at one end and the rest of the figure consisting of clusters of bird heads. In both the north and east, major sculptures were often monumental in scale, some 20 feet long. Large openwork panels were also carved, showing humans, animals, and birds. Figures in the southern, or Wosera, style are generally standing; they have ovoid heads that are often surmounted by birds.

Painting styles also varied. Bark paintings found on the ceremonial house gables of the northern Abelam are broad, large-scale depictions of spirit faces, figures, and animals. Paintings by the southern Abelam tend to be smaller in scale and painted not in flat areas of colour but with much fine line and cross-hatching.

Masks, which were worn for initiations, were generally confined to basketry hoods with elaborate openwork eye panels and noses. Small basketry masks were attached to yams during rituals, and men wore pointed basketry crests as hair ornaments. This pointed form was repeated among the Wosera on a huge scale as a ritual headpiece made of feathers.

The Abelam made a wide range of small decorated objects, including cups, spoons, whistles, and spinning tops in coconut shell; arm ornaments, daggers, and gouges in bone; spears, digging sticks, hand drums, and stirrers in wood; and pots in clay. All were incised with human faces or with closely spaced, complicated designs incorporating the typical Abelam scroll and oval patterns.

The Sawos and the river-dwelling Iatmul, who historically derive from the Sawos, worked in styles totally different from those of the people to the north. Their ceremonial houses were long rectangular structures, with upper stories elevated on posts often carved with ancestral faces and figures. The gables were not of exaggerated size but had masks in wood or basketry. King posts, which had female figures carved at their bases, extended high above the house roofs and were topped with carvings of human beings grasped by eagles.

Human-figure sculpture was a major theme in Iatmul and Sawos art. Human figures and faces and a wealth of curvilinear ornament adorned numerous sacred objects, including flutes, slit gongs, trumpets, drums, and an array of less familiar musical instruments that simulated the voices of spirits. They were also to be found on such mundane equipment as stools, headrests, bowls, palettes,

tools, weapons, and canoes. As a rule the figures were naturalistic within the limits of certain standard conventions, which varied between the eastern (Parambei) and the western (Nyaura) Iatmul. The figures of the east tended to be more gracile than those of the west, which were frequently stocky and burly. The profiles of faces on eastern Iatmul figures often had a graceful S-curve, while those from western Iatmul and the Sawos had heavy jaws, high cheekbones, and sunken eyes under horizontal brows. These same features characterized the long-nosed wooden *mei* masks of the Iatmul. Other types of masks, however, represented mythological birds, crocodiles, fish, and other animals. These were generally constructed of basketry and painted bark and were often of great size.

Perhaps the most striking material used in Iatmul-Sawos art was human skulls. These enthusiastic headhunters covered the skulls of victims and ancestors with clay and painted them in the patterns used in life. The skulls were then displayed on racks made of painted bark sheets or were mounted on puppets for use at initiations and funerary ceremonies.

In the far-eastern section of the Sepik region, around the Ramu River, the peoples living along the coast and on offshore islands engaged in extensive cultural exchanges, trading dances, masks, slit gongs, and carvings. The Murik people at the mouth of the Sepik River were particularly active in this regard. Tribal styles thus spread widely. In some areas local styles incorporated or were supplanted by imported styles, but in many localities a multitude of distinct styles existed side by side.

Although styles vary, most figure sculpture from the eastern Sepik depicts standing males (females exist but are unusual). The figures range in size from miniature to larger than life. They have ovoid heads that droop forward and limbs that are slightly flexed. Some are fitted with actual human skulls. Both figures and masks frequently feature enormously exaggerated noses, which signify masculinity (females have short noses). Besides ritual objects, a wide range of utilitarian equipment, from canoe prows to bowls, was decorated with carved representations of humans, birds, and animals. The carvings were often augmented by the tight geometric patterning that was characteristic of Murik art in particular.

Through the flat, swampy country west of the eastern

coastal hills, several tributaries flow northward to the lower Sepik, each associated with a particular artistic style. These rivers are, from east to west, the Porapora, the Keram, and the Yuat. The art of the Porapora area is related to lower Ramu styles but is less elaborate and profuse. Ceremonial house posts were carved with figures in a plain, almost geometric style—a style that was also used in carving stafflike figures with dishlike receptacles for ancestral skulls.

The Kambot tribe of the Keram River, on the other hand, combined sculpture and painting in complex, ambitious designs to decorate their ceremonial houses. The houses' long, horizontal gables were filled with painted compositions of an ancestral hero with his wives and animals. Paintings also adorned the interiors, and the gable painting was often replicated on a grand scale in feather mosaics on wood slabs—a unique technique in the Sepik. Sacred objects included large panels of basketry that had human skulls attached and were decorated with clay, shells, and boar tusks. Small versions of the panels were attached to sacred flutes. Wood carvings included rectangular shields, which were engraved and painted, and small-featured hemispheric or oval masks. Huge figures of crocodiles were constructed of painted bark sheets for initiations.

The Yuat River people, especially the Biwat (Mundugumor), carved slit gongs, shields, masks, and various types of figure sculpture. Masks, like those of the Kambot, were usually hemispheric. Small figures used as flute stops had grossly enlarged heads that projected forward; they were often carved in conjunction with parrots and other creatures. Masks, as well as wood snakes used in sorcery and other such objects, often bristled with spike forms, which are a common motif in Biwat art. In relief carving, such as can be seen on shields, almost every line or band is serrated, creating a dazzling effect. The same technique was used in enormous paintings of crocodiles that were displayed at yam-harvest ceremonies.

The opposed-hook style of Sepik sculpture was predominant along the middle reaches of the Sepik River and among the hills ranging across the southern border of the Sepik valley, including the Hunstein Mountains. The most spectacular works in this style were figures carved by the Alamlak in the eastern Sepik Hills. The figures, known as *yipwon*, represent patron spirits of hunting and war. They are topped by a downcurved hook; directly beneath

The
southern
tributaries

The
southern
Sepik
Hills

this is a human face, and below that is a vertical series of downcurved hooks. An oval element, representing the heart, appears next at about the centre of the figure; below the heart is a series of upturned hooks, and the whole is supported on a single leg. Small examples of these *yipwon* were personal amulets; larger figures, up to two metres high or more, were clan-owned property kept in ceremonial houses.

A second type of carving has also been recovered, usually from burial rock shelters of the Ewa, a now much-diminished group south of the Alamblak. These figures are related in general form to the *yipwon*, but their bodies are expressed as panels and scrolls rather than hooks. Other flat figures are of females in frontal positions with raised arms and hands.

The Bahinemo west of the Alamblak carved opposed-hook objects with no head or leg. They also made masks, for display only, which incorporated hooks and human features; these represented bush and water spirits. Groups farther west made hook carvings of the Bahinemo type and also carved hook patterns on shields and slit gongs. Other hook carvings are of uncertain provenance. They often have right-angled rather than curved hooks.

That the hook style was once predominant throughout much of the Sepik area is suggested by traces of it in still other styles. South of the river, masks of some Yuat, Kera, and middle Ramu rivers groups are framed in series of hooks. More remarkable, from far north of the Sepik, a number of the Abelam's carvings incorporated opposed hooks in the form of bird beaks.

A number of small groups lived along the upper reaches of the Sepik River. The most productive were the Kwoma. Like the Abelam, they celebrated yam cults in ceremonial houses that were basically roofs supported on posts, without walls. The ridgepoles of the houses were carved with mythical characters, human and animal. The ceilings were covered with bark paintings with semiabstract designs recalling characters and incidents in myths; the finials on the gables were also carved with mythical figures and birds. Similar designs were used on pottery feast bowls and on daggers made from human bones.

The main nonarchitectural carvings—*yena*, human heads;

mindja, long boardlike carvings with a head at one end; and *nogwi*, figures of women—were made for the three main rituals of the yam cult. The carving style is simple and massive, with heads having straight brows above a slightly concave facial plane on which appear conical eyes, a long, heavy nose, and a small V-shaped mouth.

Astrolabe Bay. The people of Astrolabe Bay, southeast of the coastal Sepik-Ramu area, carved as their most important works large ancestor figures, few of which now remain. Most of the figures are standing males, posed frontally. Their shoulders are hunched well forward of the torso, their arms hang straight down, and their hands are placed horizontally on the hips. The face is triangular with the chin extending below the chest; ornaments project downward from the mouth. A long, narrow nose hangs down from rigidly horizontal brows; the protruding eyes are round and staring.

Other works from the area include oval masks with teardrop-shaped eyes, enormous arched noses, and elaborate openwork ears. Shields were disk-shaped and were decorated with relief carvings of X-shapes and circles. Bowls, arm shells, drums, and bull-roarers were incised with small geometric patterns. The same angular patterns were used for tapa paintings.

The Huon Gulf. The cultures and art styles of the Huon Gulf have strong links to those of both Astrolabe Bay and southwestern New Britain, especially in architecture and carving, which was made in large quantities. The main theme, the human figure, was expressed in blocky, almost cubist forms, with the nearly rectangular head sunk deeply between the shoulders. Large freestanding examples of such figures can be found in both standing and kneeling positions. Smaller figures were used as supporting poles for ceremonial houses, as the shafts of suspension hooks, as ladle handles, and as the supports for headrests and betel mortars. Masks, in bark cloth or wood, used the same convention. Other types of objects, however, were decorated with geometric patterns.

The most famous products of the area are the large, shallow, basically oval bowls that were made on Tami Island and traded to the mainland and New Britain. Most have a human face carved at one end, with the rest of the bowl serving as an elaborate headdress; others were carved in the forms of birds and fish. The designs were incised and filled in with lime to stand out against the black background.

Tami
Island
bowls

The Massim area. The islands off the extreme southeastern tip of New Guinea were linked by the kula trading cycle, which distributed not only shell valuables—the ostensible motive of the transactions—but also quantities of other goods. Notable among these were carvings in dark hardwood, which was the special product of Kiriwina, the largest of the Trobriand Islands.

The great variety of design motifs ranged from abstract shapes to both stylized and naturalistic bird, human, and animal forms. Incised designs most frequently featured curvilinear patterns, which could be easily adapted to represent stylized snakes or birds; the incisions were usually filled in with lime to make the design stand out. Among the items carved were mortars and spatulas used to prepare betel nut; long, flat war clubs; splashboards and decorative panels attached to the prow and stern of seagoing canoes;

and dance paddles (two semicircular panels connected by a handhold bar). Dance paddles were sometimes painted, but, in general, painting of wooden objects was minimal. Painting was mainly used to decorate the gables of yam storehouses and on convex oval war shields.

The Gulf of Papua. The succession of cultures situated along the vast Gulf of Papua and in the deltas of the rivers flowing into it produced one of the richest complexes of art styles in New Guinea. In general, the people believed that they owed much of their basic culture to Kiwai, the large island at the mouth of the Fly River to the west, even though their societies showed important local variations. The groups who lived in the swamplands of the west were cannibalistic and practiced orgiastic rites; those who dwelt on the beaches of the east were not given to either practice. All, however, built huge longhouses—in the west these were communal dwellings, in the east they were reserved for men. Most of the groups shared certain types of masks, as well as carved sacred boards with ancestral or supernatural representations in relief. Much of the carving is, indeed, two-dimensional.

The Bamu-Turama area

At the far west of the western area, the art of the Bamu and Turama rivers is largely a somewhat geometrized version of Kiwai sculpture, including some oversize human figures. Two other types of objects were universal in the area from the Bamu River to Goaribari Island at the midpoint of the gulf. They are a dome-shaped basketry mask, which was usually covered with clay and painted and featured a long protruding nose, and sacred boards in quasi-human form. The oval-shaped sacred boards have a face at the top, the indication of a neck, and vertical slots on the body that suggest arms flanking vertical uprights or drawn-up legs. The boards were kept in shrines, as male and female pairs, with human skulls suspended from the uprights. Three-dimensional works from the western gulf had simpler forms—often retaining the natural shape of the wood—but they were carved in elaborate relief.

Farther east, around Wapo Creek, the Era River, and Uramu Island, sacred boards had faces, but, instead of bodies, the field shows a vertical sequence of floating abstract designs, which can be read as extremely stylized anatomic elements. The small silhouetted human figures had upraised arms but were not used as skull racks. Masks in the area were sometimes dome-shaped, but, unlike those from the Bamu-Turama section, they had protuber-

ant jaws. The eastern section of the gulf also developed a flat, oval mask made of basketry covered in bark cloth; the masks were almost identical in shape with the sacred wooden boards and were painted with similar designs.

The lower Fly River. On Kiwai, the large island at the mouth of the Fly River, initiation was marked by the display of naturalistic, almost life-size figures of ancestral men and women. Their heads were virtually identical with the masks made on Saibai Island in the Torres Strait. Small pendant figures from Kiwai were, however, extremely stylized and flat and were covered with a chevron pattern. Much the same facial design was used on canoe splashboards. Large figures were also carved on the coast along the river in a distinctive style in which faces have squared-off jaws. This style of face was repeated on the shafts of the great numbers of arrows made for trade.

The Marind-anim. The people of the coast and hinterland areas of New Guinea northwest of the Torres Strait and east of Frederik Hendrik Island (Pulau Yos Sudarsa), in what is now the Indonesian province of Irian Jaya, included the large tribe of the Marind-anim. Their material culture was limited, except in one respect: the ephemeral art produced for the celebrations of their initiatory cults. The most elaborate performances of the three main cults were held by groups living along the coast.

The central figures of Marind myth are the *dema*; these were considered not only the ancestors of the present clans but also the creators of all the elements of the world. The *dema* were represented at initiations, which could take from several days to many months to perform, by costumed men and by effigies. The costumes were, if not naturalistic, highly allusive accumulations of objects that recalled the *dema* and their creations. The wearer's basic disguise was a fibre costume. He carried on his back or head at least one large effigy carved in softwood; the effigy was partially painted, but it was mainly decorated with white, red, and blue seeds. The costume was also hung with flat semiabstract panels covered with seeds. Small masks and feather headdresses completed the assembly.

This complexity of style did not carry over into Marind sculpture, which was simple, sometimes crude. The largest works were tall posts with animals and geometric designs carved in high relief; these were used for temporary feast

houses. Sometimes large posts, with upright winglike projections on either side, were erected as grave markers. These may be akin to carved forked posts on which the Marind hung head-hunting trophies.

The southwestern coast. The two main groups living on the southwestern coast of New Guinea between the Vogelkop Peninsula (Jazirah Doberai) and Frederik Hendrik Island are the Mimika (Kamoro) to the west and the Asmat to the east. Their styles have much in common.

Carving was the major art among the Mimika and was usually closely associated with initiatory and other rituals. Human figures were the primary subject. They were typically depicted standing with slender limbs. The legs were usually slightly flexed; the hands were held at chest level or under the chin, and the head was a short cylinder with miniscule features. Incised designs were used to decorate the figures, but the repertoire of patterns was limited. The most important design element was a pointed oval, representing the navel, a symbol of birth and, by extension, of life itself.

The largest works of the Mimika are tall poles carved as funerary memorials. These generally consist of a vertical series of figures, with the uppermost figure holding a large triangular panel that projects outward and is carved with the standard designs in openwork. Larger-than-life-size figures of pregnant women used in rites devoted to increasing human fertility were usually displayed at the ceremonial house during a ritual celebrating the creation of the cosmos.

Canoe prows, hand drums, boards, and other objects were decorated with openwork or low-relief carving for ceremonial purposes. Masks were not carved but were made of netting. They were usually conical or hoodlike and sometimes had wooden eyes attached but were generally featureless. The netting section was attached to cane epaulets and bands around the chest. Painting and the decoration of domestic objects were relatively uncommon among the Mimika.

Asmat art, including the art of some neighbouring groups, presents a similar, but somewhat richer, picture. Four style areas can be distinguished, two on the coast (northwest and central) and two inland, with many local variations. During the 20th century an increasing naturalism has affected figure sculpture, particularly among the central

Figure 19: Mask, rattan, sennit, and other materials. From the Asmat people, Upper Pomatsj River tributary, Irian Jaya. In the Metropolitan Museum of Art, New York City. Height 203.2 cm.

Asmat; size, too, has tended to increase. Sculpture is the primary art form; indeed, it has a mythical character in that humanity itself is said to derive from carvings made by a creator hero. Most carvings are made in conjunction with a cycle of feast-ceremonials held in a set sequence. Painting is unknown except on carvings, where white tends to predominate, with some red and black. Seeds of various colours are used decoratively, particularly on the skulls preserved by these cannibalistic headhunters.

The central Asmat are known for their large memorial poles, called *mbis* or *bisj*. The poles are similar in design to those of the Mimika. The openwork carvings on the triangular projections incorporate crescent shapes, S-shapes, stylized hands, birds' heads, and other symbols of head-hunting. The figures on the poles represent or commemorate clan members who were killed by enemy tribes. Smaller versions of the poles were used in the interiors of the ceremonial houses as supports for crossbeams. The poles have a symbolic relationship to canoes and sometimes stand on a canoe-shaped base. Canoe prows were often decorated with large carved figures and head-hunting motifs similar to those on the *bisj* poles. Head-hunting symbols were also frequently carved onto the sides of canoes and onto memorial carvings in the form of stylized crocodiles. Wooden war shields in the central Asmat area are rectangular in shape, with a small phallic projection at the top. The front surface is carved with a bold design of crescent shapes, outlined in low relief by narrow bands.

In contrast, the shields of the northwestern Asmat are rounded at the ends, with a human face, or sometimes an openwork human figure, carved at the top. The front is carved with a vertical row of symbols (usually flying foxes), and the field is densely covered with small subsidiary designs. The largest works by the northwestern Asmat are enormous "soul ships" displayed at initiations. They follow the general form of canoes, except that they do not have bottoms. They do have elaborate prow and

stern carvings, and a number of carved figures representing water spirits sit in the body of the canoe.

Asmat masks, like those of the Mimika, are woven. They often feature wooden eyepieces or are crowned with a flat wood silhouette of a tortoise. They cover not merely the head and shoulders but also much of the torso. The rest of the body is screened with a bushy mass of fibre strips. The masks were particularly used in a ceremony to expel spirits of the dead from the village.

Carving in the inland areas was restricted; it was used for the ornamentation of spears and digging sticks but was prominent only on shields. The designs are more geometric but are otherwise similar to those of the central Asmat.

The Highlands. The central cordillera of New Guinea is inhabited largely by agriculturalists. Although the area has the highest population density of the island, it is also the least productive of works of visual art of a permanent nature.

In the eastern Highlands in Papua New Guinea, shields are painted with geometric designs related to those of the Telefomin and other groups to the north. Figure representations are limited to images made of coiled basketry. Such figures are carried at festivals in the southern Highlands. The most remarkable are the squat fertility figures (*yupin*) of the western Enga. Thin boards carved in openwork are used to represent the dead in festivals farther east.

Masks are fairly common throughout the area, especially in the eastern Highlands. They are generally made of gourds, with hair, feathers, teeth, and other materials applied for features. The Asaro River "Mudmen" are particularly well known for the grotesque imagination they display in making their clay masks.

The most important manifestation of art in the New Guinea Highlands is body decoration. Although decoration usually involves an individual's entire body, the main focus is the head, which is adorned with a great variety of hats and wigs. The most striking materials used are feathers. The area is famous for its many species of birds of paradise, and it is their magnificent plumage that the Highlanders exploit. Each major tribal group has its own local style, which is rich in symbolic content.

The Admiralty Islands. The traditional culture of the Admiralty Islands, which lie northeast of the Sepik River area of New Guinea and are administratively part of Papua New Guinea, is now practically extinct. Although the population consisted of many different language groups, the people have been popularly divided into three artistic style groups: the Usiai, who lived in the interior of Manus Island (Great Admiralty Island), the largest of the Admiralty Islands; the Matankor, who lived on the small islands to the north, east, and southeast of Manus; and the largest group, the Manus, who lived on the southern coast of Manus as well as on some offshore islands. Each group relied on the others for some items of food and manufactures; trade was active and frequent.

The Matankor produced wood carvings and decorated objects, each island having its own specialties. For example, the people on Baluan made bird-shaped bowls, ladles, and spatulas; on Lou, obsidian was carved into great hemispheric bowls; on Rambutyo figures and anthropomorphic lime spatulas were common; and the people on Pak made beds (used nowhere else in Melanesia) and slit gongs. Although the Matankor were neither culturally nor linguistically homogeneous, their art style shows a considerable uniformity. Surface designs consisted largely

of repeated triangles, diamonds, rectangles, and opposed curves, often in bordered bands, sometimes in openwork or relief. These busy, if repetitious, patterns were often accented in black and white on expanses of red background; generally they were employed as strips or in small areas rather than covering an entire object.

Human or crocodile figures are common themes and were used to top house ladders, bed frames, and bedposts and to decorate canoe prows and sterns. Freestanding oversize male and female figures, probably of ancestors, were placed on either side of the doors of men's houses. Human figures also appeared on slit gongs, with the upper body carved as one projecting lug and the legs at the gong's other end. The human figure was usually shown standing, with the arms hanging straight down and the hands either free or placed on the hips. The torso and limbs tended to be square in section, but the calves were angular. The head was ovoid in shape, and the mouth was often set at a right angle to a prognathous, muzzlelike face. A characteristic male hairstyle consisted of a cylinder capped with a sphere rising from the top of the head.

Among the most impressive Matankor objects are the hemispheric bowls on four short legs. These were equipped with a pair of spiral handles representing crocodiles' tails, and bands of designs were carved around the rims. The standard repertoire of abstract and representational motifs was also adapted to small carved objects, such as ladle handles. A favourite ornament was the *kapkap*, a breastplate consisting of a carved tortoiseshell plate mounted on a giant clam shell.

New Ireland. The long, narrow island of New Ireland shows three distinct style areas: the northwest, the centre, and the southeast. The first area is celebrated for its *malanggan* carvings and masks, which share their name with a series of religious ceremonies held primarily as funerary celebrations but also (by extension) for the validation of land claims, the establishment of subclans, and other important events. In this most elaborate style of Oceania, the usual form of the face has horizontal brows, with the deep-set eyes inlaid with bright sea-snail opercula; the nose is strongly arched and massive; and the jaws, broad horizontal rectangles, show a formidable array of serrated teeth. The fully three-dimensional figures usually have added attributes, including bird and animal forms; they often clutch frameworks of rods, which enclose them. Flat areas are pierced in intricate patterns, a technique that was probably fostered when the islanders acquired steel tools. All works were painted for fullest effect in sharply defined areas of black, white, red, and yellow; small sections of black cross-hatching and other patterns often further enhanced the design.

Malanggan carvings on poles display either individual figures or several figures stacked vertically. Freestanding carvings often illustrate mythological incidents and can be of great size. Pigs, birds, and fish are the subjects of other carvings. Seated figures used for rainmaking ceremonies were constructed from tree trunks, bamboo, and other materials; they had raised hands and were fitted with carved heads.

Some *malanggan* masks are almost indescribably complicated, with the basic style of carved face adorned with long vertical tusks and other protrusions, fitted with openwork side panels of birds and fish, surmounted with birds, snakes, and figures, and enclosed within a lattice of bars. Some simpler types have seminaturalistic faces.

Other *malanggan* carvings are horizontal panels. There are several types, including one with a fish head at each end and human figures between them, another with apertures in the middle through which men put their heads, and one with representations of the moon. One type of carving that depicted a bird struggling with a snake was sometimes mounted on the head of a figure.

In central New Ireland the primary objects of mortuary cults were carvings known as *uli*. These are standing figures with female breasts and male genitals; they sometimes have raised hands and may support smaller figures in front of them or on their shoulders. The head is usually large and is topped by a thin, upright crest; the eyes are inlaid with shell, the nose is hooked, and the

wide mouth exposes the teeth above a triangular chin. The body of the *uli*, like that of the *malanggan*, is often enclosed in sweeping bands. The intricate polychromy of the *malanggan* is absent, however; white is the main colour, with touches of red and black. Small *uli* were perched on conical constructions; large ones were housed in similarly conical huts. The ceremonies associated with the *uli* were elaborate, but their significance—apart from a relationship to fertility and warfare—is obscure. Wood figures in the same powerful style were topped with skulls over which clay had been modeled; these were used in rainmaking as well as in mortuary ceremonies. Among some central groups, mortuary ceremonies also featured a large bark and cane disk with a central aperture framed by petallike projections. The disk was painted red and yellow and was kept in a hut with posts carved with the same emblem, apparently of the sun. Skulls were displayed in the disk's central aperture. The design was echoed in the *kapkaps*, which were worked with exquisite delicacy in central New Ireland.

The southeastern style area of New Ireland includes small nearby islands and the northern Gazelle Peninsula of New Britain. In the north of this area, figure sculpture takes the form of small chalk figures of males and females, with rounded faces, round eyes, straight noses, and wide, toothy mouths. The hands are joined in front of the torso. The white chalk is accentuated with touches of black and red—a colour scheme prevalent throughout southeastern New Ireland. Sometimes said to have been made for mortuary ceremonies, the chalk figures more probably were used by secret societies such as those on the Gazelle Peninsula.

Several types of masks were made in the area. The masks of the Tanga Islands were ephemeral constructions of bark and fibre over bamboo frames. They were semiconical in shape, with long backswept ears, thin upturned noses, and extended chins or beards. On the neighbouring mainland, masks were made of the same materials but were more naturalistic. Masks from the southwest were made of wood and had faces similar to those of the chalk figures. The end walls of houses were frequently screened with planks that were incised or painted with small and sparse units of design, often showing stylized animals and fish. Architectural sculpture, however, was rare except in the Tanga Islands and on the southwestern coast.

New Britain. Knowledge of art in New Britain has largely been limited to the coastal areas and to the Gazelle

Figure 22: *Uli* figure, wood. From the northeast coast of New Ireland, Papua New Guinea. In the Museum of Ethnology, Basel, Switz.

Museum für Völkerkunde, Basel, Switz.; photograph, Hans Hinz, Basel.

Peninsula in the northeast. Masks, dance shields, and other ceremonial objects are the primary works.

The Tolai people on the coast of the Gazelle Peninsula probably emigrated from southeastern New Ireland and thus share certain style characteristics, such as boomerang-shaped canoe prows, with that area. The human figure is a common subject of Tolai art and is almost always depicted standing, with arms bent and hands held to the ears. Carved faces are naturalistic, sometimes with long beards, but in paintings the face is often reduced to round eyes and a crescent-shaped mouth. Other common motifs are disks with long triangles below them and spirals.

Tolai art

Museum für Völkerkunde, Basel, Switz.; photograph, Hans Hinz, Basel

Figure 21: Cult house with *malanggans*. The house is made of wood, bamboo, small palm leaves, and croton leaves. The figures are carved in wood and painted with earth pigments and yellow oil colour. The house was erected to commemorate 14 deceased persons from the village. From Medina, New Ireland, Papua New Guinea. In the Museum of Ethnology, Basel, Switz.

Much Tolai art was incorporated into the ritual of two male secret societies, the Iniet and the Dukduk. Iniet initiations were held in walled enclosures lined with paintings of human figures. Long panels of openwork carving showing human figures, animals, and abstract designs were carried in one initiation dance, while the frontal bones of human skulls, which had been over-modeled, painted, and embellished with hair and beards, were worn as masks in other dances. Wooden human figures of various sizes, as well as small chalk or soft stone figures (usually human but sometimes of an animal), were also used.

The Dukduk society used male (*dukduk*) and female (*tubuan*) masks. Both types are cone-shaped and were constructed of cane and fibre. The *dukduk* is taller than the *tubuan* and is faceless. The *tubuan* has circular eyes and a crescent-shaped mouth painted on a dark background. Both masks have short, bushy capes of leaves.

The mountains south of the Tolai's coastal area are inhabited by the Baining, who consist of several groups of seminomads. Virtually their only works of art were masks and other objects carried in dances; these, however, being constructed of light materials (bamboo covered with bark cloth), were often of great size. The most remarkable came from the Chachet (northwestern Baining), who constructed figures up to 40 feet high for daytime mourning ceremonies. The Chachet figures had essentially tubular bodies with rudimentary arms and legs and tall heads with gaping mouths and painted eyes. Among other Baining groups, the best-known type of mask consisted of a flat upper panel, which was either circular or divided into two lobes, and a gaping mouth, from which hung a chinlike or tonguelike form. Two enormous circular eyes were painted on the flat panel. All the Baining groups used, in addition to masks, dance headpieces made of painted vertical panels or poles topped with images painted on bark cloth. The masks and the painted designs represented many items of the natural world.

The masks of the small Sulka group on the southeastern coast of New Britain were, like those of the Baining, made of ephemeral materials—in this case, narrow strips of pith bound together into a cone shape. The colour scheme of the Sulka masks is brilliant: white, black, yellow, and green designs over a bright pink background. On masks representing the human head, a swelling at the top indicates the brow, while the eyes, nose, mouth, and chin are indicated with paint or attached elements. On featureless masks, the main cone supports either another cone with a

painted underside or a large, flat, painted disk. The Sulka used wood to carve female figurines; headpieces in the shape of dogs, praying mantises, or women; and convex, oval battle shields.

The western part of New Britain presents a scene of overlapping styles influenced both by other areas of the island and by nearby New Guinea. The wood-carving style of the Kilege, for instance, was almost identical with that of the Siassi and Tami islands in its themes and patterns. Carvings on drums, a number of small objects, and, in particular, the most important type of wooden mask exemplify this affinity.

The Solomon Islands. The Solomon Islands lie south-east of New Ireland. The most important islands artistically are Buka and Bougainville in the west; Choiseul, Vella Lavella, Santa Isabel, and the New Georgia group in the centre; and Guadalcanal, Malaita (Mala Mara), Ulawa, and San Cristobal in the east. Although there are various regional and local styles, in general the art of the Solomon Islands is characterized by the predominant use of the colour black, with white and red used primarily for details; the use of borders or patterned bands of design; the use of mother-of-pearl inlay; and an emphasis on the human head.

Figures on the Solomon Islands were usually depicted in a sitting or squatting position, but on Buka Island standing figures can be found. The Buka figures are somewhat perfunctorily carved, with squared-off forms and engraving on the faces. Females have slightly flared, flat-topped coiffures, while those of males are mitrelike and pointed. The human figure was a common subject on Buka. Ceremonial houses were built with posts shaped like human figures, and forked posts carved with human heads stood in front of the houses to receive the corpses of war victims. Buka-language speakers living on the northern coast of Bougainville Island sculpted comparable figures but in a more naturalistic style. These were painted glossy black, with some red and white detail representing scarification.

A constant motif in Buka-Bougainville two-dimensional

The
kokorra

art is the *kokorra*, a silhouette of a squatting or standing human figure with upraised hands and the male mitre-like coiffure. This figure—or the head alone—was painted and carved in bas-relief upon a great variety of objects, including canoes, paddles, slit gongs, dance clubs, and architectural elements.

The central Solomon Islanders were vigorous head-hunters, building canoes of great size for their expeditions. The general model throughout the archipelago had tall, upcurved prow and stern posts, which were decorated with rows of shells and, at the waterline of the prow, a small carving (*musumusu*) of the head and arms of a guardian spirit. The *musumusu* sometimes incorporated bird characteristics. Human figures were usually depicted with the lower half of the face jutting forward boldly. Shields in the area were normally made of plain wickerwork and had a tapered oval outline. Some were decorated with shell inlay outlining elongated anthropomorphic beings and other motifs. In New Georgia, dancing human figures, rings, and other designs were carved in openwork on panels made of tridacna shell. The panels were used to enclose small shrines for ancestral skulls.

A major focus of southern Solomon culture was bonito fishing, with its symbolic relationship to sea spirits and ancestors. The roofs of canoe houses, which were the centres of male activities, were supported on huge posts carved with full-length figures of bonito, sharks, and ancestors. Model canoes and large carvings of bonito were kept in these houses, and ancestral skulls were enshrined there. Fish and animal motifs can also be found on a variety of smaller objects, including finials, finely worked *kapkaps*, and bowls. One of the most common forms of bowls, which were made in large numbers for both religious and daily use, represents a bird holding a fish in its beak and standing on a shark. Figures that combined human and animal features, such as a shark with human legs, were also common, especially on Malaita and Ulawa. Some human figures and heads featured the prognathous face characteristic of central Solomon sculpture, but the general style in the southern islands was more naturalistic in human proportions and features. Shell inlay was applied to bowls and other objects, including ceremonial clubs and dance staffs, though less lavishly than in the central Solomons.

Vanuatu. Following great disruption and depopulation in the 19th century, practically nothing remains of the cultures of northern and southern Vanuatu. The central islands of the archipelago—the large island of Malakula, Pentecost (Pentecôte) to the northeast, and Ambrym to the east—are the most significant artistically. Although this group comprises several distinct style areas, it shares certain cultural characteristics. The major socioreligious institution of Vanuatu was the graded society, a hierarchical system of ceremonies performed by men and women to attain greater prestige. The number of grades and their names, as well as the name of the system itself, varied from place to place, but in all areas the grade ceremonies included the sacrifice of pigs or boars, feast giving, and the production of physical memorials. The memorial sculpture was prescribed in form and was made in wood or from the trunks of tree fern, an easily worked material resembling compacted pine needles.

On the northeastern Malakula coast and on some small neighbouring islands, large dance grounds surrounded by stone monoliths and dolmens were set up at stages of the grade ceremonies. The stones were covered by simple shelters with the main wood post carved into human form. The head on such figures was half the height of the whole post; it was shaped like an elongated diamond and had circular eyes, a long nose, and a crescent-shaped mouth. These posts supported a ridgepole consisting of a tree trunk, the spreading roots of which were roughly shaped into the likeness of a hawk. The same image was also used for the ridgepole of ceremonial houses and on huge ceremonial banners of bark and bamboo. The bodies of these hawks are shaped like diamonds, their wings are triangular, and their heads resemble the stylized carvings of birds made for canoe prows.

The eastern coast of Malakula, Pentecost Island, and Ambrym Island together form another style area. The slit

gongs of Ambrym are the largest and most elaborately carved of any in Vanuatu. As in all parts of Vanuatu where they were used, the Ambrym slit gongs were set around the dance grounds, standing upright or at a slight angle. They are found in two main forms. In the north of the island, the gongs terminate in huge three-dimensional heads with puny arms below them. The forehead and the back of the head are scored with deep cross-hatching; the eyebrows are arched, with disk-shaped eyes filling the space below them; and the concave oval facial plane is almost filled by a massive carved nose. The slit gongs of western Ambrym, on the other hand, taper upward to an even greater height and have two to three faces in the elongated-diamond style carved on them in relief. The northern Ambrym style of face is also found on the fern-wood figures made for grade ceremonies. These figures were sometimes of humans, with oversize heads, globular torsos, and slight limbs, but they could also have human heads with zoomorphic bodies. All were originally coated with clay and painted with vivid polychrome body-painting designs. Masks from the area include one type carved in hardwood that was common to both Ambrym and southern Pentecost; it has a bulging forehead, prominent cheeks, pierced eyes, a grinning mouth, and a huge, arched nose. Brilliantly coloured masks made from softwood were apparently usually comedic in intent.

The southern coastal peoples of Malakula, including some in the southern mountains, employed a wealth of objects not only for grade ceremonies but also for farming and initiation rituals. A major technique involved the use of a vegetable compound moistened with coconut milk to model heads or oversize seated figures over coconuts, bamboo frames, or other hard materials. The skulls of important men were also covered with the compound and then mounted on bodies of fern wood and bamboo adorned with beaded armlets and the tusks of sacrificed pigs. Smaller heads were sometimes fastened to the shoulders of these figures. All the modeled works were fully painted, with a great use of deep blue, white, red, and yellow. Most of the modeled heads, figures, and masks have boars' tusks protruding from their mouths. Helmet masks are janiform or have quadruple faces or are surmounted

system of
Vanuatu

with seated figures. Carving was less significant in the southern areas than in the rest of Vanuatu, and figures were somewhat flat and squat, with broad faces indicated only by a summary series of horizontal grooves.

In the mountainous northern region, sculpture appears to have been confined to large heads in fern wood and small janiform heads on spear shafts. These were carved in a powerful geometric style; the deeply cut, sharp-edged ridges and hemispheres approach total abstraction.

New Caledonia. The art of New Caledonia consists almost entirely of wood sculpture; painting was used only to accentuate, in red and white, details of the carvings, which were otherwise entirely blackened. The central feature of every village was a circular ceremonial house with low walls and a towering conical thatched roof. These houses were equipped with a wealth of architectural sculpture. On either side of the door stood a massive jamb with a stylized face at the top; the rest of the jamb was ornamented with geometric designs. The jambs were spanned by a lintel with abstract patterns, while a carved head stood between them as a sill. Inside the house, opposite the doorway, additional large figures served to demarcate special areas. The roof was crowned with a tall finial, which combined a face with stylized elements representing limbs and a headdress. Independent heads and figures of ancestors were carved on the tops of stakes planted in the ground near the ceremonial houses, at spots where their commemorative rituals had been carried out. All these architectural carvings could be claimed and carried off by the maternal relatives of the clan for which they were made; consequently, both the actual objects and their styles were widely dispersed.

The north of New Caledonia is the richest area of the island in sculpture. The masks made there are particularly striking. The long wooden faces have strongly arched eyebrows, glaring eyes (sometimes round but usually bean-shaped), and grinning, crescent-shaped, toothy mouths. The nose springs forward from between the cheeks like a great parrot beak. Other masks of the same general style have equally prominent bulging and rounded noses.

Masks from farther south are almost square; the features are flatter and angular, and the horizontal, slotted mouths are edged with red seeds. A beard of human hair hangs from the chin, and a cylindrical basket topped with a mop of human hair crowns the head. A cloak of black feathers completes the ensemble. The dancers who wore these costumes are said to have impersonated ancestral water spirits.

Similar faces and clothing can be seen on some of the

figures carved onto the posts of ceremonial houses. Other figures have faces in the same styles but have domed, neckless heads; their bodies and limbs are cylindrical or ovoid and are markedly nipped in at the joints. A few small carvings show infants lying on baby carriers; they were used in magic for human fertility. Small carved heads used as a kind of currency and small heads carved on spear shafts complete the New Caledonian range of figure sculpture.

War clubs had stylized phallic, tortoise, and bird-head ornamentation. The ceremonial adz, an object unique to the island, consisted of a nephrite disk mounted on a decorated shaft; it served both as a symbol of chiefly office and as a cosmic symbol.

POLYNESIAN VISUAL ART

By comparison with the art of Melanesia, Polynesian art appears modest in scale and relatively simple in both form and imagery. This is a somewhat deceptive impression, however; the rapid adoption of Christianity in Polynesia led to the obsolescence and destruction of many types of objects now known only through the records of early explorers. The conception of Polynesian art that is gained from extant objects is therefore incomplete and must be corrected and amplified through the study of early writings and drawings. These make it clear that large-scale works were common and that Polynesian imagery was at times as dynamic and creative as Melanesian.

Fiji, Tonga, and Samoa. Ethnogeographically, Fiji is usually considered to be the easternmost island group of Melanesia. As a result of trade links and direct migration in both prehistoric and historic times, however, it has much in common culturally and socially with its Polynesian neighbours to the east, Samoa and Tonga. In fact, the arts of these three island groups can be discussed together.

The endemic nature of warfare in Fiji led to the production of great numbers of wooden clubs, which were the principal weapons. At least 10 types of clubs were made, each with several subtypes. Considerable care was lavished on the engraved designs that decorated the clubs; sometimes the designs were even inlaid with whale ivory, probably by Tongan craftsmen. Fewer types of clubs were made in Tonga, but they were often completely covered in fine geometric patterning interspersed with tiny silhouettes of human or animal figures. Samoa shared a few club types with Fiji but is more notable for its wooden spears, which have graceful, elaborate barbs.

Tapa cloth was made in vast quantities and in lengths up to hundreds of yards. It was generally left plain white for daily use and decorated for special occasions. But in Fiji black, brown, and reddish dyes derived from various barks were used to decorate even everyday cloth with bold, dense geometric designs. Several techniques were used; stenciling was the most prevalent in Fiji, but freehand drawing, rubbing, and block printing were also practiced.

In historic times, pottery was made only in Fiji. Bowls carved out of wood usually had four legs in Fiji but a dozen or so in Samoa. Fijian bowls, in particular, show considerable variety of form. Large food bowls were often in the form of turtles. Small, shallow, footed dishes used by priests were usually shaped like hearts, crescents, or abstract forms, but a few resemble canoes or highly stylized humans or flying ducks.

Surviving examples of figure sculpture from all three island groups are extremely rare, and all known examples are small in size. Wooden deity figures from Tonga generally have a stocky torso, which is set well forward of protruding buttocks and short sturdy legs. The arms are stiff and straight. The head is disproportionately large; the face is flat, with the features barely indicated. The whole surface is smooth. The Tongans also carved small female figures in whale ivory; the earliest examples known are tiny, indicating a sparing use of rare material. Some small examples were strung in groups as necklaces. Later pieces, probably carved after whaling made ivory more common, are somewhat larger. A few double figures were made as suspension hooks, and some were exported to Fiji. Wooden figures from Fiji and Samoa are in much the same style, but they are less clearly defined in form.

The Cook Islands. The Cook Islands group includes Aitutaki, Atiu, Mitiaro, Rarotonga, and Mangaia, among others. Religious effigies are the main surviving works from the area, and both abstract and semirepresentational sculptural styles can be found on all the islands.

On Mangaia, the surface of virtually every decorated object was incised with the so-called K-motif, a dense pattern of cross-hatching interspersed with zigzags and concentric diamonds. Mangaian deities were represented by long cylindrical shafts with flared ends cut to form a group of vertical fins. The fins were pierced and carved into a series of arches, each perhaps representing a human figure with an arched back.

Similar emblems of divinity were made on Aitutaki, but in a simpler style; instead of having flared ends, the shafts were topped by flat panels that were engraved and partially pierced with geometric designs. The edges of some panels were serrated. Sacred staffs from Atiu and Mitiaro were topped by a dome flanked by pointed ovals, the lower end of the staff was spatulate or cylindrical, and the shaft itself supported vertical rows of arches. Gods in human shape were also carved on Aitutaki; they resemble Tahitian figures in posture, but their hands are more oval, their features are mere slits, their bellies droop and protrude, and their limbs are puny and square in section.

Some of the finest examples of Polynesian sculpture are from Rarotonga. Small figures of gods, originally placed on the prows of canoes, were depicted in a deep squatting stance. Their heads make up about half the total height, with the facial features reduced to simple forms—the nose is expressed only by the upper lip. The figures all have exaggerated phalli, and some were painted with black geometric designs. Rarotongan staff gods have similar facial features, but their heads are flattened into essentially two profiles. The midsection of the staff god consists of alternating full-face and profile figures. Below this is a long shaft, which is swathed in a quantity of painted tapa and terminates in a phallus.

The Society Islands. The few remaining examples of traditional art from the Society Islands come mainly from Tahiti, the largest island of the group. Figure sculptures, all in wood, resemble Tongan forms in general, but they exhibit a flowing curve of the back and buttocks rather than the Tongan rigidity and protuberance. The head tends to be longer and is somewhat broader across the cheeks, the jawlines more sharply defined.

Figures of the gods took several forms; most were kept at the marae (sacred enclosure), often in special wooden containers housed in portable shelters. Hollow, life-size figures made of basketry or wood were used to hold red and yellow feathers, which were highly valued—even sacred—in these islands. Smaller divine emblems include shaped lengths of wood that were partly wrapped in braided sennit; lengths of sennit were sometimes sewn onto these figures to indicate features and limbs. Large numbers of thin, tall wooden slabs were set up on the marae; they were carved with openwork geometric designs and topped with figures of birds, human beings, or spiked projections. They closely resemble the god symbols of the Cook Islands.

Small figures were also used to decorate the prows and high, upward curving sternposts of smaller canoes. Large war canoes, which were up to 100 feet long, were equipped with towering sternposts carved with a vertical series of human figures. Carved posts of a similar model were also set up as boundary markers, as were small, crude stone figures.

As a rule, personal property and household equipment in the Society Islands were simple and unadorned, but fly whisks, which were necessary to keep off the swarms of flies that plagued and disgusted the islanders, usually had some ornamentation. The handles were generally carved of wood and were frequently topped with a single figure, which was sometimes depicted perched on one leg. A few handles were assembled from ivory segments that had been carved in openwork and tied together with sennit; these usually terminated in an arched-back (“acrobatic”) human figure.

Garments worn on the Society Islands, including large ponchos, were of painted or printed tapa. In battle, men of high status wore tubular headdresses with protruding crests and gorgets decorated with bands of feathers, shark teeth, and dog hair. The most extraordinary costumes were those of mourners; they consisted of masks and aprons made of mother-of-pearl, crescent-shaped breastplates decorated with mother-of-pearl shells, and feather cloaks.

Decorative patterns used in the Austral Islands

The Austral (Tubuai) Islands. The surfaces of works from the southern Austral Islands were often incised with dense patterns of triangles, crescents, stars, and cross-hatching. The edges of such works were often notched in rows. Such lavish decoration covers carvings from Raivavae, including a few female figures with extremely summary facial features and indications of gorgets and headdresses. The same motifs cover small bowls, long-handled ladles, and broad-bladed ceremonial paddles—which exist in such numbers as to make it likely that many were made for sale soon after the arrival of European collectors. The most remarkable carving from Raivavae is found on tall and slender standing drums. The lower halves of the drums are carved in openwork, with rows of minute dancing figures alternating with rows of crescent shapes, which in some cases represent the dancers' skirts. The same repertoire of patterns was also used on tapa and to ornament wooden elements of houses.

The style of Rurutu, to the north of the group, uses the star design and chevrons but is otherwise less ornate. Some objects were traded to other islands, the most common being fly-whisk handles, which were exported to Tahiti. Each handle was topped by a pair of figures placed back to back. The shaft below was incised with chevrons or, more characteristically, consisted of a vertical series of spoons. Slender spearheads were carved with miniature stylized pigs, resembling phalli. The same images, as well as stylized testicles, birds, and geometric forms, were carved in ivory and strung as necklaces exported to Mangaia. Carved wooden shafts partly covered with woven sennit were sacred objects on Rurutu, as elsewhere in Polynesia.

Perhaps the only surviving example of figure sculpture from Rurutu is one of the most impressive Polynesian sculptures: an image of the god A'a in the act of creating men and other gods. The primary figure, in Society Islands style, has 30 small stylized figures arranged symmetrically on its torso, limbs, and face, 10 being placed as the facial

features. The figure has a hollow back and when found contained 24 small figures (now lost).

The Marquesas (Marquises) Islands. The most characteristic feature of Marquesas art is a strict conventionalization of the human face. It has huge eyes (circular or pointed ovals), with a continuous curved brow line that is connected to a nose shown as two small, broad semi-circles; the mouth is shaped like a horizontal oblong. The design is admirably suited to works in both two and three dimensions.

Marquesan figure sculpture, in wood and stone, represented deified ancestors. The head on such a figure was typically shaped like a dome or a vertical cylinder; the almost featureless torso showed the familiar Polynesian forward arch of the back but placed no emphasis on the buttocks; the legs were ponderous, carved rather than bent, and the arms were slight, with the hands resting on the stomach. Life-size and oversize figures were kept on the platforms of the sacred enclosures. The walls of such platforms also often incorporated stone slabs with faces carved in relief. Stone figures appear to have been used as votive offerings or in fishing magic.

Other small figures in wood, usually engraved with tattoo patterns, were lashed as steps to stilt poles used in competitive races at commemorative festivals for the dead. Tiny figures in the same convention also appear on the various types of ivory ear ornament, on small bone cylinders worn in the hair or used as toggles, on the wooden or ivory handles of semicircular fans, which were plaited from coconut leaflets or pandanus leaves, or on small ivory tobacco pipes. Two types of spectacular head ornament were worn by men. One was a headband with a mother-of-pearl shell supporting an openwork tortoiseshell plaque, somewhat analogous to a Melanesian *kapkap*, the other a coronet of concave strips of white shell alternating with engraved strips of tortoiseshell.

The usual Marquesan weapons were spears and clubs, the latter having flared semicircular upper ends carved with faces and geometric designs. Decorated household objects included engraved bowls and gourds with engraved lids; stone pounders had shafts carved with human heads.

Easter Island. Besides the great prehistoric stone figures already described, the Easter Islanders in more recent times created a remarkable body of small sculpture in wood. The best-known are two types of male figures and one type of female figure, presumably all of ancestral significance. Some of the male figures are naturalistic, with an upright stance and somewhat slack and paunchy bodies; the hands, placed at the hips, have the typical elongated fingers of the stone colossi. The second, better-known type is one of the more extraordinary images in Oceanic art: it represents a bowed, skeletal figure with sunken abdomen, protruding rib cage and spine, and emaciated limbs. The face is skull-like, with a jutting nose and bared teeth. Both the naturalistic and the skeletal male figures were worn ceremonially as pendants. In contrast to these fully three-dimensional figures, the female figures are frontal and flattened, except for the head; they have one arm placed across the torso and the other across the belly. All the figures wear goatee beards and have mythical creatures carved in low relief on the craniums. A few of both the male and the female figures have the double heads found elsewhere in Polynesia (e.g., Tahiti). As in all Easter Island wooden sculpture, the glaring eyes were indicated by tiny disks of obsidian set in rings of bird or fish bone. Other carvings are of bird-headed human figures associated with the cult of a bird-god; still other human figures have the heads of lizards. Besides these there is a range of small, largely inexplicable grotesques.

Crescent-shaped wood carvings with a bearded human head on each tip were worn as pectorals; carvings of fish worn in the same manner served as emblems of authority. Women wore small spheres carved with relief designs as charms.

For commemorative funerary ceremonies, enormous bark-cloth effigies, painted with tattoo designs, were set up in front of the image platforms. Only a few miniature bark-cloth figures of this type have survived.

Long clubs with human heads carved at one end were

Easter Island figure sculpture

used for fighting. Graceful paddlelike objects, actually extremely stylized human figures, were carried in dances.

Easter Island abounds in works engraved on exposed rock surfaces, including outlines of turtles, fish, and above all the bird-headed men of the bird cult. In addition to the petroglyphs, paintings of birds, dance paddles, and other subjects exist in caves or on the interior surfaces of stone house walls.

New Zealand. It is estimated that by the beginning of the classic period of Maori art and culture about 90 percent of the population lived in the North Island of New Zealand. The smaller groups of the South Island were apparently more conservative, and it was thus largely in the north that a spectacular florescence of sculpture and architecture took place.

Two major carving styles existed. The northwestern style (especially in reliefs) featured undulating, serpentine shapes; human bodies and limbs were tubular or triangular in section and often intertwined. Heads were peaked, with gaping mouths that often had hands and arms looped through them. Large areas of surface remained smooth, while small sections and details, such as lips and eyebrows, were finely patterned. The eastern style of human figures was basically naturalistic, apart from oversize heads; the stances of figures resembled those of central Polynesia, with short legs, swaybacks, and hands on the torso, but the neck was well defined. Some faces were naturalistic portraits; others were ferociously stylized, with slanting oval eyes, distorted mouths, and outstretched tongues. Both styles of faces were usually covered with tattoo designs, while scrolls and other designs accentuated the shoulders, hips, and knees.

The northwestern style is thought to be older than the eastern, partly on the basis of oral tradition and partly because the "central-Polynesian" aspect of the eastern style suggests that it may have developed as a result of later immigration. There was a considerable mobility of local styles. Innovation, however much desired, was nevertheless restrained to some extent by the existence of a recognized repertoire of named patterns, predominantly scrolls, which sustained a continuity of style.

National Museum of New Zealand, Wellington, New Zealand (B17580)

Figure 30: Storehouse doorway, wood, red lead paint. From the Maori people, New Zealand. In the National Museum of New Zealand, Wellington. Height 92 cm.

The continual quest for prestige in Maori society encouraged men of high status to commission and own important works. The choice of such works changed throughout Maori history. It appears that war canoes were the most prestigious works in the 18th century. Communal war canoes, which were up to 100 feet long, were lavishly decorated with carving and painting. In most parts of the country the attached prow carving had a figure leaning forward with arms stretched behind it; a thin panel carved with openwork spirals ran from the figure to a transverse slab, on the back of which was yet another figure, which looked down the length of the canoe from a squatting position. The sternpost was a high vertical slat with openwork scrolls and a small figure seated at the foot. More figures were carved in relief along the hull; their eyes were sometimes inlaid with mother-of-pearl. The whole canoe was painted red, with black-and-white details, and had feather streamers hung from the sternpost.

In the first half of the 19th century, following population changes resulting from intensified tribal warfare, the introduction of firearms, and the spread of Western diseases, a number of local styles were extinguished, and, after the European suppression of fighting, the decorated storehouse came into prominence. As a precaution against vermin, these food storehouses were elevated on posts, which were often in human shape. The houses had pitched roofs and deep porches. The outer gable was fitted with bargeboards, usually carved with a complex mythological scene of several figures hauling ashore a whale (a symbol of plenty), which was represented by an abstract pattern of spirals indicating its jaws. At the peak of the gable stood a mask or small figure, and at the foot of the bargeboards were sills with reliefs of ancestors. In some large storehouses, vertical panels between the ends of the sill and the bargeboards were carved with copulating figures—another reference to fertility—while still more figures were carved on a small door and on panels at the back of the porch.

Largely because of the influence of the artist Raharuhi Rukupo, the meetinghouse subsequently became the central object of local tradition and pride, as it remains to this day. The meetinghouse follows the same principles of design as the storehouse, but it is built at ground level. The exterior carvings stress not the aspect of abundance but ancestral power: indeed, the whole building symbolizes the tribal founding ancestor, with the gable mask representing his face, the bargeboards his arms, and the ridgepole his spine. The porch is undecorated, except for large lintels above the door and the frame around a single window. The interior, however, is fully furnished with relief panels of frontal ancestral figures alternating with panels of laced reed in polychrome geometric patterns. The lower sections of the house posts are carved as small ancestral images. Beams and rafters are painted in prescribed red, white, and black designs.

The prevalence of warfare in the later phases of Maori history led to the construction of defensive earthworks and palisades around hilltop villages. The gates were massive planks, carved above the entrance with major ancestral figures. The palisades incorporated posts with further ancestral figures, often much bigger than life-size.

Maori material culture differed from that of the rest of Polynesia in the absence of certain types of objects (such as stools and neck rests), in the addition of others, but above all in its ornateness. Images of divinities are rare outside of architecture, except for "god sticks" (rods with heads at the upper end). Weapons included a range of short hand-club types, in wood, nephrite, or whalebone, reflecting early Polynesian models. Some had human figures carved in relief near the grip (overall engraving of the blade was a late development). Staff clubs had ends carved as faces with sharp protruding tongues. Chiefs owned carved adzes with fine nephrite blades as insignia of status. Lavish relief carving covers the entire surface of small flutes, paint cups, and, above all, lidded treasure boxes.

The highly valued nephrite, classed in several grades of beauty, was employed not only for clubs and hooks but also for a variety of pendants. The best-known depict small frontal human figures in contorted poses. Cloaks, the usual garment of both sexes, were woven of flax, bor-

dered with geometric patterned bands. Feathers (pigeon and kiwi) and dog's hair ornamented others. Like other Maori arts, weaving was a highly ritualized process.

The Hawaiian Islands. Like those of the Marquesas Islands and Easter Island, the artists of the Hawaiian Islands developed their own variants on Polynesian style. This resulted partly from isolation, partly from the structure of religious belief, and partly from the existence of a warlike aristocracy. Featherwork, for example, was made and used in other parts of Polynesia, but no other group produced anything as spectacular as the feather cloaks, capes, and helmets of Hawaiian chiefs. These were worn not only for important ceremonial occasions but also for actual combat. In fact, the relatively small trapezoidal capes, thought to be an early form, were designed so that the fit of the straight edge around the neck would afford some protection from attack. Larger cloaks have rounded necks and rounded lower edges with flaring sides; they were constructed of mostly red and yellow feathers, with some black and green. The feathers were attached in bunches to a netted base. The cloaks were decorated with triangles, lozenges, circles, squares, and sweeping crescents. With the cloaks, chiefs wore wicker helmets, shaped as caps with crescentic crests, which were also covered in feathers. Heads of the war god were also made of wickerwork covered with red feathers; the mouths on such heads were set with dog's teeth, and the eyes were made of large mother-of-pearl plates with wooden knobs for the pupils. Some were equipped with locks of human hair, others had crests resembling those of the helmets. These formidable images were carried into battle on long poles.

Wooden figures of divinities fall into several types and styles. The largest formed part of the settings of the sacred enclosures. Posts, carved at the top with rudimentary human forms, including heads with slanting eyes, wide mouths, and chevron-shaped brows, were parts of fences. Flat figures or faces topped with panels decorated with chevrons or silhouettes were kept inside the enclosures. Three-dimensional, full-length figures or busts on posts stood at the gate of the enclosure, at points within it, and in a semicircle facing a sacrificial altar. They were often well over life-size. The majority that survive are

in the so-called Kona-district style dating from the late 18th to early 19th century; like the feathered war-god heads, they are associated with the reign of Kamehameha I (1782–1819). The bodies of the figures are massive assemblages of swelling conical or tubular segments, often sharply demarcated. The heads are proportionately large and have thrusting chins; the extremely exaggerated hori-

Hawaiian

zontal mouths are shaped like a figure eight and are filled with menacing teeth and outlined with ridges. The heads are crowned with voluminous knobbed coiffures; plaits sweep down and back, incorporating the ridged eyes.

The conventions of Kona-style bodies occur in some earlier figures, including smaller figures of gods mounted on props, apparently personally owned by chiefs. Many differences in detail exist. Some of the figures have crested helmets, while others have elaborate tiered headdresses, triple-peaked headdresses, or none at all. Several were clearly made as pairs. Small figures without props were privately owned by families. Many of these have Kona-style bodies, helmets, crests, and other such features, but some female figures were carved in a fleshy, naturalistic style and were adorned with human hair. The small figures embodied protective gods and spirits and were used as containers for sorcery materials. Human figures adorn a number of other items, including bowls and racks for spears and poles. They are sometimes positioned with raised hands or in a headstand.

The Hawaiians made many types of personal ornament. The best-known is probably the hook-shaped whale ivory pendant, which was traditionally strung on coils of human hair. For clothing, especially for loincloths, skirts, and cloaks, the Hawaiians impressed and painted tapa with geometric designs in red and brown; the manufacturing tradition continued long after Western contact, with subsequent changes in designs and use of colour.

The Polynesian outliers. Small populations speaking Polynesian languages live within the geographic areas of Melanesia and Micronesia, on islands in the Caroline, Solomon, and Vanuatu groups. They are apparently immigrants, largely from western Polynesia, who arrived at various times in the latter 1st millennium AD. Although in many cases the culture of these groups is generally Micronesian, their art often resembles Polynesian works. Figure sculpture, for example, often exhibits the characteristic protruding buttocks. Some figures have flat faces with horizontal brows and pointed chins similar to those found in western Polynesia.

A marked feature of decorative design in much of this area is the repetition of small triangles in rows. This theme is also expressed in three dimensions as rows of pyramids or truncated pyramids. The design is found on dance paddles, canoe prows, house posts, bowls, headrests, stools, and other small objects.

MICRONESIAN VISUAL ART

Micronesia can be divided into two style areas. Western Micronesia consists of the island groups in the western Caroline archipelago, including Palau and the states of Yap and Truk (Chuuk). Eastern Micronesia includes the eastern Caroline Islands, the Marshall Islands, and Kiribati. The Mariana Islands, which lie north of the Caroline Islands, do not figure in this account, because of the obliterating effects of late 17th-century Spanish occupation on their population and its culture.

Throughout Micronesia, forms are exceedingly basic; decorative detail is largely geometric, consisting of bands of solid colour and rows of triangles in various patterns. Zoomorphs and anthropomorphs are relatively rare and are often expressed as silhouettes. The most frequent use of even this amount of decoration is found in the western Carolines, diminishing to none in eastern Micronesia.

The most frequently decorated items in the western Carolines were buildings and canoes, reflecting their importance in Micronesian society. Indeed, double-hulled canoes with crescent-shaped sterns and prows served as models for shrines constructed in Palau, Truk, and other smaller islands. Carved birds were sometimes placed in the shrines. The actual canoes of Truk were given elegant prow and stern ornaments with highly stylized sea swallows standing beak to beak. The most impressive buildings in the western region are the men's houses of Palau, which incorporate the greatest incidence of representational art in Micronesia. The gables were screened with horizontal planks that were engraved and painted with mythical and historical scenes. A life-size figure of a seated woman was often attached at the lower centre of the gable. The carved

Figure 33: Female figure from a clubhouse gable, wood. From Palau. In the Metropolitan Museum of Art, New York City. Height 65.4 cm.

face of a god appeared at the peak of the gable. Other architectural elements, including the posts and beams, featured relief carvings similar to those on the gable. Palauan carving was otherwise restricted to large ceremonial bowls and covered boxes in avian form and to stools. The wood was treated to produce a dark red surface and was inlaid sparingly with tridacna shell in abstract patterns. Some modeling was used to decorate ceramic oil lamps.

In Yap the ceremonial houses were less lavishly adorned. Posts and beams were painted with silhouettes of dugongs and with black-and-white patterns of triangles or were carved with human and animal figures. Crude figures of birds and animals were hung in front of the house gables. The houses stood on platforms of coral blocks, onto which faces were sometimes carved. A trident, sometimes with a bird perched on the central prong, was a characteristic feature of Yapese art and is found on prow and stern canoe carvings, headdresses, and house decorations.

Eastern Micronesia produced no significant carving, apart from paddle-shaped dance staffs and plain, fan-shaped canoe prows. Material culture as a whole was simple and utilitarian. Kiribati warriors wore armour—trousers and jackets with high protective panels at the back of the neck. These suits were woven of sennit and embroidered in human hair with geometric designs.

Weaving of banana and hibiscus fibre on backstrap looms was practiced throughout the Caroline Islands, except in Palau. The fine yarns, which were dyed black, brown, and red, were woven into loincloths, sashes, skirts, and burial shrouds. Their geometric patterning paralleled the designs used in carved decorations and tattooing. In the Marshall Islands, pandanus and coconut strips were plaited into square mats worn as clothing. These were decorated with borders of checks, stripes, and rectilinear designs, which were closely related to social rank and degrees of sanctity. (D.Ne.)

Micronesia

Music and dance

THE ROLE OF MUSIC AND DANCE

Music and dance in Polynesia and Micronesia are audible and visual extensions of poetry, whereas in Melanesia they are aimed more at spectacular display during times of life crises and as a part of secret-society rituals. The differences between Melanesian and Polynesian-Micronesian music and dance reflect more basic differences between the Big Man sociopolitical structure found in many parts of Melanesia and the dynastic chiefdoms of Polynesia and Micronesia.

Melanesia. The leader, or Big Man, in many Melanesian societies is often a self-made man; he becomes a leader by creating followers, succeeding because he possesses skills that command respect in his society, such as oratory, bravery, gardening prowess, and magical powers. He amasses goods and has great public giveaways, often in connection with the erection of a Big Man's dwelling or a

Polynesian
influence
in Mela-
nesia and
Micronesia

men's house, the purchase of higher grades of rank in secret societies, the sponsorship of funeral or other religious ceremonies, or the installation and consecration of slit gongs (or slit-drums, percussion instruments made from hollowed-out logs or living tree trunks). These ceremonies occasion spectacular performances of music and dance as well as extraordinary displays of visual art.

Imper-
sonation
of other-
worldly
beings

There are basically two kinds of dance in these Melanesian ceremonies: dances of impersonation and dances of participation. In the first type, the dancer impersonates mythical or ancestral beings; the dance-actor becomes someone else, and his attire is usually distinctly unhuman or supernatural—consisting often of huge masks and a full otherworldly costume. The dance movements are dictated by the two considerations that the impersonated beings are not human and that the dancer's attire is difficult to move in. Thus, the movements are those of legs and swaying bodies; the arms are often covered and frequently used to steady the costume and mask or perhaps hold a drum to accompany the dance. The movements do not interpret recited poetry; however, the accompanying sounds of musical instruments may represent the voices of the supernatural beings.

The dances of participation are often extensions of these dramatic ceremonies, for individuals who do not impersonate spirits often join in and dance with them, imitating the steps of the supernatural. In dances celebrating head-hunting, warfare, funeral rites, or fertility—in which the entire community sometimes participates—the same movements are used, often to the accompaniment of drumming and communal singing. The dances have a character of spontaneity and do not require long and arduous training. Their aim is not the simultaneous flawless execution of music and intricate movements but, rather, the creation of a mass rhythmic environment that might be characterized as a visual extension of rhythm. If words are associated, they are repetitious and seem not to tell a story; they may even be unintelligible. Although the specific structure of any single dance tradition in Melanesia is not yet known, it seems probable that the isolated units of movement would be primarily those of legs and body.

Polynesia. The entirely different world of Polynesia stands in contrast. Polynesian dance is a visual extension of poetry that uses chant or heightened speech as a vehicle for the praise and honour of high-ranking chiefs or visitors. In Polynesia, power resides in chiefly office, and traditional oral texts tell of a chief's deeds and his descent from the gods. Genealogical rank is a distinctive feature of Polynesian societies, and music and dance pay allegiance to the rank-based sociopolitical structure, reflecting and validating the system of social distinctions and interpersonal relationships. In these societies, where power resides in the office and the regime is long and enduring, spe-

cialists compose poetry, add music and movement, and rehearse the performers for many months before a public ceremony. Movements are primarily those of hands and arms, and interpretation is that of a storyteller. The dancers do not become characters in a drama, and their stylized gestures do not correspond to words or ideas as they do in literature-inspired dance traditions of Indonesia and Southeast Asia. In Polynesia the dancer interprets a story orally, usually chanting or reciting metred poetry, and accompanies the words with actions. Yet, although Polynesian dance texts are based on traditional stories, legends, or myths, a story is not "told" in the usual sense: traditional literature is referred to in a roundabout way, but the poetry is often the vehicle for saying something else, usually something relevant to the occasion at which it is presented. In addition, the order of the dances and the choice and placement of the dancers often supply further information about the social structure.

The structure is known for at least three Polynesian dance traditions—Tongan, Tahitian, and Hawaiian—and the basic units of movement are primarily those of the arms. The only Polynesian dance tradition, however, that has been thoroughly studied is the Tongan. Tongan dance is a visual extension of poetry and is closely intertwined with social organization. This sung poetry is a series of references to mythology, chiefly genealogies, famous scenic places, and contemporary events. The dances, which are performed either standing or sitting, interpret selected words of the text with hand and arm movements. The distinguishing characteristics of Tongan dance are the emphasis on the rotation of the lower arm and the flexion and extension of the wrist, as well as a quick sideward tilt of the head. The legs are used mainly to keep time with sideward stepping movements, and there is a marked absence of hip or torso movement. In pre-European times an important dance was the *me'etu'upaki*—a paddle dance performed by a large group of men in accompaniment to singing and a slit gong, which was often played by a high-ranking chief. This dance is still performed today. Group dances called *me'elaufola* were performed by men or women separately in accompaniment to singing, long bamboo stamping tubes, and percussion sticks. An evolved form of this dance, which flourishes today, the *lakalaka*, is performed by men and women together in accompaniment to sung poetry only. Solo and small group dances performed by one, four, or eight women often follow the large group dances and are more concerned with beautiful movements than with interpretation of poetry, although the same movements are used. In the 20th century, Polynesian dances can be classified into six genres, three of which have survived from pre-European times. The most acculturated dance type, the *tau'olunga*, is a combination of Tongan and Samoan movements accompanied by Western-

style singing in conjunction with stringed instruments.

Micronesia. Music and dance in Micronesia, though certainly not the same as their Polynesian counterparts, are closely related to them. With the exception of Truk in the central Carolines, which displays traits of Melanesian and possibly Indonesian influence, the music structure of all parts of Micronesia is predominantly word-determined, as is that of Polynesia. Dance movements are mainly of hands and arms in accompaniment to poetry. In some islands, such as Yap (in the western Carolines) and Kiribati, there is a similar concern for rank in the placement of dancers, as well as the emphasis on rehearsed execution of songs and movements. But, although movements and types of dance have a superficial similarity to those of Polynesia, there are differences. In the Yap empire, for example, dancers from Ulithi, Woleai, and other islands performed and taught their choreography and texts to the Yapese as tribute, even though the dance texts were in languages unintelligible to the Yapese dancers; the function of movements was not to illustrate a story but to decorate it. Instead of acknowledging a chief's deed or genealogy, the Yapese dancers demonstrated the overlordship of Yap to the other islands. Even in Ifalik, where texts were in their own language, the movements did not interpret poetry but were apparently abstractly decorative. The same is true for the Kiribati. Thus, Polynesian dance could be characterized as illustration of poetry and Micronesian dance as decoration of poetry, while music in both areas serves as an elevated form of audible performance for poetry.

In many parts of Micronesia, dance and music were associated with tattooing, and with the decline of tattooing has come the virtual demise of these genres. The importance and dependence of the Micronesians on the sea is illustrated in poetry, music, and dance. In some areas, dances were performed on a platform of canoes; canoe-like paddles were used in other dances, and, in some areas, performers wore head ornaments modeled after canoe parts.

Again, the specific structure of any of the Micronesian dance traditions is not known, but apparently the basic units are primarily those of hands and arms and, if early descriptions are to be believed, the head.

Australia. Music and dance of Australian Aborigines are important elements of sacred ceremonies that reenact mythological origins of the tribes and ensure the continued supply of foods through the propitiation of totemic plants and animals. Little is known about the internal structure or basic movements of the various Aboriginal dance traditions; however, in general terms there are often mimetic movements that involve the entire body to add a visual interpretative extension to the oral tradition of the tribe.

MUSICAL INSTRUMENTS

Oceanic cultures have developed a large variety of sound-producing instruments. Some are unique, such as the fric-

tion blocks of New Ireland: three to four plaques carved out of a wooden block are rubbed with the hands to produce shrieking or hollow-resonant sounds, depending on size (8 to 80 inches for the entire instrument). Many instruments are used not in musical contexts but for other purposes—for example, to produce the voices of supernatural beings (in Melanesia), as lures (shark rattles), as toys, and for communication.

Musical instruments proper generally lack provision for musical efficiency and easy handling. Flutes have no or few finger holes and no air ducts. Tuning devices with drums are rare, as are fixed resonators with chordophones (stringed instruments), which are represented only by simple types of musical bows and zithers. In general, instrumental music is culturally less important than vocal music, and in some areas it is absent altogether. In some other areas, however, such as the Solomon Islands, there are highly developed pan-flute orchestras.

Although some types of instruments—e.g., conch trumpets and slit-drums—can be found in many parts of Oceania (excepting Australia), others occur only locally or are distinguishing features of certain musical areas. Open, hourglass-shaped drums with one membrane are typical of New Guinea and Melanesia, while Polynesians use drums of cylindrical shape that are technically kettle-drums. Flutes of various types are usually blown with the mouth in Melanesia, with the nose in Polynesia (nose flutes), and both ways in western Micronesia. In contrast to their simple technical structure, which is the more demanding on the skills of the player, some instruments display elaborate ornamentation related to their function as cult objects in Melanesia, or they may be highly carved and finished befitting their function of honouring gods and chiefs in Polynesia.

REGIONAL STYLES AND TRADITIONS

Melanesia. Melanesia, including New Guinea, houses a multitude of regional musical styles, few of which have been thoroughly investigated. The diversity, which parallels the linguistic situation, is assumed to be a result both of migrations and of the relative isolation of ethnic groups due to geographic conditions. Intergroup contacts, including European influences, mostly since the late 19th century, have had a clear influence on present styles.

Generally speaking, Melanesian music tends to be less word-determined than Polynesian and Micronesian music. Melody, rhythm, and form appear to be shaped by intrinsically musical principles rather than by the structure and meaning of accompanying text. In fact, song texts in Melanesia often use archaic or foreign languages and are thus frequently unintelligible to all participants in a performance.

Melodic characteristics. Musical scale and melodic movement have been primary criteria in the Western

Dance as
ornament
to poetry

The triadic
and
pentatonic
forms

analysis of Melanesian music. The main types of melodic form are triadic, in which the melody moves exclusively or predominantly on the steps of a triad (three tones, each a third apart, as C-E-G); and pentatonic, which uses five steps within an octave, the melodic structure typically emphasizing seconds, fourths, and fifths. Other types include "narrow," in which melodic movement is restricted to an ambit (range) of a third; and "tiled," in which the melody consists of a sequence of short narrow phrases on different tonal levels, always in a descending order.

Several attempts have been made to link these types of melodic form with specific cultures within Melanesia. In the mid-20th century the Dutch scholar Jaap Kunst attributed the tiled type found in the interior of western New Guinea, the Torres Strait, and Australia to "a people who, without doubt, emigrated from Asia to Australia—where the majority of them finally settled—by way of New Guinea and Torres Strait." Triadic melody style has been connected with speakers of non-Austronesian (Papuan) languages in New Guinea and elsewhere in Melanesia, while pentatonic structure is described as an element of Austronesian culture in Melanesia. But, whenever new data become available, previous hypotheses on the distribution of stylistic characteristics and their attribution to ethnic and cultural groupings usually have to be revised.

Also, rarely is the music of an ethnic group found to be based on one single principle of melodic structure. In most cases a mixture of several principles is apparent, with one or the other prevailing.

Musical style and cultural context. This mixture of musical structures holds true for the few New Guinea groups whose music has been studied in its cultural context: the Monumbo, the Kate, the Watut, and the Kaluli. A more detailed discussion of Kate music illustrates the stylistic heterogeneity of the Kate, who live in the hinterland of the Huon Peninsula of northeastern Papua New Guinea and speak a non-Austronesian (Papuan) language, while some of their neighbours on the coast and on adjacent islands speak Austronesian (Melanesian) languages. A Lutheran mission was established in that area in 1886.

Before the mission terminated their non-Christian religious activities, the Kate shared with their neighbours, specifically the Melanesian-speaking Jabem, Bukawa, and Tami, a secret initiation cult that provided for an exchange of music and dances among participants. The mission introduced "Christian songs" with texts in Kate language and European church tunes; but missionaries also created "Christian" adaptations of traditional Kate melodies, which were more readily acceptable than Lutheran hymns.

By about 1910 the Kate experienced a twofold cultural change resulting from the continuing contact with their Melanesian-speaking neighbours and from the impact of European colonial culture. But many aspects of their pre-colonial culture were then still functioning or in fresh memory. Music and dance activities were connected with childbirth, children's games, initiation, hunting, agriculture, ceremonial bartering of pigs, warfare, and death—the latter occasion being the only one to prohibit dancing. Consequently, initiation ceremonies, which usually extended over two years, had to be interrupted whenever a death occurred. In addition to music and dance in ceremonial context, there were songs for entertainment and expression of individual sentiments or experiences. Most of the common social dances and dance songs were adopted from the offcoast Siassi Islands, including texts that were unintelligible to the Kate.

Structural characteristics of Kate music include triadic and pentatonic melody, both pure and in various degrees of blending; monophony (music having a single voice part); reverting and progressive strophes (stanzas) of varying lengths; basically isorhythmic organization (*i.e.*, using recurring rhythmic patterns); and a wide range of tempi. Analysis of stylistic characteristics in relation to context and historical data revealed that triadic melody and short progressive strophes are associated with the old, non-Austronesian (Papuan) stratum of Kate culture. Pentatonic melody and longer, reverting strophes seem to represent Melanesian influence, while a specific melody style characterized by the use of several pentatonic modes

in succession ("modulating pentatony"), very wide ambit, and extended strophic form can be attributed to European culture contact.

For the Kaluli, a group of rain-forest dwellers in the Southern Highlands province of Papua New Guinea, the American anthropologist Steven Feld has demonstrated the integration of diverse musical structures and natural sounds under one aesthetic ideology. The concept of "lift-up-over sounding," which calls for a continuity of overlapping sound qualities and the avoidance of unison, governs all Kaluli musical expression, including recently acquired Christian church tunes and pan-New Guinea popular music, and thus projects Kaluli ethnic identity.

The Solomon Islands. While the music of New Guinea and western Melanesia—particularly the Bismarck Archipelago—is predominantly vocal and monophonic, the music of the Solomon Islands is largely determined by use of highly developed panpipes. These instruments have three to nine closed tubes, usually doubled by open tubes that sound the higher octave. New instruments are tuned by comparison with old "masters," at the occasion of special ceremonies. Panpipes are used in orchestras alone and in conjunction with song. Vocal melodic style, which is characterized by triadic structure, wide melodic leaps, elaborate polyphony (several simultaneous voice parts), a specific timbre, or tone colour, and frequent change of register, is apparently an imitation of panpipe music. Types of polyphony include parallel melodic movement a third or a sixth apart, a practice most likely a result of overblowing the double panpipes, which may produce such parallels automatically.

The 'Are'are people of Malaita, in the Solomon Islands, distinguish four types of panpipe ensemble and more than 20 musical types. The music of panpipe ensembles enjoys the highest prestige among the 'Are'are. They have an extensive system of thought about music that centres on 'au, their word for bamboo, the material of which panpipes are made. Their system of musical concepts is so far not written, however; instead, it is passed on orally among specialists as a music theory that is in some respects homologous to European music theory.

The triadic melody style of the Solomon Islanders seems to have spread into adjacent western Polynesia, where similar melodic types are found in Tuvalu and Futuna.

Micronesia. From the Carolines in the west to Kiribati in the east, most traditional music is accompanied by dancing in standing or sitting posture. Group singing with rhythmic accompaniment by body and ground beats or concussion sticks is the prevailing type of musical performance. Purely instrumental music was performed on nose and mouth flutes in the Carolines and Marianas.

Except in the central Carolines (Truk), where musical influences from Melanesia and eastern Indonesia are prominent, elements of chanting and metred declamation are the most conspicuous characteristics of musical structure, underlining the importance of poetry versus intrinsically musical principles. Vocal polyphony takes the forms of drone (sustained note heard against a melody) and parallel movement in a variety of intervals, with fourths most common.

Micronesia is the least-known part of Oceania, as far as music and dance are concerned. On some of the atolls in Kiribati, consecrations of assembly halls, races of boat models, and meetings between local groups were or still are connected with performances of dances in which both women and men participated. Active participation and choreographic role are determined by individual proficiency as dancer and singer and by social rank. The *ruoia* is a sequence of standing dances in which movements are slow and mainly those of the arms and hands. In introductory and main dances, up to six leading dancers, male or female, pose as "gliding frigate birds" in front of the other dancers, who are lined up according to status in their patrilineal (kinship groups). All dancers participate in chanting long poems that are rehearsed beforehand. Endings of dance songs are frequently shouted, and texts of the final dance in a sequence are recited in heightened speech throughout. There are also sitting dances, with arm and hand movements similar to those of the standing

sian dance

dances, and stick dances. Dance gestures are not illustrative of the song texts, which are not generally understood by performers or audience.

The texts of traditional dance songs were "received" by composers from ancestor spirits (*anti*) in special rituals and probably in trance. Since the early 20th century, multipart singing of European church tunes has spread throughout the area. In consequence of a general culture change, social dances based on traditional movement patterns but accompanied by adaptations of Western music have become dominant.

Polynesia. Since the second half of the 18th century, all parts of Polynesia have undergone a drastic cultural change that affected music and dance traditions severely. At present, adaptations of Western musical forms are predominant throughout the area. Both European church singing introduced by various missions and secular styles, ranging from the whalers' chanteys to modern international entertainment music, have participated in this process. Yet, remnants or elements of precontact Polynesian music have survived almost everywhere, either alongside of or within acculturated styles—because of a marked traditionalism, as in Hawaii and New Zealand, or because of a delayed acculturation process, as in many of the smaller and remoter islands.

Common traits. The first useful descriptions of Polynesian music and dance come from Captain James Cook and his companions on his exploration voyages (1768–80). Such reports of early travelers agree with 20th-century research in suggesting that, despite regional variance, the concepts and structural characteristics of music and dance are highly similar throughout Polynesia. Music serves as a vehicle for Polynesian poetry, as dance is its illustration. The central role of the word explains why Polynesian music is primarily vocal. The only noteworthy traditional instruments used independently from song are the nose flute and the musical bow. Accompaniment of song includes body percussion (e.g., slaps, claps), drums, and various idiophones (instruments the bodies of which vibrate to produce sound, such as rattles and slit-drums).

The most obvious stylistic characteristics of songs, common to all parts of Polynesia, result from word orientation. Most traditional songs can be classified as chant, as recitation in heightened speech, or as a blending of both. In some areas—for example, Tuvalu—the same text may be performed in either style. Chanting uses a limited number of tone levels, mostly a third or a fourth apart, and numerous tone repetitions. Rhythmic organization varies from recitative bound to the accents of the words to strict repetition of rhythmic patterns. Vocal polyphony is widespread throughout Polynesia and undisputedly indigenous. It was described by 18th-century explorers when foreign influence could hardly have affected the style of music. The most common form of polyphony, reported from almost all Polynesian groups with the marked exception of the Maori (of New Zealand) and Hawaiians, is drone produced by a second part that follows the melody rhythmically while repeating one—usually the basic—tone. All authorities agree that pure drone is a precontact element of Polynesian music. Other forms of polyphony occur locally and are believed to be a result of European influence; especially notable among these is imitational counterpoint (simultaneous, interwoven melodies using melodic imitation among the voice parts).

Beyond these basic common traits, Polynesian peoples have developed musical forms and stylistic characteristics that are distinctive for individual groups of islands.

Hawaii. What is generally known as "Hawaiian music" is the result of the acculturation that began in the early 19th century and that was greatly enhanced by the introduction (c. 1820) of Christian hymn tunes. The ukulele, so closely connected with this almost entirely Western style of singing, is a local version of the Portuguese *bragha*, a small guitar imported to Hawaii about 1879. The Hawaiian, or steel, guitar is a metal-stringed adaptation of the European instrument that is played by stopping the strings with a metal bar.

Despite the predominance of Western—and, more recently, Asian—influences, some evolved forms of pre-

contact Hawaiian music and dance have been preserved. Their stylistic characteristics fall well within the limits of what has been described as common Polynesian elements.

The Society Islands. The inhabitants of the Society Islands, whose ritual and profane dances accompanied by polyphonic chanting, nose flute, and drum playing were admired by 18th-century explorers, experienced a particularly rapid and thorough Westernization of their music. Still, the modern Tahitian *himene*, contrapuntal compositions in as many as six voices, retain some indigenous elements of music structure derived from polyphonic chant. The term *himene* is derived from "hymn," but the style includes both traditional Christian hymn texts and traditional Polynesian texts. The *himene* represent a highly developed form of a hybrid Polynesian-European music style.

The Maori. The Maori of New Zealand have lost most of their instrumental music in the process of acculturation but have preserved many of their traditional chants and dances, which are classified according to function and contents of the text. Among the more prominent types are the lullabies (*oriori*), the laments (*tangi*), the incantations (*karakia*), the love songs (*waiata aroha*), the historical or genealogical recitations (*patere*), and the dance songs (*haka*). They are either recited in heightened speech or sung on narrow melodic lines undulating around a central tone, *oro*. Rhythm is largely word-bound. Any polyphony is considered a fault of performance. One important aesthetic concept requires a performance to be uninterrupted even by breaks for breathing. Consequently, chants are usually performed by two or more singers who take breaths at different moments. As in all of Polynesia, the younger generations favour adaptations of Western music.

Western archipelagoes. The musical traditions of western Polynesia are better known than those of any other part of Oceania. Descriptive monographs are available for Samoa, Tonga, Bellona Island (a Polynesian outlier in the Solomon Islands), Tokelau, Wallis and Futuna, and Tuvalu. There is a considerable degree of stylistic and terminological coherence that characterizes western Polynesia as a distinct musical province within Polynesia.

Before Western contact, music in Tuvalu was closely connected with social rank, religion, and magic. There are no detailed descriptions of dances; vocal styles included recitation in heightened speech and chant with drone polyphony (common to most of Polynesia) and triadic melodies resembling those of the Solomons. The Samoan emissaries of the London Missionary Society who converted the people of Tuvalu to Christianity (1861–76) destroyed the traditional social hierarchy and suppressed dances and songs either related to non-Christian beliefs or simply not fitting for their concepts of morality. They introduced pentatonic Christian songs characterized by two-part contrapuntal polyphony resulting from overlapping antiphony (contrasting groups of singers). This "pentatonic antiphony" is believed by some authorities to have developed in Samoa under European influence. By 1900, it seems to have become the predominant musical style in Tuvalu for both religious and secular topics. From 1914, church hymns and school songs in four-part European harmony began to replace "pentatonic antiphony" as the favourite style. By 1960, four-part harmony was the almost exclusive style of church, school, and dance tunes. International "Hawaiian" music is gradually penetrating the islands as mass media and Western musical instruments such as guitars and ukuleles become available. Remnants of the earlier traditions persist only with members of the older generations, although outside interest has stimulated a modest revival movement. (Di.C./A.Ka.)

Literature

THE ROLE OF THE AUTHOR

Creativity in many parts of the Pacific is perceived in terms of *mana*, a word of Pacific origin that is commonly used in Melanesian and Polynesian languages to express the power or force that is concentrated in objects or persons. This includes creative energy, which emanates from supernatural sources. Even though creativity has divine

The

himene

Emphasis
on words
in Polynesian
songs

Mana

origins, mana is never exclusively the possession of supernatural beings. It is available to chiefs because of their closeness to supernatural powers, and ordinary people can also increase their creativity by performing appropriate rituals or by studying and acquiring skills. Outstanding creative individuals have mana in greater abundance than ordinary individuals, but every individual has the potential for some form of creativity.

Each individual may express his creativity in different ways, however, and three broad categories of literary artists can be described. In Polynesia the traditional artist was the priest-poet, who served both as a priest or magician and as an entertainer. The priest-poets were in the employment of chiefs and had well-defined functions. They sometimes formed a distinct hereditary caste; in other cases they were drawn from chiefly clans and were occasionally even high chiefs themselves. The priest-poets became obsolete as the traditional chiefdoms gave way to Western colonization and nationhood, but in most parts of the Pacific there are still what has been called "free-lance," or "unattached," practitioners. These include wandering poets and minstrels who, unlike the priest-poets, do not go through any formal rigid training and do not claim to have special mana. They learn their trade by listening to other artists. Sometimes their function is socially recognized and they receive payment for their performances. As in most cultures, there are also amateur artists, including occasional versifiers, choral singers, and individuals such as grandmothers who tell stories and thus contribute to oral literature.

This classification of artists as professional, free-lance, or amateur emphasizes the significance of individual talent in both oral and written literature. Because the names of individual composers or poets do not feature prominently in oral literature, it has led to the popular belief that oral literature is communally created. There are, of course, instances of communal or group involvement in the creation of certain kinds of oral literature; at the centre of all creative activity, however, is a chief composer who bears ultimate responsibility for the creation. In *Return to the Islands* (1957), Sir Arthur Grimble vividly relates how oral poems were composed in Kiribati. He describes the first stirring of poetry as a "divine spark of inspiration," which gives the poet his mana. This mana, in turn, causes the poet to remove himself from society into his "house of song," wherein he will sit in travail with a poem that is yet unborn. After the poem is formed in the poet's mind, he calls together some of his close friends and recites the "rough draft" of his poem. Grimble observes,

It is the business of his friends to interrupt, criticise, interject suggestions, applaud, or howl down, according to their taste. Very often, they do howl him down, too, for they are themselves poets. On the other hand, if the poem, in their opinion, shows beauty, they are indefatigable in abetting its perfection. . . . When all their wit and wisdom has been poured out upon him, they depart. He remains alone again—probably for several days—to reflect upon their advice, accept, reject, accommodate, improve, as his genius dictates.

Although the author of a written work is easier to identify and recognize, the role of such writers in Oceania is more difficult to define. Written literature depends greatly on readership, and in much of Oceania the writer's language (usually English) and major genres (e.g., novel, short story) are nonindigenous to the region. Consequently, written literature from the Pacific is better known internationally than in Oceania itself. The level of literacy in English—especially in Papua New Guinea, where about 700 traditional languages are spoken—is not high. Interest in local literatures is generally confined to the emerging educated elite in the urban centres. For the majority of people throughout Oceania, traditional oral literatures, such as storytelling and dance and musical performances, still satisfy their aesthetic needs. (S.)

ORAL TRADITIONS

Understanding of the content of Oceanic oral literature is limited. Nevertheless, a few general comments about traditional forms, types, and themes can be made. First, because the purpose of literature is to communicate, it demands an audience. In the case of an oral literature, communication depends first on memory, and this usually

means that such memory aids as rhythm and stock formulas and phrases are an important element of all texts. The majority of Oceanic texts keep closely to traditional forms and appear to be committed to memory and then are communicated in a strictly unvarying manner. This is, however, only approximately the case, because the various techniques of formalization can allow for a rather fluid text. The tradition can be made evident at the lexical level, with the possibility of a great freedom of syntax. It only prevents prosodic elements from taking on primary importance.

The literary occasions of the Oceanian peoples are, as in other cultures, reflected in sacred literature, political literature, and frivolous—even erotic—texts. This division, however, should not be taken to represent an attempt at classification; any such pigeonholing would be inconvenient indeed, because such a large number of texts defy neatness and straddle two categories. But there are certainly two poles between which the various forms of literary expression can be placed. On the one hand, there is a body of works that appeals to Western readers and is made accessible to them by its use of the poetic image. On the other hand, there are many texts, often brief, in which each word is frequently a complete image. This kind of text is part and parcel of the culture that has produced it and requires a veritable arsenal of commentaries of others to interpret the key words and to unravel its significance to nonnative readers. Texts are, basically, of two kinds: (1) recitatives, whose form is rigid; they can be expanded but not transformed; in this category belong all the songs or chants that accompany dances (whether the performers be standing or seated), funeral chants, songs that accompany children's games, and those with an erotic significance; and (2) public orations, in which the elements are formally but roughly organized, giving the speaker the right to vary the presentation within certain limits established for this literary genre. Such discourses, which can aptly be delivered as a high-level political oration and as a funeral eulogy or remembrance speech, can also, in a more simple form, commemorate such events as a birth or a marriage.

Oceanic themes are those that appear in other literatures of the world: love and death, defiance and hatred, nostalgia for the past, and the pleasure of the moment. Nature provides the necessary images. There is, nevertheless, a barrier between Oceanic literature and that of other cultures. Although it presents a familiar mental universe, it does so in what is often an allusive manner that demands an intimate knowledge of local place-names, local political geography, and land division before its meaning can be understood: the owl, for example, is symbolic of a given place, the lizard of some other, and the sea eagle associated with a third.

Melanesia. Melanesian oral literatures are better known to contemporary scholarship than are Polynesian because over a longer period they remained untampered with by Western anthropologists and scholars and were, therefore, not distorted by them. Because of this, they are of great interest, although they are only just being recovered. Researchers have amassed a body of astonishingly rich oral literature and have been able to establish just what the function of each text was in the life of the society they studied. The results of their work have obliged scholars to reexamine their conceptions of the oral literary tradition. It now emerges that not even words, symbols, or places have any fixed significance: the vocabulary is at once coherent and diversified, for it is used in a way that takes into account the momentary interest of the parties present.

The traditional speech. A traditional speech may be "hurled" by a speaker to a crowd, which typically responds with a muffled cry at the end of each "sentence." It is the quality of accord reached between the crowd and the speaker that comprises the "new content" of the familiar, traditional speech (henceforth becoming part of its tradition), while the accord also conveys what other cultures would call the "message"—the new stage in a rising political career, perhaps, or a declaration denoting peace between combatants or the beginning of a war. Anyone analyzing the speech itself has to search for and consider carefully all the possible interpretations and temporal con-

Types of
oral texts

Audience
response

The status
of written
literature

ditions it might have. The traditional form of the speech is respected all the more because it allows this variation of content—within acceptable limits—to be conveyed by nuances that may easily escape observers from other cultures.

The form of the speech also presents a somewhat thorny problem. On the surface, it is a simple enumeration of the local groups and their symbols (that is, the portion of the land that is theirs, together with its animals, plants, weather conditions, and so on). The recitation of these physical realities is an affirmation of their very society, and they are stated one after the other, linked by some stock connecting phrase. Each listed item is given its precise geographic location; of special importance are the names of special places where authority is exercised or where rites are practiced. The whole constitutes a world vision, or system, in which the individual society and its members have their place. The native audience is perfectly familiar with the spatial affirmation of their society contained in the speech, and, from the dry enumeration of its components, they are able to supply for themselves a history of alliances and wars and to remodel the traditional text until it fits the conditions of the present. The orator's delivery, the nuances he maintains or introduces into the speech, are a sign of his success.

The myth. Another kind of oral literature, less easily defined, is the one commonly understood as myth (a term borrowed from Western classical culture). Involved here are all formalized recitatives, straightforwardly delivered, whose apparent aim is to give the account of a rite, for example, or to describe the situation of some group of family lineage (perhaps in connection with land ownership or political status) or to tell of the origin of man and his culture. The recitative may involve as little as 10 lines, or it may take three hours to narrate. In any given local culture, the rules that govern the way in which the texts' content is formalized and those that govern the way in which they are recited are consistent. The symbolic vocabulary, formally identical with that used in public speeches, carries elaborate but acknowledged references. A text may be established on the basis of a single symbol, but, in general, the symbolic pattern is so complex that other cultures have great difficulty in understanding it. Indeed, it is only possible to decipher its meaning if the cultural significance of every place mentioned in the text is understood, if it is known what creature or being is worshiped where and to the benefit of which group, and often only if the itineraries that are the subject of a majority of the myths are entirely familiar to the interpreter, so that old place-names—and thus their meaning—that are referred to in the text can be identified.

Polynesia and Micronesia. Polynesian and Micronesian oral literatures are similar in structure, but they vary in detail from island to island. Little is known about the Micronesian texts, however, and work on the interpretation of Polynesian oral literature has been hindered. Authentic oral texts were not collected when the opportunity was at hand, and it is now often too late to do so because the traditions—especially of religion—that maintained them have not survived. The few studies of Polynesian and Micronesian oral literatures that have been published have generally analyzed simplistic summaries rather than authentic texts. Nevertheless, they give a glimpse of how widespread certain legendary cycles were. The most frequently recurring legend, from a geographic point of view, is that of the trickster figure Maui-tiki-tiki, who was a fisherman of the islands and who discovered fire. He can be recognized, on the fringes of the Polynesian area, as the god of the first fruits of the yam harvest. He was sometimes revered under a symbolic manifestation or sometimes as a less abstract figure.

The few scraps of knowledge available about the indigenous literatures of Australia and Micronesia, as well as those of Polynesia, indicate that the figures of their great mythological cycles were simultaneously general symbols and local divinities. The people saw no contradiction in this double manifestation: great cultural heroes were naturally assigned to a specific place when an individual within that culture would establish a reverential dialogue with any one of them.

(J.Gt./Ed.)

MODERN LITERATURE

Development of written literature. Although literacy is a precondition for the development of written literature, the relationship between literacy and literary growth is not simple. In many areas of Oceania, literacy in the vernacular languages existed for more than 100 years before significant literature in the local languages appeared. The slow emergence of written literature can be explained by such factors as the strength of traditional oral literatures, the lack of serious oppression (which might have stimulated nationalistic or protest writings), limited resources, a condition of dependency, and the indifference of missionaries and the ruling elites toward indigenous literatures.

The growth of written literature did not begin in earnest until after the establishment of the University of Papua New Guinea (1965) and the University of the South Pacific (1968). The most significant works have been written in English and have come from the regions served by the two universities (Papua New Guinea and the Cook Islands, Fiji, Kiribati, Nauru, Niue, the Solomon Islands, Tonga, Tuvalu, Vanuatu, and Western Samoa). This can be attributed to the combination of forces that converged in these regions in the 1960s and '70s: the agitation of political independence, the growth of regional consciousness, the establishment of universities, a growing awareness of other Third World writing, the use of Pacific-oriented curricula in schools, an increased confidence in the English language and its use as a language of creative expression, the widespread growth of English-language newspapers, the emergence of small commercial printers, an overall improvement of material condition throughout the area, the emergence of educated elites, and greater democratization and Westernization of social and political institutions.

Although some of these factors were also present in parts of Micronesia, they provided little or no impetus to literary development. By the late 20th century, Micronesia still could not claim to have a written literature of its own. In French Polynesia and New Caledonia, some indigenous writing in French has developed, but with remarkably different variables: the main orientation is not toward the other Pacific states but toward France. Easter Island, separated from other Pacific island states by distance, has remained relatively isolated from recent cultural developments in the Pacific. In this Spanish-speaking Polynesian island, the beginning of indigenous writing is focused on biographies and histories.

The first creative efforts of many indigenous writers were published in *Unispac*, the University of the South Pacific student newspaper. In 1973 several of the writers featured in the newspaper formed the South Pacific Creative Arts Society, which then established the literary magazine *Mana*. At about the same time, Ulli Beier, who had already played a significant role in the development of Nigerian literature, established *Kovave*, a journal of New Guinea writing, and *Gigibori*, a journal focusing on New Guinea cultures. Since then the number of literary journals in Oceania has proliferated and includes *Bikmaus* (formerly *Papua New Guinea Writing*) and *Ondobondo* in Papua New Guinea and *Moana*, *Faikava*, and *Sinnet* elsewhere in the South Pacific. Although the most significant writing has been in English, there are signs of a renewed interest in writing in local languages. The Samoan journal *Moana* is devoted to writing in the Samoan language, the bilingual *Faikava* includes writing in Tongan and English, and *Sinnet* has attempted to publish writings in English, Hindi, and Fijian. In Papua New Guinea and to a lesser extent in the Solomon Islands, some writers have experimented with Melanesian Pidgin, but no writing of distinction has appeared in that language.

Early writings. The earliest written works by Pacific Islanders were mission-inspired autobiographical writings in the vernacular languages. No fictional or imaginative writing emerged during this early period. The first published work with some literary merit was Florence Frisbie's autobiography, *Miss Ulysses from Puka-Puka* (1948), originally written in English, Rarotongan, and Pukapukan.

The first published novel from Oceania was *Makutu* (1960) by Thomas Davis, a Cook Islander, and Lydia Henderson, his New Zealand-born wife. Like their earlier

Literary
journals

The
trickster
figure in
legend

autobiography, *Doctor to the Islands* (1954), it was written in English. The novel, which deals with the cultural conflict between Pacific and Western values in an imaginary land called Fenua Lei, has more in common with the "South Seas" literature of Stevenson, Maugham, and other European writers than with modern Oceanic writing. Although *Makutu* has few of the stereotypes of South Seas literature, it is nonetheless written with the European reader in mind.

Later writings. In the 1970s, reacting against the distortions in the European vision of the Pacific, writers such as Albert Wendt of Western Samoa argued for a literature written by Pacific Islanders. In Wendt's novella *Flying Fox in a Freedom Tree* (1974), the protagonist-narrator explains that he has "decided to become the second Robert Louis Stevenson, a tusitala or teller of tales, but with a big difference. I want to write a novel about me." Similarly, Epeli Hau'ofa of Tonga in his poem "Blood in the Kava Bowl" maintained that it is only the insider who has real access to a culture's deeper consciousness. These writers were echoing what was said in Africa, the West Indies, and other former colonial countries about literature: a culture must be written about from the inside, and the literature should be for the benefit of the local people.

Political unrest in the late 1980s, particularly in Fiji, Vanuatu, and Papua New Guinea, profoundly altered Pacific writers' perceptions about power and authority. Hau'ofa, the playwrights Vilisoni Herenkiko and Larry Thomas, the short-story writer Subramani, and others were no longer willing to accept the view that life in Oceania is ordered and culturally cohesive. Their works, which explore the subjects of individual and ethnic identity and the tensions and fragmentation of multicultural society, have ushered in a new phase in Oceanic literature.

The influence of oral traditions. The role of oral traditions in modern Oceanic literature is extremely significant and has been recognized by both writers and critics. In the early phase, the task of collecting and translating oral texts was an integral part of overall literary development and often inspired the creation of an original work. In addition, a variety of oral texts has been incorporated by Oceanic writers in short fiction, ranging from a Fijian cautionary tale in "The Taboo" (1980) by Akanisi Sobusobu and the legend about the Fijian shark-god Dakuwaqa in "A Childhood Experience" (1972) by Sitiveni Kalouniviti to anecdotes, jokes, risqué tales, and tall tales in Epeli Hau'ofa's *Tales of the Tikongs* (1983). Oral forms have also been used in written works for specific thematic purposes. For example, Vincent Eri in his first novel, *The Crocodile* (1970), tried to give a sense of the spiritual world of the precontact society of Papua New Guinea, and he used traditional myths, legends, and tales of magic to express the life of a village where the sacred and secular coexist.

Perhaps the author who has been the most successful at integrating oral and written literatures has been Albert Wendt. Wendt began writing in the 1960s when there was no commonly recognized Oceanic literary style or store of techniques. Consequently, he invented for himself a mode of expression rich in Oceanic imagery, mythology, and colloquialism; and he invested and enriched the borrowed forms of the novel and the short story with a variety of narrative styles derived from traditional oral texts. He adopted the techniques of the raconteur and conversationalist, who freely mingle jokes, gossip, legends, and proverbs in their discourse, and fused them with the novelistic techniques of interior monologue and deployment of symbolism. Wendt's particular achievement has been his ability to absorb the history, myths, and other oral traditions of his country and to synthesize them with contemporary realities and the idiosyncracies of written fiction, imposing upon it all a vision that is his own. (S.)

BIBLIOGRAPHY. General characteristics of Oceanic civilizations, with analyses of culture and religion as the root of the arts, are explored in PETER BELLWOOD, *Man's Conquest of the Pacific: The Prehistory of Southeast Asia and Oceania* (1978); and DOUGLAS L. OLIVER, *Oceania: The Native Cultures of Australia and the Pacific Islands*, 2 vol. (1989).

Visual arts: Well-illustrated studies of the region as a whole include JEAN GUIART, *The Arts of the South Pacific*, trans. from French (1963); ALFRED BUEHLER, TERENCE BARROW, and CHARLES P. MOUNTFORD, *The Art of the South Sea Islands: Including Australia and New Zealand*, rev. ed. (1968); CARL A. SCHMITZ, *Oceanic Art: Myth, Man, and Image in the South Seas*, trans. from German (1969); SIDNEY M. MEAD (ed.), *Exploring the Visual Art of Oceania: Australia, Melanesia, Micronesia, and Polynesia* (1979); GEORGE A. CORBIN, *Native Arts of North America, Africa, and the South Pacific* (1988), a general introduction to aboriginal art; and PETER GATHERCOLE, ADRIENNE L. KAEPLER, and DOUGLAS NEWTON, *The Art of the Pacific Islands* (1979).

The Aboriginal art of Australia is examined in DACRE STUBBS, *Prehistoric Art of Australia* (1974); ROBERT HUGHES, *The Art of Australia*, rev. ed. (1970); and RONALD M. BERNDT and E.S. PHILLIPS (eds.), *The Australian Aboriginal Heritage: An Introduction Through the Arts*, 2nd ed. (1978). For a survey of Melanesian art, see WALDEMAR STÖHR, *Kunst und Kultur aus der Südsee: Sammlung Clausmeyer Melanesien* (1987); and DOUGLAS NEWTON, *New Guinea Art in the Collection of the Museum of Primitive Art* (1967). On Polynesia as a whole, see EDWARD DODD, *A Pictorial Peregrination Through the Shapely and Harmonious, Often Enigmatical, Sometimes Shocking Realms of Polynesian Art* (1967; also published as *Polynesian Art*, 1969); ALLEN WARDWELL, *The Sculpture of Polynesia* (1967); and TERENCE BARROW, *Art and Life in Polynesia* (1972). Smaller areas are discussed in J. HALLEY COX and WILLIAM H. DAVENPORT, *Hawaiian Sculpture*, rev. ed. (1988); TERENCE BARROW, *The Art of Tahiti and the Neighbouring Society, Austral, and Cook Islands* (1979); and SIDNEY M. MEAD (ed.), *Te Maori: Maori Art from New Zealand Collections* (1984). On Micronesia, see JEROME FELDMAN and DONALD H. RUBINSTEIN, *The Art of Micronesia* (1986), a brief catalog with informative essays and a bibliography. (D.Ne.)

Music and dance: A general introduction is found in WILLIAM P. MALM, *Music Cultures of the Pacific, the Near East, and Asia*, 2nd ed. (1977). HANS FISCHER, *Sound-Producing Instruments in Oceania: Construction and Playing Technique, Distribution and Function*, rev. ed. (1986; originally published in German, 1958), provides a comprehensive study of the subject. For Melanesian music, see HUGO ZEMP, "Areäre Classification of Musical Types and Instruments" and "Aspects of Areäre Musical Theory," two original studies of music, musical instruments, and concepts in a Solomon Islands culture, both in *Ethnomusicology*, 22:37-67 (January 1978) and 23:5-48 (January 1979), respectively; JAAP KUNST, *Music in New Guinea*, trans. from Dutch (1967), covering western New Guinea; and STEVEN FELD, *Sound and Sentiment: Birds, Weeping, Poetics, and Song in Kaluli Expression* (1982), a penetrating study of the symbolic and emotional dimensions of music in a small-scale culture of Papua New Guinea. For Polynesia, see ADRIENNE L. KAEPLER, *Polynesian Dance: With a Selection for Contemporary Performances* (1983), a description of dances and songs from several island areas; JOHANNES C. ANDERSEN, *Maori Music, with Its Polynesian Background* (1934, reprinted 1978), covering Polynesia in general with an emphasis on New Zealand; E.G. BURROWS, *Native Music of the Tuamotus* (1933, reprinted 1971), a study of Tuamotu chant in its cultural context, and *Songs of Uvea and Futuna* (1945, reprinted 1971), examining two small western Polynesian islands; JANE MINK ROSSEN, *Songs of Bellona Island*, 2 vol. (1987), a description of musical categories and styles of a Polynesian population in the Solomon Islands; E.S. CRAIGHILL HANDY and JANE LATHROP WINNE, *Music in the Marquesas Islands* (1925, reprinted 1971); HELEN H. ROBERTS, *Ancient Hawaiian Music* (1926, reprinted 1971); and JANE FREEMAN MOULIN, *The Dance of Tahiti* (1979), a detailed analysis. Micronesian dance is described in a short study, MARY BROWNING, *Micronesian Heritage* (1970). (Di.C./A.Ka.)

Literature: A general survey of literature is provided in NORMAN SIMMS, *Silence and Invisibility: A Study of the Literature of the Pacific, Australia, and New Zealand* (1986). Emerging literatures are further analyzed in H.H. ANNIAH GOWDA (ed.), *Essays in S. Pacific Literature* (1977); SUBRAMANI, *South Pacific Literature: From Myth to Fabulation* (1985); and SUBRAMANI (ed.), *The Indo-Fijian Experience* (1979), an anthology with the editor's descriptive introduction. Other useful anthologies with commentary include JOHANNES C. ANDERSEN, *Myth & Legends of the Polynesians* (1928, reprinted 1986); ALBERT WENDT (ed.), *Lali: A Pacific Anthology* (1980); ULLI BEIER (ed.), *Black Writing from New Guinea* (1973), and *Voices of Independence: New Black Writing from Papua New Guinea* (1980); BERNARD GADD (ed.), *Pacific Voices: An Anthology of Writing by and About Pacific People* (1977); and *Mana* (semiannual). Oceans

When viewed from space, the predominance of the oceans on the Earth is readily apparent. The oceans and their marginal seas cover nearly 71 percent of the Earth's surface, with an average depth of 3,795 metres (12,450 feet). The exposed land occupies the remaining 29 percent of the planetary surface and has a mean elevation of only 840 metres (2,756 feet). Actually, all the elevated land could be hidden under the oceans and the Earth reduced to a smooth sphere that would be completely covered by a continuous layer of seawater 2,686 metres deep. This is known as the sphere depth of the oceans and serves to underscore the abundance of water on the Earth's surface.

The Earth is unique in the solar system because of its distance from the Sun and its period of rotation. These combine to subject the Earth to a solar radiation level that maintains the planet at a mean surface temperature of 16° C (61° F), which varies little over annual and night-day cycles. This mean temperature allows water to exist on the Earth in all three of its phases—solid, liquid, and gaseous. No other planet in the solar system has this feature. The liquid phase predominates on the Earth. By volume, 97.957 percent of the water on the planet exists as oceanic water and associated sea ice. The gaseous phase and droplet water in the atmosphere constitute 0.001 percent. Fresh water in lakes and streams makes up 0.036 percent, while groundwater is 10 times more abundant at 0.365 percent. Glaciers and ice caps constitute 1.641 percent of the Earth's total water volume.

Each of the above is considered to be a reservoir of water. Water continuously circulates between these reservoirs in what is called the hydrologic cycle, which is driven by energy from the Sun. Evaporation, precipitation, movement of the atmosphere, and the downhill flow of river water, glaciers, and groundwater keep water in motion

between the reservoirs and maintain the hydrologic cycle.

The large range of volumes in these reservoirs and the rates at which water cycles between them combine to create important conditions on the Earth. If small changes occur in the rate at which water is cycled into or out of a reservoir, the volume of a reservoir changes. These volume changes may be relatively large and rapid in a small reservoir or small and slow in a large reservoir. A small percentage change in the volume of the oceans may produce a large proportional change in the land-ice reservoir, thereby promoting glacial and interglacial stages. The rate at which water enters or leaves a reservoir divided into the reservoir volume determines the residence time of water in the reservoir. The residence time of water in a reservoir, in turn, governs many of the properties of that reservoir.

This article focuses on the oceanic reservoir of the world. It discusses in general terms the properties of this body of water and the processes that occur within it and at its boundaries with the atmosphere and the crust of the Earth. The article also delineates the major features of the ocean basins, along with those of the continental margins and shorelines. Considered, too, are the economic aspects of the oceans, including some of the environmental problems linked with the utilization of marine resources.

For specifics concerning the relationship of the oceans to the other reservoirs of the Earth's waters, see *HYDROSPHERE, THE*. See also *BIOSPHERE, THE*, for coverage of the life-forms that populate the marine environment. Information about the nature, scope, and methods of oceanography and marine geology are provided in *EARTH SCIENCES, THE*.

For coverage of other related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 212, 221, 222, 223, 231, 232, 241, and 10/33, and the *Index*.

General considerations

RELATIVE DISTRIBUTION OF THE OCEANS

Those conducting oceanic research generally recognize the existence of three major oceans, the Pacific, Atlantic, and Indian. (The Arctic Ocean is considered an extension of the Atlantic.) Arbitrary boundaries separate these three bodies of water in the Southern Hemisphere. One boundary extends southward to Antarctica from the Cape of Good Hope, while another stretches southward from Cape Horn. The last one passes through Malaysia and Indonesia to Australia, and then on to Antarctica. Many subdivisions can be made to distinguish the limits of seas and gulfs that have historical, political, and sometimes ecological significance (see Figure 1). However, water properties, ocean currents, and biological populations do not necessarily recognize these boundaries. Indeed, many researchers do not either. The oceanic area surrounding the Antarctic is considered by some to be the Southern Ocean.

If area-volume analyses of the oceans are to be made, then boundaries must be established to separate individual regions. In 1921 Erwin Kossina, a German geographer, published tables giving the distribution of oceanic water with depth for the oceans and adjacent seas. This work was updated in 1966 by H.W. Menard and S.M. Smith. The latter only slightly changed the numbers derived by Kossina. This was remarkable, since the original effort relied entirely on the sparse depth measurements accumulated by individual wire soundings, while the more recent work had the benefit of acoustic depth soundings collected since the 1920s. This type of analysis, called hypsometry, allows quantification of the surface area distribution of the oceans and their marginal seas with depth.

The distribution of oceanic surface area with 5° increments of latitude shows that the distribution of land and water on the Earth's surface is markedly different in the Northern and Southern hemispheres (Figure 2). The Southern Hemisphere may be called the water hemisphere, while the Northern Hemisphere is the land hemisphere. This is especially true in the temperate latitudes.

This asymmetry of land and water distribution between the Northern and Southern hemispheres makes the two hemispheres behave very differently in response to the annual variation in solar radiation received by the Earth. The Southern Hemisphere shows only a small change in surface temperature from summer to winter at temperate latitudes. This variation is controlled primarily by the ocean's response to seasonal changes in heating and cooling. The Northern Hemisphere has one change in surface temperature controlled by its oceanic area and another controlled by its land area. In the temperate latitudes of the Northern Hemisphere, the land is much warmer than the oceanic area in summer and much colder in winter. This situation creates large-scale seasonal changes in at-

mospheric circulation and climate in the Northern Hemisphere that are not found in the Southern Hemisphere.

MAJOR SUBDIVISIONS OF THE OCEANS

The surface areas and volumes of water contained in the oceans and major marginal seas are shown in Table 1. If the volume of an ocean is divided by its surface area, the mean depth is obtained. The data in this table indicate that with or without marginal seas, the Pacific is the largest ocean in both surface area and volume, the Atlantic is next, and the Indian is the smallest.

The Atlantic exhibits the largest change in surface area and volume when its marginal seas are subtracted. This indicates that the Atlantic has the greatest area of bordering seas, many of which are shallow.

Table 1 does not indicate how the oceanic water is distributed with depth except at the sea surface. Hypsometry can show how the area of each ocean or marginal sea changes as depth changes. A special curve known as a hypsometric, or hypsographic, curve can be drawn that portrays how the surface area of the Earth is distributed with elevation and depth (see Figure 3). This curve has been drawn for the total Earth and all its oceans. Individual oceans and seas are not portrayed, although similar curves can be constructed for each ocean and subdivision. The average depth of the world's oceans, 3,795 metres, and the average elevation of the land, 840 metres, are indicated. The highest point on land, Mount Everest (8,848 metres), and the deepest point in the ocean, located in the Mariana Trench (11,034 metres), mark the upper and lower limits of the curve, respectively. Since this curve is drawn on a grid of elevation versus the Earth's area, the area under the curve covering the 29.2 percent of the Earth's surface that is above sea level is the volume of land above sea level. Similarly, the area between sea level and the curve depicting the remaining 70.8 percent of the Earth's surface below sea level represents the volume of water contained in the oceans.

Portions of this curve describe the area of the Earth's surface that exists between elevation or depth increments. On land, little of the Earth's total area—only about 4 percent—is at elevations above 2,000 metres. Most of the land, 25.3 percent of the total Earth, is between 0 and 2,000 metres. About 13.6 percent of the total land area is at higher elevations, with 86.4 percent between 0 and 2,000 metres when the areas are determined relative to land area only. In the oceans, the percentages of the area devoted to depth increments yield information about the typical structure and shape of the oceanic basins. The small depth increment of 0–200 metres occupies about 5.4 percent of the Earth's total area or 7.6 percent of the oceans' area. This approximates the world's area of continental shelves, the shallow flat borderlands of the continents that have been alternately covered by the oceans during interglacial

stages and uncovered during glacial periods (see below the section *Continental margins: Continental shelf*).

At depths between 200 and 1,000 metres and between 1,000 and 2,000 metres an area only slightly larger, 6.02 percent of the Earth's total area or 8.5 percent of the oceans' area, is found. These depths are related to the regions of the oceans that have very steep slopes where depth increases rapidly. These are the continental slope regions that mark the true edge of the continental land-masses. Marginal seas of moderate depths and the tops of seamounts, however, add their area to these depth zones when all the oceans are considered. The majority of the oceanic area lies between 4,000 and 5,000 metres.

The continental shelf region varies immensely from place to place. The seaward boundary of the continental shelf historically is determined by the 100-fathom, or 200-metre, depth contour. However, 85 fathoms, or 170 metres, is a closer approximation. The true boundary at any given location is marked by a rapid change in slope of the seafloor known as the shelf break. This change in slope may be nearly at the coastline in areas where crustal plates converge, as along the west coast of North and South America, or it may be located more than 1,000 kilometres seaward of the coast, as off the north coast of Siberia. The average width of the shelf is about 75 kilometres, and the shelf has an average slope of about 0.01°, a slope that is barely discernible to the human eye. Seaward of the shelf break, the continental slope is inclined by about 4°.

ORIGIN OF THE OCEAN WATERS

The huge volume of water contained in the oceans (and seas), 137×10^7 cubic kilometres, has been produced during the geologic history of the Earth. There is little information on the early history of the Earth's waters. However, fossils dated from the Precambrian some 3.3 billion years ago show that bacteria and cyanobacteria (blue-green algae) existed, indicating the presence of water during this period. Carbonate sedimentary rocks, obviously laid down in an aquatic environment, have been dated to 1 billion years ago. Also, there is fossil evidence of primitive marine algae and invertebrates from the outset of the Cambrian period some 570 million years ago.

The presence of water on the Earth at even earlier times is not documented by physical evidence. It has been suggested, however, that the early hydrosphere formed in response to condensation from the early atmosphere. The ratios of certain elements on the Earth indicate that the planet formed by the accumulation of cosmic dust and was slowly warmed by radioactive and compressional heating. This heating led to the gradual separation and migration of materials to form the Earth's core, mantle, and crust. The early atmosphere is thought to have been highly reducing and rich in gases, notably in hydrogen, and to include water vapour.

The Earth's surface temperature and the partial pressures of the individual gases in the early atmosphere affected the atmosphere's equilibration with the terrestrial surface.

Figure 2: Distribution of land and ocean waters by latitude. The surface areas of the landmasses and the oceans are almost equal in the mid-latitudes of the Northern Hemisphere. By contrast, land is nearly absent in the same latitudes of the Southern Hemisphere.

Photo-chemical production of oxygen

As time progressed and the planetary interior continued to warm, the composition of the gases escaping from within the Earth gradually changed the properties of its atmosphere, producing a gaseous mixture rich in carbon dioxide (CO_2), carbon monoxide (CO), and molecular nitrogen (N_2). Photodissociation (*i.e.*, separation due to the energy of light) of water vapour into molecular hydrogen (H_2) and molecular oxygen (O_2) in the upper atmosphere allowed the hydrogen to escape and led to a progressive increase of the partial pressure of oxygen at the Earth's surface. The reaction of this oxygen with the materials of the surface gradually caused the vapour pressure of water vapour to increase to a level at which liquid water could form. This water in liquid form accumulated in isolated depressions of the Earth's surface, forming the nascent oceans. The high carbon dioxide content of the atmosphere at this time would have allowed a buildup of dissolved carbon dioxide in the water and made these early oceans acidic and capable of dissolving surface rocks that would add

to the water's salt content. Water must have evaporated and condensed rapidly and accumulated slowly at first. The required buildup of atmospheric oxygen was slow because much of this gas was used to oxidize methane, ammonia, and exposed rocks high in iron. Gradually, the partial pressure of the oxygen gas in the atmosphere rose as photosynthesis by bacteria and photodissociation continued to supply oxygen. Biological processes involving algae increased, and they gradually decreased the carbon dioxide content and increased the oxygen content of the atmosphere until the oxygen produced by biological processes outweighed that produced by photodissociation. This, in turn, accelerated the formation of surface water and the development of the oceans. (For further details on the formation and development of the oceans, see below *Chemical and physical properties of seawater: Chemical evolution of the oceans.*) (A.C.D.)

Chemical and physical properties of seawater

COMPOSITION OF SEAWATER

The chemical composition of seawater is influenced by a wide variety of chemical transport mechanisms. Rivers add dissolved and particulate chemicals to the oceanic margins. Wind-borne particulates are carried to mid-ocean regions thousands of kilometres from their continental source areas. Hydrothermal solutions that have circulated through crustal materials beneath the seafloor add both dissolved and particulate materials to the deep ocean. Organisms in the upper ocean convert dissolved materials to solids, which eventually settle to greater oceanic depths. Particulates in transit to the seafloor, as well as materials both on and within the seafloor, undergo chemical exchange with surrounding solutions. Through these local and regional chemical input and removal mechanisms, each element in the oceans tends to exhibit spatial and temporal concentration variations. Physical mixing in the oceans (thermohaline and wind-driven circulation; see below *Circulation of the ocean waters*) tends to homogenize the chemical composition of seawater. The opposing influences of physical mixing and of biogeochemical input and removal mechanisms result in a substantial variety of chemical distributions in the oceans.

Dissolved inorganic substances. In contrast to the behaviour of most oceanic substances, the concentrations of the principal inorganic constituents of the oceans (Table 2) are remarkably constant. For 98 percent of the oceans' volume, the concentrations of the constituents shown in the Table vary by less than 3 percent from the values given in columns 2 and 3. Furthermore, with the exception of inorganic carbon, the principal constituents shown in the Table have very nearly fixed ion concentration ratios (column 4). Calculations indicate that, for the main constituents of seawater, the time required for thorough oceanic mixing is quite short compared to the time that

would be required for input or removal processes to significantly change a constituent's concentration. The concentrations of the principal constituents of the oceans vary primarily in response to a comparatively rapid exchange of water (precipitation and evaporation), with relative concentrations remaining nearly constant.

Salinity is used by oceanographers as a measure of the total salt content of seawater. Practical salinity, symbol S , is determined through measurements of a ratio between the electrical conductivity of seawater and the electrical conductivity of a standard solution. Practical salinity can be used to calculate precisely the density of seawater samples. Because of the constant relative proportions of the principal constituents, salinity can also be used to directly calculate the concentrations of the major ions in seawater. Using the relative concentrations shown in column 4 of Table 2, ionic concentrations are calculated as 0.015577 mole per kilogram multiplied by salinity multiplied by relative concentration. The measure of practical salinity was originally developed to provide an approximate measure of the total mass of salt in one kilogram of seawater. Seawater with S equal to 35 contains ap-

proximately 35 grams of salt and 965 grams of water.

Although the 11 constituents shown in Table 2 account for more than 99.5 percent of the dissolved solids in seawater, many other constituents are of great importance to the biogeochemistry of the oceans. Such chemicals as inorganic phosphorus (HPO_4^{2-} and PO_4^{3-}) and inorganic nitrogen (NO_3^- , NO_2^- , and NH_4^+) are essential to the growth of marine organisms. Nitrogen and phosphorus are incorporated into the tissues of marine organisms in approximately a 16:1 ratio and are eventually returned to solution in approximately the same proportion. As a consequence, in much of the oceanic waters dissolved inorganic phosphorus and nitrogen exhibit a close covariance. Figure 4 shows dissolved inorganic phosphorus distributions in the Pacific Ocean. The observed distributions strongly bear the imprint of phosphorus incorporation by organisms in the surface waters of the ocean and of the return of the phosphorus to solution via a rain of biological debris remineralized in the deep ocean. Inorganic phosphate concentrations in the western Pacific (Figure 4) range from somewhat less than 0.1 micromole per kilogram (1×10^{-7} mole per kilogram) at the surface to approximately 3 micromoles/kg (3×10^{-6} mole/kg) at depth. Inorganic nitrogen ranges between somewhat less than 1 micromole/kg and 45 micromoles/kg along the same section of ocean and exhibits a striking covariance with phosphate.

A variety of elements essential to the growth of marine organisms, as well as some elements that have no known biological function, exhibit nutrient-like behaviour broadly similar to nitrate and phosphate. Silicate is incorporated into the hard structural parts of certain types of marine organisms (diatoms and radiolarians) that are abundant in the upper ocean. Dissolved silicate concentrations range between less than 1 micromole/kg (1×10^{-6} mole/kg) in surface waters to approximately 180 micromoles/kg (1.8×10^{-4} mole/kg) in the deep North Pacific. The concentration of zinc, a metal essential to a variety of biological functions, ranges between approximately 0.05 nanomole/kg (5×10^{-11} mole/kg) in the surface ocean to as much as 6 nanomoles/kg (6×10^{-9} mole/kg) in the deep Pacific. The distribution of zinc in the oceans is observed to generally parallel silicate distributions. Cadmium, though having no known biological function, generally exhibits distributions that are covariant with phosphate and concentrations that are even lower than those of zinc.

Many elements, including the essential trace metals iron, cobalt, and copper, show surface depletions but in general exhibit behaviour more complex than that of phosphate, nitrate, and silicate. Some of the complexities observed in elemental oceanic distributions are attributable to the adsorption of elements on the surface of sinking particles. Adsorptive processes, either exclusive of or in addition to biological uptake, serve to remove elements from the upper ocean and deliver them to greater depths. The distribution patterns of a number of trace elements are complicated by their participation in oxidation-reduction (electron-exchange) reactions. In general, electron-exchange reactions lead to profound changes in the solubility and reactivity of trace metals in seawater. Such reactions are important to the oceanic behaviour of a variety of elements, including iron, manganese, copper, cobalt, chromium, and cerium.

The processes that deliver dissolved, particulate, and gaseous materials to the oceans ensure that they contain, at some concentration, very nearly every element that is found in the Earth's crust and atmosphere. The principal components of the atmosphere, nitrogen (78.1 percent), oxygen (21.0 percent), argon (0.93 percent), and carbon dioxide (0.035 percent), occur in seawater in variable proportions, depending on their solubilities and oceanic chemical reactions. In equilibrium with the atmosphere, the concentrations of the unreactive gases, nitrogen and argon, in seawater (0°C , salinity 35) are 616 micromoles/kg and 17 micromoles/kg, respectively. For seawater at 35°C , these concentrations would decrease by approximately a factor of two. The solubility behaviours of argon and oxygen are quite similar. For seawater in equilibrium with the atmosphere, the ratio of oxygen and argon concentrations is approximately 20.45. Since oxygen is a reactive gas

*Concentrations at salinity equal to 34.7. †Ionic concentrations are conventionally expressed in molecular units. One mole per kilogram is equivalent to 6.023×10^{23} ions or molecules per kilogram of seawater. The relative concentrations in column 4 provide the number of ions of each constituent in one kilogram of seawater as compared to the number of chloride ions in one kilogram of seawater.

essential to life, oxygen concentrations in seawater that are not in direct equilibrium with the atmosphere are quite variable. Although oxygen is produced by photosynthetic organisms at shallow, sunlit ocean depths, oxygen concentrations in near-surface waters are established primarily by exchange with the atmosphere. Oxygen concentrations in the oceans generally exhibit minimum values at intermediate depths and relatively high values in deep waters. This distribution pattern results from a combination of biological oxygen utilization and physical mixing of the ocean waters. Estimates of the extent of oxygen utilization in the oceans can be obtained by comparing concentrations of oxygen with those of argon, since the latter are only influenced by physical processes. The physical processes that influence oxygen distributions include, in particular, the large-scale replenishment of oceanic bottom waters with cold, dense, oxygen-rich waters sinking toward the bottom from high latitudes. Due to the release of nutrients that accompanies the consumption of oxygen by biological debris, dissolved oxygen concentrations generally appear as a mirror image of dissolved nutrient concentrations, such as those shown in Figure 4.

While the atmosphere is a vast repository of oxygen compared to the oceans, the total carbon dioxide content of the oceans is very large compared to that of the atmosphere. Carbon dioxide reacts with water in seawater to form carbonic acid (H_2CO_3), bicarbonate ions (HCO_3^-), and carbonate ions (CO_3^{2-}). Approximately 90 percent of the total organic carbon in seawater is present as bicarbonate ions. The formation of bicarbonate and carbonate ions from carbon dioxide is accompanied by the liberation of hydrogen ions (H^+). Reactions between hydrogen ions and the various forms of inorganic carbon buffer the acidity of seawater. The relatively high concentrations of both total inorganic carbon and boron—as $\text{B}(\text{OH})_3$ and $\text{B}(\text{OH})_4^-$ —in seawater (see Table 2) are sufficient to maintain the pH of seawater between 7.4 and 8.3. (The term pH is defined as the negative logarithm of the hydrogen ion concentration in moles per kilogram. Thus, a pH equal to 8 is equivalent to 1×10^{-8} mole of H^+ ions per kilogram of seawater.) This is quite important because the extent and rate of many reactions in seawater are highly pH-dependent. Carbon dioxide produced by the combination of oxygen and organic carbon generally produces an acidity maximum (pH minimum) near the depth of the oxygen minimum in seawater. In addition to exchange with the atmosphere and, through respiration, with the biosphere, dissolved inorganic carbon concentrations in seawater are influenced by the formation and dissolution of the calcareous shells

(CaCO_3) of organisms (foraminiferans, coccolithophores, and pteropods) abundant in the upper ocean.

Dissolved organic substances. Processes involving dissolved and particulate organic carbon are of central importance in shaping the chemical character of seawater. Marine organic carbon principally originates in the uppermost 100 metres of the oceans where dissolved inorganic carbon is photosynthetically converted to organic materials. The "rain" of organic-rich particulate materials, resulting directly and indirectly from photosynthetic production, is a principal factor behind the distributions of many organic and inorganic substances in the oceans. A large fraction of the vertical flux of materials in the uppermost waters is converted to dissolved substances within the upper 400 metres of the oceans. Dissolved organic carbon (DOC) accounts for at least 90 percent of the total organic carbon in the oceans. Estimates of DOC appropriate to the surface of the open ocean range between roughly 100 and 500 micromoles of carbon per kilogram of seawater. DOC concentrations in the deep ocean are 5 to 10 times lower than surface values. DOC occurs in an extraordinary variety of forms, and, in general, its composition is controversial and poorly understood. Conventional techniques have indicated that, in surface waters, about 15 percent of DOC can be identified as carbohydrates and combined amino acids. At least 1–2 percent of DOC in surface waters occurs as lipids and 20–25 percent as relatively unreactive humic substances. The relative abundances of reactive organic substances, such as amino acids and carbohydrates, are considerably reduced in deep ocean waters. Dissolved and particulate organic carbon in the surface ocean participates in diel cycles (*i.e.*, those of a 24-hour period) related to photosynthetic production and photochemical transformations. The influence of dissolved organic matter on ocean chemistry is often out of proportion to its oceanic abundance. Photochemical reactions involving DOC can influence the chemistry of vital trace nutrients such as iron, and, even at dissolved concentrations on the order of one nanomole/kg (1×10^{-9} mole/kg), dissolved organic substances in the upper ocean waters are capable of greatly altering the bioavailability of essential trace nutrients, as, for example, copper and zinc.

Effects of human activities. Although the oceans constitute an enormous reservoir, human activities have begun to influence their composition on both a local and a global scale. The addition of nutrients (through the discharge of untreated sewage or the seepage of soluble mineral fertilizers, for example) to coastal waters results in increased phytoplankton growth, high levels of dissolved

Problems of marine pollution

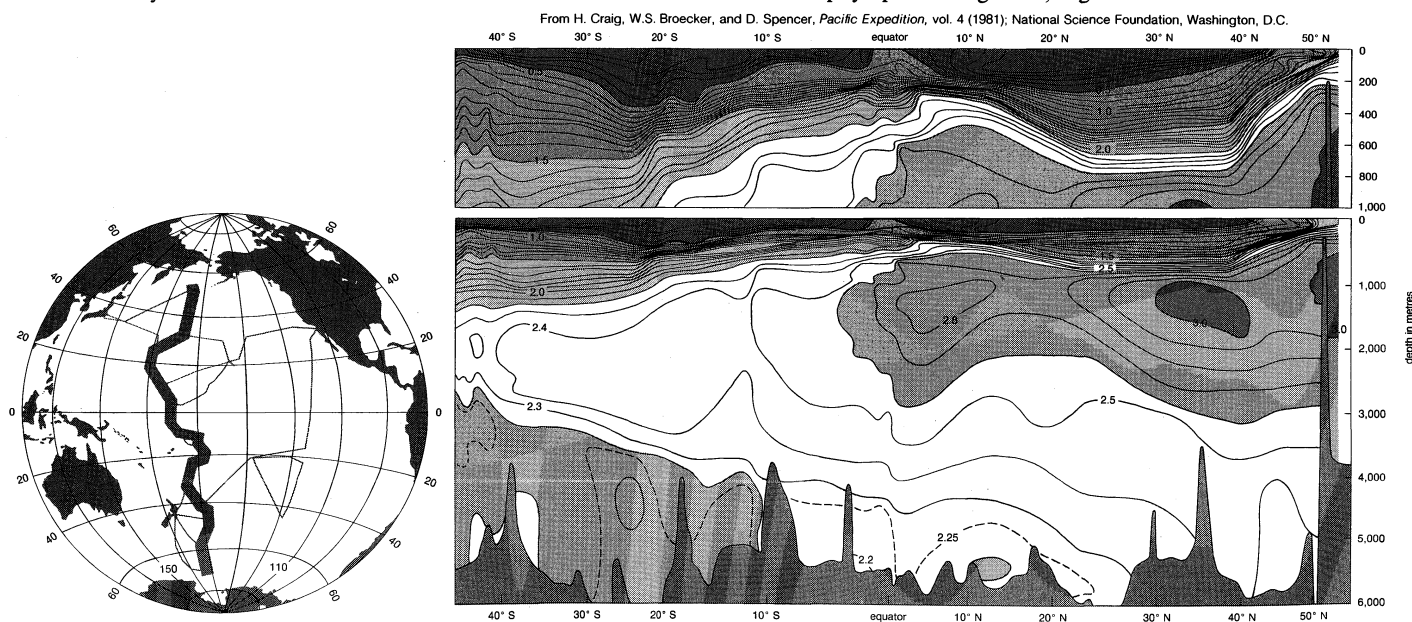

Figure 4: Vertical distribution of dissolved inorganic phosphate concentrations (in micromoles per kilogram) in the western Pacific Ocean. The vertical exaggeration is 2500:1 in the top section and 1000:1 in the bottom section. The segment of the ocean surveyed is shown in the inset at the lower left (see text).

and particulate organic materials, decreased penetration of light through seawater, and alteration of the community structure of bottom-dwelling organisms. Through industrial and automotive emissions, lead concentrations in the surface ocean have increased dramatically on a global scale compared with preindustrial levels. Certain toxic organic compounds, such as polychlorinated biphenyls (PCBs), are found in seawater and marine organisms and are attributable solely to the activities of humankind. Although most radioactivity in seawater is natural (approximately 90 percent as potassium-40 and less than 1 percent each as rubidium-87 and uranium-238), strontium-90 and certain other artificial radioisotopes have unique environmental pathways and potential for bioaccumulation. Among the most dramatic influences of human activities on a global scale is the remarkable increase of carbon dioxide levels in the atmosphere. Atmospheric carbon dioxide levels are expected to double by the middle of the 21st century, with potentially profound consequences for global climate and agricultural patterns. It is thought that the oceans, as a great reservoir of carbon dioxide, will ameliorate this consequence of human activities to some degree. (For more specific information on this subject, see *HYDROSPHERE, THE: Impact of human activities on the hydrosphere: Buildup of greenhouse gases.*) (R.H.By.)

CHEMICAL EVOLUTION OF THE OCEANS

The chemical history of the oceans has been divided into three stages. The first is an early stage in which the Earth's crust was cooling and reacting with volatile or highly reactive gases of an acidic, reducing nature to produce the oceans and an initial sedimentary rock mass. This stage lasted until about 3.5 billion years ago. The second stage was a period of transition from the initial to essentially modern conditions, and it is estimated to have ended 2 to 1.5 billion years ago. Since that time it is likely that there has been little change in seawater composition.

The early oceans. The initial accretion of the Earth by agglomeration of solid particles occurred about 4.6 billion years ago. Heating of this initially cool, unsorted conglomerate by the decay of radioactive elements and the conversion of kinetic and potential energy to heat resulted in the development of a liquid iron core and the gross internal zonation of the Earth (see *EARTH: The structure and composition of the solid Earth*). It has been concluded that formation of the Earth's core took about 500 million years. It is likely that core formation resulted in the escape of an original primitive atmosphere and its replacement by one derived from loss of volatile substances from the Earth's interior. Whether most of this degassing took place during core formation or soon afterward or whether there has been significant degassing of the Earth's interior throughout geologic time is uncertain. Recent models of Earth formation, however, suggest early differentiation of the Earth into three major zones (core, mantle, and crust) and attendant early loss of volatile substances from the interior. It is also likely that the Earth, after initial cold agglomeration, reached temperatures such that the whole Earth approached the molten state. As the initial crust of the Earth solidified, volatile gases would be released to form an atmosphere that would contain water, later to become the hydrosphere; carbon gases, such as carbon dioxide, methane, and carbon monoxide; sulfur gases, mostly hydrogen sulfide; and halogen compounds, such as hydrochloric acid. Nitrogen also may have been present, along with minor amounts of other gases. Gases of low atomic number, such as hydrogen and helium, would escape the Earth's gravitational field. Substances degassed from the planetary interior have been called excess volatiles because their masses cannot be accounted for simply by rock weathering. An estimate of the masses of the various volatiles degassed throughout geologic time is given in Table 3.

At an initial crustal temperature of about 600° C, almost all these compounds, including water (H₂O), would be in the atmosphere. The sequence of events that occurred as the crust cooled is difficult to construct. Below 100° C all the H₂O would have condensed, and the acid gases would have reacted with the original igneous crustal minerals to

Table 3: Estimate of "Excess Volatiles"

form sediments and an initial ocean. There are at least two possible pathways by which these initial steps could have been accomplished.

One pathway assumes that the 600° C atmosphere contains, together with other compounds, water (as vapour), carbon dioxide, and hydrochloric acid in the ratio of 20:3:1 and would cool to the critical temperature of water. The water vapour therefore would have condensed into an early hot ocean. At this stage, the hydrochloric acid would be dissolved in the ocean (about 1 mole per litre), but most of the carbon dioxide would still be in the atmosphere with about 0.5 mole per litre in the ocean water. This early acid ocean would react vigorously with crustal minerals, dissolving out silica and cations and creating a residue that consisted principally of aluminous clay minerals that would form the sediments of the early ocean basins. This pathway of reaction assumes that reaction rates are slow relative to cooling. A second pathway of reaction, which assumes that cooling is slow, is also possible. In this case, at a temperature of about 400° C most of the water vapour would be removed from the atmosphere by hydration reactions with pyroxenes and olivines. Under these conditions, water vapour would not condense until some unknown temperature was reached, and the Earth might have had at an early stage in its history an atmosphere rich in carbon dioxide and no ocean: the surface would have been much like that of present-day Venus.

The pathways described are two of several possibilities for the early surface environment of the Earth. In either case, after the Earth's surface had cooled to 100° C, it would have taken only a short time geologically for the acid gases to be used up in reactions involving igneous rock minerals. The presence of bacteria and possibly algae in the fossil record of rocks older than 3 billion years attests to the fact that the Earth's surface had cooled to temperatures lower than 100° C by this time and that the neutralization of the original acid gases had taken place. If most of the degassing of primary volatile substances from the Earth's interior occurred early, the chloride released by reaction of hydrochloric acid with rock minerals would be found in the oceans and seas or in evaporite deposits, and the oceans would have a salinity and volume comparable to those that they have today.

This conclusion is based on the assumption that there has been no drastic change in the ratios of volatiles released through geologic time. The overall generalized reaction indicative of the chemistry leading to formation of the early oceans can be written in the form: primary igneous rock minerals + acid volatiles + H₂O → sedimentary rocks + oceans + atmosphere. Notice from this equation that if all the acid volatiles and H₂O were released early in the history of the Earth and in the proportions found today, then the total original sedimentary rock mass produced would be equal to that of the present time, and ocean salinity and volume would be near what they are now. If, on the other hand, degassing were linear with time, then the sedimentary rock mass would have accumulated at a linear rate, as would oceanic volume. However, the salinity of the oceans would remain nearly the same if the ratios of volatiles degassed did not change with time. The most likely situation is that presented here—namely, that major degassing occurred early in Earth history, after which minor amounts of volatiles were released episodically or continuously for the remainder of geologic time. The salt content of the oceans based on the

Early
salinity
and
volume

constant proportions of volatiles released would depend primarily on the ratio of sodium chloride (NaCl) locked up in evaporites to that dissolved in the oceans. If all the sodium chloride in evaporites were added to the oceans today, the salinity would be roughly doubled. This value gives a sense of the maximum salinity the oceans could have attained throughout geologic time.

Production
of oxygen

One component missing from the early terrestrial surface was free oxygen because it would not have been a constituent released from the cooling crust. As noted earlier, early production of oxygen was by photodissociation of water in the atmosphere as a result of absorption of ultraviolet light. The reaction is $2\text{H}_2\text{O} + h\nu \rightarrow \text{O}_2 + 2\text{H}_2$, in which $h\nu$ represents a photon of ultraviolet light. The hydrogen produced would escape into space, and the O_2 would react with the early reduced gases by reactions such as $2\text{H}_2\text{S} + 3\text{O}_2 \rightarrow 2\text{SO}_2 + 2\text{H}_2\text{O}$. Oxygen production by photodissociation gave the early reduced atmosphere a start toward present-day conditions, but it was not until the appearance of photosynthetic organisms approximately 3.3 billion years ago that it was possible for the accumulation of oxygen in the atmosphere to proceed at a rate sufficient to lead to today's oxygenated environment. The photosynthetic reaction leading to oxygen production may be written $6\text{CO}_2 + 6\text{H}_2\text{O} + h\nu \rightarrow \text{C}_6\text{H}_{12}\text{O}_6 + 6\text{O}_2$, in which $\text{C}_6\text{H}_{12}\text{O}_6$ represents sugar.

The transition stage. The nature of the rock record from the time of the first sedimentary rocks (about 3.5 billion years ago) to approximately 2 to 1.5 billion years ago suggests that the amount of oxygen in the atmosphere was significantly lower than today and that there were continuous chemical trends in the sedimentary rocks formed and, more subtly, in oceanic composition. The source rocks of sediments during this time were likely to be more basaltic than would later ones; sedimentary detritus was formed by the alteration of these rocks in an oxygen-deficient atmosphere and accumulated primarily under anaerobic marine conditions. The chief difference between reactions involving mineral-ocean equilibria at this time and at the present time was the role played by ferrous iron. The concentration of dissolved iron in the present-day oceans is low because of the insolubility of oxidized iron oxides. During the period 3.5 to 1.5 billion years ago, oxygen-deficient environments were prevalent; these favoured the formation of minerals containing ferrous iron (reduced state of iron) from the alteration of basaltic rocks. Indeed, the iron carbonate siderite and the iron silicate greenalite, in close association with chert and the iron sulfide pyrite, are characteristic minerals that occur in middle Precambrian iron formations (those about 1.5 to 2.4 billion years old). The chert originally was deposited as amorphous silica; equilibrium between amorphous silica, siderite, and greenalite at 25°C and one atmosphere total pressure requires a carbon dioxide pressure of about $10^{-2.5}$ atmosphere, or 10 times the present-day value.

The oceans at this time can be thought of as the solution resulting from an acid leach of basaltic rocks, and because the neutralization of the volatile acid gases was not restricted primarily to land areas as it is presently, much of this alteration may have occurred by submarine processes. The atmosphere at the time was oxygen-deficient; anaerobic depositional environments with internal carbon dioxide pressures of about $10^{-2.5}$ atmosphere were prevalent, and the atmosphere itself may have had a carbon dioxide pressure near $10^{-2.5}$ atmosphere. If so, the pH of early ocean water was lower than that of modern seawater, the calcium concentration was higher, and the early ocean water was probably saturated with respect to amorphous silica (about 120 parts per million [ppm]).

The pH of
early ocean
water

To simulate what might have occurred, it is helpful to imagine emptying the Pacific basin, throwing in great masses of broken basaltic material, filling it with hydrochloric acid so that the acid becomes neutralized, and then carbonating the solution by bubbling carbon dioxide through it. Oxygen would not be permitted into the system. The hydrochloric acid would leach the rocks, resulting in the release and precipitation of silica and the production of a chloride ocean containing sodium, potassium, calcium, magnesium, aluminum, iron, and re-

duced sulfur species in the proportions present in the rocks. As complete neutralization was approached, aluminum could begin to precipitate as hydroxides and then combine with precipitated silica to form cation-deficient aluminosilicates. The aluminosilicates, as the end of the neutralization process was reached, would combine with more silica and with cations to form minerals like chlorite, and ferrous iron would combine with silica and sulfur to make greenalite and pyrite. In the final solution, chlorine would be balanced by sodium and calcium in roughly equal proportions, with subordinate potassium and magnesium; aluminum would be quantitatively removed, and silicon would be at saturation with amorphous silica. If this solution were then carbonated, calcium would be removed as calcium carbonate, and the chlorine balance would be maintained by abstraction of more sodium from the primary rock. The sediments produced in this system would contain chiefly silica, ferrous iron silicates, chloritic minerals, calcium carbonate, calcium magnesium carbonates, and minor pyrite.

If the hydrochloric acid added were in excess of the carbon dioxide, the resultant ocean would have a high content of calcium chloride, but the pH would still be near neutrality. If the carbon dioxide added were in excess of the chlorine, calcium would be precipitated as the carbonate until it reached a level approximately that of the present oceans—namely, a few hundred parts per million.

If this newly created ocean were left undisturbed for a few hundred million years, its waters would evaporate and be transported onto the continents (in the form of precipitation); streams would transport their loads into it. The sediment created in this ocean would be uplifted and incorporated into the continents. Gradually, the influence of the continental debris would be felt, and the pH might shift slightly. Iron would be oxidized out of the ferrous silicates to produce iron oxides, but the water composition would not vary a great deal.

The primary minerals of igneous rocks are all mildly basic compounds. When they react in excess with acids such as hydrochloric acid and carbon dioxide, they produce neutral or mildly alkaline solutions plus a set of altered aluminosilicate and carbonate reaction products. It is highly unlikely that ocean water has changed through time from a solution approximately in equilibrium with these reaction products, which are clay minerals and carbonates.

The modern oceans. The oceans probably achieved their modern characteristics 2 to 1.5 billion years ago. The chemical and mineralogical compositions and the relative proportions of sedimentary rocks of this age differ little from their Paleozoic counterparts (those dating from about 570 to 245 million years ago). The fact that the acid sulfur gases had been neutralized to sulfate by this time is borne out by calcium sulfate deposits of late Precambrian age (roughly 570 million to 1.6 billion years old). Chemically precipitated ferric oxides in late Precambrian sedimentary rocks indicate available free oxygen, whatever its percentage. The chemistry and mineralogy of middle and late Precambrian shales is similar to that of Paleozoic shales. Thus, it appears that continuous cycling of sediments like those of the present time has occurred for 1.5 to 2 billion years and that these sediments have controlled oceanic composition.

It was once thought that the saltiness of the modern oceans simply represents the storage of salts derived from rock weathering and transported to the oceans by fluvial processes. With increasing knowledge of the age of the Earth, however, it was realized that, at the present-day rate of delivery of salts to the oceans or even at much reduced rates, the total salt content and the mass of individual salts in the oceans could be attained in geologically short-time intervals compared to the Earth's age. The total mass of salt in the oceans can be accounted for at present-day rates of stream delivery in about 12 million years. The mass of dissolved silica in ocean water can be doubled in only 20,000 years by addition of stream-derived silica; to double sodium would take 70 million years. It then became apparent that the oceans were not simply an accumulator of salts, but as water evaporated from the oceans, along with some salt, the introduced salts must

Salt
content of
the oceans

be removed in the form of minerals. Thus, the concept of the oceans as a chemical system changed from that of a simple accumulator to that of a steady-state system in which rates of inflow of materials into the oceans equal rates of outflow. The steady-state concept permits influx to vary with time, but it would be matched by nearly simultaneous and equal variation of efflux. Calculations of rates of addition of elements to the oceanic system and removal from it show that for at least 100 million years the oceanic system has been in a steady state with approximately fixed rates of major element inflow and outflow and, thus, fixed chemical composition. (F.T.M./R.H.By.)

PHYSICAL PROPERTIES OF SEAWATER

Water is a unique substance. Not only is water the most abundant substance at the Earth's surface, but it also has the most naturally occurring physical states of any Earth material or substance (solid, liquid, and gas) and the greatest capacity to do things without being altered significantly. It is essential for sustaining life on Earth and affects the physical environment in a myriad of ways, as evidenced by the sculpting of landscape features by moving water, the maintaining of the Earth's radiation balance by atmospheric water vapour transfer, and the transporting of inorganic and organic materials about the planet's surface by the oceans. The addition of salt to water changes the behaviour of water only slightly.

Salinity distribution. A discussion of salinity, the salt content of the oceans, requires an understanding of two important concepts: (1) the present-day oceans are considered to be in steady state, receiving as much salt as they lose (see above), and (2) the oceans have been mixed over such a long time period that the composition of sea salt is everywhere the same in the open ocean. This uniformity of salt content results in oceans in which the salinity varies little over space or time.

The range of salinity observed in the open ocean is from 33 to 37 grams of salt per kilogram of seawater or parts per thousand (‰). For the most part, the observed departure from a mean value of approximately 35‰ is caused by processes at the Earth's surface that locally add or remove fresh water. Regions of high evaporation have elevated surface salinities, while regions of high precipitation have depressed surface salinities. In nearshore regions close to large freshwater sources, the salinity may be lowered by dilution. This is especially true in areas where the region of the ocean receiving the fresh water is isolated from the open ocean by the geography of the land.

Areas of the Baltic Sea may have salinity values depressed to 10‰ or less. Increased salinity by evaporation is accentuated where isolation of the water occurs. This effect is found in the Red Sea, where the surface salinity rises to 41‰. Coastal lagoon salinities in areas of high evaporation may be much higher. The removal of fresh water by evaporation or the addition of fresh water by precipitation does not affect the constancy of composition of the sea salt in the open sea. A river draining a particular soil type, however, may bring to the oceans only certain salts that will locally alter the salt composition. In areas of high evaporation where the salinity is driven to very high values, precipitation of particular salts may alter the composition too. At high latitudes where sea ice forms seasonally, the salinity of the seawater is elevated during ice formation and reduced when the ice melts.

At depth in the oceans, salinity may be altered as seawater percolates into fissures associated with deep-ocean ridges and crustal rifts involving volcanism. This water then returns to the ocean as superheated water carrying dissolved salts from the magmatic material within the crust. It may lose much of its dissolved load to precipitates on the seafloor and gradually blend in with the surrounding seawater, sharing its remaining dissolved substances.

Salt concentrations as high as 256‰ have been found in hot but dense pools of brine trapped in depressions at the bottom of the Red Sea. The composition of the salts in these pools is not the same as the sea salt of the open oceans.

The salinities of the open oceans found at the greater depths are quite uniform in both time and space with

average values of 34.5 to 35‰. These salinities are determined by surface processes such as those described above when the water, now at depth, was last in contact with the surface.

The average distribution of the surface salinity of the open oceans is depicted in Figure 5. This figure shows the response of the salinity of the ocean surface to the latitudinal variation in exchange of water between the oceans and the atmosphere. It also shows the impact of major ocean currents that displace surface water from one latitudinal zone to another. The northward displacement of subtropical water of higher salinity by the Gulf Stream and the North Atlantic Current is evident.

The intertropical convergence, with its high precipitation centred about 5° N, supports the tropical rain forests of the world and leaves its imprint on the oceans as a latitudinal depression of surface salinity. At approximately 30°–35° N and 30°–35° S, the subtropical zones called the horse latitudes are belts of high evaporation that produce major deserts and grasslands on the continents and cause the surface salinity to rise. At 50°–60° N and 50°–60° S, precipitation again increases. The general trend of mid-ocean salinity with latitude follows the trend of observed evaporation and precipitation shown in Figure 6.

Temperature distribution. Mid-ocean surface temperatures vary with latitude in response to the balance between incoming solar radiation and outgoing long-wave radiation. There is an excess of incoming solar radiation at latitudes less than approximately 45° and an excess of radiation loss at latitudes higher than approximately 45°. Superimposed on this radiation balance are seasonal changes in the intensity of solar radiation and the duration of daylight hours due to the tilt of the Earth's axis to the plane of the ecliptic and the rotation of the planet about this axis. The combined effect of these variables is that average ocean surface temperatures are higher at low latitudes than at high latitudes. Because the Sun, with respect to the Earth, migrates annually between the tropic of Cancer and the tropic of Capricorn, the yearly change in heating of the Earth's surface is small at low latitudes and large at mid- and higher latitudes.

Water has an extremely high heat capacity, and heat is mixed downward during summer surface-heating conditions and upward during winter surface cooling. This heat transfer reduces the actual change in ocean surface temperatures over the annual cycle. In the tropics the ocean surface is warm year-round, varying seasonally about 1° to 2° C. At mid-latitudes the mid-ocean temperatures vary about 8° C over the year. At the polar latitudes the surface temperature remains near the ice point of seawater—about –1.9° C.

Land temperatures have a large annual range at high latitudes because of the low heat capacity of the land surface. Figure 7 shows the average zonal temperature of the open oceans and land, as well as annual temperature ranges. Proximity to land, isolation of water from the open ocean, and processes that control stability of the surface water combine to increase the annual range of nearshore ocean surface temperature.

In winter, prevailing winds carry cold air masses off the continents in temperate and subarctic latitudes, cooling the adjacent surface seawater below that of the mid-ocean level. In summer, the opposite effect occurs, as warm continental air masses move out over the adjacent sea. This creates a greater annual range in sea surface temperatures at mid-latitudes on the western sides of the oceans of the Northern Hemisphere but has only a small effect in the Southern Hemisphere as there is little land present. Instead, the oceans of the Southern Hemisphere act to control the air temperature, which in turn influences the land temperatures of the temperate zone and reduces the annual temperature range over the land.

Currents carry water having the characteristics of one latitudinal zone to another zone. The northward displacement of warm water to higher latitudes by the Gulf Stream of the North Atlantic and the Kuroshio (Japan Current) of the North Pacific creates sharp changes in temperature along the current boundaries or thermal fronts, where these northward-moving flows meet colder water flowing

water away from the lee coasts of the landmasses to produce areas of coastal upwelling of water from depth and reduce surface temperatures.

Temperatures in the oceans decrease with increasing depth. There are no seasonal changes at the greater depths. The temperature range extends from 30° C at the sea surface to -1° C at the seabed. Like salinity, the temperature at depth is determined by the conditions that the water encountered when it was last at the surface. In the low latitudes the temperature change from top to bottom in the oceans is large. In high temperate and Arctic regions, the formation of dense water at the surface that sinks to depth produces nearly isothermal conditions with depth.

Areas of the oceans that experience an annual change in surface heating have a shallow wind-mixed layer of elevated temperature in the summer. Below this nearly isothermal layer 10 to 20 metres thick, the temperature decreases rapidly with depth, forming a shallow seasonal thermocline (*i.e.*, layer of sharp vertical temperature change). During winter cooling and increased wind mixing at the ocean surface, convective overturning and mixing erase this shallow thermocline and deepen the isothermal layer. The seasonal thermocline re-forms when summer returns. At greater depths, a weaker nonseasonal thermocline is found separating water from temperate and subpolar sources.

Below this permanent thermocline, temperatures decrease slowly. In the very deep ocean basins, the temperature may be observed to increase slightly with depth. This occurs when the deepest parts of the oceans are filled by water with a single temperature from a common source. This water experiences an adiabatic temperature rise as it sinks. Such a temperature rise does not make the water column unstable because the increased temperature is caused by compression, which increases the density of the water. For example, surface seawater of 2° C sinking to a depth of 10,000 metres increases its temperature by about 1.3° C. When measuring deep-sea temperatures, the

adiabatic temperature rise, which is a function of salinity, initial temperature, and pressure change, is calculated and subtracted from the observed temperature to obtain the potential temperature. Potential temperatures are used to identify a common type of water and to trace this water back to its source.

Thermal properties. The unit of heat called the gram calorie is defined as the amount of heat required to raise the temperature of one gram of water 1° C. The kilocalorie, or food calorie, is the amount of heat required to raise one kilogram of water 1° C. Heat capacity is the amount of heat required to raise one gram of material 1° C under constant pressure. In the International System of Units (SI), the heat capacity of water is one kilocalorie per kilogram per degree Celsius. Water has the highest heat capacity of all common Earth materials; therefore, water on the Earth acts as a thermal buffer, resisting temperature change as it gains or loses heat energy.

The heat capacity of any material can be divided by the heat capacity of water to give a ratio known as the specific heat of the material. Specific heat is numerically equal to heat capacity but has no units. In other words, it is a ratio without units. When salt is present, the heat capacity of water decreases slightly. Seawater of 35‰ has a specific heat of 0.932 compared to 1.000 for pure water.

Specific heat of seawater

Pure water freezes at 0° C and boils at 100° C under normal pressure conditions. When salt is added, the freezing point is lowered and the boiling point is raised. The addition of salt also lowers the temperature of maximum density below that of pure water (4° C). The temperature of maximum density decreases faster than the freezing point as salt is added.

At 30‰ salinity, the temperature of maximum density is lower than the initial freezing point of saltwater. Therefore, a maximum density is never achieved, as seawater of this salinity is cooled because freezing occurs first. At 24.70‰ salinity, the freezing point and the temperature of maximum density coincide at -1.332° C. At salinities typical of the open oceans, which are greater than 24.7‰, the freezing point is always higher than the temperature of maximum density.

When water changes its state, hydrogen bonds between molecules are either formed or broken. Energy is required to break the hydrogen bonds, which allows water to pass from a solid to a liquid state or from a liquid to a gaseous state. When hydrogen bonds are formed, permitting water to change from a liquid to a solid or from a gas to a liquid, energy is liberated. The heat energy input required to change water from a solid at 0° C to a liquid at 0° C is the latent heat of fusion and is 80 calories per gram of ice.

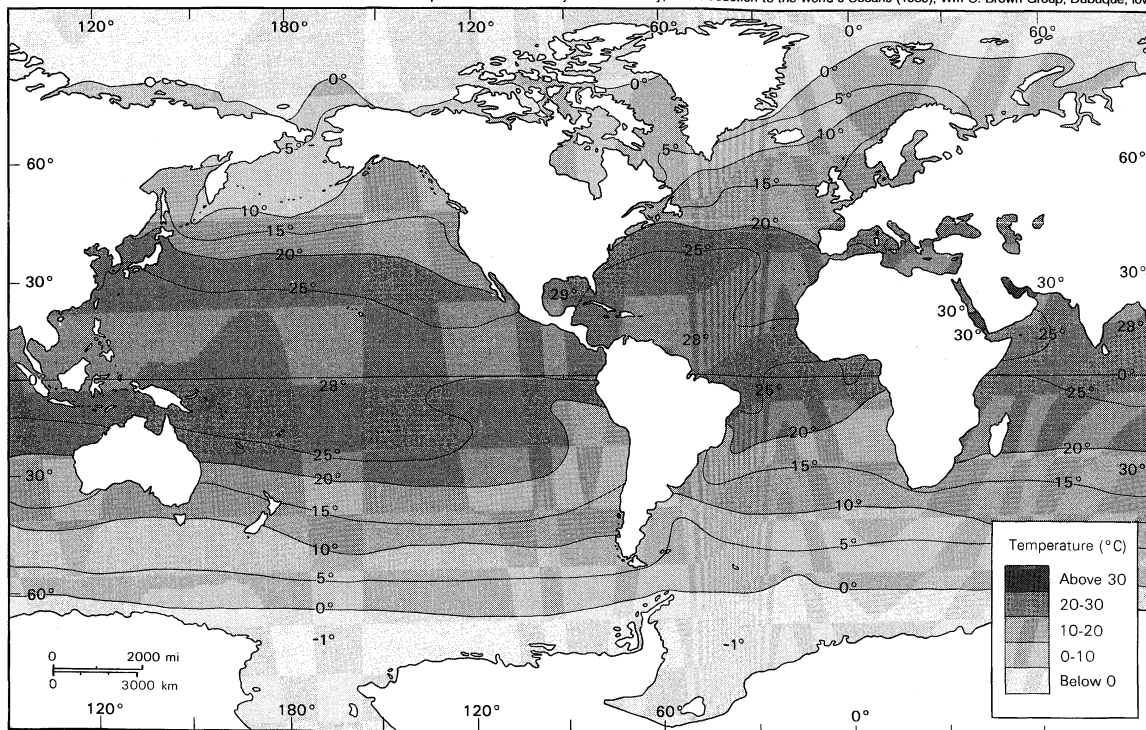

Figure 8: Ocean surface temperatures (in Celsius) during summer in the Northern Hemisphere. The isotherms (lines of equal temperature) in general parallel the equator except in a few areas where ocean currents cause marked displacements.

Table 4: Effect of Salinity on Temperature of Maximum Density

Salinity ‰	0	10	20	30	35
Freezing point	0.00	−0.53	−1.08	−1.63	−1.91
Temperature of maximum density	4.0	1.92	−0.20	−2.40	−3.42

Water's latent heat of fusion is the highest of all common materials. Because of this, heat is released when ice forms and is absorbed during melting, which tends to buffer air temperatures as land and sea ice form and melt seasonally.

When water converts from a liquid to a gas, a quantity of heat energy known as the latent heat of vaporization is required to break the hydrogen bonds. At 100° C, 540 calories per gram of water are needed to convert one gram of liquid water to one gram of water vapour under normal pressure. Water can evaporate at temperatures below the boiling point, and ice can evaporate into a gas without first melting in a process called sublimation. Evaporation below 100° C and sublimation require more energy per gram than 540 calories. At 20° C about 585 calories are required to vaporize one gram of water. When water vapour condenses back to liquid water, the latent heat of vaporization is liberated. The evaporation of water from the surface of the Earth and its condensation in the atmosphere constitute the single most important way that heat from the Earth's surface is transferred to the atmosphere. This process is the source of the power that drives hurricanes and a principal mechanism for cooling the surface of the oceans. The latent heat of vaporization of water is the highest of all common substances.

Density of seawater and pressure. The density of a material is given in units of mass per unit volume and expressed in kilograms per cubic metre in the SI system of units. In oceanography the density of seawater has been expressed historically in grams per cubic centimetre. The density of seawater is a function of temperature, salinity, and pressure. Because oceanographers require density measurements to be accurate to the fifth decimal place, manipulation of the data requires writing many numbers to record each measurement. Also, the pressure effect can be neglected in many instances by using potential temperature. These two factors led oceanographers to adopt a density unit called sigma-*t* (σ_t). This value is obtained by subtracting 1.0 from the density and multiplying the remainder by 1,000. The σ_t has no units and is an abbreviated density of seawater controlled by salinity and temperature only.

The σ_t of seawater increases with increasing salinity and decreasing temperature. Table 5 demonstrates how density expressed as σ_t changes with both salinity and temperature under conditions of normal atmospheric pressure. Seawater of 35‰ and 5° C in the Table has a density of 1.02770 grams per cubic centimetre (g/cm³).

The relationship between pressure and density is demonstrated by observing the effect of pressure on the density of seawater at 35‰ and 0° C (Table 6). Because a one-metre column of seawater produces a pressure of about one decibar (0.1 atmosphere), the pressure in decibars is approximately equal to the depth in metres. (One decibar is one-tenth of a bar, which in turn is equal to 10⁵ newtons per square metre.)

Increasing density values demonstrate the compressibility of seawater under the tremendous pressures present in the deep ocean. If seawater were incompressible, each cubic centimetre of water in the water column would expand, and density values at all depths would be equal in Table

Table 5: Sigma-*t* (σ_t) Values of Seawater

Salinity ‰	5	10	20	30	35
Temperature (°C)					
0	3.97	8.01	16.07	24.10	28.13
5	4.01	7.97	15.86	23.74	27.70
10	3.67	7.56	15.32	23.08	26.97
15	3.01	6.85	14.50	22.15	25.99

25	0.87	4.62	12.10	19.60	23.36
30	−0.57	3.15	10.57	18.01	21.75

6. If the average pressure over 4,000 metres (the approximate mean depth of the ocean) is calculated, it is found to be approximated by that at 2,000 metres. The average volume change due to pressure for each gram of water in the entire water column is (1/1.02813–1/1.03747) cm³/g, or 0.00876 cm³/g. Because the number of grams of water in a column of seawater 4 × 10⁵ centimetres in length is equal to the number of centimetres times the average density of the water, 1.03747 g/cm³, the expansion of the entire water column is about 4 × 10⁵ cm × 0.00876 cm³/g × 1.03747 g/cm³, or an average sea level rise of about 36 metres if the area of the oceans is considered constant.

Table 6: Density Changes with Depth (Seawater 35‰ and 0° C)

depth (m)	pressure (decibars)	density (g/cm ³)
0	0	1.02813
1,000	1,000	1.03285
2,000	2,000	1.03747
4,000	4,000	1.04640
6,000	6,000	1.05495
8,000	8,000	1.06315
10,000	10,000	1.07104

The temperature of maximum density and the freezing point of water decrease as salt is added to water, and the temperature of maximum density decreases more rapidly than the freezing point. At salinities less than 24.7‰ the density maximum is reached before the ice point, while at the higher salinities more typical of the open oceans the maximum density is never achieved naturally. Table 5 shows that at 5‰ a density maximum is found between 0° and 10° C. (Its actual position is at 3° C, where the σ_t value is 4.04 for 5‰ salinity.) This ability of low-salinity water and, of course, fresh water to pass through a density maximum makes them both behave differently from marine systems when water is cooled at the surface and density-driven overturn occurs.

During the fall a lake is cooled at its surface, the surface water sinks, and convective overturn proceeds as the density of the surface water increases with the decreasing temperature. By the time the surface water reaches 4° C, the temperature of maximum density for fresh water, the density-driven convective overturn has reached the bottom of the lake, and overturn ceases. Further cooling of the surface produces less dense water, and the lake becomes stably stratified with regard to temperature-controlled density. Only a relatively shallow surface layer is cooled below 4° C. When this surface layer is cooled to the ice point, 0° C, ice is formed as the latent heat of fusion is extracted. In a deep lake the temperature at depth remains at 4° C. In the spring the surface water warms up and the ice melts. A shallow convective overturn resumes until the lake is once more isothermal at 4° C. Continued warming of the surface produces a stable water column.

In seawater in which the salinity exceeds 24.7‰, convective overturn also occurs during the cooling cycle and penetrates to a depth determined by the salinity and temperature-controlled density of the cooled water. Since no density maximum is passed, the thermally driven convective overturn is continuous until the ice point is reached where sea ice forms with the extraction of the latent heat of fusion. Since salt is largely excluded from the ice in most cases, the salinity of the water beneath the ice increases slightly and a convective overturn that is both salt- and temperature-driven continues as sea ice forms.

The continuing overturn requires that a large volume of water be cooled to a new ice point dictated by the salinity increase before additional ice forms. In this manner, very dense seawater that is both cold and of elevated salinity is formed. Such areas as the Weddell Sea in Antarctica produce the densest water of the oceans. This water, known as Antarctic Bottom Water, sinks to the deepest depths of the oceans. The continuing overturn slows the rate at which the sea ice forms, limiting the seasonal thickness of the ice. Other factors that control the thickness of ice are the rate at which heat is conducted through the ice layer and the insulation provided by snow on the ice. Seasonal sea ice seldom exceeds about two metres in thickness. During

Seawater density as a function of temperature, salinity, and pressure

Compressibility of seawater under high pressure

Seawater of extremely high density

the warmer season, melting sea ice supplies a freshwater layer to the sea surface and thereby stabilizes the water column (see below *Ice in the sea*).

Surface processes that alter the temperature and salinity of seawater drive the vertical circulation of the oceans. Known as thermohaline circulation, it continually replaces seawater at depth with water from the surface and slowly replaces surface water elsewhere with water rising from deeper depths (see below *Circulation of the ocean currents: Thermohaline circulation*).

Optical properties. Water is transparent to the wavelengths of electromagnetic radiation that fall within the visible spectrum and is opaque to wavelengths above and below this band. However, once in the water, visible light is subject to both refraction and attenuation.

Light rays that enter the water at any angle other than a right angle are refracted (*i.e.*, bent) because the light waves travel at a slower speed in water than they do in air. The amount of refraction, referred to as the refractive index, is affected by both the salinity and temperature of the water. The refractive index increases with increasing salinity and decreasing temperature. This relationship allows the refractive index of a sample of seawater at a constant temperature to be used to determine the salinity of the sample.

Some of the Sun's radiant energy is reflected at the ocean surface and does not enter the ocean. That which penetrates the water's surface is attenuated by absorption and conversion to other forms of energy, such as heat that warms or evaporates water, or is used by plants to fuel photosynthesis. Sunlight that is not absorbed can be scattered by molecules and particulates suspended in the water. Scattered light is deflected into new directional paths and may wander randomly to eventually be either absorbed or directed upward and out of the water. It is this upward scattered light and the light reflected from particles that determine the colour of the oceans, as seen from above.

Water molecules, dissolved salts, organic substances, and suspended particulates combine to cause the intensity of available solar radiation to decrease with depth. Observations of light attenuation in ocean waters indicate that not only does the intensity of solar radiation decrease with depth but also the wavelengths present in the solar spectrum are not attenuated at the same rates. Figure 9 shows the distribution of light intensity with wavelength at the ocean surface and at depth. It is apparent that both short wavelengths (ultraviolet) and long wavelengths (infrared) are absorbed rapidly and are not available for scattering. Only blue-green wavelengths penetrate to any depth, and because the blue-green light is most available for scattering, the oceans appear blue to the human eye. Changes in the colour of the ocean waters are caused either by the colour of the particulates in suspension and dissolved substances or by the changing quality of the solar radiation at the ocean surface as determined by the angle of the Sun and atmospheric conditions. In the clearest ocean waters only about 1 percent of the surface radiation remains at a depth of 150 metres. No sunlight penetrates below 1,000 metres.

There are many ways of measuring light attenuation in the oceans. A common method involves the use of a Secchi disk, a weighted round white disk about 30 centimetres in diameter. The Secchi disk is lowered into the ocean to the depth where it disappears from view; its reflectance equals the intensity of light backscattered from the water. This depth in metres divided into 1.7 yields an attenuation, or extinction, coefficient for available light as averaged over the Secchi disk depth. The light extinction coefficient, x , may then be used in a form of Beer's law, $I_z = I_0 e^{-xz}$, to estimate I_z , the intensity of light at depth z from I_0 , the intensity of light at the ocean surface. This method gives no indication of the attenuation change with depth or the attenuation of specific wavelengths of light.

A photocell may be lowered into the ocean to measure light intensity at discrete depths and to determine light reduction from the surface value or from the previous depth value. The photocell may sense all available wavelengths or may be equipped with filters that pass only certain

Figure 9: Variation in the spectral quality of sunlight with depth in the sea.

The total energy—the area below each curve—decreases with increasing depth, and the colour peak shifts toward the blue side of the system as selective absorption takes place (see text).

From A.C. Duxbury, *The Earth and Its Oceans*, © 1971 A.C. Duxbury, Addison-Wesley Publishing Co. Inc., Reading, Mass., after G. Neumann and W.J. Pierson, *Principles of Physical Oceanography*, © 1966, by permission of the authors

wavelengths of light. Since I_z and I_0 are known, changing light intensity values may be used in Beer's law to determine how the attenuation coefficient changes with depth and quality of light. Measurements of this type are used to determine the level of photosynthesis as a function of radiant energy level with depth and to measure changes in the turbidity of the water caused by particulate distribution with depth.

Different areas of the oceans tend to have different optical properties. Near rivers, silt increases the suspended particle effect. Where nutrients and sunlight are abundant, phytoplankton (unicellular plants) increase the opacity of the water and lend it their colour. Organic substances from excretion and decomposition also have colour and absorb light. Table 7 shows the attenuation of light in different ocean regions with variations in their properties governing scattering and absorption.

Solar radiation received at the ocean surface is constantly changing in time and space. Cloud cover, atmospheric dust, atmospheric gas composition, roughness of the ocean surface, and elevation angle of the Sun combine to change both the quality and quantity of light that enters the ocean. When the Sun's rays are perpendicular to a smooth ocean surface, reflectance is low. When the solar rays are oblique to the ocean surface, reflectance is increased. If the ocean is rough with waves, reflectance is increased when the Sun is at high elevation and decreased when it is at low elevation. Since latitude plays a role in the elevation of the Sun above the horizon, light penetration is always less at the higher latitudes. Cloud cover, density layering, fog, and dust cause refraction and atmospheric scattering of sunlight. When strongly scattered, the Sun's rays are not unidirectional and there are no shadows. Light enters the ocean from all angles under this condition, and the elevation angle of the Sun loses its importance in controlling surface reflectance. Percent of reflectance of direct sunlight related to the Sun's elevation angle is shown in Table 8 for a smooth ocean surface. The solar energy available to penetrate the ocean is 100 percent minus the tabulated reflectance value.

These data indicate that water is a good absorber of solar radiation.

Acoustic properties. Water is an excellent conductor of sound, considerably better than air. The attenuation of sound by absorption and conversion to other energy forms is a function of sound frequency and the properties of water.

The attenuation coefficient, x , in Beer's law, as applied to sound, where I_z and I_0 are now sound intensity values, is dependent on the viscosity of water and inversely proportional to the frequency of the sound and the density of the water. High-pitched sounds are absorbed and converted to heat faster than low-pitched sounds. Sound velocity in water is determined by the square root of elasticity divided by the water's density. Because water is only slightly compressible, it has a large value of elasticity and therefore conducts sound rapidly. Since both the elasticity and density of seawater change with temperature, salinity, and pressure, so does the velocity of sound.

Water as an excellent conductor of sound

Causes of ocean colour changes

*According to Jerlov.

In the oceans the speed of sound varies between 1,450 and 1,570 metres per second. It increases about 4.5 metres per second per each degree C increase and 1.3 metres per second per each 1‰ increase in salinity. Increasing pressure also increases the speed of sound at the rate of about 1.7 metres per second for an increase in pressure of 100 metres in depth, which is equal to approximately 10 bars, or 10 atmospheres.

Table 8: Sunlight Reflectance

Sun's elevation angle	90°	50°	40°	30°	20°	10°	5°
Reflectance (%)	3	3	4	6	12	27	42

The greatest changes in temperature and salinity with depth that affect the speed of sound are found near the surface. Changes of sound speed in the horizontal are usually slight except in areas where abrupt boundaries exist between waters of different properties. The effects of salinity and temperature on sound speed are more important than the effect of pressure in the upper layers. Deeper in the ocean, salinity and temperature change less with depth, and pressure becomes the important controlling factor.

In regions of surface dilution, salinity increases with depth near the surface, while in areas of high evaporation salinity decreases with depth. Temperature usually decreases with depth and normally exerts a greater influence on sound speed than does the salinity in the surface layer of the open oceans. In the case of surface dilution, salinity and temperature effects on the speed of sound oppose each other, while in the case of evaporation they reinforce each other, causing the speed of sound to decrease with depth. Beneath the upper oceanic layers the speed of sound increases with depth.

If a sound wave (sonic pulse) travels at a right angle to these layers, as in depth sounding, no refraction occurs; however, the speed changes continuously with depth, and an average sound speed for the entire water column must be used to determine the depth of water. Variations in the speed of sound cause sound waves to refract when they travel obliquely through layers of water that have different properties of salinity and temperature. Sound waves traveling downward and moving obliquely to the water layers will bend upward when the speed of sound increases with depth and downward when the speed decreases with depth. This refraction of the sound is important in the sonar detection of submarines because the actual path of a sound wave must be known to determine a submarine's position relative to the transmitter of the sound. Refraction also produces shadow zones that sound waves do not penetrate because of their curvature (see Figure 10A and 10B).

At depths of approximately 1,000 metres, pressure becomes the important factor: it combines with temperature and salinity to produce a zone of minimum sound speed. This zone has been named the SOFAR (sound fixing and ranging) channel (see Figure 11). If a sound is generated by a point source in the SOFAR zone, it becomes trapped by refraction. Dispersed horizontally rather than in three directions, the sound is able to travel for great distances. Hydrophones lowered to this depth many kilometres from the origin of the sound are able to detect the sound pulse. The difference in arrival time of the pulse at separate listening posts may be used to triangulate the position of the pulse source.

Hearing is an important sensory mechanism for marine animals because seawater is more transparent to sound than to light. Animals communicate with each other over

long distances and also locate objects by sending directional sound signals that reflect from targets and are received as echoes. Information about the size of a target is gained by varying the frequency of the sound; high-frequency (or short-wavelength) sound waves reflect better from small targets than low-frequency sound waves. The intensity and quality of the returning signal also provide information about the properties of the reflecting target.

Ice in the sea. Formation of sea ice was briefly discussed above (see *Density of seawater and pressure*). Sea ice formation is a thermal physical property of water and plays a role in driving convective overturn in the oceans. It does so by increasing the density of the seawater under the forming ice and thereby helps to drive convective overturn.

There are two types of ice in the seas: sea ice, which is ice formed by the freezing of seawater, and ice that has come from land, such as icebergs and ice islands.

Sea ice. From an initial stage of so-called frazil crystals (floating needles and platelets) and sludge composed of them, sea ice grows to a compact aggregate of crystals of pure ice with pockets of seawater entrapped between them. Because of this composition, the salinity of sea ice is lower than that of the seawater from which it has grown. The initial sea-ice salinity may vary between 2 and 20 parts per thousand; the more rapid the freezing, the saltier the ice, as brine can be trapped in cavities in the forming ice and become isolated from the seawater.

After sea ice has formed, a process of salt removal by drainage of part of the enclosed brine sets in, because the cells in which it is contained are not completely isolated.

Old ice has very low salinity, on the order of 1 part per thousand or less.

The growth rate of sea ice depends on surface temperature, the depth of snow cover, and the heat flux in the underlying water. In the central Arctic, the thickness of an ice cover formed in one growing season is about two metres. If the ice is not broken up or melted each season, it finally reaches an equilibrium thickness of about three to four metres in five to eight years, when the annual ablation (loss by any means) at the top and the bottom equals the annual growth. In the Antarctic, perennial sea ice is found only in the Weddell Sea and a narrow strip around the continent. Most of the Antarctic sea ice is seasonal and reaches a thickness of about 1.5 metres by the end of October.

The high albedo (or reflectivity) of sea ice and its snow cover (80 percent, compared to 5–10 percent for liquid water), the insulation characteristics of ice and snow, and the latent heat of fusion combine to affect the heat budget of the oceans during both freezing and thawing.

The boundaries of the sea ice are highly variable. In the Norwegian and Greenland seas, deviations of 300 kilometres north or south of the average position are not uncommon. The estimated mean areas of sea ice at the end of the summer and at the end of the winter in the Arctic are 9 million square kilometres (3.5 million square miles) and 12 million square kilometres, respectively. In the Antarctic, the corresponding values are 4 million square kilometres and 20 million square kilometres. The mean total volume of sea ice on Earth is 40,000 to 50,000 cubic kilometres (9,600 to 12,000 cubic miles), and the total amount of freezing and melting that occurs each year has been estimated at 30,000 cubic kilometres.

In the Arctic, it is possible to distinguish three regimes of sea ice: the great inner core, the permanent polar cap of sea ice (the Arctic pack), which covers about six million square kilometres; around this the true drift ice or pack ice; and the landfast ice, which is present during nine months of the year, when it fringes the shores of the Arctic Ocean out to the 22-metre depth line. Large amounts of pack ice drift southward each year. The ice discharge through the gap between Greenland and Spitsbergen is estimated to be 3,000 cubic kilometres per year. On the west side of the North Atlantic, the pack ice reaches approximately latitude 45° N in winter and spring. On the east side, along the Norwegian coast, the sea remains open up to 73° N.

Ice islands and icebergs. Ice islands, of which a number have been found drifting in Arctic waters, are heavy sheets of ice that are far thicker than sea ice. Their thickness may amount to 50 metres, 5 metres of which project above water. The surface area of the largest known ice island is about 1,000 square kilometres; others are far smaller. Ice islands consist of a kind of glacierlike snow ice. The majority probably have been formed by the breaking of the shelf ice that borders the north coast of Ellesmere Island. The first ice island reported has undergone little change in configuration since its detection in 1946.

Icebergs are formed by the calving (detaching of parts) of glaciers or of inland ice that reaches the sea. The main sources of icebergs in the northern seas are the valley glaciers of Greenland, which produce some 12,000 to 15,000 sizable icebergs annually. Almost as many are

calved by the glaciers reaching the sea on the eastern seaboard as by those on the west coast, but the icebergs deriving from the east side do not travel much farther south than Cape Farvel, the southern tip of Greenland. The icebergs of the west coast, on the other hand, after traveling northward and across to the other side of Baffin Bay, are carried far south, along Baffin Island and Labrador, by the Labrador Current. It is estimated that about 1 in every 20 icebergs derived from west Greenland ends up south of Newfoundland (48° N), the greatest numbers arriving there in April, May, and June.

The icebergs of the Antarctic derive from an ice barrier, or shelf ice, a layer of ice that stretches out from the inland ice into the ocean. It rests on the bottom near shore, but farther out to sea it floats on the water. Because of their origin, the Antarctic icebergs are much longer than they are high, occasionally measuring some tens of kilometres in length. For this reason they are called table bergs.

The frequency with which icebergs occur in the Southern Ocean (see above) does not vary much with the season in contrast to the North Atlantic occurrences. Generally speaking, October and November are the months in which they are most numerous in the south because of the release of the bergs from the pack ice in the southern spring. They reach farthest north from November to February. The average northern boundary for icebergs is about 40° S in the Atlantic Ocean, between 40° and 50° S in the Indian Ocean, and about 50° S in the Pacific. At least several thousands of them are adrift every year in the southern seas. (P.Gr./A.C.D.)

Circulation of the ocean waters

GENERAL OBSERVATIONS

The general circulation of the oceans defines the average movement of seawater, which, like the atmosphere, follows a specific pattern. Superimposed on this pattern are oscillations of tides and waves, which are not considered part of the general circulation. There also are meanders and eddies that represent temporal variations of the general circulation. The ocean circulation pattern exchanges water of varying characteristics, such as temperature and salinity, within the interconnected network of oceans and is an important part of the heat and freshwater fluxes of the global climate. Horizontal movements are called currents, which range in magnitude from a few centimetres per second to as much as 4 metres per second. A characteristic surface speed is about 5 to 50 centimetres per second. Currents diminish in intensity with increasing depth. Vertical movements, often referred to as upwelling and downwelling, exhibit much lower speeds, amounting to only a few metres per month. As seawater is nearly incompressible, vertical movements are associated with regions of convergence and divergence in the horizontal flow patterns.

Ocean circulation derives its energy at the sea surface from two sources that define two circulation types: (1) wind-driven circulation forced by wind stress on the sea surface, inducing a momentum exchange, and (2) thermohaline circulation driven by the variations in water density imposed at the sea surface by exchange of ocean heat and water with the atmosphere, inducing a buoyancy exchange. These two circulation types are not fully independent, since the sea-air buoyancy and momentum exchange are dependent on wind speed. The wind-driven circulation is the more vigorous of the two and is configured as large gyres that dominate an ocean region. The wind-driven circulation is strongest in the surface layer. The thermohaline circulation is more sluggish, with a typical speed of one centimetre per second, but this flow extends to the seafloor and forms circulation patterns that envelop the global ocean.

DISTRIBUTION OF OCEAN CURRENTS

Maps of the general circulation at the sea surface, such as the one shown in Figure 12, are constructed from a vast amount of data obtained from inspecting the residual drift of ships after course direction and speed are accounted for in a process called dead reckoning. This information is

amplified by satellite-tracked drifters at sea. The pattern is nearly entirely that of wind-driven circulation.

Deep-ocean circulation (Figure 13) consists mainly of thermohaline circulation. The currents are inferred from the distribution of seawater properties, which trace the spreading of specific water masses. The distribution of density or field of mass is also used to estimate the deep currents. Direct observations of subsurface currents are made by deploying current meters from bottom-anchored moorings and by setting out neutral buoyant instruments whose drift at depth is tracked acoustically.

CAUSES OF OCEAN CURRENTS

The general circulation is governed by the equation of motion, one of Sir Isaac Newton's fundamental laws of mechanics applied to a continuous volume of water. This equation states that the product of mass and current acceleration equals the vector sum of all forces that act on the mass. Besides gravity, the most important forces that cause and affect ocean currents are horizontal pressure-gradient forces, Coriolis forces, and frictional forces. Temporal and inertial terms are generally of secondary importance to the general flow, though they become important for transient features of meanders and eddies.

Pressure gradients. The hydrostatic pressure, p , at any depth below the sea surface is given by the equation $p = gpz$, where g is the acceleration of gravity, p is the density of seawater, which increases with depth, and z is the depth below the sea surface. This is called the hydrostatic equation, which is a good approximation for the equation of motion for forces acting along the vertical. Horizontal differences in density (due to variations of temperature and salinity) measured along a specific depth cause the hydrostatic pressure to vary along a horizontal plane or geopotential surface, a surface perpendicular to the direction of the gravity acceleration. Horizontal gra-

dients of pressure, though much smaller than vertical changes in pressure, give rise to ocean currents.

In a homogeneous ocean, which would have a constant potential density, horizontal pressure differences are possible only if the sea surface is tilted. In this case, surfaces of equal pressure, called isobaric surfaces, are tilted in the deeper layers by the same amount as the sea surface. This is referred to as the barotropic field of mass. The unchanged pressure gradient gives rise to a current speed independent of depth. The oceans of the world, however, are not homogeneous. Horizontal variations in temperature and salinity cause the horizontal pressure gradient to vary with depth. This is the baroclinic field of mass, which leads to currents that vary with depth. The horizontal pressure gradient in the ocean is a combination of these two mass fields.

The tilt, or topographic relief, of the isobaric surface marking sea surface (defined as $p = 0$) can be constructed from a three-dimensional density distribution (Figure 14) using the hydrostatic equation. Since the absolute value of pressure is not known at any depth in the ocean, the sea surface slope is presented relative to that of a deep isobaric surface; it is assumed that the deep isobaric surface is level. Since the wind-driven circulation attenuates with increasing depth, an associated decrease of isobaric tilt with increasing depth is expected. Representation of the sea surface relief relative to a deep reference surface is a good representation of the absolute shape of the sea surface. The total relief of the sea surface amounts to about two metres, with "hills" in the subtropics and "valleys" in the polar regions. This pressure head drives the surface circulation.

Coriolis effect. The rotation of the Earth about its axis causes moving particles to behave in a way that can only be understood by adding a rotational dependent force. To an observer in space, a moving body would continue to

Barotropic and baroclinic fields of mass

Dietrich, *Allgemeine Meereskunde*, copyright © 1957 by Gebrüder Borntraeger, Berlin, copyright © 1963 John Wiley & Sons, Inc., reprinted by permission of John Wiley & Sons, Inc.

move in a straight line unless the motion were acted upon by some other force. To an Earth-bound observer, however, this motion cannot be along a straight line because the reference frame is the rotating Earth. This is similar to the effect that would be experienced by an observer standing on a large turntable if an object moved over the turntable in a straight line relative to the "outside" world. An apparent deflection of the path of the moving object would be seen. If the turntable rotated counterclockwise, the apparent deflection would be to the right of the direction of the moving object, relative to the observer fixed on the turntable. This remarkable effect is evident in the behaviour of ocean currents. It is called the Coriolis force, named after Gustave-Gaspard Coriolis, a 19th-century French engineer and mathematician. For the Earth, horizontal deflections due to the rotational induced Coriolis force act on particles moving in any horizontal direction. There also are apparent vertical forces, but these are of minor importance to ocean currents. Because the Earth rotates from west to east about its axis, an observer in the Northern Hemisphere would notice a deflection of a moving body toward the right. In the Southern Hemisphere, this deflection would be toward the left. At the equator there would be no apparent horizontal deflection.

It can be shown that the Coriolis force always acts perpendicular to motion. Its horizontal component, C_h , is proportional to the sine of the geographic latitude (θ), given as a positive value for the Northern Hemisphere and a negative value for the Southern Hemisphere) and the speed, c , of the moving body. It is given by $C_h = c(2\omega \sin \theta)$, where $\omega = 7.29 \times 10^{-5}$ radian per second is the angular velocity of the Earth's rotation.

Frictional forces. Movement of water through the oceans is slowed by friction, with surrounding fluid moving at a different velocity. A faster-moving fluid layer tends to drag along a slower-moving layer, and a slower-moving layer will tend to reduce the speed of a faster-moving layer. This momentum transfer between the layers is referred to as frictional forces. The momentum transfer is a product

of turbulence that moves kinetic energy to smaller scales until at the centimetre scale it is dissipated as heat. The wind blowing over the sea surface transfers momentum to the water. This frictional force at the sea surface (*i.e.*, the wind stress) produces the wind-driven circulation. Currents moving along the ocean floor and the sides of the ocean also are subject to the influence of boundary-layer friction. The motionless ocean floor removes momentum from the circulation of the ocean waters.

Geostrophic currents. For most of the ocean volume away from the boundary layers, which have a characteristic thickness of 100 metres, frictional forces are of minor importance, and the equation of motion for horizontal forces can be expressed as a simple balance of horizontal pressure gradient and Coriolis force. This is called geostrophic balance.

On a nonrotating Earth, water would be accelerated by a horizontal pressure gradient and would flow from high to low pressure. On the rotating Earth, however, the Coriolis force deflects the motion, and the acceleration ceases only when the speed, c , of the current is just fast enough to produce a Coriolis force that can exactly balance the horizontal pressure-gradient force. This geostrophic balance is given as $dp/dn = \rho c 2\omega \sin \theta$, where dp/dn is the horizontal pressure gradient. From this balance, it follows that the current direction must be perpendicular to the pressure gradient because the Coriolis force always acts perpendicular to the motion. In the Northern Hemisphere this direction is such that the high pressure is to the right when looking in current direction, while in the Southern Hemisphere it is to the left. This type of current is called a geostrophic current. The simple equation given above provides the basis for an indirect method of computing ocean currents. The relief of the sea surface (see Figure 14) also defines the streamlines (paths) of the geostrophic current at the surface relative to the deep reference level. The hills represent high pressure, and the valleys stand for low pressure. Clockwise rotation in the Northern Hemisphere with higher pressure in the centre of rotation is called anticyclonic motion. Counterclockwise rotation with lower pressure in its centre is cyclonic motion. In the Southern Hemisphere the sense of rotation is the opposite, because the effect of the Coriolis force has changed its sign of deflection.

Ekman layer. The wind exerts stress on the ocean surface proportional to the square of the wind speed and in the direction of the wind, setting the surface water in motion. This motion extends to a depth of about 100 metres in what is called the Ekman layer, after the Swedish oceanographer V. Walfrid Ekman, who in 1902 deduced these results in a theoretical model constructed to help explain observations of wind drift in the Arctic. Within the oceanic Ekman layer the wind stress is balanced by the Coriolis force and frictional forces. The surface water is directed at an angle of 45° to the wind, to the right in the Northern Hemisphere and to the left in the Southern Hemisphere. With increasing depth in the boundary layer, the current speed is reduced, and the direction rotates farther away from the wind direction following a spiral form, becoming antiparallel to the surface flow at the base of the layer where the speed is $1/23$ of the surface speed. This so-called Ekman spiral may be the exception rather than the rule, as the specific conditions are not often met, though deflection of a wind-driven surface current at somewhat smaller than 45° is observed when the wind field blows with a steady force and direction for the better part of a day. The average water particle within the Ekman layer moves at an angle of 90° to the wind; this movement is to the right of the wind direction in the Northern Hemisphere and to its left in the Southern Hemisphere. This phenomenon is called Ekman transport, and its effects are widely observed in the oceans.

Since the wind varies from place to place, so does the Ekman transport, forming convergence and divergence zones of surface water. A region of convergence forces surface water downward in a process called downwelling, while a region of divergence draws water from below into the surface Ekman layer in a process known as upwelling. Upwelling and downwelling also occur where the wind blows

Geostrophic balance

Downwelling and upwelling

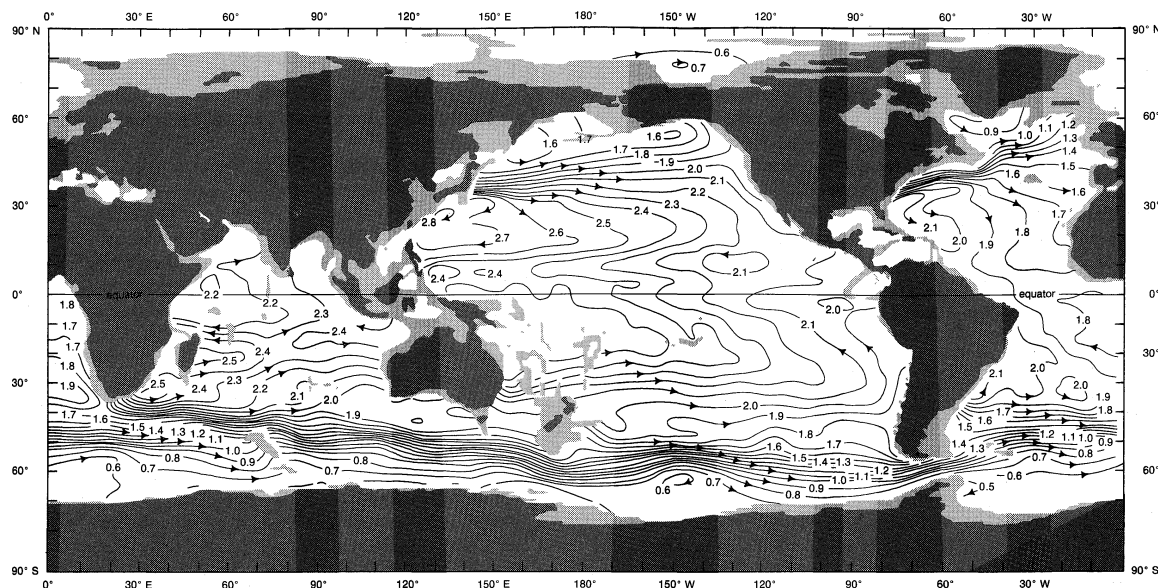

Figure 14: Sea surface topographic relief relative to the 2,000-decibar (about 2,000-metre depth) isobaric surface.

The sea surface topography is expressed in energy units (10 metres squared per second squared), with a factor that makes the numbers numerically similar to metres. The geostrophic current flows along lines of equal sea-level elevation in the direction indicated by the arrow heads.

From S. Levitus, *Climatological Atlas of the World Ocean* (1982); National Oceanic and Atmospheric Administration

parallel to a coastline. The principal upwelling regions of the world are along the eastern boundary of the subtropical ocean waters, as, for example, the coastal region of Peru and northwestern Africa. Upwelling in these regions cools the surface water and brings nutrient-rich subsurface water into the sunlit layer of the ocean, resulting in a biologically productive region. Upwelling and high productivity also are found along divergence zones at the equator and around Antarctica. The primary downwelling regions are in the subtropical ocean waters—e.g., the Sargasso Sea in the North Atlantic. Such areas are devoid of nutrients and are poor in marine life.

The vertical movements of ocean waters into or out of the base of the Ekman layer amount to less than one metre per day, but they are important since they extend the wind-driven effects into deeper waters. Within an upwelling region, the water column below the Ekman layer is drawn upward. This process, with conservation of angular momentum on the rotating Earth, induces the water column to drift toward the poles. Conversely, downwelling forces water into the water column below the Ekman layer, inducing drift toward the equator. An additional consequence of upwelling and downwelling for stratified waters is to create a baroclinic field of mass (see above). Surface water is less dense than deeper water. Ekman convergences have the effect of accumulating less dense surface water. This water floats above the surrounding water, forming a hill in sea level and driving an anticyclonic geostrophic current that extends well below the Ekman layer. Divergences do the opposite; they remove the less dense surface water, replacing it with denser, deeper water. This induces a depression in sea level with a cyclonic geostrophic current.

The ocean current pattern produced by the wind-induced Ekman transport is called the Sverdrup transport, after the Norwegian oceanographer H.U. Sverdrup, who formulated the basic theory in 1947. Several years later (1950), the American geophysicist and oceanographer Walter H. Munk and others expanded Sverdrup's work, explaining many of the major features of the wind-driven general circulation by using the mean climatological wind stress distribution at the sea surface as a driving force (Figure 15).

WIND-DRIVEN CIRCULATION

Wind stress induces a circulation pattern that is similar for each ocean. In each case, the wind-driven circulation

is divided into large gyres that stretch across the entire ocean: subtropical gyres extend from the equatorial current system to the maximum westerlies in a wind field near 50° latitude, and subpolar gyres extend poleward of the maximum westerlies (see below). The depth penetration of the wind-driven currents depends on the intensity of ocean stratification: for those regions of strong stratification, such as the tropics, the surface currents extend to a depth of less than 1,000 metres. Within the low-stratification polar regions, the wind-driven circulation reaches all the way to the seafloor.

Equatorial currents. At the equator the currents are for the most part directed toward the west, the North Equatorial Current in the Northern Hemisphere and the South Equatorial Current in the Southern Hemisphere. Near the thermal equator, where the warmest surface water is found, there occurs the eastward-flowing Equatorial Counter Current. This current is slightly north of the geographic equator, drawing the northern fringe of the South Equatorial Current to 5° N. The offset to the Northern Hemisphere matches a similar offset in the wind field. The east-to-west wind across the tropical ocean waters induces Ekman transport divergence at the equator, which cools the surface water there.

At the geographic equator a jetlike current is found just below the sea surface, flowing toward the east counter to the surface current. This is called the Equatorial Undercurrent. It attains speeds of more than 1 metre per second at a depth of nearly 100 metres. It is driven by higher sea level in the western margins of the tropical ocean, producing a pressure gradient, which in the absence of a horizontal Coriolis force drives a west-to-east current along the equator. The wind field reverses the flow within the surface layer, inducing the Equatorial Undercurrent.

Equatorial circulation undergoes variations following the irregular periods of roughly three to eight years of the Southern Oscillation (*i.e.*, fluctuations of atmospheric pressure over the tropical Indo-Pacific region). Weakening of the east-to-west wind during a phase of the Southern Oscillation allows warm water in the western margin to slip back to the east by increasing the flow of the Equatorial Counter Current. Surface water temperatures and sea level decrease in the west and increase in the east. This event is called El Niño. The combined El Niño/Southern Oscillation effect has received much attention because it is associated with global-scale climatic variability (see below *Impact of ocean-atmosphere interactions on weather and climate: El Niño/*

Equatorial Undercurrent

Figure 15: Circulation pattern for the Pacific Ocean north of 10° S calculated from the zonal component of the large-scale wind field shown at the left. The streamlines in map view represent the transport of seawater. Between the adjacent lines flow 10 million cubic metres of water per second.

From W.H. Munk, *Journal of Meteorology* (1950)

Southern Oscillation and climatic change). In the tropical Indian Ocean, the strong seasonal winds of the monsoons induce a similarly strong seasonal circulation pattern.

The subtropical gyres. These are anticyclonic circulation features. The Ekman transport within these gyres forces surface water to sink, giving rise to the subtropical convergence near 20°–30° latitude. The centre of the subtropical gyre is shifted to the west. This westward intensification of ocean currents was explained by the American meteorologist and oceanographer Henry M. Stommel (1948) as resulting from the fact that the horizontal Coriolis force increases with latitude. This causes the poleward-flowing western boundary current to be a jetlike current that attains speeds of two to four metres per second. This current transports the excess heat of the low latitudes to higher latitudes. The flow within the equatorward-flowing interior and eastern boundary of the subtropical gyres is quite different. It is more of a slow drift of cooler water that rarely exceeds 10 centimetres per second. Associated with these currents is coastal upwelling that results from offshore Ekman transport.

The strongest of the western boundary currents is the Gulf Stream in the North Atlantic Ocean. It carries about 30 million cubic metres of ocean water per second through the Straits of Florida and roughly 80 million cubic metres per second as it flows past Cape Hatteras off the coast of North Carolina, U.S. Responding to the large-scale wind field over the North Atlantic, the Gulf Stream separates from the continental margin at Cape Hatteras. After separation, it forms waves or meanders that eventually generate many eddies of warm and cold water. The warm eddies, composed of thermocline water normally found south of the Gulf Stream, are injected into the waters of the continental slope off the coast of the northeastern United States. They drift to the southeast at rates of approximately five to eight centimetres per second, and after a year they rejoin the Gulf Stream north of Cape Hatteras. Cold eddies of slope water are injected into the region south of the Gulf Stream and drift to the southwest. After two years they reenter the Gulf Stream just north of the Antilles Islands. The path that they follow defines a clockwise-flowing recirculation gyre seaward of the Gulf Stream. (For additional details on the Gulf Stream, see below *Impact of ocean-atmosphere interactions on weather and climate: The Gulf Stream and Kuroshio systems*.)

Among the other western boundary currents, the Kuroshio of the North Pacific is perhaps the most like the Gulf Stream, having a similar transport and array of

eddies. The Brazil and East Australian currents are relatively weak. The Agulhas Current has a transport close to that of the Gulf Stream. It remains in contact with the margin of Africa around the southern rim of the continent. It then separates from the margin and curls back to the Indian Ocean in what is called the Agulhas Retroflection. Not all the water carried by the Agulhas returns to the east; about 10 to 20 percent is injected into the South Atlantic Ocean as large eddies that slowly migrate across it.

The subpolar gyres. The subpolar gyres are cyclonic circulation features. The Ekman transport within these features forces upwelling and surface water divergence. In the North Atlantic the subpolar gyre consists of the North Atlantic Current at its equatorward side and the Norwegian Current that carries relatively warm water northward along the coast of Norway. The heat released from the Norwegian Current into the atmosphere maintains a moderate climate in northern Europe. Along the east coast of Greenland is the southward-flowing cold East Greenland Current. It loops around the southern tip of Greenland and continues flowing into the Labrador Sea. The southward flow that continues off the coast of Canada is called the Labrador Current. This current separates for the most part from the coast near Newfoundland to complete the subpolar gyre of the North Atlantic. Some of the cold water of the Labrador Current, however, extends farther south.

In the North Pacific the subpolar gyre is composed of the northward-flowing Alaska Current, the Aleutian Current (also known as the Subarctic Current), and the southward-flowing cold Oyashio Current. The North Pacific Current forms the separation between the subpolar and subtropical gyres of the North Pacific.

In the Southern Hemisphere, the subpolar gyres are less defined. Large cyclonic flowing gyres lie poleward of the Antarctic Circumpolar Current and can be considered counterparts to the Northern Hemispheric subpolar gyres. The best-formed is the Weddell Gyre of the South Atlantic sector of the Southern Ocean (see above). The Antarctic coastal current flows toward the west. The northward-flowing current off the east coast of the Antarctic Peninsula carries cold Antarctic coastal water into the circumpolar belt. Another cyclonic gyre occurs north of the Ross Sea.

Antarctic Circumpolar Current. The Southern Ocean links the major oceans by a deep circumpolar belt in the 50°–60° S range. In this belt flows the Antarctic Circumpolar Current from west to east, encircling the globe at high latitudes. It transports 125 million cubic metres of

North
Atlantic
and
Norwegian
currents

seawater per second over a path of about 24,000 kilometres and is the most important factor in diminishing the differences between oceans. The Antarctic Circumpolar Current is not a well-defined single-axis current but rather consists of a series of individual filaments separated by frontal zones. It reaches the seafloor and is guided along its course by the irregular bottom topography. Large meanders and eddies develop in the current as it flows. These features induce poleward transfer of heat, which may be significant in balancing the oceanic heat loss to the atmosphere above the Antarctic region farther south.

THERMOHALINE CIRCULATION

The general circulation of the oceans consists primarily of the wind-driven currents. These, however, are superimposed on the much more sluggish circulation driven by horizontal differences in temperature and salinity—namely, the thermohaline circulation. The thermohaline circulation reaches down to the seafloor and is often referred to as the deep, or abyssal, ocean circulation. Measuring seawater temperature and salinity distribution is the chief method of studying the deep-flow patterns. Other properties also are examined; for example, the concentrations of oxygen, carbon-14, and such synthetically produced compounds as chlorofluorocarbons are measured to obtain resident times and spreading rates of deep water.

In some areas of the ocean, generally during the winter season, cooling or net evaporation causes surface water to become dense enough to sink. Convection penetrates to a level where the density of the sinking water matches that of the surrounding water. It then spreads slowly into the rest of the ocean. Other water must replace the surface water that sinks. This sets up the thermohaline circulation. The basic thermohaline circulation is one of sinking of cold water in the polar regions, chiefly in the northern North Atlantic and near Antarctica. These dense water masses spread into the full extent of the ocean and gradually upwell to feed a slow return flow to the sinking regions. A theory for the thermohaline circulation pattern

was proposed by Stommel and Arnold Arons in 1960 (Figure 16).

In the Northern Hemisphere, the primary region of deep water formation is the North Atlantic; minor amounts of deep water are formed in the Red Sea and Persian Gulf. A variety of water types contribute to the so-called North Atlantic Deep Water. Each one of them differs, though they share a common attribute of being relatively warm (greater than 2° C) and salty (greater than 34.9 parts per thousand) compared with the other major producer of deep and bottom water, the Southern Ocean (0° C and 34.7 parts per thousand). North Atlantic Deep Water is primarily formed in the Greenland and Norwegian seas, where cooling of the salty water introduced by the Norwegian Current induces sinking. This water spills over the rim of the ridge that stretches from Greenland to Scotland, extending to the seafloor to the south as a convective plume. It then flows southward, pressed against the western edge of the North Atlantic. Additional deep water is formed in the Labrador Sea. This water, somewhat less dense than the overflow water from the Greenland and Norwegian seas, has been observed sinking to a depth of 3,000 metres within convective features referred to as chimneys. Vertical velocities as high as 10 centimetres per second have been observed within these convective features. A third variety of North Atlantic Deep Water is derived from net evaporation within the Mediterranean Sea. This draws surface water into the Mediterranean through the Strait of Gibraltar. The mass of salty water formed within the Mediterranean exits as a deeper stream. It descends to depths of 1,000 to 2,000 metres in the North Atlantic Ocean, forming the uppermost layer of North Atlantic Deep Water. The outflow in the Strait of Gibraltar reaches as high as 2 metres per second, but its total transport amounts to only 5 percent of the total North Atlantic Deep Water formed. The outflow of the Mediterranean plays a significant role in boosting the salinity of North Atlantic Deep Water.

The blend of North Atlantic Deep Water, with a total formation rate of 15 to 20 × 10⁶ cubic metres per second,

From Henry Stommel, *The Gulf Stream: A Physical and Dynamical Description*, originally published by the University of California Press; reprinted by permission of The Regents of the University of California

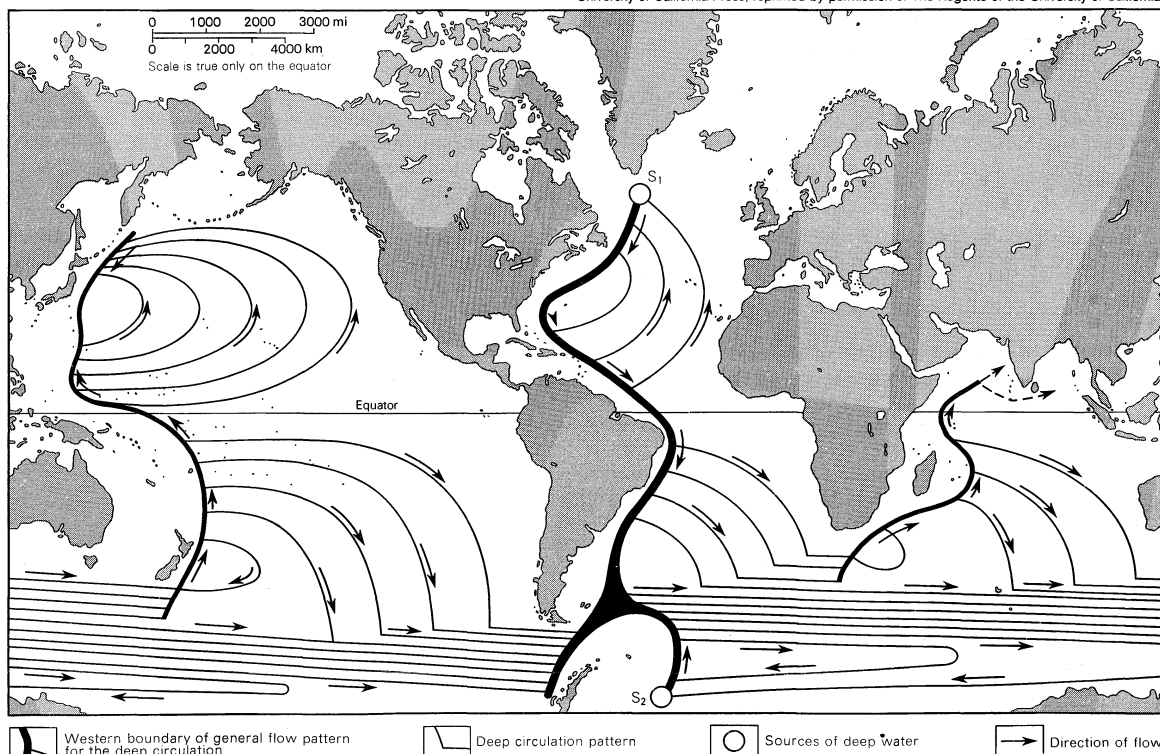

Figure 16: Circulation pattern of deep flow proposed by Henry Stommel and Arnold Arons. According to their theory, surface water sinks down into the deep ocean at two sites: the northern North Atlantic (S₁) and the Weddell Sea (S₂). Primary pathways of meridional motion occur in the western boundaries of the ocean basins. These deep western-boundary currents lose water to the ocean interior, where the deep water slowly upwells and drifts poleward to renew the surface water in the regions at which sinking occurs.

Abyssal
circulation

quickly ventilates the Atlantic Ocean, resulting in a residence time of less than 200 years. The deep water spreads away from its source along the western side of the Atlantic Ocean and, on reaching the Antarctic Circumpolar Current, spreads into the Indian and Pacific oceans. The sinking of North Atlantic Deep Water is compensated for by the slow upwelling of deep water, mainly in the Southern Ocean, to replenish the upper stratum of water that has descended as North Atlantic Deep Water. North Atlantic Deep Water exported to the other oceans must be balanced by the inflow of upper-layer water into the Atlantic. Some water returns as cold, low-salinity Pacific water through the Drake Passage in the form of what is known as Antarctic Intermediate Water, and some returns as warm salty thermocline water from the Indian Ocean around the southern rim of Africa.

Remnants of North Atlantic Deep Water mix with Southern Ocean water to spread along the seafloor into the North Pacific Ocean. Here, it upwells to a level of 2,000–3,000 metres and returns to the south lower in salinity and oxygen but higher in nutrient concentrations as North Pacific Deep Water. This North Pacific Deep Water is eventually swept eastward with the Antarctic Circumpolar Current. Modification of deep water in the North Pacific is the direct consequence of vertical mixing, which carries into the deep ocean the low salinity properties of North Pacific Intermediate Water. The latter is formed in the northwestern Pacific Ocean. Because of the immenseness of the North Pacific and the extremely long residence time (more than 500 years) of the water, enormous quantities of North Pacific Deep Water can be produced by vertical mixing.

Considerable volumes of cold water generally of low salinity are formed in the Southern Ocean. Such water masses spread into the interior of the global ocean and to a large extent are responsible for the anomalous cold, low-salinity state of the modern oceans. The circumstances leading to this role for the Southern Ocean are related to the existence of a deep-ocean circumpolar belt around Antarctica that was established some 25 million years ago by the shifting lithospheric plates which make up the Earth's surface (see below *Ocean basins*). This belt establishes the Antarctic Circumpolar Current, which isolates Antarctica from the warm surface waters of the subtropics. The Antarctic Circumpolar Current does not completely sever contact with the lower latitudes. The Southern Ocean does have access to the waters of the north, but through deep- and bottom-water pathways. The basic dynamics of the Antarctic Circumpolar Current lifts dense deep water occurring north of the current to the ocean surface south of it. Once exposed to the cold Antarctic air masses, the upwelling deep water is converted to the cold Antarctic Bottom Water and Antarctic Intermediate Water. The southward and upwelling deep water, which carries heat injected into the deep ocean by processes farther north, is balanced by the northward spread of cooler, fresher, oxygenated water masses of the Southern Ocean. It is estimated that the overturning rate of water south of the Antarctic Circumpolar Current amounts to 35 to 45 million cubic metres per second, most of which becomes Antarctic Bottom Water.

Antarctic
Bottom
Water

The primary site of Antarctic Bottom Water formation is within the continental margins of the Weddell Sea, though some is produced in other coastal regions, such as the Ross Sea. Also, there is evidence of deep convective overturning farther offshore. Antarctic Bottom Water, formed at a rate of 30 million cubic metres per second, slips below the Antarctic Circumpolar Current and spreads to regions well north of the equator. Slowly upwelling and modified by mixing with less dense water, it returns to the Southern Ocean as deep water.

The remaining upwelling of deep water spreads near the surface to the north, where it forms Antarctic Intermediate Water within the Antarctic Circumpolar Current zone and spreads along the base of the thermoclines farther north. This water mass forms a sheet of low-salinity water that demarcates the lower boundary of the subtropical thermocline. It upwells into the thermocline, partly compensating for the sinking of North Atlantic Deep Water. (A.L.G.)

Waves of the sea

There are many types of ocean waves. Waves differ from each other in size and in terms of the forces that drive them. Waves represent an oscillatory motion of seawater at regular time intervals or periods. Some may be running, or progressive, waves in which the crests propagate, while others are stationary, or standing, waves. Two of the more common types of waves, gravity waves and tides, are considered here. For gravity waves, the stabilizing force—*i.e.*, the force that attempts to restore the crests and troughs of the waves to the average sea level—is the Earth's gravity. The distance between the crests, or wavelength, of gravity waves range from a few centimetres to many kilometres. Tiny waves at the ocean surface with a wavelength of less than 1.7 centimetres are called capillary waves. Their restoring force is the surface tension of seawater. Capillary waves are direct products of the wind stress exerted on the sea surface and tend to feed wind energy into gravity waves, which characteristically have longer wavelengths.

Capillary
waves

Tides are essentially gravity waves that have long periods of oscillation. They may be called forced waves, because they have fixed, prescribed periods that are strictly determined by astronomical forces induced by the relative movements of the Moon, Earth, and Sun. Sometimes the term "tidal wave" is used incorrectly to include such phenomena as surges, which are called storm tides, or destructive waves known as tsunamis that are induced by undersea earthquakes. In the following discussion, the use of the words tide and tidal is restricted to tides of astronomical origin and the forces and phenomena associated with them. Figure 17 shows the different types of surface waves and their relative amounts of energy.

SURFACE GRAVITY WAVES

Of the nontidal kinds of running surface waves, three types may be distinguished: wind waves and swell, wind surges, and sea waves of seismic origin (tsunamis).

Wind waves and swell. Wind waves are the wind-generated gravity waves. After the wind has abated or shifted or the waves have migrated away from the wind field, such waves continue to propagate as swell.

The dependence of the sizes of the waves on the wind field is a complicated one. A general impression of this dependence is given by the descriptions of the various states of the sea corresponding to the scale of wind strengths known as the Beaufort scale (Table 9), after the British admiral Sir Francis Beaufort, who drafted it in 1808, using as his yardstick the surface of sail that a fully rigged warship of those days could carry in the various wind forces. In the Table the Beaufort wind force is followed by the name given to such a wind at sea, and the next column provides the range of wind speeds. When considering the descriptions of the sea surface, it must be remembered that the size of the waves depends not only on the strength of the wind but also on its duration and its fetch—*i.e.*, the length of its path over the sea.

The theory of waves starts with the concept of simple waves, those forming a strictly periodic pattern with one wavelength and one wave period and propagating in one

Wave
character-
istics and
motion

Figure 17: Types of surface waves and their relative energy levels.

direction. Real waves, however, always have a more irregular appearance. They may be described as composite waves, in which a whole spectrum of wavelengths, or periods, is present and which have more or less diverging directions of propagation. In reporting observed wave heights and periods (or lengths) or in forecasting them, one height or one period is mentioned as the height or period, however, and some agreement is needed in order to guarantee uniformity of meaning. The height of simple waves means the elevation difference between the top of a crest and the bottom of a trough. The significant height, a characteristic height of irregular waves, is by convention the average of the highest one-third of the observed wave heights. Period, or wavelength, can be determined from the average of a number of observed time intervals between the passing of successive well-developed wave crests over a certain point, or of observed distances between them.

Wave period and wavelength are coupled by a simple relationship: wavelength equals wave period times wave speed, or $L = TC$, when L is wavelength, T is wave period, and C is wave speed.

The wave speed of surface gravity waves depends on the depth of water and on the wavelength, or period; the speed increases with increasing depth and increasing wavelength, or period. If the water is sufficiently deep, the wave speed is independent of water depth. This relationship of wave speed to wavelength and water depth (d) is given by the equations below. With g being the gravity acceleration (9.8 metres per second squared), $C^2 = gd$, when the wavelength is 20 times greater than the water depth (waves of this kind are called long gravity waves or shallow-water waves); and $C^2 = gL/2\pi$, when the wavelength is less than two times the water depth (such waves are called short waves or deep water waves). For waves with lengths between 2 and 20 times the water depth, the wave speed is governed by a more complicated equation combining these effects:

$$C = \frac{gL}{2\pi} \tanh(2\pi \frac{d}{L}),$$

where \tanh is the hyperbolic tangent.

A few examples are listed below for short waves, giving the period in seconds, the wavelength in metres, and wave speed in metres per second:

period T (sec)	1	2	4	8	16
wavelength L (m)	1.56	6.2	25.0	100	400
wave speed in deep water (m/sec)	1.56	3.1	6.2	12.5	25.0

Wave
trains and
group
velocity

Waves often appear in groups as the result of interference of wave trains of slightly differing wavelengths. A wave group as a whole has a group speed that generally is less than the speed of propagation of the individual waves; the two speeds are equal only for groups composed of long waves. For deepwater waves, the group velocity (V) is half the wave speed (C). In the physical sense, group velocity is the velocity of propagation of wave energy. From the dynamics of the waves, it follows that the wave energy per unit area of the sea surface is proportional to the square of the wave height, except for the very last stage of waves running into shallow water, shortly before they become breakers.

The height of wind waves increases with increasing wind speed and with increasing duration and fetch of the wind (*i.e.*, the distance over which the wind blows). Together with height, the dominant wavelength also increases. Finally, however, the waves reach a state of saturation because they attain the maximum significant height to which the wind can raise them, even if duration and fetch are unlimited. For instance, winds of 5 metres per second, 15 metres per second, and 25 metres per second may raise waves with significant heights up to 0.5 metre, 4.5 metres, and 12.5 metres, respectively, with corresponding wavelengths of 16 metres, 140 metres, and 400 metres, respectively.

After becoming swell, the waves may travel thousands of kilometres over the ocean, particularly if the swell is from the large storms of moderate and high latitudes, whence it easily may travel into the subtropical and equatorial zones, and the swell of the trade winds, which runs into the equatorial calms. In traveling, the swell waves grad-

ually become lower; energy is lost by internal friction and air resistance and by energy dissipation because of some divergence of the directions of propagation (fanning out). With respect to the energy loss, there is a selective damping of the composite waves, the shorter waves of the wave mixture suffering a stronger damping over a given distance than the longer ones. As a consequence, the dominant wavelength of the spectrum shifts toward the greater wavelengths. Therefore, an old swell must always be a long swell.

When waves run into shallow water, their speed of propagation and wavelength decrease, but the period remains the same. Eventually, the group velocity, the velocity of energy propagation, also decreases, and this decrease causes the height to increase. The latter effect may, however, be affected by refraction of the waves, a swerving of the wave crests toward the depth lines and a corresponding deviation of the direction of propagation. Refraction may cause a convergence or divergence of the energy stream and result in a raising or lowering of the waves, especially over nearshore elevations or depressions of the sea bottom.

In the final stage, the shape of the waves changes, and the crests become narrower and steeper until, finally, the waves become breakers (surf). Generally, this occurs where the depth is 1.3 times the wave height.

Wind surges. Running wind surges are long waves caused by a piling up of the water over a large area through the action of a traveling wind or pressure field. Examples include the surge in front of a traveling storm cyclone,

Table 9: The Beaufort Scale

Beaufort number	name of wind	wind speed		description of sea surface
		knots	km/hr	
0	calm	<1	<1	like a mirror
1	light air	1-3	1-5	ripples with the appearance of scales are formed, but without foam crests
2	light breeze	4-6	6-11	small wavelets, still short but more pronounced; crests have a glassy appearance and do not break
3	gentle breeze	7-10	12-19	large wavelets; crests begin to break; foam of glassy appearance, perhaps scattered white horses
4	moderate breeze	11-16	20-28	small waves, becoming longer; fairly frequent white horses
5	fresh breeze	17-21	29-38	moderate waves, taking a more pronounced long form; many white horses are formed (chance of some spray)
6	strong breeze	22-27	39-49	large waves begin to form; the white foam crests are more extensive everywhere (probably some spray)
7	moderate gale	28-33	50-61	sea heaps up and white foam from breaking waves begins to be blown in streaks along the direction of the wind
8	fresh gale	34-40	62-74	moderately high waves of greater length; edges of crests begin to break into spindrift; the foam is blown in well-marked streaks along the direction of the wind
9	strong gale	41-47	75-88	high waves; dense streaks of foam along the direction of the wind; crests of waves begin to topple, tumble, and roll over; spray may affect visibility
10	whole gale	48-55	89-102	very high waves with overhanging crests; the resulting foam, in great patches, is blown in dense white streaks along the direction of the wind; on the whole the surface of the sea takes a white appearance; the tumbling of the sea becomes heavy and shock-like; visibility affected
11	storm	56-65	103-117	exceptionally high waves (small and medium-sized ships might be for a time lost to view behind the waves); the sea is completely covered with long white patches of foam lying along the direction of the wind; everywhere the edges of the wave crests are blown into froth; visibility affected
12-17	hurricane	above 65	above 117	the air is filled with foam and spray; sea completely white with driving spray; visibility very seriously affected

Genera-
tion of
tsunamis

particularly the devastating hurricane surge caused by a tropical cyclone, and the surge occasionally caused by a wind convergence line, such as a traveling front with a sharp wind shift.

Waves of seismic origin. A tsunami (Japanese: *tsu*, "harbour," and *nami*, "sea") is a very long wave of seismic origin that is caused by a submarine or coastal earthquake, landslide, or volcanic eruption. Such a wave may have a length of hundreds of kilometres and a period on the order of a quarter of an hour. It travels across the ocean at a tremendous speed. (Tsunamis are long waves traveling at the wave speed given by $C^2 = gd$.) To a depth of 4,000 metres, for instance, the corresponding wave speed is about 200 metres per second, or 720 kilometres per hour. In the open ocean the height of tsunamis may be less than one metre, and they pass unnoticed. As they approach a continental shelf, however, their speed is reduced and their height increases dramatically. Tsunamis have caused enormous destruction of life and property, piling up in coastal waters at places thousands of kilometres away from their point of origin, particularly in the Pacific Ocean.

Standing, or seiche, waves. A freestanding wave may arise in an enclosed or nearly enclosed basin as a free swinging or sloshing of the whole water mass. Such a standing wave is also called a seiche, after the name given to the oscillating movements of the water of Lake Geneva, Switz., where this phenomenon first was studied seriously. The period of oscillation is independent of the force that first brought the water mass out of equilibrium (and that is supposed to have ceased thereafter), but depends only on the dimensions of the enclosing basin and on the direction in which the water mass is swinging. Assuming a simple rectangular basin of constant depth and the most simple lengthwise oscillation, the period of oscillation (T) is equal to two times the length of the basin divided by the wave speed computed from the shallow-water formula above. This relationship may be written: $T = L/C$, in which L equals two times the length of the basin and C is the wave speed found from the formula, using the known depth of the basin. Besides this fundamental tone (or response to stimuli), the water mass also may swing according to an overtone, showing one or more nodal lines across the basin.

The water in an open bay or marginal sea also may perform such a free oscillation as a standing wave, the difference being that in an open bay the greatest horizontal displacements are not in the middle of the bay but at the mouth. For the fundamental period of oscillation, the formula given above is used with a wavelength equal to four times the length (from the mouth to the closed end) of the bay. In practice, of course, it is more difficult than that, because the form of a bay or marginal sea is irregular and the depth differs from place to place. The North Sea has a period of lengthwise swinging of about 36 hours. The cause of such free oscillations may be a temporary wind or pressure field, which brought the sea surface out of its horizontal position and which afterward ceased to act more or less abruptly, leaving the water mass out of equilibrium.

Internal waves. Gravity waves also occur on internal "surfaces" within oceans. These surfaces represent strata of rapidly changing water density with increasing depth, and the associated waves are called internal waves. Internal waves manifest themselves by a regular rising and sinking of the water layers around which they centre, whereas the height of the sea surface is hardly affected at all. Because the restoring force, excited by the internal deformation of the water layers of equal density, is much smaller than in the case of surface waves, internal waves are much slower than the latter. Given the same wavelength, the period is much longer (the movements of the water particles being much more sluggish), and the speed of propagation is much smaller; the formulas for the speed of surface waves include the acceleration of gravity, g , but those for internal waves include the gravity factor times the difference between the densities of the upper and the lower water layer divided by their sum.

The cause of internal waves may lie in the action of tidal forces (the period then equaling the tidal period) or in

the action of a wind or pressure fluctuation. Sometimes, a ship may cause internal waves (dead water) if there is a shallow, brackish upper layer.

OCEAN TIDES

The tides may be regarded as forced waves, partially running waves and partially standing waves. They are manifested by vertical movements of the sea surface (the height maximum and minimum are called high water [HW] and low water [LW]) and in alternating horizontal movements of the water, the tidal currents. The words ebb and flow are used to designate the falling tide and the rising tide, respectively.

Tide-generating forces. The forces that cause the tides are called the tide-generating forces. A tide-generating force is the resultant force of the attracting force of the Moon or the Sun and the force of inertia (centrifugal force) that results from the orbital movement of the Earth around the common centre of gravity of the Earth-Moon or Earth-Sun system.

Considering the Earth-Moon system, at any time the tide-generating force is directed vertically upward at the two places on the Earth where the Moon is in the vertical (on the same and on the opposite side of the Earth); it is directed vertically downward at all places (forming a circle) where the Moon is in the horizon at that moment. At all other places, the tide-generating force also has a horizontal component. Because this pattern of forces is coupled to the position of the Moon with respect to the Earth and because for any place on the Earth's surface the relative position of the Moon with respect to that place has, on the average, a periodicity of 24 hours 50 minutes, the tide-generating force felt at any place has that same periodicity. When the Moon is in the plane of the equator, the force runs through two identical cycles within this time interval because of the symmetry of the global pattern of forces described above. Consequently, the tidal period is 12 hours 25 minutes in this case; it is the period of the semidiurnal lunar tide. The fact that the Moon is alternately to the north and to the south of the equator causes an inequality of the two successive cycles within the time interval of 24 hours 50 minutes. The effect of this inequality is formally described as the superposition of a partial tide called the diurnal lunar tide, with the period of 24 hours 50 minutes, on the semidiurnal lunar tide.

In the same manner, the Sun causes a semidiurnal solar tide, with a 12-hour period, and a diurnal solar tide, with a 24-hour period. In a complete description of the local variations of the tidal forces, still other partial tides play a role because of further inequalities in the orbital motions of the Moon and the Earth.

The interference of the solar-tidal forces with the lunar-tidal forces (the lunar forces are about 2.2 times as strong) causes the regular variation of the tidal range between spring tide, when it has its maximum, and neap tide, when it has its minimum.

Although the tide-generating forces are very small in comparison with the Earth's force of gravity (the lunar tidal force at its maximum being only 1.14×10^{-7} times the force of gravity), their effects upon the sea are considerable because of their horizontal component. Since the Earth is not surrounded by an uninterrupted envelope of water but rather shows a very irregular alternation of sea and land, the mechanism of the response of the oceans and seas to the tidal forces is extremely complex. A further complication is caused by the deflecting force of the Earth's rotation (the Coriolis force; see above).

In enclosures formed by gulfs and bays, the local tide is generated by interaction with the tides of the adjacent open ocean. Such a tide often takes the form of a running tidal wave that rotates within the confines of the enclosure. In some semi-enclosed seas, such as the Mediterranean, Black, and Baltic seas, a standing wave, or tidal seiche, may be generated by the local tide-raising forces.

In these seas, the tidal range of sea level is only on the order of centimetres. In the open ocean, it generally is on the order of tens of centimetres. In bays and adjacent seas, however, the tidal range may be much greater, because the shape of a bay or adjacent sea may favour the

Running
tidal wave

Cause of
internal
waves

enhancement of the tide inside; in particular, there may be a resonance of the basin concerned with the tide. The largest known tides occur in the Bay of Fundy, where spring tidal ranges up to 15 metres have been measured.

Tidal bores. Tidal bores form on rivers and estuaries near a coast where there is a large tidal range and the incoming tide is confined to a narrow channel. They consist of a surge of water moving swiftly upstream headed by a wave or series of waves. Such bores are quite common. There is a large one, known as the *mascaret* on the Seine, which forms on spring tides and reaches as far upriver as Rouen. There is a well-known bore on the Severn, in England, and another forms on the Petitcodiac River, which empties into the Bay of Fundy in New Brunswick. The classic example is the bore on the Ch'ien-t'ang described by Commander W. Osborne Moore of the British navy in 1888 and 1892. He reported heights of 2.5 to 3.5 metres.

When a tidal bore forms in a river, the direction of flow of the water changes abruptly as the bore passes. Before it arrives, the water may be still or, more usually, a small freshwater current flows outward toward the sea. The tide comes in as a "wall of water" that passes up the river. Behind the bore, the current flows upriver. At the division between the moving water behind the bore and the still water in front, there is a wave, the water surface behind being higher than it is in front. This wave must travel more quickly than the water particles behind it, because, as the advancing water travels upriver, it collects the still water in front and sets it in motion. Upriver, the advancing tide will consist not of salt water from the sea but rather of fresh water that has passed farther down and been collected and returned in front of the incoming tide. It is therefore necessary to distinguish between the velocity of the advancing wave and that of the water particles just behind it.

(P.Gr./R.A.R.T./A.L.G.)

Density currents in the oceans

GENERAL OBSERVATIONS

Density currents are currents that are kept in motion by the force of gravity acting on a relatively small density difference caused by variations in salinity, temperature, or sediment concentration. As noted above, salinity and temperature variations produce stratification in oceans. Below the surface layer, which is disturbed by waves and is lighter than the deeper waters because it is warmer or less saline, the oceans are composed of layers of water that have distinctive chemical and physical characteristics, which move more or less independently of each other and which do not lose their individuality by mixing even after they have flowed for hundreds of kilometres from their point of origin.

Stratified
flow

An example of this type of density current, or stratified flow, is provided by the water of the Mediterranean Sea as it flows through the Strait of Gibraltar out into the Atlantic. Because the Mediterranean is enclosed in a basin that is relatively small compared with the ocean basins and because it is located in a relatively arid climate, evaporation exceeds the supply of fresh water from rivers. The result is that the Mediterranean contains water that is both warmer and more saline than normal deep-sea water, the temperature ranging from 12.7° to 14.5° C and the salinity from 38.4 to 39.0 parts per thousand. Because of these characteristics, the Mediterranean water is considerably denser than the water in the upper parts of the North Atlantic, which has a salinity of about 36 parts per thousand and a temperature of about 13° C. The density contrast causes the lighter Atlantic water to flow into the Mediterranean in the upper part of the Strait of Gibraltar (down to a depth of about 200 metres) and the denser Mediterranean water to flow out into the Atlantic in the lower part of the strait (from about 200 metres to the top of the sill separating the Mediterranean from the Atlantic at a depth of 320 metres). Because the strait is only about 20 kilometres wide, both inflow and outflow achieve relatively high speeds. Near the surface the inflow may have speeds as high as two metres per second, and the outflow reaches speeds of more than one metre per second at a depth of about 275 metres. One result of the high current

speeds in the strait is that there is a considerable amount of mixing, which reduces the salinity of the outflowing Mediterranean water to about 37 parts per thousand. The outflowing water sinks to a depth of about 1,500 metres or more, where it encounters colder, denser Atlantic water. It then spreads out as a layer of more saline water between two Atlantic water masses.

TURBIDITY CURRENTS

Density currents caused by suspended sediment concentrations in the oceans are called turbidity currents. They appear to be relatively short-lived, transient phenomena that occur at great depths. Turbidity currents are thought to be caused by the slumping of sediment that has piled up at the top of the continental slope, particularly at the heads of submarine canyons (see below *Continental margins: Submarine canyons*). Slumping of large masses of sediment creates a dense sediment-water mixture, or slurry, which then flows down the canyon to spread out over the ocean floor and deposit a layer of sand in deep water. Repeated deposition forms submarine fans, which are analogous to the alluvial fans found at the mouths of many river canyons. Sedimentary rocks that are thought to have originated from ancient turbidity currents are called turbidites.

Although large-scale turbidity underflows have never been directly observed in the oceans, there is much evidence supporting their occurrence. This evidence may be briefly summarized: (1) Telegraph cables have been broken in the deep ocean in a sequence that indicates some disturbance at the bottom moving from shallow to deep water at speeds on the order of 20 to 75 kilometres per hour, or 10 to 40 knots. The trigger for this phenomenon is commonly, though not exclusively, an earthquake near the edge of the continental slope. The only disturbance that seems capable of being transmitted downslope at the required speed is a large turbidity current. The best-known example of such a series of cable breaks took place in the North Atlantic following the 1929 earthquake under the Grand Banks of Newfoundland (Figure 18), but other examples have been described from the Magdalena River delta (Colombia), the Congo delta, the Mediterranean Sea north of Orleansville and south of the Straits of Messina, and Kandavu Passage, Fiji. (2) Cores taken from the ocean bottom in the area downslope from cable breaks reveal layers of sand interbedded with normal deep-sea pelagic or hemipelagic oozes (sediments formed in the deep sea by quiet settling of fine particles). In the case of the cable breaks south of the Grand Banks, a large-diameter core taken from the axis of a submarine canyon in the continental slope contained 1 centimetre of gray clay underlain by at least

Evidence
for
turbidity
currents

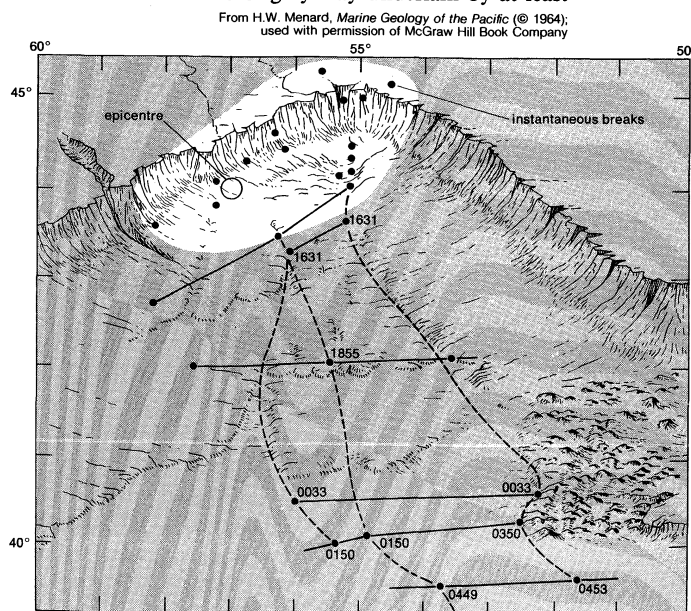

Figure 18: Location of cables (heavy lines) and times of breaks following the Grand Banks earthquake of 1929.

20 centimetres of gray pebble and cobble gravel. Cores farther south showed a graded layer about one metre-thick of coarse silt and fine sand. The presence of these gravel and sand layers is consistent with the hypothesis that they were deposited by the turbidity current that broke the cables. (3) Coring has revealed layers of fine-grained sand or coarse silt at many other localities in the abyssal plains of the oceans. These layers are generally moderately well sorted and contain microfossils characteristic of shallow water that are also size-sorted. In some cases the layers are laminated and arranged in a definite sequence (Figure 19). It is clear that the sand forming these layers has been moved down from shallow water, and in many cases the only plausible mechanism appears to be a turbidity current. (4) At the base of many submarine canyons there occur very large submarine fans. Deep-sea channels on the fan surfaces extend for many tens of kilometres and have depths of more than 100 metres and widths of one kilometre or more. Submarine levees are a prominent feature, and these project above the surrounding fan surface to elevations of 50 metres or higher. The gross characteristics of such channels suggest that they were formed by a combination of erosion and deposition by turbidity currents. (5) Thick deposits of interbedded graded sandstones and fine-grained shales are common in the geologic record. In some cases there is good fossil evidence that the shales were deposited in relatively deep water, perhaps as much as several thousand metres deep. Relatively deepwater deposition is also suggested by the absence of sedimentary structures characteristic of shallow water. The interbedded sandstones, however, contain shallow-water fossils that are sorted by size, have a sharp basal contact with the shale below and a transitional contact with the shale above, and display a characteristic sequence of sedimentary structures (Figure 19). The structures include erosional marks made originally on the mud surface but now preserved as casts on the base of the sandstone bed (sole marks) and internal structures including some or all of the following: massive

Turbidites

graded unit, parallel lamination, ripple cross-lamination or convolute lamination, and an upper unit of parallel lamination. This combination of textural and structural features can be explained by deposition from a current that slightly erodes the bottom and then deposits sand that becomes finer grained as the velocity gradually wanes. The properties inferred from these ancient sandstone deposits are consistent with the properties of turbidity currents inferred from laboratory experiments.

In spite of the convincing nature of the evidence, there are still some objections to the turbidity current hypothesis. Most geologists and oceanographers accept that such currents exist and that the currents are important agents of erosion and sediment deposition, in both modern and ancient seas, but researchers believe that the turbidity current hypothesis has been overworked. There is evidence, for example, which suggests that currents flowing parallel to submarine contours exist in many ocean basins. These bottom currents have been observed in a few cases, and velocities as high as 20 to 50 centimetres per second have been recorded. These currents can produce some of the features that previously had been attributed to turbidity current action. Moreover, nearly all features of sands that are produced by turbidity currents can be formed by shallow-water action, such as fluvial processes. Hence the problem of discriminating between deposits formed by turbidity currents and deposits formed by other current types is quite complex and requires a careful assessment of all lines of evidence in each case. Some ancient sandstones have been interpreted as "fluxoturbidites" because the sedimentary structures and other properties suggest a transporting agent intermediate between turbidity currents and large-scale slumping and sliding of sediment.

Impact of ocean-atmosphere interactions on weather and climate

SEASONAL AND INTERANNUAL OCEAN-ATMOSPHERE INTERACTIONS

General considerations. The notion of a connection between the temperature of the surface layers of the oceans and the circulation of the lowest layer of the atmosphere, the troposphere, is a familiar one. The surface mixed layer of the ocean is a huge reservoir of heat when compared to the overlying atmosphere. The heat capacity of an atmospheric column of unit area cross-section extending from the ocean surface to the outermost layers of the atmosphere is equivalent to the heat capacity of a column of seawater of 2.6-metre depth. The surface layer of the oceans is continuously being stirred by the overlying winds and waves, and thus a surface mixed layer is formed that has vertically uniform properties in temperature and salinity. This mixed layer, which is in direct contact with the atmosphere, has a minimum depth of 20 metres in summer and a maximum depth exceeding 100 metres in late winter in the mid-latitudes. In lower latitudes the seasonal variation in the mixed layer is less marked than at higher latitudes, except in regions such as the Arabian Sea where the onset of the southwestern Indian monsoon may produce large changes in the depth of the mixed layer. Temperature anomalies (*i.e.*, deviations from the normal seasonal temperature) in the surface mixed layer have a long residence time compared with those of the overlying turbulent atmosphere. Hence they may persist for a number of consecutive seasons and even for years.

Long-lived temperature anomalies

Observational studies to investigate the relationship between anomalies in ocean surface temperature and the tropospheric circulation have been undertaken primarily in the Pacific and Atlantic. They have identified large-scale ocean surface temperature anomalies that have similar spatial scales to monthly and seasonal anomalies in atmospheric circulation. The longevity of the ocean surface temperature anomalies, as compared with the shorter dynamical and thermodynamical "memory" of the atmosphere, has suggested that they may be an important predictor for seasonal and interannual climate anomalies.

Link between ocean surface temperature and climate anomalies. First, it is useful to consider some examples

of the association between anomalies in ocean surface temperature and irregular changes in climate. The Sahel, a region that borders the southern fringe of the Sahara in Africa, experienced a number of devastating droughts during the 1970s and '80s, which can be compared with a much wetter period during the 1950s. Figure 20 shows the difference in ocean surface temperature during the period from July to September between the "driest" and "wettest" rainfall seasons in the Sahel after 1950. Of particular note are the higher-than-normal surface temperatures in the tropical South Atlantic, Indian, and Southeast Pacific oceans and the lower-than-normal temperatures in the North Atlantic and Pacific oceans. This example illustrates that climate anomalies in one region of the world may be linked to ocean surface temperature changes on a global scale. Global atmospheric modeling studies undertaken during the mid-1980s have indicated that the positions of the main rainfall zones in the tropics are sensitive to anomalies in ocean surface temperature similar to that depicted in Figure 20.

Shorter-lived climate anomalies, on time scales of months to one or two years, also have been related to ocean surface temperature anomalies. The equatorial oceans have the largest influence on these climate anomalies because of the evaporation of water. A relatively small change in ocean surface temperature, say, of 1°C , may result in a large change in the evaporation of water into the atmosphere. The increased water vapour in the lower atmosphere is condensed in regions of upward motion known as convergence zones. This process liberates latent heat of condensation, which in turn provides a major fraction of the energy to drive tropical circulation and is one of the mechanisms responsible for the El Niño/Southern Oscillation phenomenon discussed later in this article.

Given the sensitivity of the tropical atmosphere to variations in tropical sea surface temperature, there also has been considerable interest in their influence on extratropical circulation. The sensitivity of the tropospheric circulation to surface temperature in both the tropical Pacific and Atlantic oceans has been shown in theoretical and observational studies alike. Figure 21 demonstrates the correlation between the equatorial ocean surface temperature in the east Pacific (the location of El Niño) and the atmospheric circulation in the middle troposphere during winter. The atmospheric pattern is a characteristic circulation type known as the Pacific-North American (PNA) mode. Such patterns are intrinsic modes of the atmosphere, which may be forced by thermal anomalies in the

Figure 21: Correlation between sea surface temperature in the eastern equatorial Pacific Ocean (region from the 180th meridian eastward to the coast of South America, from 6°N to 6°S) and the Northern Hemisphere circulation in the middle troposphere during the cold season (November to April) for the period between 1950 and 1979. Contours are at intervals of 0.1; the dashed contours indicate negative correlations.

tropical atmosphere and which in their turn are forced by tropical ocean surface temperature anomalies. As noted earlier, enhanced tropical sea surface temperatures increase evaporation into the atmosphere. In the 1982–83 El Niño event a pattern of circulation anomalies similar to that in Figure 21 occurred throughout the Northern Hemisphere during winter. These modes of the atmosphere, however, account for much less than 50 percent of the variability of the circulation in mid-latitudes, though in certain re-

Sensitivity of the tropical atmosphere to ocean surface temperature

gions (northern Japan, southern Canada, and the southern United States), they may have sufficient amplitude for them to be used for predicting seasonal surface temperature perhaps up to two seasons in advance.

The response of the atmosphere to mid-latitude ocean surface anomalies has been difficult to detect unambiguously because of the complexity of the turbulent westerly flow between 20° and 60° latitude in both hemispheres. This flow has many properties of nonlinear chaotic systems and thus exhibits behaviour that is difficult to predict beyond a couple of weeks. The atmosphere alone can exhibit large fluctuations on seasonal and longer time scales without any change in external forcing conditions, such as ocean surface temperature. Notwithstanding this inherent problem, some effects of ocean surface temperature anomalies on the atmosphere have been observed and modeled.

The influence of the oceans on the atmosphere in the mid-latitudes is greatest during autumn and early winter when the ocean mixed layer releases to the atmosphere the large quantities of heat that it has stored up over the previous summer. Anomalies in ocean surface temperature are indicative of either a surplus or a deficiency of heat available to the atmosphere. The response of the atmosphere to ocean surface temperature, however, is not random geographically. The circulation over the North Atlantic and northern Europe during early winter has been found to be sensitive to large ocean surface temperature anomalies south of Newfoundland. When a warm positive anomaly exists in this region, an anomalous surface anticyclone occurs in the central Atlantic at a similar latitude to the temperature anomaly, and an anomalous cyclonic circulation is located over the North Sea, Scandinavia, and central Europe. With colder than normal water south of Newfoundland, the circulation patterns are reversed, producing cyclonic circulation over the central Atlantic and anticyclonic circulation over Europe. The sensitivity of the atmosphere to ocean surface temperature anomalies in this particular region is thought to be related to the position of the overlying storm tracks and jet stream. The region is the most active in the Northern Hemisphere for the growth of storms associated with very large heat fluxes from the surface layer of the ocean.

Another example of a similar type of air-sea interaction event has been documented over the North Pacific Ocean. A statistical seasonal relationship exists between the summer ocean temperature anomaly in the Gulf of Alaska and the atmospheric circulation over the Pacific and North America during the following autumn and winter. The presence of warmer-than-normal ocean surface temperature in the Gulf of Alaska results in increased cyclone development during the subsequent autumn and winter. The relationship has been established by means of monthly sea surface temperature and atmospheric pressure data collected over 30 years in the North Pacific Ocean.

The air-sea interaction events in both the North Pacific and North Atlantic oceans discussed above raise questions as to how the anomalies in ocean surface temperature in these areas are initiated, how they are maintained, and whether they yield useful information for atmospheric prediction beyond the normal time scales of weather forecasting (*i.e.*, one to two weeks). Statistical analysis of previous case studies have shown that ocean surface temperature anomalies initially develop in response to anomalous atmospheric forcing. Once developed, however, the temperature anomaly of the ocean surface tends to reinforce and thereby maintain the anomalous atmospheric circulation. The mechanisms thought to be responsible for this behaviour in the ocean are the surface wind drift, wind mixing, and the interchange of heat between the ocean and atmosphere. The question of prediction is therefore difficult to answer, as these events depend on a synchronous and interconnected behaviour between the atmosphere and the surface layer of the ocean, which allows for positive feedback between the two systems.

FORMATION OF TROPICAL CYCLONES

Tropical cyclones represent still another example of sea-air interactions. These storm systems are known as hur-

ricanes in the North Atlantic and eastern North Pacific and as typhoons in the western North Pacific. The winds of such systems revolve around a centre of low pressure in an anticlockwise direction in the Northern Hemisphere and in a clockwise direction in the Southern Hemisphere. The winds attain velocities in excess of 115 kilometres per hour, or 65 knots, in most cases. Tropical cyclones may last from a few hours to as long as two weeks, the average lifetime being six days.

The oceans provide the source of energy for tropical cyclones both by direct heat transfer from their surface (known as sensible heat) and by the evaporation of water. This water is subsequently condensed within a storm system, thereby releasing latent heat energy. When a tropical cyclone moves over land, this energy is severely depleted and the circulation of the winds is consequently weakened.

Such storms are truly phenomena of the tropical oceans. They originate in two distinct latitude zones, between 4° and 22° S and between 4° and 35° N. They are absent in the equatorial zone between 4° S and 4° N. Most tropical cyclones are spawned on the poleward side of the region known as the intertropical convergence zone (ITCZ).

More than two-thirds of observed tropical cyclones originate in the Northern Hemisphere, and roughly the same proportion occur in the Eastern Hemisphere. The North Pacific has more than one-third of all such storms, while the southeast Pacific and South Atlantic are normally devoid of them. Most northern hemispheric tropical cyclones occur between May and November, with peak periods in August and September. The majority of southern hemispheric cyclones occur between December and April, with peaks in January and February.

Conditions associated with cyclone formation. The formation of tropical cyclones is strongly influenced by the temperature of the underlying ocean or, more specifically, by the thermal energy available in the upper 60 metres of ocean waters. Typically, the underlying ocean should have a temperature in excess of 26° C in this layer. This temperature requirement, however, is only one of five that need to be met for a tropical cyclone to form and develop. The other preconditions relate to the state of the tropical atmosphere between the sea surface and a height of 16 kilometres, the boundary of the tropical troposphere. They can be summarized as follows:

1. A deep convergence of air must occur in the troposphere between the surface and a height of seven kilometres that produces a cyclonic circulation in the lower troposphere overlain by an anticyclonic circulation in the upper troposphere. The stronger the inflow, or convergence, of the air, the more favourable are the conditions for tropical cyclone formation.

2. The vertical shear of the horizontal wind velocity between the lower troposphere and the upper troposphere should be at minimum. Under this condition the heat and moisture are retained rather than being exchanged and diluted with the surrounding air. Monsoonal and trade wind flows are characterized by a large vertical shear of the horizontal wind and so are not generally conducive to tropical cyclone development.

3. A strong vertical coupling of the flow patterns between the upper and lower troposphere is required. This is achieved by large-scale deep convection associated with cumulonimbus clouds.

4. A high humidity level in the middle troposphere from three to six kilometres in height is more conducive to the production of deep cumulonimbus convection and therefore to stronger vertical coupling in the troposphere.

All these conditions may be met but still not lead to cyclone formation. It is thought that the most important factor is the presence of a large-scale cyclonic circulation in the lower troposphere. The above conditions occur for a period of 5 to 15 days and are followed by less favourable conditions for a duration of 10 to 20 days.

Once a tropical cyclone has formed, it usually follows certain distinct stages during its lifetime. In its formative stage the winds are below hurricane force and the central pressure is about 1,000 millibars. The formative period is extremely variable in length, ranging from 12 hours to a few days. This stage is followed by a period of inten-

Tem-
perature
criterion

Inter-
connected
behaviour
between
the atmo-
sphere and
the oceanic
surface
layer

sification, when the central pressure drops rapidly below 1,000 millibars. The winds increase rapidly, and they may achieve hurricane force within a radius of 30 to 50 kilometres of the storm centre. At this stage the cloud and rainfall patterns become well organized into narrow bands that spiral inward toward the centre. In the mature phase the central pressure stops falling and, as a consequence, the winds no longer increase. The region of hurricane force winds, however, expands to occupy a radius of 300 kilometres or more. This expansion is not symmetrical around the storm centre; the strongest winds occur toward the right-hand side of the centre in the direction of the cyclone's path. The period of maturity may last for one to three days. The terminal stage of a tropical cyclone is usually reached when the storm strikes land, followed by a resultant increase in energy dissipation by surface friction and a reduction in its energy supply of moisture. A reduction in moisture input into the storm system may also take place when it moves over a colder segment of the ocean. A tropical cyclone may regenerate in higher latitudes as an extratropical depression, but it loses its identity as a tropical storm in the process. The typical lifetime of a tropical cyclone from its birth to death is about six days.

The paths of tropical cyclones show a wide variation. In both the North Atlantic and the North Pacific, the paths tend to be initially northwestward and then recurve toward the northeast at higher latitudes. It is now known that the tracks of tropical cyclones are largely determined by the large-scale tropospheric flow. This fact opens up the possibility that, with the aid of high-resolution numerical models, accurate predictions of their tracks may become feasible. The development of polar-orbiting and geostationary satellites has made it possible to accurately track cyclones over the remotest areas of the tropical oceans.

Effects of tropical cyclones on ocean waters. A tropical cyclone can affect the thermal structure and currents in the surface layer of the ocean waters in its path. Cooling of the surface layer occurs in the wake of such a storm. As can be seen in Figure 22, maximum cooling occurs on the right of a hurricane's path in the Northern Hemisphere. In the wake of Hurricane Hilda's passage through the Gulf of Mexico in 1964 at a translational speed of only five knots, the surface waters were cooled by as much as 6° C. Tropical cyclones that have higher translational velocities cause less cooling of the surface. The surface cooling is caused primarily by wind-induced upwelling of cooler water from below the surface layer. The warm surface water is simultaneously transported toward the periphery of the cyclone, where it downwells into the deeper ocean layers (Figure 23). Heat loss across the air-sea interface and the wind-induced mixing of the surface water with those of the cooler subsurface layers make a significant but smaller contribution to surface cooling.

In addition to surface cooling, tropical cyclones may induce large horizontal surge currents and vertical displacements of the thermocline. The surge currents have their largest amplitude at the surface, where they may reach ve-

Figure 23: (Top) Surface wind pattern around a symmetrical stationary hurricane in simplified form. (Bottom) Induced water motions.

From G.A. Franceschini and S.Z. El-Sayad, "Effect of Hurricane Inez (1966) on the Hydrography and Productivity of the Western Gulf of Mexico," *Deutsche Hydrographische Zeitschrift* (April 21, 1968)

locities approaching one metre per second. The horizontal currents and the vertical displacement of the thermocline observed in the wake of a tropical cyclone oscillate close to the inertial period. These oscillations remain for a few days after the passage of the storm and spread outward from the rear of the system as an internal wake on the thermocline. The vertical motion may transport nutrients from the deeper layers into the sunlit surface waters, which in turn promotes phytoplankton blooms (*i.e.*, the rapid growth of diatoms and other minute one-celled organisms). The ocean surface temperature normally recovers to its precyclone value within 10 days of a storm's passage.

Influence on atmospheric circulation and rainfall. Tropical cyclones play an important role in the general circulation of the atmosphere, accounting for 2 percent of the global annual rainfall and between 4 and 5 percent of the global rainfall in August and September at the height of the Northern Hemispheric cyclone season. For a local area, the occurrence of a single tropical cyclone can have a major impact on the region's annual rainfall. Furthermore, tropical cyclones contribute approximately 2 percent of the kinetic energy of the general circulation of the atmosphere, some of which is exported from the tropics to higher latitudes.

THE GULF STREAM AND KUROSHIO SYSTEMS

The Gulf Stream. This major current system, as described earlier, is a western boundary current that flows poleward along a boundary separating the warm and more saline waters of the Sargasso Sea to the east from the colder, slightly fresher continental slope waters to the north and west. The warm, saline Sargasso Sea, composed of a water mass known as North Atlantic Central Water, has a temperature that ranges from 8° to 19° C and a salinity between 35.10 and 36.70 parts per thousand. This is one of the two dominant water masses of the North Atlantic Ocean, the other being the North Atlantic Deep Water, which has a temperature of 2.2° to 3.5° C and a salinity between 34.90 and 34.97 parts per thousand, and which occupies the deepest layers of the ocean (generally below 1,000 metres). The North Atlantic Central Water occupies the upper layer of the North Atlantic Ocean between roughly 20° and 40° N. The "lens" of this water is at its lowest depth of 1,000 metres in the northwest Atlantic and becomes progressively shallower to the east and south. To the north it shallows abruptly and outcrops at the surface in winter (Figure 24), and it is at this point that the Gulf Stream is most intense.

The Gulf Stream flows along the rim of the warm North Atlantic Central Water northward from the Florida Straits

Path of the Gulf Stream

Surface cooling

Figure 24: The approximate depth of the North Atlantic Central Water, as indicated by the depth of the 10° C isothermal surface in the western North Atlantic. Depth values are in metres.

From H. Stommel, *The Gulf Stream* (1966); University of California Press and Cambridge University Press, after C.O.D. Iselin, *Papers in Physical Oceanography and Meteorology*, vol. 4, no. 4 (1936)

along the continental slope of North America to Cape Hatteras. There, it leaves the continental slope and turns northeastward as an intense meandering current that extends toward the Grand Banks of Newfoundland. Its maximum velocity is typically between one and two metres per second. At this stage, a part of the current loops back onto itself, flowing south and east. Another part flows eastward toward Spain and Portugal, while the remaining water flows northeastward as the North Atlantic Drift (also called the North Atlantic Current) into the northernmost regions of the North Atlantic Ocean between Scotland and Iceland.

The southward-flowing currents are generally weaker than the Gulf Stream and occur in the eastern lens of the North Atlantic Central Water or the subtropical gyre (see above *Circulation of the ocean waters: Wind-driven circulation: The subtropical gyres*). The circulation to the south on the southern rim of the subtropical gyre is completed by the westward-flowing North Equatorial Current, part of which flows into the Gulf of Mexico; the remaining part flows northward as the Antilles Current. This subtropical gyre of warm North Atlantic Central Water is the hub of the energy that drives the North Atlantic circulation. It is principally forced by the overlying atmospheric circulation, which at these latitudes is dominated by the clockwise circulation of a subtropical anticyclone. This circulation is not steady and fluctuates in particular on its poleward side where extratropical cyclones in the westerlies periodically make incursions into the region. On the western side, hurricanes (during the period from May to November) occasionally disturb the atmospheric circulation. Because of the energy of the subtropical gyre and its associated currents, these short-term fluctuations have little influence on it, however. The gyre obtains most of its energy from the climatological wind distribution over periods of one or two decades. This wind distribution drives a system of surface currents in the uppermost 100 metres of the ocean. Nonetheless, these currents are not simply a reflection of the surface wind circulation as they are influenced by the Coriolis force (see above *Circulation of the ocean waters: Wind-driven circulation: Coriolis effect*). The wind-driven current decays with depth, becoming negligible below 100

metres. The water in this surface layer is transported to the right and perpendicular to the surface wind stress because of the Coriolis force. Hence an eastward-directed wind on the poleward side of the subtropical anticyclone would transport the surface layer of the ocean to the south. On the equatorward side of the anticyclone the trade winds would cause a contrary drift of the surface layer to the north and west. Thus surface waters under the subtropical anticyclone are driven toward the mid-latitudes at about 30° N. These surface waters, which are warmed by solar heating and have a high salinity by virtue of the predominance of evaporation over precipitation at these latitudes, then converge and are forced downward into the deeper ocean.

Over many decades this process forms a deep lens of warm, saline North Atlantic Central Water. The shape of the lens of water is distorted by other dynamical effects, the principal one being the change in the vertical component of the Coriolis force with latitude known as the beta effect. This effect involves the displacement of the warm water lens toward the west, so that the deepest part of the lens is situated to the north of the island of Bermuda rather than in the central Atlantic Ocean. This warm lens of water plays an important role, establishing as it does a horizontal pressure gradient force in and below the wind-drift current. The sea level over the deepest part of the lens is about one metre higher than outside the lens. The Coriolis force in balance with this horizontal pressure gradient force gives rise to a dynamically induced geostrophic current, which occurs throughout the upper layer of warm water. The strength of this geostrophic current is determined by the horizontal pressure gradient through the slope in sea level. The slope in sea level across the Gulf Stream has been measured by satellite radar altimeter to be one metre over a horizontal distance of 100 kilometres, which is sufficient to cause a surface geostrophic current of one metre per second at 43° N.

The large-scale circulation of the Gulf Stream system is, however, only one aspect of a far more complex and richer structure of circulation. Embedded within the mean flow is a variety of eddy structures that not only put kinetic energy into circulation but also carry heat and other important properties, such as nutrients for biological systems. The best known of these eddies are the Gulf Stream rings, which develop in meanders of the current east of Cape Hatteras. Though the eddies were mentioned as early as

Transport of heat and nutrients

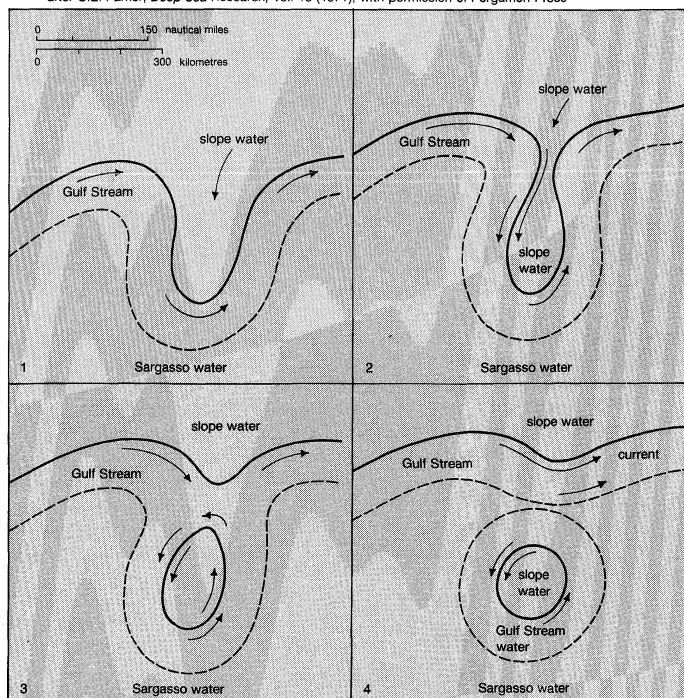

Figure 25: Gulf Stream ring generation from (1-4) meander formation to separation (see text).

The effect of the wind on surface currents

1793 by Jonathan Williams, a grandnephew of Benjamin Franklin, they were not systematically studied until the early 1930s by the oceanographer Phil E. Church. Intensive research programs were finally undertaken during the 1970s. Gulf Stream rings have either warm or cold cores. The warm rings are typically 100 to 300 kilometres in diameter and have a clockwise rotation. They consist of waters from the Gulf Stream and Sargasso Sea and form when the meanders in the Gulf Stream pinch off on its continental slope side (see Figure 25). They move generally westward, flowing at the speed of the slope waters, and are reabsorbed into the Gulf Stream at Cape Hatteras after a typical lifetime of about six months. The cold core rings, composed of a mixture of Gulf Stream and continental slope waters, are formed when the meanders pinch off to the south of the Gulf Stream. They are a little larger than their warm-core counterparts, characteristically having diameters of 200 to 300 kilometres and an anticlockwise rotation. They move generally southwestward into the Sargasso Sea and have lifetimes of one to two years. The cold-core rings are usually more numerous than warm-core rings, typically 10 each year as compared with five warm-core rings annually.

The Kuroshio. This western boundary current is similar to the Gulf Stream in that it produces both warm and cold rings. The warm rings are generally 150 kilometres in diameter and have a lifetime similar to their Gulf Stream counterparts. The cold rings form at preferential sites and in most cases drift southwestward into the Western Pacific Ocean. Occasionally a cold ring has been observed to move northwestward and eventually be reabsorbed into the Kuroshio.

Poleward transfer of heat. A significant characteristic of the large-scale North Atlantic circulation is the poleward transport of heat depicted in Figure 26. Heat is transferred in a northward direction throughout the North Atlantic. This heat is absorbed by the tropical waters of the Pacific and Indian oceans, as well as of the Atlantic, and is then transferred to the high latitudes, where it is finally given up to the atmosphere.

The mechanism for the heat transfer is principally by thermohaline circulation rather than by wind-driven circulation (see above *Circulation of the ocean waters: Thermohaline circulation*). Circulation of the thermohaline type involves a large-scale overturning of the ocean, with warm and saline water in the upper 1,000 metres moving northward and being cooled in the Labrador, Greenland, and Norwegian seas. The density of the water in contact with the atmosphere is increased by surface cooling, and the water subsequently sinks below the surface layer to the lowest depths of the ocean. This water is mixed with the surrounding water masses by a variety of processes to form North Atlantic Deep Water. The water moves slowly southward as the lower limb of the thermohaline circulation. It is this overturning circulation that is responsible for the warm winter climate of northwestern Europe (notably the British Isles and Norway) rather than the horizontal wind-driven circulation discussed above.

The North Atlantic Drift, which is an extension of the Gulf Stream system to the south, provides this northward flow of warm and saline waters into the polar seas. This feature makes the circulation of the North Atlantic Ocean uniquely different from that of the Pacific Ocean, which has a less effective thermohaline circulation. Although there is a northward transfer of heat in the North Pacific, the subtropical wind-driven gyre in the upper ocean is mainly responsible for it. Thus the Kuroshio on the western boundary of the North Pacific gyre is principally driven by the surface wind circulation of the North Pacific.

Studies of the sediment cores obtained from the ocean floor have indicated that the ocean surface temperature was as much as 10° C cooler than today in the northernmost region of the North Atlantic Ocean during the last glacial maximum some 18,000 years ago. This difference in surface temperature would indicate that the warm North Atlantic Drift was much reduced compared to what it is at present, and hence the thermohaline circulation was considerably weaker. In contrast, the Gulf Stream was probably more intense than it is today and exhibited a large shift from its present path to an eastward flow at 40° N. (N.C.W.)

EL NIÑO/SOUTHERN OSCILLATION AND CLIMATIC CHANGE

As was explained earlier, the oceans can moderate the climate of certain regions. Not only do they affect such geographic variations, but they also influence temporal changes in climate. The time scales of climate variability range from a few years to millions of years and include the so-called ice age cycles that repeat every 20,000 to 40,000 years, interrupted by interglacial periods of "optimum" climate, such as the present. The climatic modulations that occur at shorter scales include such periods as the Little Ice Age from the early 16th to the mid-19th centuries, when the global average temperature was approximately 1° C lower than it is today. Several climate fluctuations on the scale of decades have occurred in the 20th century, such as warming from 1910 to 1940, cooling from 1940 to 1970, and the warming trend since 1970.

Although many of the mechanisms of climate change are understood, it is usually difficult to pinpoint the specific causes. Scientists acknowledge that climate can be affected by factors external to the land-ocean-atmosphere climate system, such as variations in solar brightness, the shading effect of aerosols injected into the atmosphere by volcanic activity, or the increased atmospheric concentration of "greenhouse" gases (e.g., carbon dioxide, nitrous oxide, methane, and chlorofluorocarbons) produced by human activities. However, none of these factors explain the periodic variations observed during the 20th century, which may simply be manifestations of the natural variability of climate. The existence of natural variability at many time scales makes the identification of causative factors such as human-induced warming more difficult. Whether change is natural or caused, the oceans play a key role and have a moderating effect on influencing factors.

The El Niño phenomenon. The shortest, or interannual, time scale relates to natural variations that are perceived as years of unusual weather—*e.g.*, excessive heat, drought, or storminess. Such changes are so common in many regions that any given year is about as likely to be considered as exceptional as typical. The best example of the influence of the oceans on interannual climate anomalies is the occurrence of El Niño conditions in the eastern Pacific Ocean at irregular intervals of about 3–10 years. The stronger El Niño episodes of enhanced ocean temperatures (2° – 8° C above normal) are typically accompanied by altered weather patterns around the globe, such as droughts in Australia, northeastern Brazil, and the highlands of southern Peru, excessive summer rainfall along the coast of Ecuador and northern Peru, severe winter storminess along the coast of central Chile, and unusual winter weather along the west coast of North America.

The effects of El Niño have been documented in Peru since the Spanish conquest in 1525. The Spanish term "la corriente de El Niño" was introduced by fishermen of the Peruvian port of Paita in the 19th century; it refers to a warm, southward ocean current that temporarily dis-

Altered weather patterns accompanying stronger El Niño episodes

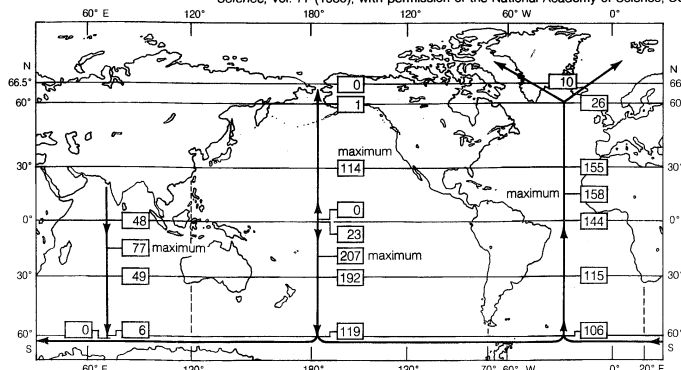

Figure 26: Annual mean meridional heat transport within the oceans. Amount of heat transport is given in units of 10^{13} watts.

places the normally cool, northward-flowing Humboldt, or Peru, Current. (The name is a pious reference to the Christ child, chosen because of the typical appearance of the countercurrent during the Christmas season.) By the end of the 19th century Peruvian geographers recognized that every few years this countercurrent is more intense than normal, extends farther south, and is associated with torrential rainfall over the otherwise dry northern desert. The abnormal countercurrent also was observed to bring tropical debris, as well as such flora and fauna as bananas and aquatic reptiles, from the coastal region of Ecuador farther north. Increasingly during the 20th century, El Niño has come to connote an exceptional year rather than the original annual event.

As Peruvians began to exploit the guano of marine birds for fertilizer in the early 20th century, they noticed El Niño-related deteriorations in the normally high marine productivity of the coast of Peru as manifested by large reductions in the bird populations that depend on anchovies and sardines for sustenance. The preoccupation with El Niño increased after mid-century, as the Peruvian fishing industry rapidly expanded to exploit the anchovies directly. (Fish meal produced from the anchovies was exported to industrialized nations as a feed supplement for livestock.) By 1971 the Peruvian fishing fleet had become the largest in its history; it had extracted very nearly 13 million metric tons of anchovies in that year alone. Peru was catapulted into first place among fishing nations, and scientists expressed serious concern that fish stocks were being depleted beyond self-sustaining levels, even for the extremely productive marine ecosystem of Peru. The strong El Niño of 1972–73 captured world attention because of the drastic reduction in anchovy catches to a small fraction of prior levels. The anchovy catch did not return to previous levels, and the effects of plummeting fish meal exports reverberated throughout the world commodity markets.

El Niño was only a curiosity to the scientific community in the first half of the 20th century, thought to be geographically limited to the west coast of South America. There was little data, mainly gathered coincidentally from foreign oceanographic cruises, and it was generally believed that El Niño occurred when the normally northward coastal winds off Peru, which cause the upwelling of cool, nutrient-rich water along the coast, decreased, ceased, or reversed in direction. When systematic and extensive oceanographic measurements were made in the Pacific in 1957–58 as part of the International Geophysical Year, it was found that El Niño had occurred during the same period and was also associated with extensive warming over most of the Pacific equatorial zone. Eventually tide-gauge and other measurements made throughout the tropical Pacific showed that the coastal El Niño was but one manifestation of basinwide ocean circulation changes that occur in response to a massive weakening of the westward-blowing trade winds in the western and central equatorial Pacific and not to localized wind anomalies along the Peru coast.

The Southern Oscillation. The wind anomalies are a manifestation of an atmospheric counterpart to the oceanic El Niño. At the turn of the century, the British climatologist Gilbert Walker set out to determine the connections between the Asian monsoon and other climatic fluctuations around the globe in an effort to predict unusual monsoon years that bring drought and famine to the Asian sector. Unaware of any connection to El Niño, he discovered a coherent interannual fluctuation of atmospheric pressure over the tropical Indo-Pacific region, which he termed the Southern Oscillation (SO). During years of reduced rainfall over northern Australia and Indonesia, the pressure in that region (*e.g.*, at what are now Darwin and Jakarta) was anomalously high and wind patterns were altered. Simultaneously, in the eastern South Pacific pressures were unusually low, negatively correlated with those at Darwin and Jakarta. A Southern Oscillation Index (SOI), based on pressure differences between the two regions (east minus west), showed low, negative values at such times, which were termed the “low phase” of the SO. During more normal “high-phase” years, the pressures

were low over Indonesia and high in the eastern Pacific, with high, positive values of the SOI. In papers published during the 1920s and '30s, Walker gave statistical evidence for widespread climatic anomalies around the globe being associated with the SO pressure “seesaw.”

In the 1950s, years after Walker's investigations, it was noted that the low-phase years of the SOI corresponded with periods of high ocean temperatures along the Peruvian coast, but no physical connection between the SO and El Niño was recognized until Jacob Bjerknes, in the early 1960s, tried to understand the large geographic scale of the anomalies observed during the 1957–58 El Niño event. Bjerknes, a meteorologist, formulated the first conceptual model of the large-scale ocean-atmosphere interactions that occur during El Niño episodes. His model has been refined through intensive research since the early 1970s.

During a year or two prior to an El Niño event (high-phase years of the SO), the westward trade winds typically blow more intensely along the equator in the equatorial Pacific, causing warm upper-ocean water to accumulate in a thickened surface layer in the western Pacific where sea level rises. Meanwhile, the stronger, upwelling-favourable winds in the eastern Pacific induce colder surface water and lowered sea levels off South America. Toward the end of the year preceding an El Niño, the area of intense tropical storm activity over Indonesia migrates eastward toward the equatorial Pacific west of the international date line (which corresponds in general to the 180th meridian of longitude), bringing episodes of eastward wind reversals to that region of the ocean. These wind bursts excite extremely long ocean waves, known as Kelvin waves (imperceptible to an observer), that propagate eastward toward the coast of South America, where they cause the upper ocean layer of relatively warm water to thicken and sea level to rise.

The tropical storms of the western Pacific also occur in other years, though less frequently, and produce similar Kelvin waves, but an El Niño event does not result and the waves continue poleward along the coast toward Chile and California, detectable only in tide-gauge measurements. Something else occurs prior to an El Niño that is not fully understood: as the Kelvin waves travel eastward along the equator, an anomalous eastward current carries warm western Pacific water farther east, and the warm surface layer deepens in the central equatorial Pacific (east of the international dateline). Additional surface warming takes place as the upwelling-favourable winds bring warmer subsurface water to the surface. (The subsurface water is warmer now, rather than cooler, because the overlying layer of warmer water is now significantly deeper than before.) The anomalous warming creates conditions favourable for the further migration of the tropical storm centre toward the east, giving renewed vigour to eastward winds, more Kelvin waves, and additional warming. Each increment of anomalies in one medium (*e.g.*, the ocean) induces further anomalies in the other (the atmosphere) and vice versa, giving rise to an unstable growth of anomalies through a process of positive feedbacks. During this time, the SO is found in its low phase.

After several months of these unstable ocean-atmosphere interactions, the entire equatorial zone becomes considerably warmer (2°–5° C) than normal, and a sizable volume of warm upper ocean water is transported from the western to the eastern Pacific. As a result, sea levels fall by 10–20 centimetres in the west and rise by larger amounts off the coast of South America, where sea surface temperature anomalies may vary from 2° to 8° C above normal. Anomalous conditions typically persist for 10–14 months before returning to normal. The warming off South America occurs even though the upwelling-favourable winds there continue unabated: the upwelled water is warmer now, rather than cooler as before, and its associated nutrients are less plentiful, thereby failing to sustain the marine ecosystem at its prior productive levels (see Figure 27).

The current focus of oceanographic research is on understanding the circumstances leading to the demise of the El Niño event and the onset of another such event

Figure 27: *The upwelling process along the coast of Peru.* A thermocline and nutricline separate the warm, nutrient-deficient upper layer from the cool, enriched layer below. Under normal conditions (top), these interfaces are shallow enough that coastal winds can induce upwelling of the lower-layer nutrients to the surface, where they support an abundant ecosystem. During an El Niño event (bottom), the upper layer thickens so that the upwelled water contains fewer nutrients, thus contributing to a collapse of marine productivity (see text).

Generation of Rossby waves

several years later. The most widely held hypothesis is that a second class of long equatorial ocean waves—Rossby waves with a shallow surface layer—is generated by the El Niño and that they propagate westward to the landmasses of Asia. There, the Rossby waves reflect off the Asian coast eastward along the equator in the form of upwelling Kelvin waves, resulting in a thinning of the upper ocean warm layer and a cooling of the ocean as the winds bring deeper, cooler water to the surface. This process is thought to initiate one to two years of colder-than-average conditions until Rossby waves of a contrary sense (*i.e.*, with a thickened surface layer) are again generated, functioning as a switching mechanism, this time to start another El Niño sequence.

Another goal of scientists is to understand climate change on the scale of centuries or longer and to make projections about the changes that will occur within the next few generations. Yet, determinations of current climatic trends from recent data are made difficult by natural variability at shorter time scales, such as the El Niño phenomenon. Many scientists are attempting to understand the mechanisms of change during an El Niño event from improved global measurements so as to determine how the ocean-atmosphere engine operates at longer time scales. Others are studying prehistoric records preserved in trees, sediments, and fossil corals in an effort to reconstruct past variations, including those like the El Niño. Their aim is to remove such short-term variations so as to be able to make more accurate estimates of long-term trends.

Ocean basins

The first major undersea survey was undertaken during the 1870s, but it was not until the last half of the 20th century that scientists began to learn what lies beneath the ocean surface in any detail. It has been determined that the ocean basins, which hold the vast quantity of water that covers nearly three-quarters of the Earth's surface, have an average depth of almost four kilometres. A number of major features of the basins depart from this average, as, for example, the mountainous ocean ridges, deep-sea trenches, and jagged, linear fracture zones (see Figure 28). Other significant features of the ocean floor include aseismic ridges, abyssal hills, and seamounts and guyots. The basins also contain a variable amount of sedimentary fill that is thinnest on the ocean ridges and usually thickest near the continental margins.

While the ocean basins lie much lower than sea level, the continents stand high—about one kilometre above sea level. The physical explanation for this condition is that the continental crust is light and thick, whereas the oceanic crust is dense and thin. Both the continental and oceanic crust lie over a more uniform layer called the mantle. As an analogy, one can think of a thick piece of styrofoam and a thin piece of wood floating in a tub of water. The styrofoam rises higher out of the water than the wood.

The ocean basins are transient features over geologic time, changing shape and depth while the process of plate tectonics proceeds. The surface layer of the Earth, the lithosphere, consists of a number of rigid plates that are in continual motion. The boundaries between the lithospheric plates form the principal relief features of the ocean basins: the crests of oceanic ridges are spreading centres where two plates move apart from each other at a rate of several centimetres per year. Molten rock material wells up from the underlying mantle into the gap between the diverging plates and solidifies into oceanic crust, thereby creating new ocean floor. At the deep-sea trenches, two plates converge, with one plate sliding down under the other into the mantle where it is melted. Thus, for each segment of new ocean floor created at the ridges, an equal amount of old oceanic crust is destroyed at the trenches, or so-called subduction zones (see below *Deep-sea trenches* and also the article *PLATE TECTONICS*). It is for this reason that the oldest segment of ocean floor, found in the far western Pacific, is apparently only about 200 million years old, even though the age of the Earth is estimated to be at least 4.6 billion years.

The dominant factors that govern seafloor relief and topography are the thermal properties of the oceanic plates, tensional forces in the plates, volcanic activity, and sedimentation. In brief, the oceanic ridges rise about two kilometres above the seafloor because the plates near these spreading centres are warm and thermally expanded. In contrast, plates in the subduction zones are generally cooler. Tensional forces resulting in plate divergence at the spreading centres also create block-faulted mountains and abyssal hills, which trend parallel to the oceanic ridges. Seamounts and guyots, as well as abyssal hills and most aseismic ridges, are produced by volcanism. Continuing sedimentation throughout the ocean basin serves to blanket and bury many of the faulted mountains and abyssal hills with time. Erosion plays a relatively minor role in shaping the face of the deep seafloor, in contrast to the continents. This is because deep ocean currents are generally slow (they flow at less than 50 centimetres per second) and lack sufficient power.

EXPLORATION OF THE OCEAN BASINS

Mapping the characteristics of the ocean basin has been difficult for several reasons. First, the oceans are not easy to travel over; second, until recent times navigation has been extremely crude, so that individual observations have been only loosely correlated with one another; and, finally, the oceans are opaque to light—*i.e.*, the deep seafloor cannot be seen from the ocean surface. Modern technology has given rise to customized research vessels, satellite and electronic navigation, and sophisticated acoustic instruments that have mitigated some of these problems.

The Challenger Expedition, mounted by the British in 1872–76, provided the first systematic view of a few of the major features of the seafloor. Scientists aboard the HMS *Challenger* determined ocean depths by means of wire-line soundings and discovered the Mid-Atlantic Ridge. Dredges brought up samples of rocks and sediments off the seafloor. The main advance in mapping, however, did not occur until sonar was developed in the early 20th century. This system for detecting the presence of objects underwater by acoustic echo provided marine researchers with a highly useful tool, since sound can be detected over several thousands of kilometres in the ocean (visible light, by comparison, can only penetrate 100 metres or so of water).

Modern sonar systems include the Seabeam multibeam echo sounder and the GLORIA scanning sonar (see EXPLORATION: *Undersea exploration: Methodology and instrumentation: Exploration of the seafloor and the Earth's crust*). They operate on the principle that the depth (or distance) of the seafloor can be determined by multiplying one-half the elapsed time between a downgoing acoustic pulse and its echo by the speed of sound in seawater (about 1,500 metres per second). Such multifrequency sonar systems permit the use of different pulse frequencies to meet different scientific objectives. Acoustic pulses of 12 kilohertz (kHz), for example, are normally employed to measure ocean depth, while lower frequencies—3.5 kHz to less than 100 hertz (Hz)—are used to map the thickness of sediments in the ocean basins. Very high frequencies of 100 kHz or more are employed in side-scanning sonar to measure the texture of the seafloor. The acoustic pulses are normally generated by piezoelectric transducers. For determining subbottom structure, low-frequency acoustic pulses are produced by explosives, compressed air, or water-jet implosion. Near-bottom sonar systems, such as the Deep Tow of the Scripps Institution of Oceanography (in La Jolla, Calif., U.S.), produce even more detailed images of the seafloor and subbottom structure. The Deep Tow package contains both echo sounders and side-scanning sonars, along with associated geophysical instruments, and is towed behind a ship at slow speed 10 to 100 metres above the seafloor. It yields very precise measurements of even finer-scale features than are resolvable with Seabeam and other comparable systems.

Another notable instrument system is ANGUS, a deep-towed camera sled that can take thousands of high-resolution photographs of the seafloor during a single day. It has been successfully used in the detection of hydrothermal vents at spreading centres (see below *Oceanic ridges*). Overlapping photographic images make it possible to construct photomosaic strips about 10–20 metres wide that reveal details on the order of centimetres.

Three major navigation systems are in use in modern marine geology. These include electromagnetic systems such as Loran and Earth-orbiting satellites (see EXPLORATION: *Undersea exploration: Basic elements of undersea exploration: Navigation*). Acoustic transponder arrays of two or more stations placed on the seafloor a few kilometres apart are used to navigate deeply towed instruments, submersibles, and occasionally surface research vessels when detailed mapping is conducted in small areas. These systems measure the distance between the instrument package and the transponder sites and, using simple geometry, compute fixes accurate to a few metres. Although the individual transponders can be used to determine positions relative to the array with great accuracy, the preciseness of the position of the array itself depends on which system is employed to locate it.

Such Earth-orbiting satellites as SEASAT and GEOSAT have uncovered some significant topographic features of the ocean basins. SEASAT, launched in 1978, carried a radar altimeter into orbit. This device was used to measure the distance between the satellite path and the surfaces of the ocean and continents to 0.1 metre. The measurements revealed that the shape of the ocean surface is warped by seafloor features: massive seamounts cause the surface to bulge over them owing to gravitational attraction. Similarly, the ocean surface downwarps over trenches. Using these satellite measurements of the

ocean surface, William F. Haxby computed the gravity field there. The resulting gravity map (Figure 29) provides comprehensive coverage of the ocean surface on a 5' by 5' grid (five nautical miles on each side at the equator). Coverage as complete as this is not available from echo soundings made from ships. Because the gravity field at the ocean surface is a highly sensitive indicator of marine topography, this map reveals various previously uncharted features, including seamounts, ridges, and fracture zones, while improving the detail on other known features. In addition, the gravity map shows a linear pattern of gravity anomalies that cut obliquely across the grain of the topography. These anomalies are most pronounced in the Pacific basin; they are apparently about 100 kilometres across and some 1,000 kilometres long. They have an amplitude of approximately 10 milligals (0.001 percent of the Earth's gravity attraction) and are aligned west-northwest—very close to the direction in which the Pacific Plate moves over the mantle below.

OCEANIC CRUST

Structure and composition. The oceanic crust differs from the continental crust in several ways: it is thinner, denser, younger, of different chemical composition, and created in a different plate-tectonic setting. The oceanic crust is formed at spreading centres on the oceanic ridges, whereas continental crust is formed above the subduction zones. The oceanic crust is about six kilometres thick. It is composed of several layers, not including the overlying sediment. The topmost layer, about 500 metres thick, includes lavas of basaltic composition (*i.e.*, rock material consisting largely of plagioclase [feldspar] and pyroxene). The lavas are generally of two types: pillow lavas and sheet flows. Pillow lavas appear to be shaped exactly as the name implies—like large overstuffed pillows about one metre in cross section and one to several metres long. They commonly form small hills tens of metres high at the spreading centres. Sheet flows have the appearance of wrinkled bed sheets. They commonly are thin (only about 10 centimetres thick) and cover a broader area than pillow lavas. There is evidence that sheet flows are erupted at higher temperatures than those of the pillow variety. On the East Pacific Rise at 8° S latitude, a series of sheet flow eruptions (possibly since the mid-1960s) have covered more than 220 square kilometres of seafloor to an average depth of 70 metres.

Below the lava is a layer composed of feeder, or sheeted, dikes that measures more than one kilometre thick. Dikes are fractures that serve as the plumbing system for transporting magmas (molten rock material) to the seafloor to produce lavas. They are about one metre wide, subvertical, and elongate along the trend of the spreading centre where they formed, and they abut one another's sides—hence the term sheeted. These dikes are also of basaltic composition. There are two layers below the dikes totaling about 4.5 kilometres in thickness. Both of these include gabbros, which are essentially basalts with coarser mineral grains. These gabbro layers are thought to represent the magma chambers, or pockets of lava, that ultimately erupt on the seafloor. The upper gabbro layer is isotropic (uniform) in structure. In some places, this layer includes pods of plagiogranite, a differentiated rock richer in silica than gabbro. The lower gabbro layer has a stratified structure and evidently represents the floor or sides of the magma chamber. This layered structure is called cumulate, meaning that the layers (which measure up to several metres thick) result from the sedimentation of minerals out of the liquid magma. The layers in the cumulate gabbro have less silica but are richer in iron and magnesium than the upper portions of the crust. Olivine, an iron-magnesium silicate, is a common mineral in the lower gabbro layer.

The oceanic crust lies atop the Earth's mantle, as does the continental crust. Mantle rock is composed mostly of peridotite, which consists primarily of the mineral olivine with small amounts of pyroxene and amphibole.

Investigations of the oceanic crust. Knowledge of the structure and composition of the oceanic crust comes from several sources. Bottom sampling during early exploration brought up all varieties of the above-mentioned

Figure 29: Gravity map of the world's ocean basins, compiled from Seasat satellite data (see text).
William F. Haxby (1987); National Geophysical Data Center, National Oceanic and Atmospheric Administration

rocks, but the structure of the crust and the abundance of the constituent rocks were unclear. Simultaneously, seismic refraction experiments enabled researchers to determine the layered nature of the oceanic crust. These experiments involve measuring the travel times of seismic waves generated by explosions (e.g., dynamite blasts) set off over distances of several tens of kilometres. The results of early refraction experiments revealed the existence of two layers beneath the sediment cover. More sophisticated experiments and analyses led to dividing these layers into two parts, each with a different seismic wave velocity, which increases with depth. The seismic velocity is a kind of fingerprint that can be attributed to a limited number of rock types. Sampled rock data and seismic results were combined to yield a model for the structure and composition of the crust.

Study of ophiolites

Great strides in understanding the oceanic crust were made by the study of ophiolites. These are slices of the ocean floor that have been thrust above sea level by the action of plate tectonics. In various places in the world, the entire sequence of oceanic crust and upper mantle is exposed. These areas include, among others, Newfoundland and the Pacific Coast Ranges of California, the island of Cyprus in the Mediterranean Sea, and the mountains in Oman on the southeastern tip of the Arabian Peninsula. Ophiolites reveal the structure and composition of the oceanic crust in astonishing detail. Also, the process of crustal formation and hydrothermal circulation, as well as the origin of marine magnetic anomalies (see below), can be studied with comparative clarity. Although it is clear that ophiolites are of marine origin, there is some

controversy as to whether they represent typical oceanic crust or crust formed in settings other than an oceanic spreading centre—behind island arcs, for example.

The age of the oceanic crust does not go back farther than about 200 million years. Such crust is being formed today at oceanic spreading centres. Many ophiolites are much older than the oldest oceanic crust, demonstrating continuity of the formation processes over hundreds of millions of years. Methods that may be used to determine the age of the crustal material include direct dating of rock samples by radiometric dating (measuring the relative abundances of a particular radioactive isotope and its daughter isotopes in the samples) or by the analyses of fossil evidence, marine magnetic anomalies, or ocean depth. Of these, magnetic anomalies deserve special attention.

A marine magnetic anomaly is a variation in strength of the Earth's magnetic field caused by magnetism in rocks of the ocean floor. Marine magnetic anomalies typically represent 1 percent of the total geomagnetic field strength. They can be stronger ("positive") or weaker ("negative") than the average total field. Also, the magnetic anomalies occur in long bands that run parallel to spreading centres for hundreds of kilometres (Figure 30) and may reach up to a few tens of kilometres in width.

Marine magnetic anomalies were first discovered off the coast of the western United States in the late 1950s and completely baffled scientists. The anomalies were charted from southern California to northern Washington and out several hundred kilometres. Victor Vacquier, a geophysicist, noticed that these linear anomalies ended at the fracture zones mapped in this area. In addition, he noticed that they had unique shapes, occurred in a predictable sequence across their trends, and could be correlated across the fracture zones. Soon thereafter, linear magnetic anomalies were mapped over the Reykjanes Ridge south of Iceland. They were found to occur on both sides of the ridge crest and parallel to it. Simultaneously, Alan Cox and several other American geophysicists documented evidence that the Earth's magnetic field had reversed in the past: the north magnetic pole had been the south magnetic pole about 700,000 years ago, and there were reasons to believe older reversals existed. Also at this time, Robert S. Dietz and Harry H. Hess were formulating the theory of seafloor spreading—the hypothesis that oceanic crust is created at the crests of the oceanic ridges and consumed in the deep-sea trenches.

It remained for Frederick J. Vine and Drummond H. Matthews of Great Britain and Lawrence W. Morley of Canada to put these observations together in a theory that explained marine magnetic anomalies. The theory rests on three assumptions: (1) that the Earth's magnetic field periodically reverses polarity; (2) that seafloor spreading occurs; and (3) that the oceanic crust is permanently magnetized as it forms and cools at spreading centres. The theory expresses the assumptions—namely, that the oceanic crust records reversals of the Earth's field as it is formed during seafloor spreading. Positive anomalies result when the crust is magnetized in a "normal" polarity parallel to the ambient field of the Earth, and negative anomalies result when the crust is "reversely" magnetized in an opposite sense. As the magnetized crust moves down the flanks of a ridge away from the spreading centre, it remains permanently magnetized and "carries" the magnetic anomalies along with it. (For further details about paleomagnetism and seafloor spreading, see PLATE TECTONICS: *Historical overview: Renewed interest in continental drift.*)

A brilliant leap in understanding was now possible. If the age of the field reversals were known, the age of the ocean crust could be predicted by mapping the corresponding anomaly. By the mid-1960s, Cox and his colleagues had put together a schedule of reversals for the last four or five million years by studying the ages and magnetic polarities of lava flows found on land. Vine and the Canadian geologist J. Tuzo Wilson applied the time scale to marine magnetic anomalies mapped over the Juan de Fuca Ridge, a spreading centre off the northwest United States (Figure 30). They thus dated the crust there and also computed the first seafloor spreading rate of about 30 millimetres per year. The rate is computed by dividing the distance of

Calculation of seafloor spreading rate

Figure 30: Magnetic anomalies off the west coast of the United States.

The gray areas represent positive anomalies formed during periods of normal polarity of the Earth's magnetic field. The white (open) areas mark negative anomalies formed when the field was reversed. The arrows show the central magnetic anomaly over three spreading centres (from north to south): Explorer, Juan de Fuca, and Gorda (see text).

an anomaly from the ridge crest by the age of the anomaly twice. Thus the oceanic crust at the Juan de Fuca Ridge is moving at about 15 millimetres per year away from the ridge crest and at about 60 millimetres per year away from the crustal segment on the opposite side of the crest.

During the 1960s and '70s marine magnetic anomalies were mapped over wide areas of the ocean basins. By using estimates of the ages of oceanic crust obtained from core samples by deep-sea drilling, a magnetic anomaly time scale was constructed, and at the same time the spreading history for the ocean basins covering the last 200 million years or so was proposed.

It is thought that the most important contributor to marine magnetic anomalies is the layer of lavas in the upper oceanic crust. A secondary contribution originates in the upper layer of gabbros. The dike layer is essentially demagnetized by the action of hydrothermal waters at the spreading centres. The dominant mechanism of permanent magnetization is the thermoremanent magnetization (or TRM) of iron-titanium oxide minerals. These minerals lock in a TRM as they cool below 200° to 300° C in the presence of the Earth's magnetic field. Although several processes are capable of altering the TRM, including reheating and oxidation at the seafloor, it is remarkably robust, as is evidenced by magnetic anomalies as old as 165 million years in the far western equatorial Pacific.

OCEANIC RIDGES

The largest features of the ocean basin are the oceanic ridges. In the past these features were referred to as mid-ocean ridges, but, as will be seen, the largest oceanic ridge, the East Pacific Rise, is far from a mid-ocean location, and the nomenclature is thus inaccurate. Oceanic ridges are not to be confused with aseismic ridges, which have an entirely different origin (see below).

Principal characteristics. Oceanic ridges are linear mountain chains comprising the largest features on Earth. They are found in every ocean basin and appear to girdle the Earth. The ridges rise from depths near 5 kilometres to an essentially uniform depth of about 2.6 kilometres and are roughly symmetrical in cross section. They can be thousands of kilometres wide. In places, the crests of the ridges are offset across transform faults, or fracture zones, which can be followed down the flanks of the ridges. (Transform faults are those along which lateral movement occurs.) The flanks are marked by sets of mountains and hills that are elongate and parallel to the ridge trend.

New oceanic crust (and part of the upper mantle, which, together with the crust, makes up the lithosphere) is formed at seafloor spreading centres at the crests of the oceanic ridges. Because of this, certain unique geologic features are found there. Fresh basaltic lavas are exposed on the seafloor at the ridge crests. These lavas are progressively buried by sediments as the seafloor spreads away from the site. The flow of heat out of the crust is many times greater at the crests than elsewhere in the world. Earthquakes are common along the crests and in the transform faults that join the offset ridge segments. Analysis of earthquakes occurring at the ridge crests indicates that the oceanic crust is under tension there. A high-amplitude magnetic anomaly is centred over the crests because fresh lavas at the crests are being magnetized in the direction of the present geomagnetic field.

The depths over the oceanic ridges are rather precisely correlated with the age of the ocean crust; specifically, it has been demonstrated that the ocean depth is proportional to the square root of crustal age (Figure 31). The theory explaining this relationship holds that the increase in depth with age is due to the thermal contraction of the oceanic crust and upper mantle as they are carried away from the seafloor spreading centre in an oceanic plate. Because such a plate is ultimately about 100 kilometres thick, contraction of only a few percent predicts the entire relief of an oceanic ridge. It then follows that the width of a ridge can be defined as twice the distance from the crest to the point where the plate has cooled to a steady thermal state. Most of the cooling takes place within 70 or 80 million years, by which time the ocean depth is about 5 to 5.5 kilometres. Because this cooling is a function of age,

slow-spreading ridges, such as the Mid-Atlantic Ridge, are narrower than faster-spreading ridges, like the East Pacific Rise (see below). Further, a correlation has been found between global spreading rates and the transgression and regression of ocean waters onto the continents. During the Early Cretaceous period about 100 million years ago, when global spreading rates were uniformly high, oceanic ridges occupied comparatively more of the ocean basins, causing the ocean waters to transgress (spill over) onto the continents, leaving marine sediments in areas now well away from coastlines.

Figure 31: Relationship between depth of oceanic crust and its age. Error bars are one standard deviation (see text).

Besides ridge width, other features appear to be a function of spreading rate. Global spreading rates range from 10 millimetres per year (mm/yr total rate) or less up to 160 mm/yr. Oceanic ridges can be classified as slow (up to 50 mm/yr), intermediate (up to 90 mm/yr), and fast (up to 160 mm/yr). Slow-spreading ridges are characterized by a rift valley at the crest. Such a valley is fault-controlled. It is typically 1.4 kilometres deep and 20 to 40 kilometres wide. Faster-spreading ridges lack rift valleys. At intermediate rates, the crest regions are broad highs with occasional fault-bounded valleys no deeper than 200 metres. At fast rates, an axial high is present at the crest. The slow-spreading rifted ridges have rough faulted topography on their flanks, while the faster-spreading ridges have much smoother flanks (Figure 32).

Distribution of major ridges and spreading centres. Oceanic spreading centres are found in all the ocean basins. In the Arctic Ocean a slow-rate spreading centre is located near the eastern side in the Eurasian basin. It can be followed south, offset by transform faults, to Iceland. Iceland has been created by a hot spot (see below) located directly below an oceanic spreading centre. The

Global
seafloor
spreading
rates

ridge leading south from Iceland is named the Reykjanes Ridge, and, although it spreads at 20 mm/yr or less, it lacks a rift valley. This is thought to be the result of the influence of the hot spot.

The Mid-Atlantic Ridge extends from south of Iceland to the extreme South Atlantic Ocean near 60° S latitude. It bisects the Atlantic Ocean basin, which led to the earlier designation of mid-ocean ridge for features of this type. The Mid-Atlantic Ridge became known in a rudimentary fashion during the 19th century. In 1855 Matthew Fontaine Maury of the U.S. Navy prepared a chart of the Atlantic in which he identified it as a shallow "middle ground." During the 1950s the American oceanographers Bruce Heezen and Maurice Ewing proposed that it was a continuous mountain range.

In the North Atlantic the ridge spreads slowly and displays a rift valley and mountainous flanks. In the South Atlantic spreading rates are between slow and intermediate, and rift valleys are generally absent, as they occur only near transform faults.

Figure 32: High-resolution bathymetric profiles across the East Pacific Rise and Mid-Atlantic Ridge. The spreading rate varies from fast (159 millimetres per year) to slow (21 millimetres per year) on the Mid-Atlantic Ridge. OSC stands for overlapping spreading centre; MAR signifies Mid-Atlantic Ridge.

A very slow oceanic ridge, the Southwest Indian Ridge, bisects the ocean between Africa and Antarctica. It joins the Mid-Indian and Southeast Indian ridges east of Madagascar. The Carlsberg Ridge is found at the north end of the Mid-Indian Ridge. It continues north to join spreading centres in the Gulf of Aden and Red Sea. Spreading is very slow at this point but approaches intermediate rates on the Carlsberg and Mid-Indian ridges. The Southeast Indian Ridge spreads at intermediate rates. This ridge continues from the western Indian Ocean in a southeasterly direction, bisecting the ocean between Australia and Antarctica. Rifted crests and rugged mountainous flanks are characteristic of the Southwest Indian Ridge. The Mid-Indian Ridge has fewer features of this kind, and the Southeast Indian Ridge has generally smoother topography. The latter also displays distinct asymmetric seafloor spreading south of Australia. Analysis of magnetic anomalies shows that rates on opposite sides of the spreading centre have been unequal at many times over the past 50 or 60 million years.

The Pacific-Antarctic Ridge can be followed from a point midway between New Zealand and Antarctica northeast to where it joins the East Pacific Rise off the margin of South America. The former spreads at intermediate to fast rates.

East Pacific Rise

The East Pacific Rise extends from this site northward to the Gulf of California, where it joins the transform zone of the Pacific-North American plate boundary. Offshore from Chile and Peru, the East Pacific Rise is currently spreading at fast rates of 159 mm/yr or more. Rates decrease to about 60 mm/yr at the mouth of the Gulf of California. The crest of the ridge displays a low topographic rise along its length rather than a rift valley. The East Pacific Rise was first detected during the Challenger Expedition of the 1870s. It was described in its gross form

during the 1950s and '60s by oceanographers, including Heezen, Ewing, and Henry W. Menard. During the 1980s, Kenneth C. Macdonald, Paul J. Fox, and Peter F. Lonsdale discovered that the main spreading centre appears to be interrupted and offset a few kilometres to one side at various places along the crest of the East Pacific Rise. However, the ends of the offset spreading centres overlap each other by several kilometres. These were identified as a new type of geologic feature of oceanic spreading centres and designated overlapping spreading centres. Such centres are thought to result from interruptions of the magma supply to the crest along its length and define a fundamental segmentation of the ridge on a scale of tens to hundreds of kilometres.

Many smaller spreading centres branch off the major ones or are found behind island arcs. In the western Pacific, spreading centres occur on the Fiji Plateau between the New Hebrides and Fiji Islands and in the Woodlark Basin between New Guinea and the Solomon Islands. A series of spreading centres and transform faults lie between the East Pacific Rise and South America near 40° to 50° S latitude. The Scotia Sea between South America and the Antarctic Peninsula contains a spreading centre. The Galápagos spreading centre trends east-west between the East Pacific Rise and South America near the equator. Three short spreading centres are found a few hundred kilometres off the shore of the Pacific Northwest. These are the Gorda Ridges off northern California, the Juan de Fuca Ridge off Oregon and Washington, and the Explorer Ridge off Vancouver Island. In a careful study of the seafloor spreading history of the Galápagos and the Juan de Fuca spreading centres, the American geophysicist Richard N. Hey developed the idea of the propagating rift. In this phenomenon, one branch of a spreading centre ending in a transform fault lengthens at the expense of the spreading centre across the fault. The rift and fault propagate at one to five times the spreading rate and create chevron patterns in magnetic anomalies and the grain of the seafloor topography resembling the wake of a boat.

Spreading centre zones and associated phenomena. From the 1970s highly detailed studies of spreading centres using deeply towed instruments, photography, and manned submersibles have resulted in new revelations about the processes of seafloor spreading. The most profound discoveries have been of deep-sea hydrothermal vents (see below) and previously unknown biological communities.

Spreading centres are divided into several geologic zones. The neovolcanic zone is at the very axis. It is 1 to 2 kilometres wide and is the site of recent and active volcanism and of the hydrothermal vents. It is marked by chains of small volcanoes or volcanic ridges. Adjacent to the neovolcanic zone is one marked by fissures in the seafloor. This may be 1 to 2 kilometres wide. Beyond this point occurs a zone of active faulting. Here, fissures develop into normal faults with vertical offsets. This zone may be 10 or more kilometres wide. At slow spreading rates the faults have offsets of hundreds of metres, creating rift valleys and rift mountains. At faster rates the vertical offsets are 50 metres or less. A deep rift valley is not formed because the vertical uplifts are cancelled out by faults that dropdown uplifted blocks. This results in linear, fault-bounded abyssal hills and valleys trending parallel to the spreading centre.

Warm springs emanating from the seafloor in the neovolcanic zone were first found on the Galápagos spreading centre. These waters were measured to have temperatures about 20° C above the ambient temperature. In 1979 hydrothermal vents with temperatures near 350° C were discovered on the East Pacific Rise off Mexico (Figure 33). Since then, similar vents have been found on the spreading centres off the Pacific Northwest coast of the United States, on the south end of the northern Mid-Atlantic Ridge, and at many locations on the East Pacific Rise.

Hydrothermal vents are localized discharges of heated seawater. They result from cold seawater percolating down into the hot oceanic crust through the zone of fissures and returning to the seafloor in a pipelike flow at the axis of the neovolcanic zone. The heated waters often carry sulfide minerals of zinc, iron, and copper leached from the

Seafloor vents

Figure 33: Hydrothermal field at a spreading centre. The black-smoker chimney is one or two metres high and is composed of sulfide minerals precipitated from hot water of approximately 350° C. The white-smoker chimney is precipitated from cooler water near 300° C and consists chiefly of silica.

From K.C. Macdonald and B.P. Luyendyk, "The Crest of the East Pacific Rise," *Scientific American* (May 1981); copyright © 1981 Scientific American, Inc., all rights reserved

crust. Outflow of these heated waters probably accounts for 20 percent of the Earth's heat loss. Exotic biological communities exist around the hydrothermal vents. These ecosystems are totally independent of energy from the Sun. They are not dependent on photosynthesis but rather on chemosynthesis by sulfur-fixing bacteria. The sulfide minerals precipitated in the neovolcanic zone can accumulate in substantial amounts and are sometimes buried by lava flows at a later time. Such deposits are mined as commercial ores in ophiolites on Cyprus and in Oman.

Magma chambers have been detected beneath the crest of the East Pacific Rise by seismic experiments. (The principle underlying the experiments is that partially molten or molten rock slows the travel of seismic waves and also strongly reflects them.) The depth to the top of the chambers is about two kilometres below the seafloor. The width is more difficult to ascertain, but is probably one to four kilometres. Their thickness seems to be about two to six kilometres based on studies of ophiolites (Figure 34). The chambers have been mapped along the trend of the crest between 9° and 13° N latitude. The top is relatively continuous, but is apparently interrupted by offsets of transform faults and overlapping spreading centres.

FRACTURE ZONES AND TRANSFORM FAULTS

Fracture zones. As was noted above, oceanic ridges (and their associated spreading centres) are offset along their trend by fracture zones. These are ridges and valleys on the order of tens of kilometres wide that cut across the crests of the ridges at approximately right angles and offset their trend (Figure 35). Typically, a regional depth offset is present across a fracture zone, owing to the juxtaposition of crust of different ages (and, therefore, depth) across it. In the Atlantic, on the slow spreading Mid-Atlantic Ridge, fracture zones are numerous and occur every 55 kilometres on average along the trend of the ridge. They offset the crest between 5 and 40 kilometres. Some of the larger fracture zones in the North Atlantic are the Gibbs at 52° N, the Atlantis at 30° N, and the Vema at 11° N. These and others can be followed across both flanks of the ridge for some 3,000 kilometres. The Vema Fracture Zone offsets the Mid-Atlantic Ridge 320 kilometres to the left. It is marked by a sediment-filled valley more than 5 kilometres deep and 10 to 20 kilometres wide and is flanked by mountains 3,500 metres high. Basalts, gabbros, and serpentinized peridotites (*i.e.*, those peridotites that have been altered in varying degrees to serpentine) of the oceanic crust and mantle have been recovered from the mountain flanks.

Fracture zones occur less frequently on the East Pacific Rise, but they offset the ridge by a greater amount. More than a dozen can be found between 20° N and 30° S.

Typical offsets are roughly 100 kilometres. Several fracture zones more than 3,000 kilometres long are found off the shore of western North America. These include the Mendocino, Murray, Molokai, and Clarion fracture zones. They are not associated with a ridge crest. Rather, they occur on the west flank of the defunct Pacific-Farallon oceanic ridge. The Farallon Plate has all but disappeared down a subduction zone that extended along the entire coast of California and Baja California until about 25 to 30 million years ago. Subduction now occurs north of the Mendocino Fracture Zone. These fracture zones off western North America were among the first mapped. Menard has traced them almost 10,000 kilometres westward across the Pacific. The continental margin of northern California is displaced to the right where the Mendocino Fracture Zone and its transform portion, the Gorda Escarpment, intersect it.

Transform faults. The portion of a fracture zone between different offset spreading centres constitutes a transform fault. Transform faults also connect spreading centres to subduction zones (deep-sea trenches). Faults of this kind are the only segments of fracture zones that are seismically active. J. Tuzo Wilson recognized this and other features and explained the phenomenon as a transfer of motion from one spreading centre to another. The American geologist W. Jason Morgan, one of the several outstanding pioneers in plate tectonics, recognized that transform faults are zones where opposing lithospheric plates slip past one another. Morgan proposed that opposing plates along an oceanic ridge crest offset by fracture zones are divided by the spreading centres and transform faults. The inactive portions of the fracture zone on the ridge flanks are scars on the ocean floor created in the transform faults.

This theory made a very dramatic prediction: namely, that the direction of motion on the transform faults was opposite to the offsets of the ridge crests. For example, if a ridge crest was offset to the left by a transform fault, implying leftward movement on a fault joining the offset crests, the movement across the transform fault was instead to the right (Figure 35). This is clear when it is realized that the plate boundaries are confined to the spreading centres and transform faults, not to the inactive part of the fracture zone. Seismic studies of earthquakes

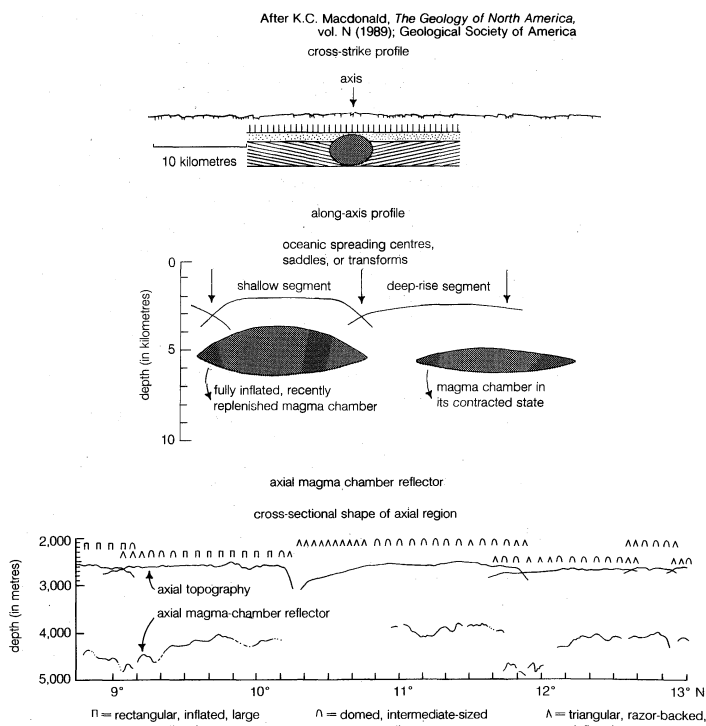

Figure 34: Cross-trend and along-trend views of an axial magma chamber on the East Pacific Rise. The two upper diagrams are idealized; the one at the bottom is made from seismic reflection surveys (see text).

Figure 35: Oceanic ridges offset by transform faults and fracture zones. The arrows show the direction of movement across the transform faults.

From W.H. Menard, *Scientific American* (September 1969); copyright © 1969 Scientific American, Inc., all rights reserved

from transform faults soon revealed that the motion was opposite, as predicted.

Not everywhere in the ocean basins are plate motions exactly parallel to transform faults. In places where a component of opening motion occurs across the transform, volcanic activity results, and the fracture zone is termed a leaky transform fault. South of New Zealand, between it and the Pacific-Antarctic Ridge, a component of shortening is occurring across a transform called the Macquarie Ridge. Here, subduction may be taking place at a slow rate.

DEEP-SEA TRENCHES

Types. Although the term trench has been applied to many deep, long linear troughs in the ocean floor, the most common and accurate usage relates it to subduction zones. According to plate tectonic theory, subduction zones are locations where a lithospheric plate bearing oceanic crust slides down into the upper mantle under the force of gravity. The result is a topographic depression where the oceanic plate comes in contact with the overriding plate, which may be either oceanic or continental. If the overriding plate is oceanic, an island arc develops (Figure 36). The trench forms an arc in plan view, and islands with explosive volcanoes develop on the overriding plate. If the overriding plate is continental, a marginal trench forms where the topographic depression appears to follow the outline of the continental margin. Explosive volcanoes are found here too. Both types of subduction zones are associated with large earthquakes that originate at a depth of as much as 700 kilometres. The deep earthquakes below subduction zones occur in a plane that dips 30° or more under the overriding plate. Typical trench depths are 8 to 10 kilometres. The longest trench is the Peru-Chile Trench, which extends some 5,900 kilometres along the west side of South America. Trenches are relatively narrow, usually less than 100 kilometres wide.

The Pacific basin is rimmed by trenches of both marginal and island arc varieties. Marginal trenches bound the west side of Central and South America from the Gulf of California to southern Chile. Although they are deeply buried in sediment, trenches are found along the western North American continental margin from Cape Mendocino (in northern California) to the Canadian border. The Aleutian Trench extends from the northernmost point in the Gulf of Alaska west to the Kamchatka Peninsula in the Soviet Union. It can be classified as a marginal trench in the east but is more properly termed an island arc west of Alaska.

In the western Pacific, the trenches are associated with island arcs. These include the Kuril, Japan, Bonin, Mariana, Ryukyu, and Philippine trenches that extend from Kamchatka to near the equator. A complex pattern of island arcs is found in Indonesia. The major island arc here is the Java Trench extending from northern Australia

to the northwestern end of Sumatra in the northeast Indian Ocean. The region of New Guinea and the Solomon Islands includes the New Britain and Solomon trenches, the latter of which joins the New Hebrides Trench directly to the south. East of this area the Tonga and Kermadec trenches extend south from the Fiji Islands to New Zealand.

Two island arcs occur in the Atlantic Ocean. The South Sandwich Trench is located west of the Mid-Atlantic Ridge between South America and Antarctica. The Puerto Rico Trench joins the Lesser Antilles Island arc in the eastern Caribbean.

Some seafloor features bear the name trench and are deep linear troughs but are not subduction zones. The Vema Trench on the Mid-Indian Ridge is a fracture zone. The Vityaz Trench northwest of Fiji is an aseismic (inactive) feature of unknown origin. The Diamantina trench (Diamantina Fracture Zone) extends westward from the southwest coast of Australia. It is a rift valley that was formed when Australia separated from Antarctica between 60 and 50 million years ago.

The deepest water on Earth (11,034 metres) is located in the southern end of the Mariana Trench near Guam. A few trenches are partially filled with sediments derived from the bordering continents. The Aleutian Trench is effectively buried east of Kodiak Island in the Gulf of Alaska. Here, the ocean floor is smooth and flat. To the west farther from the sediment supply on Alaska, the trench reaches depths of more than seven kilometres. The Lesser Antilles trench in the eastern Caribbean also is buried by sediments originating from South America.

Structure. Oceanward of trenches the seafloor is usually bulged upward in an outer ridge or rise of up to 1,000 metres relief. This condition is thought to be the elastic response of the oceanic plate bending down into a subduction zone. The landward or island-arc slope of the trench is often interrupted by a submarine ridge, which sometimes breaks the ocean surface, as in the case of the Java Trench. Such a ridge is constructed from deformed sediments scraped off the top of the descending oceanic plate and is termed an accretionary prism. A line of explosive volcanoes, extruding (erupting) a lava that forms the volcanic rock andesite, is found on the overriding plate usually 100 kilometres or so from the trench. In marginal trenches these volcanoes form mountain chains, such as the Cascades in the Pacific Northwest or the great volcanoes of the Andes. In island arcs they form active volcanic island chains, such as the Mariana Islands.

Formation of island arcs

Figure 36: Features of a typical island arc.

The deep-sea trench, volcanic line, accretionary prism, backarc basin, and third arc generally associated with island arcs are shown here.

Behind the volcanic line of island arcs are sometimes found young, narrow ocean basins. These basins are bounded on the opposite side by submarine ridges. Such interarc, or backarc, basins are sites of seafloor spreading directly caused by the dynamics of subduction. They originate at the volcanic line, so that the outer bounding submarine ridge, or third arc, represents an older portion of the volcanic line that has spread away. These backarc basins bear many of the features characteristic of oceanic spreading centres. Well-studied examples of these features are found in the Lau Basin of the Tonga arc and also west of the Mariana Islands. The Sea of Japan originated from backarc spreading behind the Japanese arc that began some 30 million years ago. At least two backarc basins have opened behind the Mariana arc, creating seafloor in two phases from about 30 to 17 million years ago in the western Parece Vela Basin and from 5 million years ago in the Mariana Trough next to the islands.

ASEISMIC RIDGES

Formation
by hot spot
volcanism

In some oceans the basin floors are crossed by long, linear and mountainous aseismic ridges. The term aseismic distinguishes these ridges from oceanic spreading centres because the former lack earthquakes. Most aseismic ridges are constructed by volcanism from a hot spot and are composed of coalescing volcanoes of various sizes. A hot spot is a magma-generating centre fixed in the Earth's deep mantle and leaves a trail of volcanic outpourings on the seafloor as an oceanic plate travels over it. This form of volcanism is not associated with the volcanism at spreading centres and is distinct from it chemically in that the magma extruded onto the surface has a higher alkali composition. (For additional information on hot spots, see VOLCANISM: *Volcanism and tectonic activity: Intraplate volcanism.*)

The Hawaiian-Emperor chain is the best displayed aseismic ridge. Earthquakes do occur here, but only at the end of the ridge where volcanism is current—in this case, on the island of Hawaii (commonly known as the Big Island) to the southeast end of the island chain. Taking into account the relief of the island of Hawaii above the seafloor, it is the largest volcanic edifice on Earth. The Hawaiian-Emperor chain stretches from the Big Island to the intersection of the Kuril and Aleutian trenches in the northwest Pacific. There are roughly 18 volcanoes or seamounts (see below) per 1,000 kilometres along the Hawaiian segment and 13 per 1,000 kilometres on the Emperor portion beyond the bend. The Hawaiian Islands are a part of the chain—the young part—that rises above sea level. The Hawaiian-Emperor chain has two main trends: (1) from the Hawaiian Islands west to the Kammu and Yuryaku seamounts (near 32° N, 168° W), the trend of the Hawaiian portion is just west of northwest; and (2) from this point to the Aleutian Trench, the trend of the Emperor segment is north-northwest. The hot spot interpretation infers that this change in trend is due to a change in the direction of Pacific Plate motion, from north-northwest prior to 38 million years ago (the age of the ridge at the change in trend) to west of northwest until the present day. Radiometric dating of rocks from the ridge indicates that it is 70 million years old at its extreme north end.

Other prominent aseismic ridges include the Ninetyeast Ridge and the Chagos-Laccadive Plateau in the Indian Ocean and the Walvis Ridge and Rio Grande Rise in the South Atlantic. The Ninetyeast Ridge is thought to have originated from hot spot volcanic activity now located at the Kerguelen Islands near Antarctica. These islands lie atop the Kerguelen Plateau, which also originated from volcanism at this hot spot. The Ninetyeast Ridge stretches parallel to 90° E longitude in a long, linear chain of seamounts and volcanic ridges from the Andaman Islands in the Bay of Bengal more than 4,500 kilometres to the south where it intersects Broken Ridge at 30° S latitude. Broken Ridge is an aseismic ridge and was once part of the Kerguelen Plateau. It was split away from the plateau as Australia separated from Antarctica.

Core samples of the seafloor along the Ninetyeast Ridge have been retrieved through deep-sea drilling. Analyses of the samples show that the ridge is slightly less than 30 mil-

lion years old in the south and about 80 million years old in the north. Additionally, sediments on the ridge indicate that parts of it were above sea level while it was being built near a spreading centre. The ridge then subsided as it rode north on the Indian Plate.

The Walvis Ridge and Rio Grande Rise originated from hot spot volcanism now occurring at the islands of Tristan da Cunha 300 kilometres east of the crest of the Mid-Atlantic Ridge. The Walvis Ridge trends northeast from this location to the African margin. The Rio Grande Rise trends roughly southeast from the South American margin toward the Mid-Atlantic Ridge. Both the Walvis Ridge and Rio Grande Rise began forming from the same hot spot near the spreading centre as the South Atlantic was in its initial opening stages 100 to 80 million years ago. The spreading centre shifted west of the hot spot about 80 million years ago, ending construction of the Rio Grande Rise but continuing to build the Walvis Ridge. Volcanic activity has since diminished, resulting in the younger part of the latter ridge being smaller. The findings of ocean drilling on the Rio Grande Rise show that it was once a volcanic island some two kilometres high.

SEAMOUNTS, GUYOTS, AND ABYSSAL HILLS

Seamounts are submarine volcanoes with more than 1,000 metres of relief. Aseismic ridges are built by chains of overlapping seamounts. A seamount is akin to a subaerial shield volcano in that it also has gently sloping sides (5° to 15°) and is constructed by nonexplosive eruptions of alkaline basalt lavas that are thought to originate from depths of roughly 150 kilometres. About 2,000 seamounts are known; they are most common in the Pacific and on fast-spreading ridges. Like the Hawaiian-Emperor chain, the lines of seamounts and islands trending northwest-southeast in the central and south Pacific (Marshall Islands, Line Islands, Tuamotu Archipelago, and Cook and Austral Islands) may be due to hot spot volcanism. Isolated seamounts also occur, and many of these are located in the far western Pacific. Another group of smaller seamounts is found in the northeastern Pacific.

Submarine
volcanoes

Flat-topped seamounts are called guyots. They are particularly abundant in the western Pacific and along the Emperor seamount chain. Bottom samples and drill cores of shallow-water sediments and fossils capping guyots have been retrieved. The presence of such geologic materials suggest that guyots are seamounts that have had their peaks planed off by wave action and have since subsided below sea level. The western Pacific guyots are capped by drowned coral atolls and reefs. These reefs are generally of Late Cretaceous age (about 95 million years old). The cause of the subsidence is attributed to the sinking of the seafloor as it moves down the flanks of an oceanic ridge. However, the reason for the demise of the coral reefs on the Cretaceous guyots is less clear. Under normal conditions, coral growth can easily keep up with sinking due to seafloor spreading. The Cretaceous guyots may have resulted from the northward drift of seamounts and reefs on the Pacific Plate away from the tropical zone of favourable growth. Another hypothesis is that the reefs were killed by unusually anoxic (oxygen-depleted) conditions that developed suddenly, a situation possibly related to intense seafloor volcanism in the Pacific at this time.

Abyssal hills are low-relief (less than 1 kilometre) features usually 1 to 10 kilometres wide and elongate parallel to spreading centres or to marine magnetic anomalies located in the vicinity of the latter. The tops of the hills are often flat, in which case they have steep sides. Gently sloping sides, however, are equally common. Abyssal hills are extremely numerous, so much so that Menard declared them "the most widespread physiographic forms of the face of the earth." Abyssal hills are most common in the Pacific basin, where they cover 80 to 85 percent of the seafloor. Because they cover the entire flanks and crests of the oceanic ridges, such hills are thought to form during crustal accretion at spreading centres. They are commonly associated with intermediate- and fast-spreading ridges. On slow-spreading ridges, such as the Mid-Atlantic, the topographic features are much larger and have steeper sides. Bottom-sampling and seismic reflection studies re-

veal that abyssal hills are relief features on the top of the oceanic crust; they are not constructed from ocean-bottom sediments. In areas such as the abyssal plains (see below), abyssal hills are buried by sediments.

Apparently the hills are constructed by two processes: volcanism and block faulting. The relative contribution of each may depend on the spreading rate. At slower rates, faulting of the oceanic crust is a dominant factor in forming the relief, and the relief of the hills is greater as the rate is slower. At the crest of a spreading centre, volcanism in the neovolcanic zone initiates the construction of volcanic hills. The zone of active faulting is where they form or are modified by block faulting. The existence of discrete and separate volcanic hills indicates that volcanism at a spreading centre is episodic.

DEEP-SEA SEDIMENTS

The ocean basin floor is everywhere covered by sediments of different types and origins. The only exception are the crests of the spreading centres where new ocean floor has not existed long enough to accumulate a sediment cover. Sediment thickness in the oceans averages about 450 metres. The sediment cover in the Pacific basin ranges from 300 to 600 metres thick, and that in the Atlantic is about 1,000 metres. Generally, the thickness of sediment on the oceanic crust increases with the age of the crust. Oceanic crust adjacent to the continents can be deeply buried by several kilometres of sediment. Deep-sea sediments can reveal much about the last 200 million years of Earth history, including seafloor spreading, the history of ocean life, the behaviour of the Earth's magnetic field, and the changes in the ocean currents and climate.

The study of ocean sediments has been accomplished by several means. Bottom samplers, such as dredges and cores up to 30 metres long, have been lowered from ships by wire to retrieve samples of the upper sediment layers. Deep-sea drilling has retrieved core samples from the entire sediment layer in several hundred locations in the ocean basins. The seismic reflection method has been used to map the thickness of sediments in many parts of the oceans. Besides thickness, seismic reflection data can often reveal sediment type and the processes of sedimentation. (For more information on the equipment and techniques used by investigators to study deep-sea sediments, see EXPLORATION: *Undersea exploration*.)

Sediment types. Deep-sea sediments can be classified as terrigenous, originating from land; biogenic, consisting largely of the skeletal debris of microorganisms; and authigenic, formed in place on the seafloor (Figure 37). Pelagic sediments, either terrigenous or biogenic, are those

that are deposited very slowly in the open ocean either by settling through the volume of oceanic water or by precipitation. The sinking rates of pelagic sediment grains are extremely slow because they ordinarily are no larger than several micrometres. However, fine particles are normally bundled into fecal pellets by zooplankton, which allows sinking at a rate of 40 to 400 metres per day.

Terrigenous sediments are transported to the oceans by rivers and wind. The sediments that reach the continental shelf are often stored in submarine canyons on the continental slope. Turbidity currents carry these sediments down into the deep sea (see above *Density currents in the oceans: Turbidity currents*). These currents create sedimentary deposits called turbidites, which are layers up to several metres thick composed of sediment particles that grade upward from coarser to finer sizes. The turbidites build sedimentary deep-sea fans adjacent to the base of the continental slope. Turbidites also are found below the major river deltas of the world where they build features called abyssal cones. The largest of these is the Ganges Fan (also called the Ganges Cone or Bengal Cone) in the Bay of Bengal east of the Indian subcontinent. It measures 3,000 kilometres long (north-south) by 1,000 kilometres wide (east-west) and is up to 12 kilometres thick. The Bengal Cone is forming from rock material eroded from the Himalayas and transported by the Ganges and Brahmaputra rivers.

Abyssal plains are formed by the accumulation of turbidites beyond the limits of deep-sea fans and abyssal cones in locations where there is a very large sediment supply. In contrast to fans and cones, abyssal plains are flat and featureless. They are prominent near both margins of the Atlantic and in the northeast Pacific. Tectonic and climate controls have influenced the formation of abyssal plains. The last major glaciation near the end of the Pleistocene epoch about 10,000 years ago greatly increased erosion and sediment supply to the deep sea, but deep-sea trenches interrupted the flow of turbidity currents to the ocean floor. Off the Pacific Northwest coast of the United States, however, the trenches were filled by turbidites, and subsequent turbidity currents passed beyond them to form the Alaska and Tufts abyssal plains.

Brown clays are a variety of pelagic sediment, mostly of terrigenous origin, which are composed largely of four different clay minerals: chlorite, illite, kaolinite, and montmorillonite. By definition, clays have less than 30 percent biogenic components. Quartz, volcanic ash, and micro-meteorites are common as minor constituents. Brown clays are widespread in the deeper areas of the oceans below four kilometres. They dominate the floor of the

Abyssal
plains

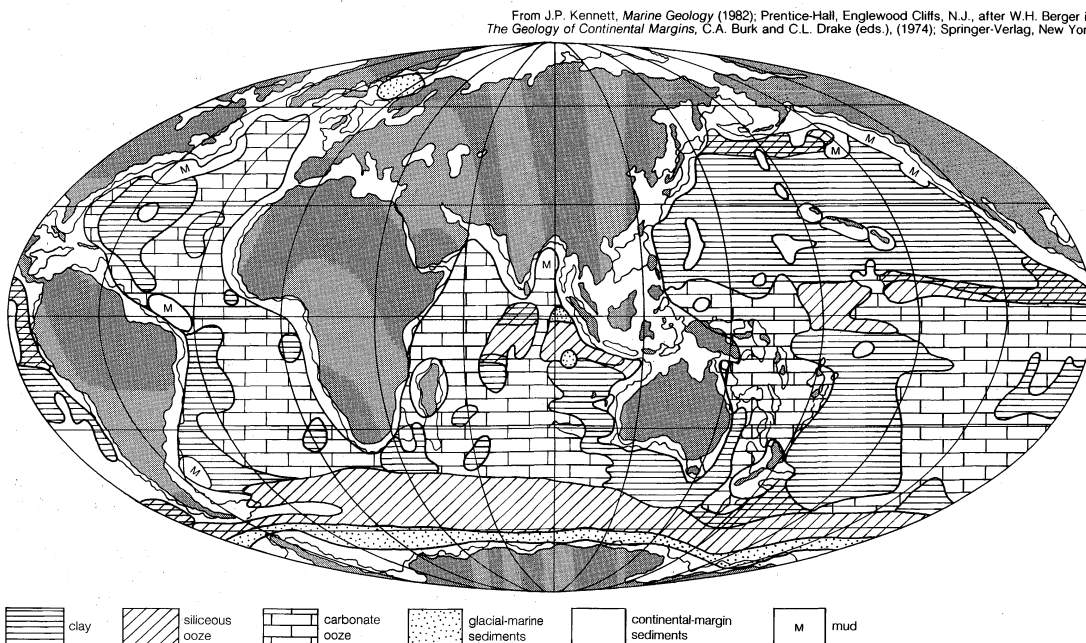

Figure 37: Global map of the distribution of sediment types on the ocean floor.

central North Pacific. Clays accumulate very slowly, averaging about one millimetre per 1,000 years. The type of clay found in a given area is a function of the source region on land and the climate. For example, chlorite is dominant in polar regions and kaolinite in the tropics. Clays are introduced into the oceans by river transport, although kaolinite is also carried by the wind from the arid regions of Africa and Australia. Montmorillonite is an alteration product of volcanic material and can form from either wind-blown volcanic ash or basaltic glass on the seafloor.

Sediments composed mostly or entirely of volcanic ash are commonly found adjacent to the island arcs and marginal trenches. These are normally deposited as turbidites. Volcanic ash that has been ejected higher than five kilometres during an eruption can be carried by wind and settle out through the atmosphere and oceans as pelagic sediment. The ocean floor encircling Antarctica is covered by glacial marine sediments. These sediments are carried by icebergs from the continent as far north as the Antarctic Convergence at 45° to 55° latitude.

Biogenic oozes are pelagic sediments that have more than 30 percent skeletal material. They can be either carbonate (or calcareous) ooze or siliceous ooze. The skeletal material in carbonate oozes is calcium carbonate usually in the form of the mineral calcite but sometimes aragonite. The most common contributors to the skeletal debris are such microorganisms as foraminiferans and coccoliths, microscopic carbonate plates that coat certain species of marine algae and protozoa. Siliceous oozes are composed of opal (amorphous, hydrated silica) that forms the skeleton of various microorganisms, including diatoms, radiolarians, siliceous sponges, and silicoflagellates. The distribution of biogenic oozes depends mainly on the supply of skeletal material, dissolution of the skeletons, and dilution by other sediment types, such as turbidites or clays.

Primary productivity in the ocean surface waters controls supply to a large extent. Productivity is high at the equator and in zones of coastal upwelling and also where oceanic divergences occur near Antarctica. Productivity is lowest in the central areas of the oceans (the gyres) in both hemispheres. Siliceous oozes are more reliable indicators of high productivity than carbonate oozes. This is because silica dissolves quickly in surface waters and carbonate dissolves in deep water; hence, high surface productivity is required to supply siliceous skeletons to the ocean floor. Carbonate oozes dominate the deep Atlantic seafloor, while siliceous oozes are most common in the Pacific; the floor of the Indian Ocean is covered by a combination of the two (see Figure 37).

Carbonate oozes cover about half of the world's seafloor. They are present chiefly above a depth of 4,500 metres; below that they dissolve quickly. This depth is named the Calcite Compensation Depth (or CCD). It represents the level at which the rate of carbonate accumulation equals the rate of carbonate dissolution. In the Atlantic basin the CCD is 500 metres deeper than in the Pacific basin, reflecting both a high rate of supply and low rate of dissolution in comparison to the Pacific. The input of carbonate to the ocean is through rivers and deep-sea hydrothermal vents. Variation in input, productivity, and dissolution rates in the geologic past have caused the CCD to vary over 2,000 metres. The CCD intersects the flanks of the world's oceanic ridges, and as a result these are mostly blanketed by carbonate oozes.

Siliceous oozes predominate in two places in the oceans: around Antarctica and a few degrees of latitude north and south of the equator. At high latitudes the oozes include mostly the shells of diatoms. South of the Antarctic Convergence diatom oozes dominate the seafloor sediment cover and mix with glacial marine sediments closer to the continent. Seventy-five percent of all the oceans' silica supply is being deposited in the area surrounding Antarctica. Radiolarian oozes are more common near the equator in the Pacific. Here, both siliceous oozes and calcareous oozes occur, but carbonate deposition dominates the region immediately near the equator. Siliceous oozes bracket the carbonate belt and blend with pelagic clays farther north and south. Because siliceous skeletons dis-

solve so quickly in seawater, only the more robust skeletal remains are found in the siliceous oozes. Thus, fossils of this kind are not completely representative of the organisms living in the waters above.

The most significant authigenic sediments in the ocean basins today are metal-rich sediments and manganese nodules. Metal-rich sediments include those enriched by iron, manganese, copper, chromium, and lead. These sediments are common at spreading centres, indicating that processes at the centres are responsible for their formation—specifically, hydrothermal circulation is the controlling factor. Deep-sea drill cores have revealed the presence of metal-rich sediments on top of ancient oceanic crust away from ridge crests. It can be inferred from this that the processes controlling their formation existed in the past, but with variations. Which type of enriched sediment is deposited depends on the degree of mixing between the hydrothermal water deep in the crust at a spreading centre and the cold seawater percolating down into the crust. Little mixing produces sulfides, liberal mixing yields manganese-rich crustal material, and intermediate conditions give rise to sediments enriched in iron and manganese.

Manganese nodules are pebbles or stones about the size of walnuts that are built of onionlike layers of manganese and iron oxides. Minor constituents include copper, nickel, and cobalt, making the nodules a potential ore of these valuable elements. Mining of manganese nodules has been the subject of study and experimentation since the 1950s (see below *Economic aspects of the oceans: Sources of minerals and other raw materials*). The nodules grow very slowly, about one to four millimetres per million years. They are found in areas of slow sedimentation, usually five millimetres per thousand years or less. The North and South Pacific hold the greatest concentration of manganese nodules; in some places, the nodules cover 90 percent of the surface of the ocean floor. Coverages this high also are found in the southernmost South Atlantic. The Indian Ocean floor is largely devoid of manganese nodules. Because seawater is supersaturated in manganese, the direct precipitation of the element onto an available surface is the most likely mode of nodule formation.

Two significant mysteries surround manganese nodules. Drilling and coring in the sediment column has shown that nodules are vastly more abundant at the seafloor than below it and that the rate of growth of nodules is 10 times slower than the lowest known sedimentation rates. If such is the case, the nodules should be quickly buried and should be common in the sediment below the seafloor. Current theories for explaining these observations propose that bottom currents keep areas of nodule growth free of sediment deposition and that burrowing organisms nudge and roll the nodules in the process of feeding, thereby keeping them at the surface of the seafloor. Observations in the deep sea support both explanations.

Sedimentation patterns. The patterns of sedimentation in the ocean basins have not been static over geologic time. The existing basins, no more than 200 million years old, contain a highly variable sedimentary record. The major factor behind the variations is plate movements and related changes in climate and ocean water circulation. Since about 200 million years ago, a single vast ocean basin has given way to five or six smaller ones. The Pacific Ocean basin has shrunk, while the North and South Atlantic basins have been created. The climate has changed from warm and mild to cool, stormy, and glacial. Plate movements have altered the course of surface and deep ocean currents and changed the patterns of upwelling, productivity, and biogenic sedimentation. Seaways have opened and closed. The Strait of Gibraltar, for example, was closed off about 6 million years ago, allowing the entire Mediterranean Sea to evaporate and leave thick salt deposits on its floor. Changes in seafloor spreading rates and glaciations have caused sea level to rise and fall, greatly altering the deep-sea sedimentation pattern of both terrigenous and biogenic sediments. The CCD has fluctuated more than 2,000 metres in response to changes in carbonate supply and the corrosive nature of ocean bottom waters. Bottom currents have changed, becoming erosive or nondepositional in some regions to produce

Manganese
nodules

Calcite
Compensa-
tion Depth

unconformities and redistributing enormous volumes of sediment to other locations. The Pacific Plate has been steadily moving northward, so that biogenic sediments of the equatorial regions are found in drill cores taken in the barren North Pacific.

EVOLUTION OF THE OCEAN BASINS THROUGH PLATE MOVEMENTS

Through most of geologic time, probably extending back 2 billion years, the ocean basins have both grown and been consumed as plate tectonics continued on Earth. The latest phase of ocean basin growth began just less than 200 million years ago with the breakup of the supercontinent Pangaea, the enormous landmass composed of nearly all the present-day continents. Since that time, the major developments have included a shrinking of the Pacific basin at the expense of the growing Atlantic and Arctic basins, the opening of the Tethys seaway circling the globe in tropical latitudes and its subsequent closing, and the opening of the Southern Ocean (see above *General considerations*) as the southern continents moved north away from Antarctica.

As was noted earlier, the oldest known oceanic crust (estimated to be about 200 million years old) is located in the far western equatorial Pacific, east of the Mariana Island arc. The Pacific ocean floor at this site was generated during seafloor spreading from a pattern of ridges and plates that had existed for some unknown period of time. At least five different seafloor spreading centres were involved (Figure 38). In the Indian Ocean the oldest segment of seafloor was formed about 165 to 145 million years ago by the rifting away of Africa and South America from Gondwana, a supercontinent consisting largely of the present-day continents of the Southern Hemisphere. At this time, Africa was joined to South America, Eurasia, and North America. Today, this old seafloor is found along the east coast of Africa from the Somali Basin to the east coast of South Africa and adjacent to Queen Maud Land and Enderby Land in East Antarctica.

Close to 180 million years ago (but before 165 million years ago), North America and Eurasia, which together made up most of the large northern continent of Laurasia, began drifting away from Africa and South America, creating the first seafloor in the central region of the North Atlantic and opening the Gulf of Mexico. The Tethys seaway also opened during this rifting phase as Europe pulled away from Africa. Shortly after this time continental fragments, including possibly Tibet, Myanmar (Burma), and Malaya, rifted away from the northwest coast of Australia and moved northward, thereby creating the oldest seafloor in the Timor Sea. During this period spreading continued in the Pacific basin with the growth of the Pacific Plate and the consumption by subduction of its bordering plates, including the Izanagi, Farallon, and Phoenix. The Pacific Plate moved northward during this phase and continues to do so today.

India and Madagascar, as a unit, rifted away from Australia and Antarctica prior to 130 million years ago and began drifting northward, creating seafloor adjacent to Western Australia and East Antarctica (Figure 39). Possibly simultaneously or shortly after this rifting began, South America started to separate from Africa, initiating the formation of seafloor in the South Atlantic Ocean.

Between 90 and 80 million years ago, Madagascar and India separated, and the spreading ridges in the Indian Ocean were reorganized. India began drifting northward directly toward Asia. During this same period Europe, joined to Greenland, began drifting away from North America, which resulted in the emergence of the seafloor in the Labrador Sea and the northernmost Atlantic Ocean. This spreading phase affected the passages in the Tethys seaway between Europe (Iberia) and northwest Africa, intermittently opening and closing it. In the southwest Pacific, New Zealand, along with the Lord Howe Rise and the Norfolk Ridge, rifted away from Australia and Antarctica between 80 and 60 million years ago, opening the Tasman Sea.

About 60 million years ago a new rift and oceanic ridge formed between Greenland and Europe, separating them

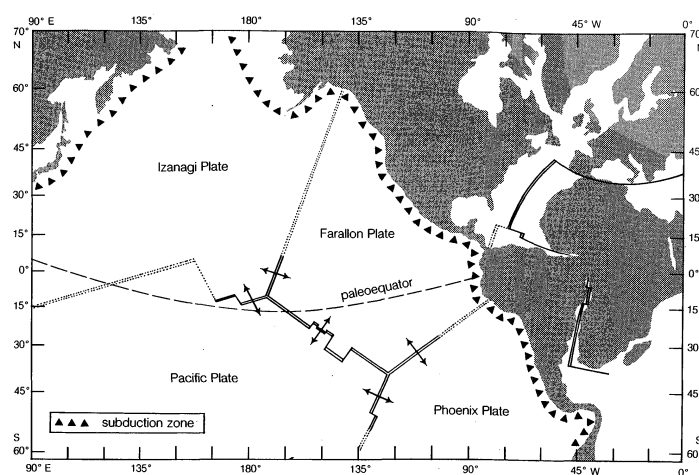

Figure 38: Possible configuration of spreading centres in the Pacific Ocean about 110 million years ago (see text).

and initiating the formation of oceanic crust in the Norwegian Sea and the Eurasian basin in the eastern Arctic Ocean (Figure 40). The Amerasian basin in the western Arctic Ocean had formed during an earlier spreading phase from about 130 to 110 million years ago. Between 60 and 50 million years ago, significant events occurred in the Indian Ocean and southwest Pacific. Australia began drifting northward, away from East Antarctica, creating seafloor there. The northward movement of Australia resulted in the emergence of several subduction zones and island arcs in the southwest and equatorial Pacific. The Indian sub-

continent first touched against the Asian continent about 53 million years ago, developing structures that preceded the main Himalayan orogeny (mountain-building event), which began in earnest some 40 million years ago.

Less than 30 million years ago, seafloor spreading ceased in the Labrador Sea. Along the west coast of North America, the Pacific Plate and the North American Plate converged along what is now California shortly after 30 million years ago. This resulted in the cessation of a long history of subduction in the area and the gradual conversion of this continental margin to a transform fault zone. Continued closure between Africa and Europe, which began about 100 million years ago, caused the isolation of the Mediterranean Sea, so that by 6 million years ago it had completely evaporated.

The present-day Mediterranean seafloor was formed during a complex sequence of rifting between small plates in this region, beginning with the separation of North America and Europe from Africa about 200 million years ago. In the eastern Mediterranean, the seafloor is no older than about 100 million years. West of Italy it was created during subsequent spreading between 30 and 20 million years ago.

The Caribbean Sea and the Gulf of Mexico formed as a result of the relative movement between North America and South America. The seafloor of the Gulf of Mexico began forming some 160 to 150 million years ago. A proto- or ancient Caribbean seafloor also was formed during this period but was later subducted. The present Caribbean seafloor consists of a captured piece of the Farallon Plate (from the Pacific basin) and is estimated to be for the most part of Cretaceous age (*i.e.*, about 120 to 85 million years old).

The seafloor in the western portion of the Philippine Sea developed between 60 and 35 million years ago. In the east, it was formed by backarc spreading from 30 million years ago (see above). The origin of the older crust is not

completely clear. It either was created by spreading in the Pacific basin and subsequent capture by the formation of the Bonin and Mariana arcs, or it resulted from backarc spreading behind trenches to the south.

PALEOCEANOGRAPHY

Through knowledge of the ocean sedimentary record, the history of plate motions, glacial changes, and established relations between present sedimentation patterns and environmental factors, it is possible to reconstruct an oceanographic history for approximately the past 200 million years. This is the emerging field of paleoceanography.

Prior to the breakup of Pangaea, one enormous ocean, Panthalassa, existed on Earth. Currents in this ocean would have been simple and slow, and the Earth's climate was, in all likelihood, warmer than today. The Tethys seaway formed as Pangaea broke into Gondwana and Laurasia (see above). In the narrow ocean basins of the central North Atlantic, restricted ocean circulation favoured deposition of evaporites (halite, gypsum, anhydrite, and other less abundant salts). Evaporites also were deposited some 100 million years ago in the equatorial regions of the South Atlantic during the early opening of this ocean.

Sequences of organic-rich, black shales were deposited during the early phases of spreading in the North and South Atlantic. These sediments indicate anoxic conditions in the deep ocean waters. The oceans must have been well stratified into dense layers to prevent the overturning and mixing required to replace depleted oxygen. Black shales also were deposited in the older areas of the eastern Indian Ocean.

During the time interval between 200 and 65 million years ago, but especially from 100 to 65 million years ago, microplankton abundance and diversity increased enormously in the oceans. This resulted in increased deposition of biogenic sediments in the ocean basin. During Cretaceous time (from 144 to 66.4 million years ago),

Panthalassa

sea level was often high, and shallow seas lapped onto the continents. This may have provided an environment favourable to the explosion in the numbers of species of foraminiferans, diatoms, and calcareous nannoplankton. Increased abundance of calcareous nannoplankton shifted the locus of carbonate sedimentation from shallow seas to the deep ocean. The end of Cretaceous time is marked by a sudden extinction of many life-forms on Earth, and marine organisms were no exception (see GEOCHRONOLOGY: *Cretaceous Period*). Coccolithophores (calcareous nannoplankton) and planktonic foraminiferans were particularly affected, and only a few species survived. Ocean sediments were suddenly less biogenic, and clays became widespread.

After Cretaceous time the Earth underwent a gradual cooling, especially at high latitudes. Deep-sea sedimentation changed as thermohaline bottom water circulation became fully developed (see above *Circulation of the ocean waters: Thermohaline circulation*). The CCD rose in the Pacific and dropped in the Atlantic as a result of changes in thermohaline circulation. An event of major significance was the spreading away of Australia from Antarctica beginning about 53 million years ago. This separation initiated limited circum-Antarctic circulation, which isolated Antarctica from the warmer oceans to the north, and led to cooling, which set the stage for later major glaciation.

At the Eocene-Oligocene boundary (36.6 million years ago), Antarctic Bottom Water began to form, resulting in greatly decreased bottom-water temperatures in both the Pacific and Atlantic oceans. Bottom-living organisms were strongly affected, and the CCD suddenly dropped from about 3,500 metres to approximately 4,000 to 5,000 metres in the Pacific. Bottom-water temperatures were generally warm, 12° to 15° C, during the time preceding this event. In a study of deep-sea sediment core material from near Antarctica, J.P. Kennett and Lowell D. Stott of the United States discovered that there was a period between roughly 50 and 35 million years ago when deep waters were very warm (20° C) and salty. The origin of these ocean waters was most likely in the low latitudes and resulted from high evaporation rates there.

The modern oceans are distinguished by very cold bottom water. The gradual changes toward this condition began 10 million years after the origination of Antarctic Bottom Water. Particularly significant among these changes was the closing of the Tethys seaway as Australia and several microcontinents moved north into the Indonesian region. Also, Australia moved far enough north that circum-Antarctic surface circulation became fully established.

The modern ocean circulation patterns and basin shapes were mostly in place by the beginning of Miocene time (nearly 24 million years ago). An exception was an ocean connection between the Pacific and Caribbean Sea in Central America that persisted until about 3 million years ago. Major and probably permanent ice sheets on Antarctica formed during Miocene time, and glacial sediments began to dominate the seafloor surrounding the continent shortly thereafter. Siliceous oozes also became widespread around Antarctica. Siliceous sedimentation increased in this area at the expense of siliceous sedimentation in equatorial regions. Ocean circulation became more vigorous, global climate became cooler, and sedimentation rates in the ocean basins increased. Planktonic microorganisms were segregated into latitudinal belts. Bottom-water flow north through the Drake Passage between South America and Antarctica began in Miocene time, resulting in erosion and nondeposition of sediments in the southwest Atlantic and southeast Pacific oceans. Also during Miocene time rifting between Greenland and Europe had progressed to a point where a connection was established between the North Atlantic and the Norwegian Sea. This resulted in the formation of North Atlantic Deep Water (see above *Circulation of the ocean waters: Thermohaline circulation*), which began flowing south along the continental rise of North America at this time. Sediments redistributed and deposited by this deep current are called contourites and have been extensively studied by Bruce Heezen, Charles D. Hollister, and Brian E. Tucholke, among others.

Sudden global cooling set in near the end of the Miocene some 6 million years ago. The strength of ocean circulation

must have increased, as evidence of increased upwelling and biological productivity is present in ocean sediments. Diatomaceous sediments were deposited in abundance around the rim of the Pacific. This cooling event is synchronous with a drop in sea level, thought to be about 40 or 50 metres by various authorities, and probably corresponds to the further growth of the Antarctic ice sheet. This lowered sea level, coupled with the closure of narrow seaways probably due to plate movements, isolated the Mediterranean Sea. Subsequently, the sea dried up, leaving evaporite deposits on its floor. The Swiss geologist Kenneth J. Hsü and the American oceanographer William B.F. Ryan have concluded that the Mediterranean probably dried up about 40 times as seaways opened and closed between 6 and 5 million years ago. This evaporation removed about 6 percent of the salt from the world ocean, which raised the freezing point of seawater and promoted further growth of the sea ice surrounding Antarctica.

Enormous ice sheets emerged in the Northern Hemisphere between 3 and 2 million years ago, and the succession of Quaternary glaciations began at 1.6 million years ago. The exact cause of the glacial period is unclear, but it is most likely related to the variability in solar isolation, increased mountain building, and an intensification of the Gulf Stream at 3 million years ago due to the closing off of the Pacific-Caribbean ocean connection in Central America. The Quaternary glaciations, of which there were probably 30 episodes, left the most dramatic record in ocean sediments of any event in the previous 200 million years. Terrigenous sedimentation rates greatly increased in response to fluctuations in sea level of up to 100 metres and a more extreme climate. Biogenic sedimentation also increased and fluctuated with the glacial episodes. Deep-sea erosion began in many places as a result of intensified bottom-water circulation. (B.P.L.)

Continental margins

GENERAL CONSIDERATIONS

Continental margins are the submarine edges of the continental crust, which is, as noted above, relatively light and isostatically high-floating in comparison with the adjacent oceanic crust. Figure 41 is a block diagram that schematically shows the physiographic divisions of a continental margin. These divisions are the continental shelf, the continental slope, and the continental rise. Characteristics of the various continental margins are shaped by a number of factors. Chief among these are tectonics, fluctuations of sea level, the size of the rivers that empty onto a margin as determined by the amount of sediment they carry, and the energy conditions or strength of the ocean waves and currents along the margin.

Margin types. Continental margins on the leading edges of tectonic plates, like those around the rim of the Pacific Ocean, are usually narrow and have steep continental slopes and either poorly developed continental rises or none at all. The continental slope is often steep and falls away directly into a deep-sea trench. In many cases, the leading-edge margins are backed by mountain ranges. Continental margins on the trailing side of tectonic plates, like those around the Atlantic Ocean, are broad, with gen-

Figure 41: Physiographic divisions of the continental margin.

Formation of Antarctic Bottom Water and its effects

Physiographic divisions

the continental slopes and well-developed continental rises. The adjacent land area is commonly a broad coastal plain (see Figure 41) that, depending on the state of sea level, may become submerged from time to time and hence part of the continental margin.

Since continental margins are the shallowest parts of the world's oceans, they are most affected by changes in sea level. Worldwide changes in sea level, called eustatic sea-level changes, have occurred throughout geologic history. The most common causes of such sea-level changes are global climatic fluctuations that lead to major glacial advances and retreats—i.e., ice ages and interglacial periods. Other causes that are not as well understood may include major mountain-building events and isostatic changes in crustal plates. When continental glaciers advance, as they did several times during the Pleistocene Epoch (which extended from about 1,600,000 to 10,000 years ago), water that would normally be in the oceans is locked up as ice on land, resulting in a drop in sea level. As the glaciers retreat, more water is fed to the ocean basins and the sea level rises. Fluctuations from highstand to lowstand have totaled 250 metres or more during Cenozoic time (roughly the last 66.4 million years), with concomitant fluctuations in exposure and flooding of the continental margins. (During a highstand the sea level is above the edge of the continental shelf, while during a lowstand it is below the shelf edge.)

Rivers bring a variety of sediments to the coast. These are classified by their mineralogy and by particle size and include sand, silt, and clay. Sand to sedimentologists is a grain of any composition from 63 to 2,000 micrometres (0.0063 to 0.2 centimetres) in its largest diameter. Silt is 4 to 62 micrometres, and clay is any particle less than 4 micrometres. Most of the detrital minerals brought to the continental margins by rivers in sand and silt sizes are quartz, feldspars, and mica; those of clay size are a suite of clay minerals that most commonly include smectite, kaolinite, and illite. (Clay can, in other words, refer either to particle size or to a group of minerals.) These, then, are the mineral constituents, which, together with calcium carbonates produced in the oceans by biogenic activity as shells and the hard parts of plants and animals, go to make up the sedimentary packages that are deposited on and constitute a fundamental part of continental margins.

A constant battle is being waged between the rivers that bring sediments eroded from the land to the sea and the

waves and currents of the receiving body of water. This dynamic struggle goes on year after year, century after century, sometimes for millions of years. Take, for example, the north coast of the Gulf of Mexico into which the Mississippi River flows. The continental margin at this site is subject to relatively low wave and current energy, and so the river has filled up most of the adjacent continental shelf with a delta and dumps roughly 256 million tons of sediment each year directly at the top of the continental slope. By contrast, the Columbia River in the Pacific Northwest of the United States carries 131 million tons to the coast, where the sediments are attacked by the large waves and currents normal for that margin. As a result, sediments are widely dispersed, and the shelf is not filled with a large subaerial delta. Figure 42 shows the discharge of sediments to the continental margins of the world.

The effects of this battle are easily seen where human activities have interfered with the transport of sediments to the sea by major rivers. For example, the Nile River delta is retreating rapidly, widening the submerged portion of the continental margin, because the Aswan High Dam has trapped much of the sediment normally fed to the delta front. The lower Mississippi River has been artificially maintained in a channel by high man-made levees. These have stopped the floods that fed much of the western delta margin. Because of this, coupled with a slow rise in sea level and the effects of canals dug in the delta wetlands, the coast has begun to retreat significantly.

When rivers carrying sediment from the interiors of continents reach the sea, several things happen. Velocity in the river jet decreases rapidly, and the sand particles drop out to be picked up by the waves and currents along the coast, where they feed beaches or barrier island systems (see CONTINENTAL LANDFORMS: *Structured landforms: Landforms produced by coastal processes: Landforms of depositional coasts*). If the river has a large enough discharge, the finer-than-sand-sized materials may be carried for kilometres onto the margin in a fresh- or brackish-water plume. The surf system then acts as a wave filter, trapping the sand in the coastal zone but allowing the finer materials to be carried out onto the margin. When estuaries are the receiving bodies of water on the coastal boundaries of continental margins, as in the case of the east coast of North America, virtually all the sediments brought down by the rivers are trapped within the confines of the estuaries.

In addition to the two primary types of continental mar-

Effects of human intervention on sedimentation

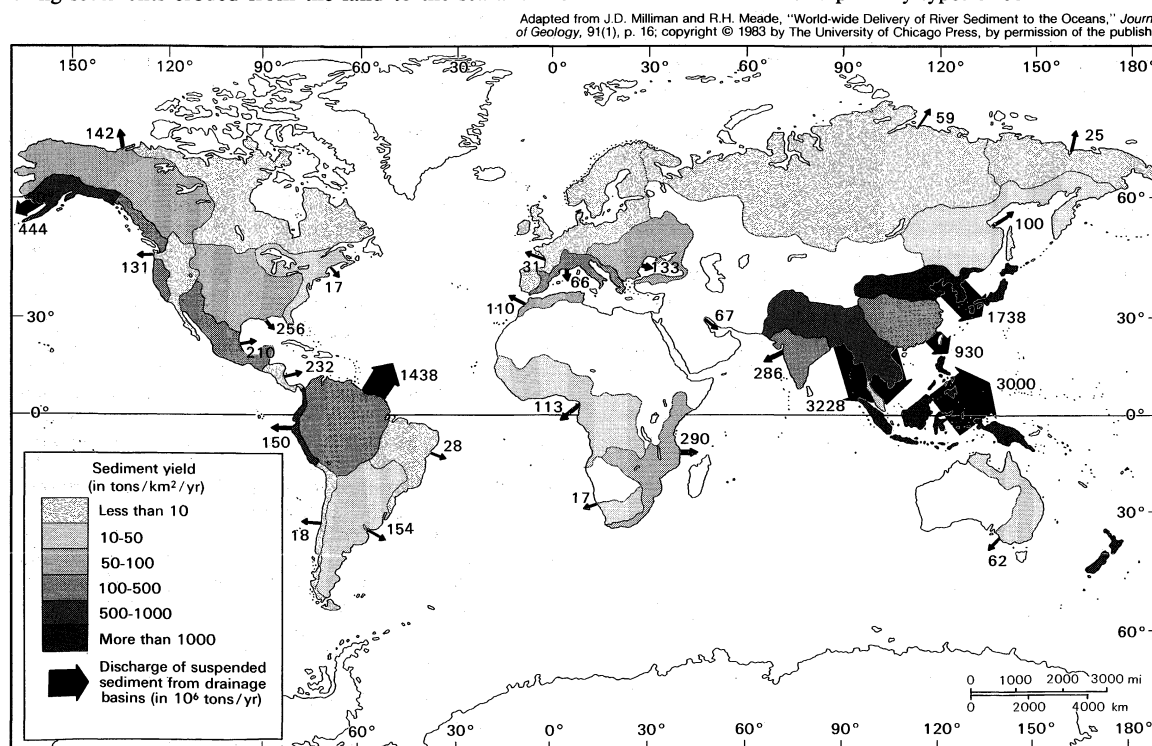

Figure 42: Discharge of sediments to the world's continental margins.

gin, there also are special types that do not readily fit either category. One of the most intensely studied margins of the world is the Borderland, the continental margin of southern California and northern Baja California. It consists of a series of offshore basins and ridges, some of which are exposed as islands. Figure 43 is a physiographic diagram of the Borderland. This system of basins and ridges formed as the result of faulting associated with the movement of the Pacific Plate past the North American Plate. It remains tectonically active today and is related to the San Andreas Fault system of California. A second special type is the marginal plateau. The Blake Plateau off the east coast of Florida is a good example. Such a plateau constitutes a portion of a continental margin that has many of the features of a normal system but is found at much greater depth—1,000 metres in the case of the Blake Plateau.

Marginal plateau

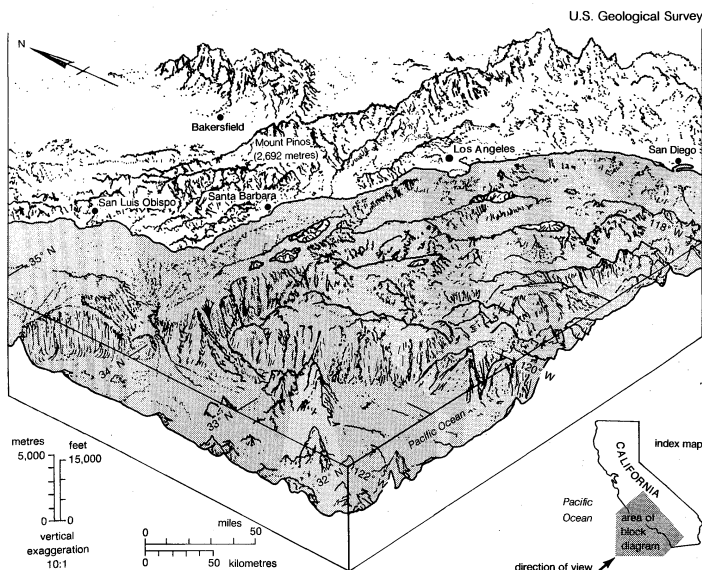

Figure 43: The Borderland of southern California.

Continental margins can be either constructional or erosional over varying periods of geologic time, depending on the combination of factors discussed above. When deposition exceeds erosion, the margin grows seaward, a process of progradation that builds out as well as up (Figure 44). When the erosive forces are predominant, the margin remains static or actually retreats over time. Some geologists think that the continental margin of the eastern United States has retreated as much as 5–30 kilometres since Cretaceous time—i.e., during the last 66 million years or so.

Economic importance of continental margins. Continental margins are very significant economically. Most of the major fisheries of the world are located on them. Of these, sport fisheries and related tourist industries are becoming increasingly important to the economies of developed nations. Paradoxically, continental margins also are one of the world's biggest dump sites. All kinds of wastes are disposed of along the margins, and the effects of pollution on their environment and ecology have become a major

After J.B. Sangree and J.M. Widmier in C.E. Payton (ed.), *Seismic Stratigraphy—applications to hydrocarbon exploration* (1977). The American Association of Petroleum Geologists

Figure 44: Prograded slope.

global concern (see also below *Economic aspects of the oceans: Waste disposal and other related actions*).

Continental margins are the only parts of the world's oceans to be effectively exploited for mineral resources. Millions of tons of sand are mined by dredges each year off the U.S. coasts alone for beach renourishment projects. From time to time placer deposits also have been worked. Examples include tin off Indonesia, gold off Alaska, and diamonds off Namibia. By far and away the largest mineral resources to be exploited from continental margins are oil and natural gas. Exploration of the continental margins by major oil companies has intensified and is expected to continue for the foreseeable future because the margins are the most likely sites of giant undiscovered petroleum deposits. Continental margins are made of thick accumulations of sedimentary rock, the type of rock in which oil and gas generally occur. In fact, most of the sedimentary rocks exposed on the continents were originally deposited on continental margins; thus, even the hydrocarbon deposits found on land were formed for the most part on ancient continental margins.

CONTINENTAL SHELF

Continental shelves make up about 8 percent of the entire oceanic area. They extend from the shore to the shelf break, the point at which the angle of inclination steepens sharply, marking the boundary between the continental shelf and the continental slope. Built entirely on continental crust, the shelves are terraces gently inclined seaward at an average slope of about 0.1° , or about 2 metres per kilometre (see above Figure 41). Most shelves have a gently rolling topography called ridge and swale. Their geology is often similar to that of the adjacent exposed portion of the continent. The width of continental shelves at the present sea-level stand varies from a few kilometres to more than 400 kilometres. Throughout geologic time, the width of continental shelves has varied greatly with the rise and fall of eustatic sea level. Figure 45 is a representation of Florida and its continental shelf 18,000 years ago and at the present time. The depth of the shelf break varies widely from about 70 metres in the Beaufort and Chukchi seas in the Arctic region to more than 400 metres off parts of Norway, with the average at about 145 metres. Abnormal depth of the shelf break is most often the result of loading by glacial ice, either at present or within the last few tens of thousands of years. A few margins, such as those off the Mediterranean coast of France and Porcupine Bank, off the western coast of Ireland, do not have a sharply defined break in slope but rather maintain a generally convex shape to the seafloor.

Ridge and swale

The American oceanographer Donald J.P. Swift has called continental shelves palimpsests, parchment writing tablets upon which stories are written after each previous writing has been erased. Each new stand of sea level "writes" a new story of sedimentation on the shelf after the previous episode has been erased by the rise or fall that preceded it but with traces of the previous environment of deposition or last erosional event remaining. The eraser is the surf, a high-energy force that erodes and reworks everything as it passes over, winnowing out the finer-than-sand-sized sediment and leaving the coarser material behind. Figure 46 is an interpreted seismic line that shows the complicated array of channels (eroded and then filled), old deltaic deposits, ancient erosional surfaces, and winnowed sand bodies that make up the continental shelf southwest of Cape San Blas on the panhandle of Florida.

How the above processes affect any particular margin depends on its tectonic setting and the size of the rivers that drain into it. On continental shelves backed by high mountain ranges, such as the Pacific coast of North and South America, the difference between high and low sea-level stands may be difficult to detect, being one of degree perhaps noticeable only by marginally increased sedimentation rates during lowstands. In many ways, continental shelves on tectonically active margins at present sea levels approximate lowstands on trailing-edge, or passive, margins.

When sea level is lowered on a trailing-edge shelf that has no adjacent high mountains, such as the Atlantic coast

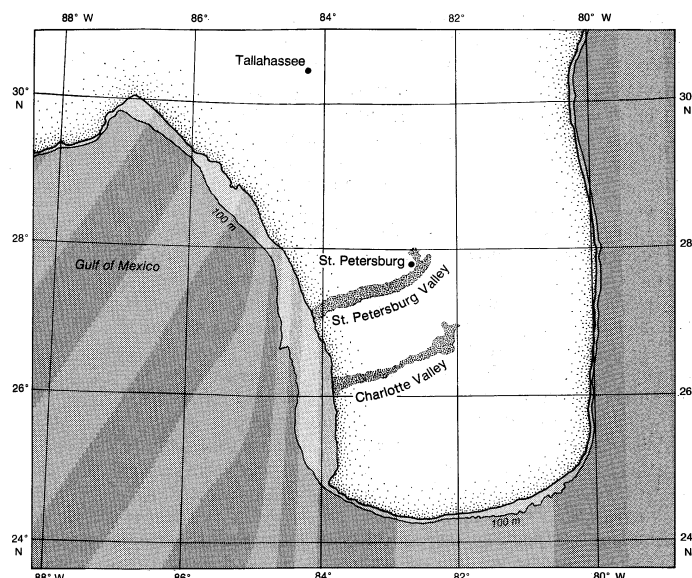

Figure 45: A representation of Florida's continental shelf some 18,000 years ago.

of North America, rivers are rejuvenated—i.e., their base level is lowered and they begin to erode their beds, carrying sediment from the continent across the former continental shelf that is now exposed and depositing it at the new coast. When sea level falls below the shelf break, the coast lies on the continental slope. As sea level rises again on tectonically stable or sinking shelves, medium- and small-sized river mouths drown and estuaries form, trapping the sediment within them and starving the shelves. In these cases, sediment for the shelf is primarily produced by erosion of the coastline as the surf zone advances landward with rising sea level. Fine-grained material is winnowed out, to be either deposited back in the estuaries or carried in steps by advective processes across the shelf to the deeper water beyond. As a result, continental shelf surfaces on trailing-edge margins into which no large rivers flow are veneered with a sand sheet lying over a complex of older deposits, some of which peek through the surface as outcrops—vestiges of an earlier story written on the palimpsest. Large rivers that drain a large, high continent, such as the Mississippi, are able to keep pace with rising sea level and deliver enough sediment to keep an estuary from forming, and, at a high stillstand like that of the present, even fill their entire shelf area. (For a description of modern deposits of this type, see *RIVERS: Rivers as agents of landscape evolution: Deltas.*)

For many years after World War II, the period when many of the world's continental shelves were first de-

Figure 46: Seismic line interpretation revealing features of the continental shelf southwest of Cape San Blas in Florida. These features, which include the filled river valley channels, old deltaic deposits, and ancient erosional surfaces shown in the top drawing, can be discerned from the seismic record section from this shelf segment, bottom.

scribed in detail, it was thought that the sand deposits on continental shelves were "relict," deposits left stranded by a higher sea level from the higher-energy regime of the surf zone that passed over them perhaps as much as a few thousand years before. Geophysical investigations of the shelf area since the mid-1970s have revealed the presence of many types of sand waves and ripple marks in seafloor sediments that show submerged continental shelf sediments to be constantly undergoing reworking and erosion. Figure 47 shows a side-scan sonograph of a large-scale sand-wave field with the associated bathymetric record. As scientific understanding of the physical processes that affect continental shelves has increased, it has been found that currents set up by large winter storms, monsoons, hurricanes, and typhoons are reworking the bottom by winnowing out the fine-grained materials and carrying them either back into the estuaries or beyond the shelf break, where they are lost from the system.

In short, the kind of sediment that covers the surface of a continental shelf is determined by the interplay among the tectonic setting, the size of the rivers that empty into it (size based on how much sediment they carry), and the wave energy that affects it, just as is the case with continental margins in general. Shelves such as that of western Florida that have been cut off from clastic input (i.e., sediments composed chiefly of quartz and clay minerals derived from erosion of the continent) may be covered with carbonate sediments. In some cases, as in the islands of The Bahamas, the carbonate shelf, called a bank, is cut off from a continental source by deep water. Continental shelves with rivers that carry sediments from the continents to the shelf and beyond only at lowstands of sea level and those that drain mountainous areas on high-energy coasts are dominated by quartz sands, and shelves with rivers that drain large continental areas and carry enough sediment to keep abreast of sea-level rise or dominate ambient wave-energy conditions will accumulate muddy sediment deposits out across their surfaces.

CONTINENTAL SLOPE AND RISE

About 8.5 percent of the ocean floor is covered by the continental slope-rise system. This system is an expression of the edge of the continental crustal block. Beyond the shelf-slope break, the continental crust thins quickly, and the rise lies partly on continental crust and partly on the oceanic crust of the deep sea. Inclination of the continental slope averages about 4° , although it can approach vertical on carbonate margins, on faulted margins, or on leading-edge, tectonically active margins such as that off the above-mentioned Borderland. Steep slopes usually have either a very poorly developed continental rise or none at all and are called escarpments. Partway down the continental slope there is often a second inflection point where the gradient drops to 1:100 to 1:700. This lower gradient area defines the continental rise, which may extend seaward several hundred kilometres to the deep seafloor at an average depth of about 4,000 metres. Although the slope-rise was formerly often divided into separate provinces, the trend among sedimentologists is to consider it as part of one continuum. The sedimentary processes that form the slope and rise, however, are quite distinct.

Formation of continental slopes. The continental slopes are temporary depositional sites for sediments. During lowstands of sea level, rivers may dump their sedimentary burden directly on them. Sediments build up until the mass becomes unstable and sloughs off to the lower slope and the continental rise. During highstands of sea level, these processes slow down as the coastline retreats landward across the continental shelf, and more of the sediments delivered to the coast are trapped in estuaries and lagoons. Still the process continues, albeit slowly, as sediments are brought across the shelf break by winnowing of the shelf surface and by advection. Slopes are sometimes scoured by such major ocean currents as the Florida Current that work to erode their surfaces. Off active major deposition centres, such as the Mississippi delta, slope sequences may accumulate through progradation, while the active slope front is continuously shedding sediments downslope by gravity processes.

Factors affecting shelf sediment type

Figure 47: (Top) Side-scan sonograph of a sand wave field and (bottom) corresponding bathymetric record.

From K.T. Logue, "Bedforms and Surface Sediments of the Northwest Florida Inner Continental Shelf" (1990); University of South Florida

Formation of continental rises. Continental rises are major depositional regimes. They consist of thick sequences of continental material that build up as the result of three sedimentary processes.

Sedimentary processes responsible for rise development

The first such process is a downslope movement of sediments by mass wasting, a set of gravity-deposition events, including submarine landslides, slumps, debris flows, and high-velocity, sediment-laden density flows known as turbidity currents (see above). Several phenomena may initiate gravity events. In tectonically active areas earthquakes are important triggering mechanisms. Even in the Atlantic they play a significant role. One of the few documented major gravity events took place on the Grand Banks of Newfoundland in 1929, when an earthquake triggered a gravity flow that possibly attained velocities of more than 90 kilometres per hour and was traced for hundreds of kilometres as it successively broke transatlantic cables. Other triggering events may be oversteepening of deposits on the sharply inclined portions of the continental slope, breaking internal waves that have been shown to affect the upper slope, and storm waves and storm-induced currents.

A second process that may be equally important, although its overall significance is subject to considerable scientific debate, is deposition from bottom currents that flow parallel to the slope of the continental rise—namely, contour currents. Resulting sediment accumulations are called contourites. The major points of contention concerning the efficacy of contour currents are (1) whether or not they are strong enough—they flow at a speed of about 20 centimetres per second—to build the huge thicknesses of sediment that make up the rises, and (2) how the sediments get into the contour currents in the first place. It is probable that most of the mass of rise material is originally brought downslope by gravity events and then redistributed by contour currents.

Vertical settling through the water column of both clastic and biogenic particles is the third contributor of slope and rise sediments. These pelagic sediments are composed of clay minerals and fine-grained particles (chiefly quartz, mica, and carbonate) swept off the continental shelf, wind-blown dust, organic detritus, and the tests of planktonic plants and animals. Chief among the last group are the tests of foraminiferans, pteropods, and coccolithophores that are composed of calcium carbonate and those of diatoms and radiolarians that are made of silicon dioxide.

SUBMARINE CANYONS

Originating on the continental shelf and cutting into the continental slope-rise system are some of the most spectacular physiographic features on the Earth—the submarine canyons. They have been the object of investigation for many years. Much of the definitive work was done by Francis P. Shepard of the United States, widely regarded as the father of modern marine geology, and Robert F. Dill, one of his students.

Characteristics. Submarine canyons come in various shapes and sizes. Many of those that have been extensively studied resemble terrestrial river-cut canyons. Submarine canyons are often V-shaped and have steep walls, sinuous courses, and tributaries that feed into them. Many end in a series of distributary channels through the continental rise (see *RIVERS: Rivers as agents of landscape evolution: Deltas: Morphology of deltas*). Distributary channels often emerge in the deep sea on abyssal plains that are found adjacent to the continents, especially in the Atlantic basin. The scale of many canyons is truly herculean. For example, the Hudson submarine canyon, which serves as a type canyon for those of the east coast of the United States, originates (or heads) on the outer edge of the continental shelf off New York harbour at a depth of about 90 metres. Hudson Canyon winds its way down the continental slope and enters the continental rise at a depth of about 2,100 metres. Higher up, where the canyon floor reaches a depth of 1,800 metres, the walls are nearly 1,220 metres high. The valley and its distributaries can be traced seaward across the continental rise for at least 300 kilometres to a depth of more than 4,500 metres.

Submarine canyons act as conduits to bring sand-sized sediments from the continental margins to the deep sea. During lowstands of sea level, rivers empty directly into the heads of many Atlantic canyons. Sand and mud are carried down these systems, many times bypassing the slope-rise system to be carried directly out onto the abyssal plains on the deep seafloor. Cores taken in abyssal plains in the Atlantic Ocean off North Carolina show distinctive shelf molluscan fragments in gravity-flow deposits that have traveled hundreds of kilometres and that can be traced back through the Hatteras submarine canyon system. During highstands of sea level, the submarine canyons off the east coast of North America are many tens of kilometres from the coastline, and the downslope movement through them is slowed down dramatically or perhaps even ceases. On the west coast of the continent where active tectonism results in a narrow margin backed by high mountains, a situation exists today that is roughly analogous to the one that prevails on a passive margin during lowstands of sea level. Submarine canyons originate close to the coast, intersecting the longshore current system and siphoning off sand to basin floors in the Borderland (see above).

Formation. The origin of submarine canyons is still not completely understood. Probably several processes contribute to their formation. The underlying question is how erosion occurs, often in solid rock, thousands of metres below the lowest known stand of sea level. Some canyons may be located on fault lines or other structural zones of weakness. They certainly are scoured by gravity flows of various types, and the collapsing of the outer portions of canyon walls plays an important part in widening them.

Submarine canyons are not present everywhere. They are rare on margins that have extremely steep continental slopes or escarpments. The reasons for this are unclear. It simply is one of many aspects of the mechanisms of submarine canyon formation that remain to be discovered.

Conduits for sand-sized sediments

Coastal and nearshore features

CORAL REEFS, CORAL ISLANDS, AND ATOLLS

Coral reefs are masses of carbonate of lime built up from the seafloor by the accumulation of the skeletons of a profusion of animals and algae; eventually they rise to the surface of the water.

Reef-building corals, chiefly the stony corals or Scleractinia, grow best in shallow, sunlit water, between the low-water mark and a depth of 11 metres, but they can still construct reefs in water as deep as 40 metres, and they may have a sparse existence between 40 and 55 metres. These corals prefer water of normal salinity and with an annual maximum temperature above 22° C but below 28° C. Their reef-building activities, however, may be carried on in waters whose minimum temperature in winter is not less than 15° C.

A second group of corals in present-day seas grows in

thickets and coppices that develop banks rather than reefs on the outer, deeper, colder, and darker parts of continental shelves and platforms. These organisms flourish in water with a winter minimum temperature ranging between about 4° and 15° C at depths of about 60 to 200 metres. In any one thicket there are commonly only two genera of delicately branching corals involved. Such coral banks are known along the eastern Atlantic shelf edge (or continental slope) from Norway to the Cape Verde islands and again off the Niger River delta and in the west Atlantic around the Gulf of Mexico, The Bahamas, and the Orinoco River delta. Off New Zealand such banks have been recognized on the Campbell Plateau and the Chatham Rise; they also occur in the northwest Pacific near Japan.

The third coral assemblage of the modern seas is associated with even colder or deeper seas; it consists of small, solitary corals of relatively few genera, known from the abyssal floors of the oceans and from the shelves around Antarctica, Patagonia, and the Falkland Islands in waters 2° to 6° C in temperature.

Fossil reefs Buried fossil reefs on ancient continental shelves are targets for petroleum exploration. The porosity of reefs and the characteristic curvature of nonporous enclosing sediments cause them to be prospective reservoirs for oil and gas. The rich oil fields of Alberta, for example, are associated with Devonian reefs (about 408 to 360 million years old). Fossil reefs recently have become targets for metal prospecting because some corals contain small percentages of metals, such as zinc and copper, selectively incorporated from seawater. A living coral reef may also have economic potential in that it constitutes a major tourist attraction.

Reef accumulation. *Tropical water conditions.* Water conditions favourable to the growth of reefs exist in tropical or near-tropical surface waters. Regional differences may result from the presence or absence of upwelling currents of colder waters or from the varying relation of precipitation to evaporation.

Tropical seas are well lit, the hours of daylight varying with the latitude. Light intensity and radiant energy also vary with the depth. Thus, at latitude 32°44' N (the Madeira Islands) the "day" in March has a length of 11 hours at a depth of 20 metres, 5 hours at 30 metres, and only about a quarter of an hour at 40 metres. Nearer

the pole these figures decrease further. Light intensity has a profound effect on the growth of the individual reef-coral skeleton because of the symbiont zooxanthellae of reef corals (see below *Biological factors*). The number of species present on a reef also may be related to light intensity and radiant energy.

Turbidity may be high in lagoons, where shallow water lies over a silt-covered seafloor and where storms and windy periods cause considerable disturbance of the bottom silt. The average transparency may be low (about 12 metres), and light penetration is reduced.

Inside the Great Barrier Reef, on the shallow continental shelf of Queensland, the oxygen content of the water is high, exceeding 90 percent saturation most of the time; in deeper water, during the calm periods of the rainy season, the saturation may fall to about 80 percent. Plant nutrients such as phosphate and nitrate show no seasonal change in quantity; both are present in very small quantities throughout the year. Constant mixing of the shallow sea prevents any stratification of the nutrients. As a result, growth of phytoplankton is possible and almost uniform throughout the year, providing a constant supply of food for the zooplankton, which in turn form the chief food supply of the corals. Some nutrients enter the lagoonal waters with the oceanic water that flows through the reef openings, but the dissolved phosphates in the lagoons are probably derived chiefly from bacterial decomposition of the organic matter on the sea bottom, as well as from detritus swept in from the reef surfaces. This environmental pattern is typical of many atoll lagoons.

Geochemistry of reefs. Minute quantities of metallic elements are present in solution in seawater and also occur in marine invertebrate skeletons, though not in the same proportions as in the surrounding water. Magnesium and strontium are the most frequently occurring trace elements in reef skeletons and are measured in parts per thousand, but barium, manganese, and iron are also present and can be measured in parts per million. In Pacific corals, 2.17 parts per million of uranium have been found, and in Florida coral, 2.36–2.95 parts per million. Strontium is concentrated in aragonitic skeletons, and magnesium in calcitic skeletons; coral aragonite has a higher strontium content than (some) molluscan aragonite; the magnesium content in the calcite of coralline algae is high; that of bar-

Trace
elements
in reef
skeletons

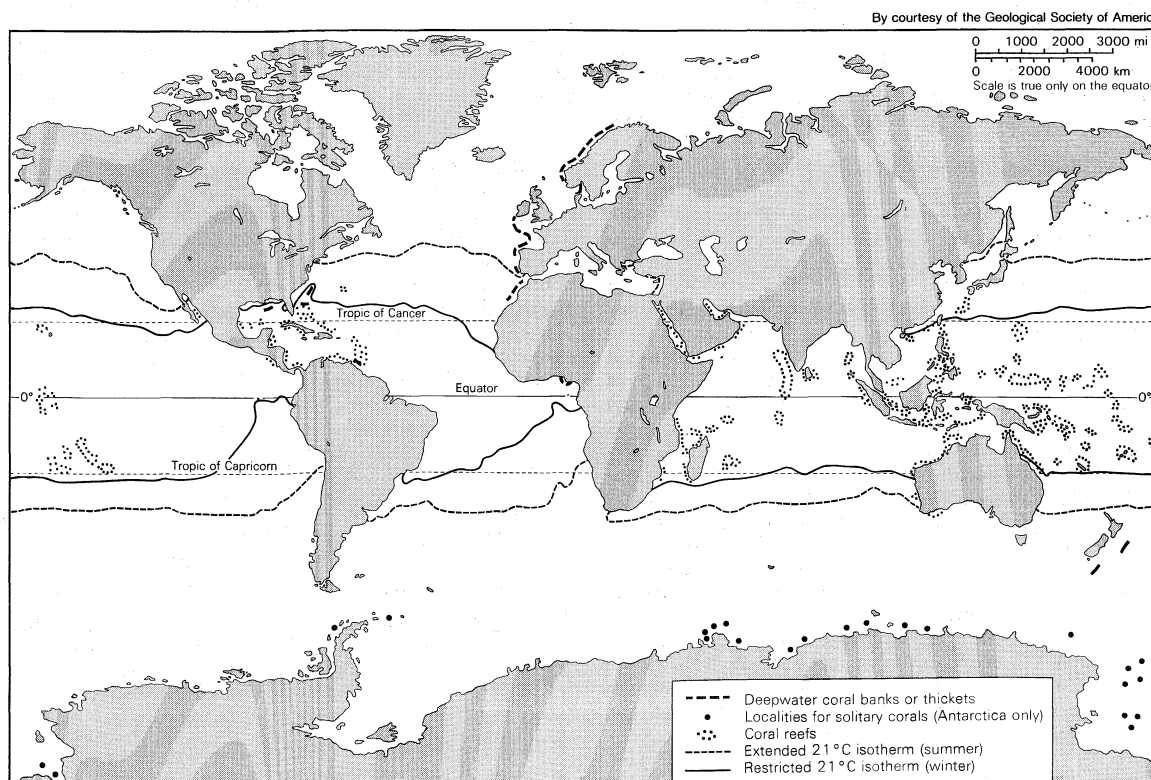

Figure 48: Distribution of coral reefs and their relation to sea-surface temperature.

nacle shells is low (11.5 parts per thousand). By identifying these trace elements and their degree of assimilation in different organisms, sediments formed predominantly of coral-skeletal detritus can be distinguished from sediment derived chiefly from mollusks or coralline algae.

Atomic-absorption spectrophotometry has shown that ultratrace elements are present in the aragonite skeleton of the hydrozoan coral *Millepora* from a reef flat on the Coral Sea Plateau off Queensland. These are, in parts per billion: lead (100), copper (71), cadmium (23), cobalt (17), nickel (1,480), iron (507), and zinc (507).

Another aspect of reef geochemistry is the carbon and oxygen isotopic composition of coral skeletons and shells. Determination of the number of carbon isotopes present provides a method of assessing the age of a sample, and determinations of oxygen isotopes present are useful in indicating water-temperature changes that occurred during the period of growth of the reef.

Winds, currents, temperature, and salinity. Winds and currents are important in shaping individual reefs and in determining the orientation, shape, and position of the coral sand cays, or "low islands," that develop on reefs. Currents are primarily those generated by the prevailing winds, but, in areas where the tidal range is great, tidal effects may become paramount.

Cays may be round, oval (or boat-shaped), or irregular in outline. They originate when sediment is lifted from the reef surface and carried leeward by waves or tidal currents and then deposited where the water velocity is reduced abruptly. Thus, they commonly form on the more protected leeward end of the reef. Wind action at low tide on these deposits may build dunes above the high-water mark. Beach rock may form by carbonate cementation of grains in deposits lying between tide levels. It then acts as a stabilizing factor. Storm waves may drive forward coral fragments derived from "stag-horn" corals growing on the windward slopes of the reef, forming shingle banks; successive, superposed banks may thus be formed. The shingle on the banks may become cemented and thus add considerable stability to the cay, as does the growth of vegetation. Hurricanes, however, may carve back the shorelines of even stabilized cays. Huge, isolated boulders of coral or coral limestone are fairly common along reef margins. Some may be remnants of a once-emergent reef platform; others are hurricane or storm jetsam.

Coral reefs are best developed where the mean annual surface-water temperatures are approximately 23° to 25° C. No significant reefs occur where such temperatures fall below about 18° C, although a few reef-coral species can exist in temperatures considerably below this. Seasonal temperature differences on any one reef are usually slight, as are differences due to depths of water or situation on the reef.

Seawater of normal oceanic salinity (between 30 and 40 parts per thousand), to which corals are restricted, is normally supersaturated in calcium carbonate (CaCO_3), so that adequate ionized calcium (Ca^{2+}) is available for the skeleton-forming process. Floods of fresh water may destroy life on inshore fringing reefs. A luxuriant reef on Stone Island, near Bowen, Queens., Australia, was killed to a depth of three metres below mean tide level by a week of cyclonic rains, in which 90.7 centimetres of rain coincided with full-moon spring tides.

Biological factors. The most significant biological determinant of reef accumulation is the presence of zooxanthellae in the living tissues of all reef corals and of many massive-shelled mollusks (Tridacnidae) and other shelled invertebrates, as well as in the soft-bodied hydrozoans, scyphozoans, and anthozoans. Zooxanthellae are now known to represent the vegetative stages of dinoflagellate algae, and their association with reef corals is symbiotic—i.e., mutually helpful. In temperate seas they occur only occasionally. Their profusion in reef animals is no doubt connected with the greater light intensity and radiant energy of reef waters, for, like other plants, zooxanthellae require sunlight for photosynthesis. They remove at the source part of the carbon dioxide, together with nitrogen, phosphorus, and (doubtless) sulfur, produced by metabolic breakdown within the coral and which would otherwise be

excreted by the corals. They greatly aid in the formation of the coral skeleton by increasing the speed with which the carbon dioxide produced in coral metabolism is removed and the speed with which the skeletal calcium carbonate is formed. Corals also may gain some nutrient from their zooxanthellae, but they probably do not need the oxygen produced during photosynthesis.

The productivity of reefs is a current focus of interest. A constant supply of food in the form of zooplankton is essential to reef corals, which are carnivorous. The zooplankton supply is dependent on an adequate phytoplankton supply, and the phytoplankton, in turn, require an adequate supply of plant nutrients dissolved in the water. An atoll in the open ocean may be compared to an oasis in a desert, as a localized centre of high productivity. In the warm, well-lit, and well-mixed lagoon waters there is a rapid turnover of the endemic planktonic (floating or swimming) and benthic (bottom-dwelling) population, perhaps 12.5 times per year. Carbonate skeletal matter is accumulated perhaps 1,000 times faster on the summit of an atoll than in the surrounding deeps.

Certain biological factors may contribute to the destruction of coral reefs: the fish and invertebrates that feed on the soft tissues of reef builders and the organisms that bore into coral rock. Of the former, the most destructive such enemy yet known is *Acanthaster planci*, the crown-of-thorns starfish, which, during the 1960s multiplied spectacularly and removed the soft tissues from large areas of many reefs in the southwest Pacific. *A. planci* feeds by evert its stomach and liquifying and absorbing the tissues of the corals. By the late 1970s it had become apparent, however, that the sudden spread of *A. planci* was part of the organism's natural life cycle and that the coral reefs could regenerate rapidly after such an infestation. Coral-rock borers include boring algae, boring sponges (of great significance), various polychaete and sipunculid worms, and many bivalves and a few gastropods. These organisms usually penetrate the rock mechanically but in some cases do so chemically. Extensive damage is caused both by their own activities and by the assistance they give to the erosive action of the sea. A phenomenon known as "bleaching" caused extensive devastation among coral reefs in the east Pacific during the early 1980s and in the Caribbean during the mid- to late 1980s. It is called bleaching because zooxanthellae (principally the so-called brown algae) are expelled, leaving the white coral exposed. While the cause of bleaching is not yet fully known and extensive research is under way, it is believed that the most likely factor is unusually high seawater temperatures, approximately 30° C.

Origin and development of reefs. Charles Darwin concluded in 1842 that barrier reefs began as reefs fringing the land around which they now form a barrier and that oceanic atoll reefs began as reefs fringing a volcanic island. Subsidence of the land fringed was thought to allow the reef to grow upward (and outward over its own forereef debris). Maximum growth would occur at the seaward edge, and lagoons would develop between the ascending barrier, or atoll, reef and the land or volcanic cone. When the volcanic cone became completely submerged, the atoll lagoon would contain only coral islands (see Figure 49).

Darwin's theory of atolls

From A.N. Strahler, *The Earth Sciences* (1963); Harper & Row, New York

Figure 49: Stages in atoll development due to sea-level rise or oceanic plate subsidence (see text).

Restrictions on reef formation

Figure 50: Plate-tectonic subsidence of the Pacific Ocean floor in the evolution of mid-ocean coral reefs. The arrows indicate either subsidence or uplift.

From A. Guilcher, *Coral Reef Geomorphology*, copyright © 1988 John Wiley & Sons, Inc., reprinted by permission of John Wiley & Sons, Inc.

Fundamentally, Darwin's concept is still valid, although many consider submergence by the rise of sea level, following melting of Pleistocene ice sheets, to be a better explanation of the latest upward growth of many reefs, particularly on continental shelves. Mid-ocean stages of coral reef development are explained by plate tectonic theory (see above *Ocean basins*), according to which the ocean floor subsides as it spreads outward from oceanic ridges. The Hawaiian Islands, with barrier reefs in the southeast grading to atolls in the northwest, is a good example of this (see Figure 50).

A reef whose surface lies above high-tide mark, either by uplift or by eustatic regression of the sea (which is determined by ice sheet-sea level relations), is subject to planing by marine erosion. If planing off is complete, a flat-topped submerged platform results; if subsidence or eustatic submergence intervenes, a wave-cut terrace is left around the reef. Terraces that may have formed in this way are known around many reefs. Some annular reefs may develop without relation to subsiding volcanic cones. When reef platforms have been uplifted above sea level, they are subjected to subaerial erosion. Surface slope, or gradient, determines the amount of runoff and is a prime factor in this erosion. Two secondary processes also are involved: (1) case hardening of steep, bare limestone surfaces by recrystallization caused by alternate wetting and drying, so that walls or knife edges result from weathering; and (2) continuous subsoil solution, if surfaces are nearly horizontal and runoff is diminished. These processes combine to produce a prominent rim and a saucer-shaped interior in emerged limestone islands. With submergence, algal and coral growth resumes, the fastest growth being on the rim and on any pinnacles that may be left. Thus an atoll or annular reef may develop along the rim around the low-lying central region, which becomes a lagoon, and coral knolls grow on former pinnacles in the lagoonal area.

Types of reefs. *Fringing reefs.* Fringing reefs form a veneer in the shallow water near or at the shore of the mainland or of islands. On shorelines where bays receive large quantities of terrestrial mud, sand, and fresh water, fringing reefs are intermittent and are restricted to promontories. Along limestone coasts, however, coastal erosion is by solution, little mud or sand is supplied, and coral growth may be almost continuous along the shore. Fringing reefs may extend as far as 1,500 metres from shore. They show ecological zonation parallel to the shore. Along mainland shores with easily eroded rocks, mudbanks may be washed into the reef flat and colonized by mangroves. Inner parts of reef flats may show low mesas of middle Holocene (perhaps 5,000 years old) and even Pleistocene emergent reefs that have not been quite planed off by marine abrasion. Geomorphologic features peculiar to raised fringing reefs have been described for the Solomon Islands, and there the complex problem of dead reefs and dead patches on reefs arises. The surface of the reef flat is mostly of dead coral, but pools occur in which live coral colonies flourish. An algal rim formed by red calcareous algae may develop on a fringing-reef margin if the reef faces strong waves and swells the year around.

This rim is commonly less spectacular than the algal ridge of the windward edge of Pacific oceanic atolls and may be developed merely as an algal platform, or pavement, on which algal encrustation over corals is thin. The seaward slope of a fringing reef, like the seaward slope of an atoll reef, is characterized by a zone of grooves and spurs to a depth of perhaps 15 metres, and it is in this zone that vigorous growth occurs. Under stable shelf conditions, the fringing reef will extend outward as the spurs elongate and the grooves fill or roof over with coral and algal growth. In tectonic belts (zones of uplift and deformation), fringing reefs may be uplifted intermittently, resulting in parallel, stepped subaerial terraces such as those of the Finsch Coast of Papua New Guinea.

Platform and patch reefs. Platform and patch reefs are characteristic of continental shelves; they may or may not lie behind a barrier reef. Reefs grow actively outward as well as upward, especially in the stable conditions of a continental shelf. Any given reef, having depth and temperature fixed by its location, will have its shape determined by the direction and force of the water currents that bring food and by the shape of the base on which it grows. Where the forces of growth are equal in all directions, radial expansion results in platformlike reefs. With further radial growth, lagoonal platform reefs develop. If the reef grows on a sand bank, elongation may result. The shape of an elongated platform reef may be determined by the orientation of rising and falling tidal currents. These may be directly opposed to each other. The boat-shaped reefs of Torres Strait, between Australia and New Guinea, apparently developed in such a pattern. Where wave-generated currents are asymmetric, horseshoe reefs develop, with convexity facing the current and the leeward ends curving round to partly surround a lagoon. Low Islets, made famous by the Great Barrier Reef Expedition of 1928–29, is the best-known example of this type. A sand cay (or cays) commonly develops on one or both of the leeward wings. Those parts of Pacific platform reefs that face strong and persistent currents characteristically have a low algal rim from which radiate grooves and spurs.

Barrier and ribbon reefs. Barrier reefs commonly present to the ocean and the trade winds a steep wall, some dropping abruptly 1,000 to 5,000 metres. On the lagoon side they grade off gently with a wedge of sediment dotted by small patch reefs, coral knolls, and coral heads. Depths in the lagoon may reach 50 to 80 metres. According to the strength of surf and swell, an algal ridge, rim, platform, or pavement develops and is commonly emergent at low water. The seaward slope has radial grooves and spurs, the grooves forming surf channels and imparting great wave resistance. Ecological zonation on the seaward slope is difficult to study because of the dangers of surf and swell. Zonation on the reef flat, parallel to the wall, is dependent mainly on depth.

A characteristic form in a barrier reef system is the wall, or ribbon, reef, emergent at low tide, such as Yonge Reef, Queens., Australia. A ribbon reef flat is commonly only 300 to 450 metres wide from the seaward wall to its lagoonward edge. Its ends may curve leeward and border the

Planing
by
marine
erosion

Horseshoe
reefs

passages between it and the next reefs in line. Rarely, there may be an unvegetated sand cay. A wall reef may develop irregular leeward prongs normal (perpendicular) to its axis by vigorous coral growth favoured by augmented turbulence associated with a high tidal range. The open leeward zone may be very wide (three kilometres) and support large, scattered reef clumps that are always submerged.

Atolls. The oceanic atoll reefs of the Pacific Ocean rise from volcanic cones that have subsided, probably intermittently, in areas of oceanic deeps. According to the Darwinian subsidence theory, the annular atoll reefs extend and grade downward into barrier reefs. The theory suggests that these barrier reefs originated as reefs that fringed a volcanic cone. On the other hand, the compound atoll reefs of the Indian Ocean, such as the Maldives and the Laccadive Islands, and of the Queensland Plateau of the Pacific Ocean, are believed to have grown above foundered continental (rather than oceanic) crustal segments. The Nicaraguan atolls rise from a seafloor of 1,000 metres or more in a volcanic province. (D.Hi./M.L.S.)

LAGOONS

Lagoons are, as indicated above, areas of relatively shallow water situated in a coastal environment and having access to the sea but separated from the open marine conditions by a barrier. The barrier may be either a sandy or shingly wave-built feature, or it may be a coral reef. Thus, there are two main types of lagoons: (1) elongated or irregular stretches of water that lie between coastal barrier islands and the shoreline, and (2) circular or irregular stretches of water surrounded by coral atoll reefs or protected by barrier coral reefs from direct wave action (Figure 51). Lagoons of the first type are characterized by quiet water conditions, fine-grained sedimentation, and, in many cases, brackish marshes. Water movements are related to discharge of river flow through the lagoon and to the regular influx and egress of tidal waters through the inlets that normally separate the barrier islands. Lagoons of the second type are best exemplified by the roughly circular quiet waters that are surrounded by coral atoll reefs. Lagoon depths are maintained at a moderate level by sedimentation, and this compensates for the subsidence that commonly attends reef formation (see above *Coral reefs, coral islands, and atolls*). Because the reef is an organic structure, the lagoonal sediments contain much calcareous material. The sheltered waters support a distinctive flora and fauna.

Coastal lagoons are widely distributed throughout the world and have been estimated to constitute about 13 percent of the total world coastline. Lagoons are more common on coasts with moderate to low tidal ranges; for example, they occur widely on low coasts of the southern Baltic, southeast North Sea, Black Sea, Caspian Sea, and Mediterranean Sea, and of the southeastern United States and the Gulf of Mexico. Lagoon coasts also occur along southern Brazil; the east coast of Madagascar; the north-eastern Soviet Union; Japan; and isolated parts of Africa, India, Australia, and New Zealand.

Lagoons are generally characteristic of coasts of low or moderate energy, occurring especially on the east coasts of continents where the swells are less violent and in high latitudes where offshore ice provides some protection. They also are associated with low coasts and rarely occur where high cliffs form the coast. They can form only where there is abundant sediment for construction of the protective barrier islands. Too much sediment from the mainland, however, can lead to delta formation rather than lagoons, although lagoons frequently occur along the outer delta margin and between delta distributaries (see also RIVERS: *Rivers as agents of landscape evolution: Deltas*).

Coral lagoons are restricted to tropical open seas that provide the conditions necessary for coral growth. They occur widely in the western Pacific, in parts of the Indian Ocean, and in isolated places in the Caribbean, mainly within 25° latitude of the equator. Coral lagoons are of great importance to many island communities in the Pacific, particularly where they provide the only quiet water for use as harbours, although the passage through the reef into the lagoon is often perilous.

Figure 51: Lagoon in the middle of the Rose Atoll, American Samoa.

Air Survey Hawaii

The clarity of the water of the coral lagoon contrasts with the considerable amount of fine sediment in barrier island lagoon water. The extensive growth of salt marsh in such lagoons often detracts from or precludes their use as harbours, but where the water is deep enough these lagoons provide sheltered anchorage and good conditions for small-boat sailing in quiet water.

Nature of the lagoon environment. *Dimensions.* Coral lagoon dimensions range from small atolls to those so wide that the coral reefs on the far side cannot be seen across the lagoon. Atoll widths range from about 2.5 to nearly 100 kilometres, but the mean value is about 20 kilometres. Depths rarely exceed 60 metres and many are shallower, usually less than 20 metres deep. The lagoon of Mayotte island in the Comoro archipelago in the Indian Ocean attains a maximum depth of about 92 metres but generally is shallower, and it is about 16 kilometres in width at its widest point; this lagoon lies behind a barrier reef that encircles the island, forming an atoll about 55 kilometres in diameter.

Barrier island lagoons are usually elongated, though irregular ones may occur where river estuaries flood behind barriers. This occurs on the east coast of the United States, where lagoons extend intermittently for nearly 1,500 kilometres along the coast. The Gippsland Lakes in Victoria, Australia, exemplify a complex lagoon system formed behind a 149-kilometre beach. Elongated lagoons up to 64 kilometres in length lie behind the beach barrier, and larger lagoons, such as Lake Wellington, lie behind the southwestern end. Postglacial subsidence has flooded the lowland in this area. The lagoons are shallow: Lake Wellington is less than 3.5 metres in depth, and much of Lake King is less than 6 metres deep. Scour holes as deep as 16.5 metres do occur, however. The elongated lagoon behind the barrier is only 1 to 1.5 metres deep, typical of barrier island lagoons.

Water circulation. The degree of water circulation depends on the width of the tidal inlets, the tidal range, and the amount of runoff from adjacent land areas. Maximum velocities are attained at the points where the water passes through the barriers. In the entrance to the Gippsland lagoons, for example, tidal currents reach 5.6 kilometres per hour, but river floods that escape to the ocean can raise the velocity to 13 kilometres per hour. Water may be blown into the lagoon by strong winds; the increased level results in an outflowing current when the wind drops. Seiches can be created in this way. Small waves can be generated within lagoons when the wind blows along their maximum dimension. These may reach 1.25 metres in height and 1.5 to 9 metres in length in the Gippsland lagoons. In coral atoll lagoons there is little or no runoff, and seawater moves in and out through the passes, where

Current velocities

Principal types

Typical sites

tidal currents reach their maxima. Velocities of 19 to 22 kilometres per hour have been recorded in the Hao Channel of the Tuamotu Archipelago.

Water temperature and salinity. In the Mayotte Lagoon the water has the same properties as the upper layers of the open ocean. The salinity is close to 35 parts per thousand, and the temperature varies between 27° and 24° C. This is typical of coral lagoons, but the temperature and salinity of barrier island lagoons are more variable because of their wider climatic range. Because they are shallow, lagoon waters approximate the air temperature: colder than the open ocean in winter, warmer in summer.

Salinities decrease as a function of the amount of runoff entering the lagoon in relation to the tidal influx. Lagoons may be considered brackish, marine, or hypersaline. Brackish lagoons receive much runoff, and salinity increases toward the tidal inlets. The Gippsland lagoons exemplify this type. The salinity at the inner end varies from 0.5 to 5 parts per thousand according to season, and central values vary between 5 and 20 parts per thousand. Hypersaline lagoons occur where evaporation exceeds inflow. Laguna Madre in Texas and Sivash Sound in the Black Sea have salinities of 65 and 132 parts per thousand, respectively. Salt deposits may form in these conditions. The denser saline water tends to lie beneath the fresher water where mixing is not severe.

Equilibrium bottom profiles. Lagoons behind coastal barriers normally are zones of fine sedimentation. Their bottom profiles, therefore, build up gradually with time. Typical depths of the Texas lagoons vary between 1.25 and 3.5 metres, and their floors are flat. Early theories that attempted to relate the form of the offshore and lagoon profile are no longer held; and because the lagoon profile changes with continued deposition, it cannot be used to establish the process of lagoon formation. The profile is usually gently undulating, but it may contain deeper channels, especially near the tidal inlets. Profiles across coral lagoons are either smooth and flat from calcareous sedimentation, or they contain knolls of growing or dead coral. There are 2,300 such knobs in the Enewetak Lagoon in the Marshall Islands.

Factors involved in lagoon formation. The essential feature that causes the lagoon to exist is the barrier that separates it from the ocean. In the coral lagoon the formation of the reef depends on the existence of suitable conditions for reef growth, which have already been mentioned briefly.

Barrier bars and sediment sources. The barrier island lagoons, on the other hand, depend not on organic processes but on waves, which act in a suitable environment, on an adequate supply of bottom material, most commonly sand. Barrier islands are formed in those areas where the coastal slope is flatter than the equilibrium slope required by the long constructive swells, the waves that build up the foreshore in front of their breakpoint. They are, therefore, found on low coasts. They may occur in areas of subsidence, stability, or emergence, wherever sufficient sand exists.

The barrier islands that form the lagoons are made of sand, but the sediments of the lagoon are usually finer, as conditions are quieter. The lagoonal muds differ from shelf muds. Glauconite is rare in lagoon muds, but oyster reefs may occur as along the Texas coast. The muds are found away from the channels in which only coarse sediment can rest, owing to strong currents. Flocculation in the saline lagoon water expedites clay deposition. The source of the fine sediment is from inland areas, and transport is by rivers. The details of lagoon sedimentation vary with the nature of the river load. Sedimentation rates are much greater in the lagoon than the adjacent open ocean, because deposition is continuous over much of the lagoon and is often aided by flocculation and vegetation. In the Texas lagoons from 1875 to 1936, 20 centimetres of deposition occurred in spite of 30 centimetres of subsidence; the sedimentation rate, therefore, was about one metre in 100 years.

Waves, tides, and surf. The barrier islands are formed by the waves, which build up their equilibrium profile by deposition on a gradient that is too flat. The level of the

growing accumulation may be raised by the wind, forming dunes. Where the land behind the growing barrier is low, it will become flooded to form a lagoon if sea level rises slowly. Such a rise of sea level has occurred during the last 20,000 years. As long as the barrier island can maintain its level above the sea, as sea level rises, the lagoon will exist until it is filled with sediment. Not all lagoons and barrier island complexes have formed during rising sea-level conditions, but where there is evidence that no open sea foreshore sediments lie on the land side of the barrier this hypothesis seems likely. In some barriers, however, outbuilding of material by glacial outwash streams or rivers may provide a suitably low gradient and enough sediment to form a barrier, as along the south coast of Iceland. In other areas material carried alongshore to form a spit may develop into a bay-mouth barrier, enclosing a lagoon. Such features can be of sand or shingle. The Fleet, a brackish body of water behind Chesil Beach in southern England, is an example of the latter type.

Waves within the lagoon may develop cusped spits along the land side of the barrier and the inner edge of the lagoon. These features may eventually break the lagoon into almost circular or oval water bodies. Examples occur on the Chukchi Sea lagoons in the Soviet Union and elsewhere where vegetation does not form marshland.

Storms and catastrophic events. Storms or tsunamis exert an effect on lagoons when they breach or overtop the barriers around a lagoon by raising the water level temporarily. Major changes in configuration can occur in a short time. Hurricanes, for instance, can cause serious effects on the coast of Texas, along which lagoons are common. Padre Island was lowered to below mean low tide at its southern end by one storm in 1919, and several washover channels were cut. The mainland shore also suffered erosion. Deposition may also occur; saline marls have been laid down on freshwater marsh, and small beach ridges may be built inside the lagoon where the high water level drives sand inland over mud. Coral reefs are more resistant to storms than are mobile sandy barriers.

The effect of time. Lagoons of both types change with time. In both, a relative rise of sea level with time is important in the development of the lagoon. In coral atolls there is evidence from deep boring that Darwin's original subsidence hypothesis of atoll formation, via barrier reefs from fringing reefs around a subsiding volcanic peak, is substantially correct in many cases. As long as the coral can maintain its growth at a suitable level as its foundation subsides, the atoll will continue to enclose a lagoon, which is floored by coral or calcareous sediment, derived from the reef, and that maintains its depth by deposition or growth.

The postglacial rise of sea level also has influenced barrier island formation in many instances. When sea level rises too fast, a barrier may be drowned and its lagoon will cease to exist.

(C.A.M.K./M.L.S.)

ESTUARIES

Estuaries are partially enclosed bodies of coastal water that have access to the sea and that receive a freshwater contribution from the land. Physically this would include river mouths (as in the case of the Mississippi River) or coastal plain drainage areas of low relief (e.g., Chesapeake Bay) that are flooded by a rise in sea level. Other examples would be submerged fjords (Scoresby Sound, Greenland) and structural basins (San Francisco Bay); and the bodies of water behind spits (Hurst Castle spit, Eng.) or barrier beaches (Ninety Mile Beach, Australia). In the case of spits and barrier beaches, the definitions of lagoons and estuaries overlap (see above *Lagoons* and especially the article *RIVERS: Rivers as agents of landscape evolution: Estuaries*).

Classification of estuaries is made on the basis of salinity distribution. Though the terminology differs slightly among different specialists on the subject, there are several basic types. They are as follows: (1) vertically mixed, wherein salinity, while constant from top to bottom at any site, increases from land to sea; (2) slightly stratified, in which saline water circulates in at the bottom, mixes with fresh water, and then flows out at the top (salinity thus increases with depth and out toward the sea); (3) highly

Brackish,
marine,
or hyper-
saline
waters

Lagoonal
sediments
and deposi-
tional rates

Basic types
of estuaries

stratified, which is similar to the slightly stratified type, but is limited to the upper layer of water above the outer sill of a fjord; and (4) salt wedge, where saline seawater intrudes in as a wedge at the bottom, while fresh water flows out and over it at the top. (M.L.S.)

GULFS AND BAYS

Any concavity of a coastline or reentrant of the sea, regardless of size, depth, configuration, and geologic structure, may be called a gulf or bay. The nomenclature for features of this type is far from uniform; names that may refer to sizable gulfs and bays in various places include bight, firth, sound, and fjord. A number of pronounced concavities of oceanic margins have no proper name at all.

The problem of terminology extends to the difference between gulfs and seas. There are many small seas, such as the Sea of Marmara (11,000 square kilometres) and the Sea of Azov (38,000 square kilometres), which, strictly speaking, are really gulfs of the ocean or other seas (the Sea of Azov is a gulf of the Black Sea). The Gulf of Aden (about 270,000 square kilometres), another example, is part of the Arabian Sea, and these water bodies have a common regime (similar tides, precipitation, evaporation, and so forth). The narrow sound of Bab el-Mandeb connects the gulf with the vast Red Sea (438,100 square kilometres) and exhibits a number of specific geomorphic features. The Red Sea, in turn, has two small gulfs to the north—namely, those of Suez and Aqaba.

The Bay of Bengal and the Arabian Sea are approximately the same size and have the same monsoonal water circulation. The Bay of Bengal is, in fact, the largest of the gulfs and bays, with a surface area of 2,172,000 square kilometres and a length of 1,850 kilometres (see Table 10). The width of a gulf may exceed its length. The Great Australian Bight has the widest mouth (2,800 kilometres). The Gulf of Guinea is the deepest; its maximum depth (6,363 metres) exceeds that of the Bay of Bengal by more than 1,000 metres.

The shape and bottom topography of gulfs and bays are amazingly diverse. They are determined by the geologic structure and development of the region. Homogeneous bedrock of low strength or resistance results in simple shapes and shallow depths. The Gulf of Riga (at the Baltic Sea) is a possible example of the type. Long narrow arms with approximately parallel shores of the south Kara Sea extend inland for about 800 kilometres. They occupy troughs that originated by erosion during a period of lower sea level (Baidaratskaya Bay, Obskaya Bay with Tazovskaya Bay tributary, Yenisey Bay, Gydanskaya Bay). Deep, angular gulfs, on the other hand, are created along fractures, faults, and rifts (*e.g.*, Varanger Fjord); they usually have irregular bottom topography. Parallel fractures form extremely deep, narrow gulfs with parallel shores, such as the Gulf of California. Genuine fjord-gulfs are notable for their very high length to width ratios (up to 50:1). In regions that have undergone nonuniform deformation and uplift, gulfs and bays of complicated and irregular shape and bottom topography are consequently formed; the Gulf of St. Lawrence is an example.

Gulfs are connected with the sea by means of one or more straits. Sometimes there may be an archipelago in the mouth of the gulf, as in the Gulf of Bothnia. There are some gulfs that open into the sea or into another gulf on opposite sides (Baffin Bay, Gulf of Aden, and the Gulf of Oman).

Single gulfs usually are formed along linear shores of the continent. If the shoreline is irregular and has a complex geologic structure, groups of gulfs of a similar nature may occur. Most shorelines have small reentrants of various size that are called bays. These features are strongly influenced by local conditions, and they are not described or classified within the context of this section, which treats major water bodies of the world. For additional information on the dynamics of water within gulfs and bays, see above *Waves of the sea*.

Factors that affect the characteristics of gulfs and bays. These bodies of water may differ from the adjacent ocean (or sea) by virtue of water properties and dynamics and processes of sedimentation. Such differences are deter-

mined by the size and the shape of a given gulf, by the depth and bottom topography, and, to a considerable extent, by the degree of isolation from the ocean. Climatic conditions also are important. Isolation from an adjacent ocean depends on the ratio of width of mouth to total surface area of a gulf or on the cross section of the mouth to total water volume. If there is a sill (a submarine ridge or rise), the ratio of depth above the sill to the depth of the gulf is of great importance. No extensive comparisons of these ratios have been made to date; hence any analysis of controlling variables must remain somewhat qualitative.

A high sill hampers the water exchange between an ocean and gulf and may lead to stagnation (oxygen deficiency) as is found in some fjords of Norway, in the Red Sea, and, particularly, in the Black Sea. Also, the presence of a sill causes independent circulation of gulf waters, generated by local winds and the runoff of rivers. Sills are not indispensable for the formation of an independent circulation, however. A narrow mouth, as in the Gulf of Bothnia, leads to the same result.

In humid climates, the waters of gulfs are freshened by river runoff. Salinity is particularly low in the gulfs of the Baltic Sea and along the southern coast of the Kara Sea. Water becomes almost fresh in their heads, especially in the spring when snow begins to thaw. Gulfs of the arid zone suffer from intensive evaporation and receive little river runoff. Thus, salinity increases markedly in this climatic regime—up to 60 parts per thousand in the Persian Gulf and up to 350 parts per thousand in the Kara-Bogaz-Gol (a gulf of the Caspian Sea). In addition to its effect on salinity, river runoff delivers organic matter and nutrient salts that may determine the specific features of life in the gulfs. The number of genera and species of organisms is small, but the organisms present tend to develop in quantities. That is why shrimp, oyster, and other fisheries are concentrated in many gulfs.

Funnel-shaped gulfs, in which the depth gradually decreases headward, usually have resonant tides. The tidal range at the head of such gulfs is several times greater than that in the open ocean (*e.g.*, Bristol Channel, Río de la Plata, Mezenskaya Bay, Shelikhova Gulf). The world maximum tidal range has been registered in the Bay of Fundy (18 metres). The regularity (magnitude and frequency) of the flood tide may be distorted in such instances, and the duration of the flood tide may become much shorter than that of the ebb tide. This may cause the phenomenon of tidal bore, in which a steep wave will move rapidly upstream for dozens of kilometres.

Gulfs of simple shape with a narrow mouth and a high degree of isolation from the ocean are often subject to seiches. These free oscillations can result from rapid changes of atmospheric pressure and, of course, from tectonic movements such as earthquakes. Seiches gradually decrease, but some oscillation continues long after their cause disappears. A high rise of the water (storm surge) occurs in long and shallow gulfs if winds from the sea are protracted. Such phenomena are difficult to predict, and the high water levels may cause floods. Seiches commonly occur at the heads of Helgoländer Bay in the North Sea and in the Gulf of Finland.

Certain aspects of sedimentation are affected by the isolation of gulfs from the ocean and river runoff. The rate of sediment accumulation in gulfs of limited area may be very high. This, of course, is a function of river discharge; sediment composition is usually similar to that of the load transported by entering rivers. Deposition of calcium carbonate often occurs in shallow gulfs in the arid zones where few if any perennial streams exist. The bottoms of long gulfs (or gulfs having sills) are usually covered with silt even at the shallowest depths (*e.g.*, Hudson Bay, the Po Hai, the inlets or *gubas* of the Kara Sea, the Gulf of Riga). Only strong tidal currents can prevent this siltation and, in some cases, cause the opposite phenomenon of bottom erosion. Currents maintain the existence of or actively deepen bottom troughs in narrow-mouthed gulfs whose depths are over 200 metres, whereas depths of adjacent parts of the open ocean are only on the order of some dozens of metres.

Waves of the open ocean either do not penetrate into

Climatic conditions, sills, and river runoff

Occurrence of seiches

comparatively isolated gulfs or, if they do, they become greatly reduced after entry. Small local waves that are related to gulf size prevail there. This tends to make gulfs quite navigable, and seaports and harbours have generally been situated on them.

Classification of gulfs and bays. The geologic structure and developmental history of gulfs and bays are as varied as are those of the continents or oceans proper. The factors discussed above influence the morphological peculiarities of gulfs, and the latter, in turn, permit some general division or classification of these features to be made. The several groups in one possible scheme are discussed here using typical gulfs and bays of each group as examples (Table 10).

Open
concavities
and
isolated
areas

Areas situated in open concavities of the continental coast (Gulf of Alaska, Bay of Biscay, Gulf of Guinea, Great Australian Bight, Bay of Bengal, Gulf of Tehuantepec, for example) are classified as the A₁ group. The depth of these gulfs in the region of the mouth usually is on the order of kilometres. The continental shelf and slope are generally pronounced. The general shape of such gulfs is simple; width of mouth usually exceeds its length. Water circulation and its physical properties are similar to those of the oceans. The character of the marine faunas does not differ from that of oceanic areas.

Large areas considerably isolated from oceans, such as the Gulf of Mexico and Baffin Bay, are designated as group A₂ (Table 10). The former includes a geosynclinal hollow, founded in Mesozoic time (from 245 to 66.4 million years ago), and finally shaped during the Tertiary period (from 66.4 to 1.6 million years ago). It is connected with the ocean by the narrow and relatively shallow straits of Florida and Yucatán. Baffin Bay is a rift hollow that is connected by straits with the Atlantic.

Ocean gulfs, such as the gulfs of Oman, California, Aden, and some others, have smaller areas and are isolated to a lesser degree. These gulfs and bays, in group A₃, have shapes that are determined by young faults and fractures. Depths in these gulfs generally exceed one kilometre. Unlike the previous group, in which gulfs might be of composite geologic structure, these occupy areas that have undergone only a single episode of deformation.

Gulfs situated on the continental shelf, such as the Bay of Fundy, Hudson Bay, Río de la Plata, San Matías Gulf (off Argentina), and others, are in group B. The depth of such gulfs is up to 200 metres or more, and their configuration is determined by geologic conditions. Because shelf areas repeatedly became dry land when the sea level fell during the ice ages, these gulfs received their final shape during the Pleistocene Epoch. The Gulf of St. Lawrence is included in this group (Table 10), though it is really intermediate between groups A₃ and B. It contains both a pronounced shelf and a long trough up to 530 metres deep.

Marginal
and shelf
areas

Gulfs of intercontinental and marginal seas are considered to be a third category. These may be divided into group C₁, which consists of gulfs of basin seas, including the deepwater part only (Aqaba) or both the deepwater and the shelf parts (the Gulf of Honduras), and group C₂, the shelf gulfs of the same seas (e.g., the Persian Gulf, Gulf of Suez, Anadysky Gulf, Bristol and Norton channels, Shelikhova Gulf).

Finally, there are the gulfs of the shelf seas (*gubas* of the Arctic seas of the Soviet Union, gulfs of the Baltic and the White Seas, the Gulf of Carpentaria, the Po Hai, and many others), which are placed in group D (Table 10). The shallow character of the shelf seas influences the water dynamics of the gulfs. Water exchange is weakened, and sediments may accumulate in the gulf mouths, thus forming submarine barriers and further reducing exchange.

(V.P.Z./M.L.S.)

Economic aspects of the oceans

The sea is generally accepted by scientists as the place where life began on Earth. Without the sea, life as it is known today could not exist. Among other functions, it acts as a great heat reservoir, leveling the temperature extremes that would otherwise prevail over the Earth and expand the desert areas. The oceans provide the least

expensive form of transportation known, and the coasts serve as a major recreational site. More importantly, the sea is a valuable source of food and a potentially important source of energy and minerals, all of which are required in ever-increasing quantities by industrialized and developing nations alike.

MEDIUM FOR TRANSPORTATION AND COMMUNICATIONS

From the beginning of recorded history, people have used the sea as a means of transporting themselves and their goods. The bulk of the tonnage of products transported throughout the world today continues to be moved in ocean vessels. The size of these vessels ranges from small boats capable of carrying a few tons to bulk carriers (e.g., supertankers) capable of transporting more than 500,000 tons of oil. The cost of transporting goods on the ocean depends on the product, the form of shipment, and the type of vessel. As the per capita consumption of materials increases, the outlook for marine transportation is one of ever-increasing tonnages and size of carrying vessels.

Since the laying of the trans-Atlantic cable in the 19th century, the oceans have served as a major means of communication between continents and islands. Hundreds of seafloor cables connect many large centres of world population. With the development of satellite communications, seafloor cables as a means of communication have decreased somewhat in importance, but they will continue to carry information for many decades to come.

In addition to communications, cable and pipes laid on the seafloor carry electrical energy, oil, and other commodities in many parts of the world.

SOURCE OF FOOD AND WATER

Fishing. Many millions of tons of edible fish and shellfish are taken from the oceans each year. Yet, the food-producing potential of the sea is considerably greater than this. The prevailing methods by which fish is taken from the oceans are inefficient. This problem is compounded by the fact that only a handful of varieties are targeted by commercial fishermen (anchovy, sardine, herring, cod, mackerel, and pollack constitute more than half of the total annual catch). Overfishing of certain varieties and areas along the continental shelves also has resulted in declining numbers and therefore catches. The decimation of the whale (many species are near extinction) and also of the anchovy off the waters of Peru exemplify the consequences of overfishing.

Several alternatives have been proposed to enhance productivity. One possibility is to extract protein concentrates from all types of fish, promoting the use of varieties formerly ignored for foodstuff. It has been estimated that this procedure could produce a sustained yield of 2 billion tons of food annually for the world's populace. Another alternative would be to use protein derived from algae cultivated on the continental shelf. A more viable course of action would be to develop the continental shelf for fish and kelp farming. The Japanese have instituted a substantial research program in this area. They have farmed oysters in their oceanic bays for many years and more recently raised sea bream and shrimp in protected environments. Commercial shrimp and oyster farms also have been developed in the United States in the shallow waters of estuaries and bays. Both commercial and research aquaculture projects have been conducted to raise abalone, Maine lobster, salmon, and edible forms of seaweed under controlled conditions. Limited sea farming has been practiced in France and Italy, both of which raise mussels and certain other shellfish.

Various marine organisms have been artificially cultivated as sources for therapeutic drugs. For example, during the late 1980s American researchers set out to grow microalgae that have a high concentration of a substance called beta-carotene, which is believed to prevent or retard the spread of certain forms of cancer.

Desalination. The need for water for domestic and agricultural purposes has grown steadily throughout the latter half of the 20th century. As a result, increasing attention has been given to desalting ocean waters and brackish waters in inland seas. Throughout the world, more than

Fish-
farming

3,500 land-based desalination plants, producing a total of more than eight billion litres (in excess of two billion gallons) per day, were in operation by the early 1990s. In general, the desalination plants are located in areas where the population has outstripped the onshore water supply and where high-cost desalinated water can be afforded. This situation tends to arise in coastal-desert areas or on densely populated islands, because the cost of pumping water through pipelines to interior areas would add prohibitively to the basic cost at the sites of desalination. The United States operates a little more than 30 percent of the world's desalination facilities. Another 20 percent or so are found in the Middle East, chiefly in Israel, Saudi Arabia, Kuwait, and the United Arab Emirates. Together, these Middle Eastern plants produce roughly two-thirds of the world's desalinated water.

A population usually can afford to pay about 10 times as much for water for domestic purposes as it does for agricultural water. Large-scale nuclear desalination facilities promise to lower the cost of desalted water at the desalination sites to a level that most industries and some agricultural enterprises can afford. As yet, however, no such plant has been constructed.

At present desalination is accomplished primarily by distillation and membrane processes. Distillation processes involve some form of evaporation and subsequent condensation. Many of the largest commercial desalination plants use multiple-effect distillation (*i.e.*, multistage-flash distillation). Roughly half of the world's desalting facilities employ distillation processes and account for approximately 75 percent of all desalinated water produced annually.

Membrane processes for desalting include reverse osmosis and electrodialysis. Of the two, reverse osmosis is the more widely used, particularly for desalting brackish waters from inland seas. In this method the natural process of osmosis is reversed by applying pressure to brine that is in contact with an osmotic membrane. The membrane impedes the passage of salt ions while allowing fresh water to move through. In electrodialysis an electric potential is

used to drive positive and negative ions of the dissolved salts through membranous filters, thereby sharply reducing the salt content of the water between the filters.

In the future, it can be expected that the ocean will become an increasingly important source of fresh water. If production and transportation costs can be lowered sufficiently, it may be possible to produce fresh water to irrigate large areas that border the oceans in many parts of the world.

ENERGY RESOURCES

There are several recognized techniques by which energy can be extracted from the sea. The major problem in taking energy resources from the sea is that they tend to be diffused over a large lateral area. A point-concentration energy source is necessary if it is to be exploited economically.

Tidal power generation. Hydraulic turbine-generator units are presently used to extract energy from ocean tides, although on a very limited scale. As of the late 1980s, operating tidal units included a 240-megawatt plant in France on the estuary of the Rance River and several smaller installations, as, for example, a 40,000-kilowatt pilot plant in the Soviet Union on the Barents Sea. There are few sites throughout the world that are suitable for harnessing tidal energy without constructing prohibitively expensive damlike structures. (These are required to trap water at high tide and release it at low tide to turn the hydraulic turbine; see ENERGY CONVERSION: *Major energy-conversion devices and systems: Turbines: Water turbines.*) Thus, it seems unlikely that tidal power will play a more significant role in the coming years.

Ocean thermal energy conversion. Another more promising technology, known as ocean thermal energy conversion (OTEC), makes use of the temperature differential between the warm surface waters of the oceans, heated by solar radiation, and its deeper cold waters, to generate power in a conventional heat engine. The difference in temperature between the surface and lower water

Utilization of temperature differentials

Methods of choice

layer can be as large as 50° C over vertical distances of as little as 90 metres in some ocean areas. To be economically practical, the temperature differential should be at least 20° C in the first 1,000 metres below the surface.

The OTEC concept was first proposed in the early 1880s by the French engineer Jacques-Arsine d'Arsonval. His idea called for a closed-cycle system, a design that has been adapted for most present-day OTEC pilot plants. Such a system employs a secondary working fluid (a refrigerant) such as ammonia. Heat transferred from the warm surface ocean water causes the working fluid to vaporize through a heat exchanger. The vapour then expands under moderate pressures, turning a turbine connected to a generator and thereby producing electricity. Cold seawater pumped up from the ocean depths to a second heat exchanger provides a surface cool enough to cause the vapour to condense. The working fluid remains within the closed system, vaporizing and reliquefying continuously.

Some researchers have centred their attention on an open-cycle OTEC system that employs water vapour as the working fluid and dispenses with the use of a refrigerant. In this kind of system warm surface seawater is partially vaporized as it is injected into a near vacuum. The resultant steam is expanded through a low-pressure steam turbogenerator to produce electric power. Cold seawater is used to condense the steam, and a vacuum pump maintains the proper system pressure.

During the 1970s and '80s the United States, Japan, and several other countries began experimenting with OTEC systems in an effort to develop a viable renewable energy source. In 1979 American researchers put into operation the first OTEC plant able to generate usable amounts of electric power—about 15 kilowatts of net power. This unit, called Mini-OTEC, was a closed-cycle system mounted on a U.S. Navy barge a few kilometres off the coast of Hawaii. In 1981–82 Japanese companies tested another experimental closed-cycle OTEC plant. Located on the Pacific Island republic of Nauru, this facility produced 35 kilowatts of net power. Since that time researchers have continued developmental work to improve heat exchangers and to devise ways of reducing corrosion of system hardware by seawater.

The prospects for the commercial application of OTEC technology seem bright, particularly on islands and in developing nations in the tropical regions where conditions are most favourable for OTEC plant operation. It has been estimated that the tropical ocean waters absorb solar radiation equivalent in heat content to that of about 170 billion barrels of oil each day. Removal of this much heat from the ocean would not significantly alter its temperature, but would permit the generation of about 10 million megawatts of electricity on a continuous basis.

SOURCE OF MINERALS AND OTHER RAW MATERIALS

Petroleum. In the mid-1950s, the production of oil and gas from oceanic areas was negligible. By the early 1980s, about 14 million barrels per day, or about 25 percent of the world's production, came from offshore wells, and the amount continues to grow. More than 500 offshore drilling and production rigs were at work by the late 1980s at more than 200 offshore locations throughout the world drilling, completing, and maintaining offshore oil wells (see FUELS, FOSSIL). Estimates have placed the potential offshore oil resources at about 2 trillion barrels, or about half of the presently known onshore potential oil sources.

It was once thought that only the continental-shelf areas contained potential petroleum resources, but discoveries of oil deposits in deeper waters of the Gulf of Mexico (about 3,000 to 4,000 metres) have changed that view. It is now believed that the continental slopes and neighbouring seafloor areas contain large oil deposits, thus enhancing potential petroleum reserves of the ocean bottom.

Offshore drilling is not without its drawbacks, however. Not only is it difficult and expensive to drill on the continental shelf and in deeper water, but there is also the risk of accidental discharges of oil that can cause serious damage to the environment and marine organisms. In spite of technological advances, inadvertent leaks, sometimes on a large scale, continue to occur.

Minerals. The rivers of the world dump billions of tons of material into the oceans each year. Seafloor springs and volcanic eruptions also add many millions of tons of elements. Even the winds contribute solid materials to the oceans in appreciable quantities. Most of these sediments rapidly settle to the seafloor in nearshore areas, in some cases forming potentially valuable placer mineral deposits. The dissolved load of the rivers, however, mixes with seawater and is gradually dispersed over the total oceanic envelope of the Earth. Because of the nature of the minerals and their mode of formation, it is convenient to consider the occurrence of ocean deposits in several environments—marine beaches, seawater, continental shelves, sub-seafloor consolidated rocks, and the marine sediments of the deep-sea floor. Minerals are mined from all of these environments except for the deep-sea floor, which was only recently recognized as a repository for mineral deposits of unbelievable extent and significant economic value.

Minerals that resist the chemical and mechanical processes of erosion in nature and that possess a density greater than that of the Earth's common minerals have a tendency to concentrate in gravity deposits known as placers. During the Pleistocene glaciations, sea level was appreciably lowered as the ocean water was transferred to the continental glaciers. Because of the cyclical nature of the ice ages and the intervening warm periods, a series of beaches were formed in nearshore areas both above and below present sea level. Also, when sea level was lowered in past ages, the streams that today flow into the sea coursed much further seaward, carrying placer minerals to be deposited in channels that are now submerged. With geophysical exploration techniques, these channels and beaches can be easily delineated, even though these features are totally covered by Holocene sediments—i.e., those deposited during the past 10,000 years.

Sand and gravel are mined from a number of offshore locations around the world, generally with hydraulic dredges. They are used primarily for construction purposes or for beach replenishment or nearshore fills.

Sulfur, which is taken from salt domes in the Gulf of Mexico, is mined by a process in which pressurized hot water is pumped into the sulfur-containing cap of the dome, melting the sulfur and forcing it to the surface. Compressed air is also used to pump sulfur to the surface; the still-molten sulfur is then conveyed to the shore through insulated pipelines.

Of considerable interest are the seafloor phosphorite deposits on the coastal shelves of many nations. The phosphorite off California occurs as nodules that vary in shape from flat slabs a few metres across to small spherical forms termed oolites. The nodules commonly are found as a single layer at the surface of coarse-grained sediments. Phosphorite composition from the California offshore area is surprisingly uniform and contains potentially economically attractive amounts of phosphorus. Another type of phosphate deposit has been discovered off the west coast of Mexico. It contains as much as 40 percent apatite (common phosphate mineral), and some experts have speculated that up to 20 billion tons of recoverable phosphate rock exist in the deposit.

Mineral deposits of enormous size and potential economic significance have been discovered on the deep ocean floor. Minerals formed in the deep sea are frequently found in high concentrations because there is relatively little clastic material generated in these areas to dilute the chemical precipitates.

An estimated 10¹⁶ tons of calcareous oozes, formed by the deposition of calcareous shells and skeletons of planktonic organisms, cover some 130 million square kilometres of the ocean floor. In a few instances, these oozes, which occur within a few hundred kilometres of most nations bordering the sea, are almost pure calcium carbonate; however, they often show a composition similar to that of the limestones used in the manufacture of portland cement.

Covering about 39 million square kilometres of the ocean floor in great bands across the northern and southern ends of the Pacific Ocean and across the southern ends of the Indian and Atlantic oceans are other oozes, consisting of the siliceous shells and skeletons of plankton animals and

Placer and near-shore deposits

Deep-sea deposits

plants. Normally these oozes could serve in most of the applications for which diatomaceous earth is used, for fire and sound insulation, for lightweight concrete formulations, as filters, and as soil conditioners.

An estimated 10^{16} tons of red clay covers about 104 million square kilometres of the ocean floor. Although compositional analyses are not particularly exciting, red clay may possess some value as a raw material in the clay-products industries, or it may serve as a source of metals in the future. The average assay for alumina is about 15 percent, but red clays from specific locations have assayed as high as 25 percent alumina; copper contents as high as 0.20 percent also have been found. A few hundredths of a percent of such metals as nickel and cobalt and a percent or so of manganese also are generally present in a micronodular fraction of the clays and in all likelihood can be separated and concentrated from the other materials by a screening process or by some other physical method.

Underlying the hot brines in the Red Sea are basins containing metal-rich sediments that potentially may prove to be of considerable significance. It has been estimated that the largest of several such pools, the Atlantis II Deep, contains several billion dollars worth of copper, zinc, silver, and gold in relatively high grades. These pools lie in about 2,000 metres of water midway between The Sudan and the Arabian Peninsula. Because of their gellike nature, pumping these sediments to the surface may prove relatively uncomplicated. These deposits are forming today under present geochemical conditions and are similar in character to certain major ore deposits on land.

The discovery, in 1978, of polymetallic sulfides at the mid-ocean spreading centres has aroused much interest. As noted elsewhere in the article, these sulfides include sediments enriched in iron and manganese. Sites of rich deposits have been located at the Galápagos spreading centre in the Gulf of California and at the East Pacific Rise.

From an economic standpoint, the most interesting oceanic sediments are manganese nodules—small, black to brown, friable lumps found to be widely distributed throughout the major oceans in the late 19th century by the Challenger and Albatross expeditions.

Many theories have been proposed to account for the formation of manganese nodules, the best probably being that the ocean is saturated at its present state of acidity-alkalinity in iron and manganese. For this reason, these elements precipitate as colloidal particles that gradually increase in size and filter down to the seafloor. Colloids of manganese and iron oxides collect many metals and tend to agglomerate as nodules at the seafloor rather than settle as particles in the general sediments. An estimated 1.5 trillion tons of manganese nodules lie on the Pacific Ocean floor alone. Averaging about four centimetres in diameter and found in concentrations as high as 38,600 tons per square kilometre, these manganese nodules contain as much as 2.5 percent copper, 2.0 percent nickel, 0.2 percent cobalt, and 35 percent manganese. In some deposits, the content of cobalt and manganese is as high as 2.5 percent and 50 percent, respectively. Such concentrations would be considered high-grade ores if found on land, and, because of the large horizontal extent of the deposit, they are a potential source of many important industrial metals.

Relatively simple mechanical cable bucket or hydraulic dredges with submerged motors and pumps can effect the mining of the nodules at rates as high as 10,000 to 15,000 tons per day, from depths as great as 6,000 metres. The estimated costs of mining and processing the nodules indicate that copper, nickel, cobalt, and other metals can be economically produced from this source.

The prospects of mining the manganese nodules and metal-rich sediments have brought home the need to resolve long-standing legal problems relating to the ownership of marine resources. During the 18th century the extent of the territorial sea (and therefore rights) was established as 3 nautical miles (5.6 kilometres) from a nation's shoreline. The area beyond the territorial sea, the so-called high seas, was regarded as open to all nations. By the mid-1940s technological advances had extended

offshore oil drilling beyond the territorial limit. This situation, together with the desire of various coastal nations to protect their fishing grounds, eventually resulted in an attempt to codify international law concerning territorial waters, ocean resources, and sea lanes. A 1982 treaty calling for the enactment of the United Nations Law of the Sea Convention was signed by 138 nations; some 30 other states, including the United States, the United Kingdom, and West Germany, refused to sign, however. The treaty extended the territorial limit of each coastal nation to a distance of 12 nautical miles and granted it sovereign rights over natural resources—living and nonliving—within an exclusive economic zone (or EEZ) of 200 nautical miles. The nations that refused to sign the treaty objected to its provisions governing seabed mining. The treaty declared the minerals on the seafloor beneath the high seas the "common heritage of mankind" and stipulated that their exploitation be directed by a global authority. While private and national mining concerns are allowed to conduct exploration and set up extraction operations, the question of seabed mineral ownership and mining rights remains largely unresolved. This situation is viewed in some quarters as the primary obstacle to full and effective utilization of seabed resources.

WASTE DISPOSAL AND OTHER RELATED ACTIONS

One of the least known but most significant uses of the sea is as an enormous dump site. In the past, the oceans were able to assimilate the wastes of society without noticeable adverse effects. However, industrialization and other concomitant developments, along with sharp increases in global population, have given rise to quantities and forms of waste that are now taxing the capacity of the oceans to absorb them. Extensive marginal areas of the oceans have been heavily polluted by human wastes ranging from the raw sewage of urban centres to junked appliances and automobiles. Less apparent but more insidious forms of pollution are toxic chemicals, nuclear wastes, and oily bilges pumped by practically all vessels using petroleum for power (see also above *Chemical and physical properties of seawater: Composition of seawater: Effects of human activities*).

Some other human activities are equally harmful to the marine environment. Massive oil spills from tanker accidents, such as the 1989 mishap involving the *Exxon Valdez* in Prince William Sound, Alaska, have not only disfigured innumerable beaches and estuaries but caused widespread damage to wildlife as well (Figure 52). Large power plants are generally located along coastlines to reduce the costs involved in cooling their condensers by water-circulation systems. Although the whole of the ocean never will be affected by the waste heat dissipated by these plants, detrimental environmental effects can be caused in the immediate area of the power-plant outfall. Herbicides and pesticides (especially the organochlorides still used by

The Law
of the Sea

Oil spills

Manga-
nese
nodules

AP/Wide World Photos

some countries) reach the oceans via the wind and rivers and contaminate marine organisms.

The fringes of the oceans—the beaches, lagoons, and bays—are the most sensitive to human action, but the continued dumping of wastes, attended by other abuses, will eventually affect the entire marine environment.

(J.L.M./Ed.)

BIBLIOGRAPHY

General considerations: Broad overviews of the oceans are provided by KEITH STOWE, *Ocean Science*, 2nd ed. (1983); DAVID TOLMAZIN, *Elements of Dynamic Oceanography* (1985); DAVID A. ROSS, *Introduction to Oceanography*, 4th ed. (1988); ALYN C. DUXBURY and ALISON B. DUXBURY, *An Introduction to the World's Oceans*, 3rd ed. (1991); M. GRANT GROSS, *Oceanography, a View of the Earth*, 5th ed. (1990); and TOM BEER, *Environmental Oceanography: An Introduction to the Behaviour of Coastal Waters* (1983). ALASTAIR COUPER (ed.), *The Times Atlas and Encyclopedia of the Sea* (1989), provides a graphic look at all aspects of the ocean. *Ocean Yearbook* (annual), contains essays on resources, transportation, and marine science, among other topics. GUSTAF ARRHENIUS, BIBHAS R. DE, and HANNES ALFVÉN, "Origin of the Ocean," in *The Sea*, vol. 5, *Marine Chemistry*, ed. by EDWARD D. GOLDBERG (1974), pp. 839–861, provides a thorough discussion of the formation of water on the Earth during early geologic history. A. GUILCHER, "Continental Shelf and Slope (Continental Margins)," in *The Sea*, vol. 3, *The Earth Beneath the Sea: History*, ed. by M.N. HILL (1963), describes the distribution and features of the margins of the continents.

(A.C.D.)

Chemical and physical properties of seawater: As an excellent starting point for the reader interested in an integrated account of ocean chemistry, physics, and biology, the classic work by H.U. SVERDRUP, MARTIN W. JOHNSON, and RICHARD H. FLEMING, *The Oceans* (1942, reissued 1970), is highly recommended. An in-depth, but quite readable, account of the general field of marine chemistry is provided by J.P. RILEY and R. CHESTER, *Introduction to Marine Chemistry* (1971). Thorough descriptions of each of the many subdisciplines in chemical oceanography can be found in the multivolume work by J.P. RILEY and G. SKIRROW (eds.), *Chemical Oceanography*, 2nd ed., including DANA R. KESTER, "Dissolved Gases Other than CO₂," vol. 1, ch. 8 (1975), pp. 497–556, a detailed discussion; P.J. LE B. WILLIAMS, "Biological and Chemical Aspects of Dissolved Organic Material in Sea Water," vol. 2, ch. 12 (1975), pp. 301–363, a good survey; J.D. BURTON, "Radioactive Nuclides in the Marine Environment," vol. 3, ch. 18 (1975), pp. 91–191; and KENNETH W. BRULAND, "Trace Elements in Sea-water," vol. 8, ch. 45 (1983), pp. 157–220, a readable account.

The Sea, vol. 1, *Physical Properties of Sea-water*, ed. by M.N. HILL (1962), contains information on all aspects of the behaviour of seawater with changes in temperature, pressure, and salt content, including discussions of density, transmission of light and sound, and sea ice properties. RHODES W. FAIRBRIDGE (ed.), *The Encyclopedia of Oceanography*, (1966), contains many useful entries on this topic, among them ROBERT GERARD, "Salinity in the Ocean," pp. 758–763, discussing spatial and temporal trends of the ocean's salinity and the processes that control it; and J. LAGRULA, "Hypsographic Curve," pp. 364–366, explaining the use of hypsometry and giving the hypsometry of the oceans and their subdivisions. H.W. MENARD and STUART M. SMITH, "Hypsometry of Ocean Basin Provinces," *Journal of Geophysical Research*, 71(18):4305–4325 (September 1966), is also useful.

(A.C.D./R.H.By.)

Circulation of the ocean waters: Useful books include those by OPEN UNIVERSITY OCEANOGRAPHY COURSE TEAM, *Ocean Circulation* (1989); GEORGE L. PICKARD and WILLIAM J. EMERY, *Descriptive Physical Oceanography: An Introduction*, 5th enlarged ed. (1990); STEPHEN POND and GEORGE L. PICKARD, *Introductory Dynamical Oceanography*, 2nd ed. (1983); HENRY STOMMEL, *A View of the Sea* (1987); and HENRY STOMMEL and DENNIS W. MOORE, *An Introduction to the Coriolis Force* (1989). The following journal articles are also of use: JAMES F. PRICE, ROBERT A. WELLER, and REBECCA R. SCHUDLICH, "Wind-driven Ocean Currents and Ekman Transport," *Science*, 238:1534–1538 (Dec. 11, 1987); W.D. NOWLIN, JR. and J.M. KLINCK, "The Physics of the Antarctic Circumpolar Current," *Reviews of Geophysics and Space Physics*, 24(3):469–491 (1986); and BRUCE A. WARREN, "Deep Circulation of the World Ocean," in BRUCE A. WARREN and CARL WUNSCH (eds.), *Evolution of Physical Oceanography* (1981), pp. 6–41.

(A.L.G.)

Waves of the sea: Books discussing waves and tides include OPEN UNIVERSITY OCEANOGRAPHY COURSE TEAM, *Waves, Tides, and Shallow-water Processes* (1989); ALBERT DEFANT, *Ebb and Flow: The Tides of Earth, Air, and Water* (1958; originally published in German, 1953); BLAIR KINSMAN, *Wind Waves: Their Generation and Propagation on the Ocean Surface* (1965,

reprinted 1984); M. GRANT GROSS, *Oceanography*, 5th ed. (1990), ch. 8, "Waves," and ch. 9, "Tides," pp. 193–241; and DAVID T. PUGH, *Tides, Surges, and Mean Sea-level* (1987). C. GARRETT and W. MUNK, "Internal Waves in the Ocean," *Annual Review of Fluid Mechanics*, vol. 11, pp. 339–369 (1979), is also of interest.

(A.L.G.)

Density currents in the oceans: H.W. MENARD, "Turbidity Currents," ch. 9 in his *Marine Geology of the Pacific* (1964), pp. 191–222, provides a review of turbidity currents, written from the point of view of marine geology. A.H. BOUMA and A. BROUWER (eds.), *Turbidities* (1964), is a symposium with an extensive bibliography on sediments deposited by turbidity currents. More recent studies include GERARD V. MIDDLETON and MONTY A. HAMPTON, "Subaqueous Sediment Transport and Deposition by Sediment Gravity Flows," ch. 11 in DANIEL JEAN STANLEY and DONALD J.P. SWIFT (eds.), *Marine Sediment Transport and Environmental Management* (1976), pp. 197–218, which describes and discusses turbidity currents, grain flows, fluidized sediment flows, and debris flows; GARY PARKER, YUSUKE FUKUSHIMA, and HENRY M. PANTIN, "Self-accelerating Turbidity Currents," *Journal of Fluid Mechanics*, 171:145–181 (1986); and RICHARD J. SEYMOUR, "Nearshore Auto-suspending Turbidity Flows," *Ocean Engineering*, 13(5):435–447 (1986).

(G.V.M./Ed.)

Impact of ocean-atmosphere interactions on weather and climate: Overviews of the general relationship between air and ocean may be found in A.H. PERRY and J.M. WALKER, *The Ocean Atmosphere System* (1977); ADRIAN E. GILL, *Atmosphere-Ocean Dynamics* (1982); and NEIL WELLS, *The Atmosphere and Ocean: A Physical Introduction* (1986).

Seasonal and interannual ocean-atmosphere interactions are discussed by C.K. FOLLAND, T.N. PALMER, and D.E. PARKER, "Sahel Rainfall and Worldwide Sea Temperatures, 1901–85," *Nature*, 320:602–607 (April 17, 1986); JOHN M. WALLACE and QUANRONG JIANG, "On the Observed Structure of the Interannual Variability of the Atmosphere/Ocean Climate System," in HOWARD CATTLE (ed.), *Atmospheric and Oceanic Variability* (1987), pp. 17–43; T.N. PALMER and SUN ZHAOBO, "A Modelling and Observational Study of the Relationship Between Sea Surface Temperature in the North-west Atlantic and the Atmospheric General Circulation," *Quarterly Journal of the Royal Meteorological Society*, 111(470):947–975 (October 1985); JEROME NAMIAS, "Negative Ocean-Air Feedback Systems Over the North Pacific in the Transition from Warm to Cold Seasons," *Monthly Weather Review*, 104(9):1107–1121 (September 1976); and R.E. DAVIS, "Predictability of Sea Level Pressure Anomalies Over the North Pacific Ocean," *Journal of Physical Oceanography*, 8(2):223–246 (March 1978).

The formation of tropical cyclones is analyzed in WILLIAM M. GRAY, "Hurricanes: Their Formation, Structure, and Likely Role in the Tropical Circulation," in D.B. SHAW (ed.), *Meteorology Over the Tropical Oceans* (1979), pp. 155–218; J.F. PRICE, "Upper Ocean Response to a Hurricane," *Journal of Physical Oceanography*, 11(2):153–175 (February 1981); D.A. BROOKS, "The Wake of Hurricane Allen in the Western Gulf of Mexico," *Journal of Physical Oceanography*, 13(1):117–129 (January 1983); and GUY A. FRANCESCHINI and SAYED Z. EL-SAYED, "Effect of Hurricane Inez (1966) on the Hydrography and Productivity of the Western Gulf of Mexico," *The German Hydrographic Journal*, 21(5):193–202 (1968).

The Gulf Stream and Kuroshio systems are described in HENRY STOMMEL, *The Gulf Stream: A Physical and Dynamical Description*, 2nd ed. (1965, reissued 1976); WILLIAM H. MACLEISH, *The Gulf Stream* (1989), including a maritime history of the current as well as scientific data; N.P. FOFONOFF, "The Gulf Stream," in BRUCE A. WARREN and CARL WUNSCH (eds.), *Evolution of Physical Oceanography* (1981), pp. 112–139; and HENRY STOMMEL and KOZO YOSHIDA (eds.), *Kuroshio: Physical Aspects of the Japan Current* (1972). More in-depth essays include HENRY STOMMEL, "Asymmetry of Inter-oceanic Fresh-water and Heat Fluxes," *Proceedings of the National Academy of Science of the United States of America*, 77(5):2377–2381 (May 1980); CARL WUNSCH, "The Ocean Circulation in Climate," in JOHN T. HOUGHTON (ed.), *The Global Climate* (1984); and ALAN R. ROBINSON (ed.), *Eddies in Marine Science* (1983).

Studies of the El Niño/Southern Oscillation phenomena and their effect on climatic change are found in P.W. GLYNN (ed.), *Global Ecological Consequences of the 1982–83 El Niño-Southern Oscillation* (1990); S. GEORGE PHILANDER, *El Niño, La Niña, and the Southern Oscillation* (1990); WARREN S. WOOSTER and DAVID L. FLUHARTY (eds.), *El Niño North: Niño Effects in the Eastern Subarctic Pacific Ocean* (1985); RICHARD T. BARBER and FRANCISCO P. CHAVEZ, "Biological Consequences of El Niño," *Science*, 222(4629):1203–1210 (Dec. 16, 1983); THOMAS Y. CANBY, "El Niño's Ill Wind," *National Geographic*, 165(2):144–183 (February 1984); M.A. CANE, "El Niño," *Annual Review of Earth and Planetary Sciences*, 14:43–70 (1986); DAVID B. ENFIELD, "El Niño, Past and Present," *Reviews of Geophysics*,

27(1):159-187 (1989); NICHOLAS E. GRAHAM and WARREN B. WHITE, "The El Niño Cycle: A Natural Oscillator of the Pacific Ocean-Atmosphere System," *Science*, 240:1293-1302 (June 3, 1988); S. GEORGE PHILANDER and E.M. RASMUSSEN, "The Southern Oscillation and El Niño," *Advances in Geophysics*, vol. 28, part A, pp. 197-215 (1985); and E.M. RASMUSSEN, "El Niño and Variations in Climate," *American Scientist*, 73(2):168-177 (March-April 1985). In addition, the entire issue of *Oceanus*, vol. 27, no. 2 (Summer 1984), is devoted to El Niño studies.

(N.C.W./D.B.En.)

Ocean basins: Overviews of the geologic features of the deep-sea floor are given in JAMES P. KENNETT, *Marine Geology* (1982); and ALAN E.M. NAIRN and FRANCIS G. STEHLI (eds.), *The Ocean Basins and Margins*, 7 vol. in 9 (1973-88). Specific topics and geographic areas are studied by ROGER L. LARSON and WALTER C. PITMAN III, "World-wide Correlation of Mesozoic Magnetic Anomalies, and Its Implications," *Geological Society of America Bulletin*, 83(12):3645-3661 (December 1972); KEN C. MACDONALD and BRUCE P. LUYENDYK, "The Crest of the East Pacific Rise," *Scientific American*, 244(5):100-116 (May 1981); ARTHUR D. RAFF and RONALD G. MASON, "Magnetic Survey off the West Coast of North America, 40° N. Latitude to 52° N. Latitude," *Geological Society of America Bulletin*, 72(8):1267-1270 (August 1961); H.W. MENARD, "The Deep-ocean Floor," *Scientific American*, 221(3):126-142 (September 1969); B. PARSONS and J.G. SCLATER, "An Analysis of the Variations of Ocean Floor Bathymetry and Heat Flow," *Journal of Geophysical Research*, 82(5):803-827 (1977); C.M. POWELL, S.R. ROOTS, and J.J. VEEVERS, "Pre-breakup Continental Extension in East Gondwanaland and the Early Opening of the Eastern Indian Ocean," *Tectonophysics*, 155:261-283 (1988); DAVID B. ROWLEY and ANN L. LOTTES, "Reconstructions of the North Atlantic and Arctic: Late Jurassic to Present," *Tectonophysics*, 155:73-120 (1988); T. SIMKINS *et al.*, (1989); and two essays in E.L. WINTERER, DONALD M. HUSSONG, and ROBERT W. DECKER (eds.), *The Eastern Pacific Ocean and Hawaii* (1989), vol. N of the series "The Geology of North America": TANYA ATWATER, "Plate Tectonic History of the Northeast Pacific and Western North America," ch. 4, pp. 21-72; and KEN C. MACDONALD, "Tectonic and Magnetic Processes on the East Pacific Rise," ch. 6, pp. 93-110. (B.P.L.)

Continental margins: FRANCIS P. SHEPARD, *Submarine Geology*, 3rd ed. (1973), is somewhat dated but still considered by many marine geologists to contain the best treatment of continental margins; many people, however, consider the second ed. (1963) to be more general and better-organized. ELIZABETH K. BERNER and ROBERT A. BERNER, *The Global Water Cycle: Biochemistry and Environment* (1987), contains much information on the contribution that rivers make to margin sediments. CREIGHTON A. BURK and CHARLES L. DRAKE (eds.), *The Geology of Continental Margins* (1974), contains a general section on continental margins and many chapters on the details of specific margins, written for the advanced student. FRANCIS P. SHEPARD and ROBERT F. DILL, *Submarine Canyons and Other Sea Valleys* (1966), is the most complete treatment of submarine canyons in one volume, written in a style easily grasped by high school as well as advanced students. LARRY J. DOYLE and ORRIN H. PILKEY (eds.), *Geology of Continental Slopes* (1979); and K.O. EMERY, "The Continental Margins," *Scientific American*, 221(3):106-122 (September 1969), are also useful.

(L.J.D.)

Coastal and nearshore features: General discussions may be found in ERIC C.F. BIRD, *Coasts: An Introduction to Coastal Geomorphology*, 3rd ed. (1984); J.L. DAVIES, *Geographical Variation in Coastal Development*, 2nd ed. (1980); and MAURICE L. SCHWARTZ (ed.), *The Encyclopedia of Beaches and Coastal Environments* (1982).

Further information on coral reefs can be found in CHARLES DARWIN, *The Structure and Distribution of Coral Reefs* (1842, reissued 1984); J.A. FAGERSTROM, *The Evolution of Reef Communities* (1987); and ANDRÉ GUILCHER, *Coral Reef Geomorphology* (1988). For more detailed information on the Great Barrier Reef and coral reef devastation, respectively, see W.G.H. MAXWELL, *Atlas of the Great Barrier Reef* (1968); DAVID

HOPLEY, *The Geomorphology of the Great Barrier* (1982); CHARLES BIRKELAND, "The Faustian Traits of the Crown-of-Thorns Starfish," *American Scientist*, 77(2):154-163 (March-April 1989); and E.H. WILLIAMS, C. GOENAGA, and V. VINCENTE, "Mass Bleachings on Atlantic Coral Reefs," *Science*, 238:877-878 (Nov. 13, 1987).

Various aspects of lagoons and estuaries are dealt with in K.H. MANN, *Ecology of Coastal Waters* (1982); GEORGE H. LAUFF (ed.), *Estuaries* (1967); BJÖRN KJERFVE (ed.), *Hydrodynamics of Estuaries*, 2 vol. (1988); STEPHEN P. LEATHERMAN, *Barrier Island Handbook*, 3rd ed. (1988); and T.E. PICKETT and R.L. INGRAM, "The Modern Sediments of Pamlico Sound, North Carolina," *Southeastern Geology*, 11(2):53-83 (1969).

Particular gulfs and bays are described in RHODES W. FAIRBRIDGE (ed.), *The Encyclopedia of Oceanography* (1966); A.J. HUXLEY (ed.), *Standard Encyclopedia of the World's Oceans and Islands* (1962); and ERIC C.F. BIRD and MAURICE L. SCHWARTZ (eds.), *The World's Coastline* (1985). (M.L.S.)

Economic aspects of the oceans: An entire issue of *Oceanus*, vol. 21, no. 4 (Winter 1984/85), is devoted to the impact of the Exclusive Economic Zone, especially as it pertains to the United States; coastal fishing, multiple-use management, marine pollution, and nonliving resources are some of the topics covered. GIULIO PONTECORVO, *The New Order of the Oceans: The Advent of a Managed Environment* (1986), deals with the new ocean regime and with the research and technology of marine resources from a global perspective, particularly emphasizing the international effects of the 1982 United Nations Law of the Sea Convention. The evolution of international marine policy and shipping law is compellingly discussed in EDGAR GOLD, *Maritime Transport* (1981), and "Ocean Shipping and the New Law of the Sea: Toward a More Regulatory Regime," *Ocean Yearbook*, vol. 6, pp. 85-96 (1986).

Discussions of the managed production of aquatic organisms include J.F. MUIR, "Aquaculture—Towards the Future," *Endeavour*, 9(1):52-55 (1985); and JOHN BARDACH, "Aquaculture: Moving from Craft to Industry," *Environment*, 30(2):6-11, 36-41 (March 1988). Desalinization processes are discussed and illustrated in ALAN D.K. LAIRD, "The Potable Sea: Taking the Salt from Saltwater," *Oceans*, 15(5):25-29 (September-October 1982); and ROBERTA FRIEDMAN, "Salt-free Water from the Sea," *Sea Frontiers*, 36(3):49-54 (May-June 1990).

Overviews of various ocean energy resources and technologies may be found in MAXWELL BRUCE, "Ocean Energy: Some Perspectives on Economic Viability," *Ocean Yearbook*, vol. 5, pp. 58-78 (1985); and TERRY R. PENNEY and DESIKAN BHARATHAN, "Power from the Sea," *Scientific American*, 256(1):86-92 (January 1987). Tidal power generation is covered by B. COUNT (ed.), *Power from Sea Waves* (1980), based on conference proceedings; and MICHAEL E. MCCORMICK, *Ocean Wave Energy Conversion* (1981). Summaries of ocean thermal energy conversion techniques and future prospects are provided by R. COHEN, "Energy from the Ocean," *Philosophical Transactions of the Royal Society of London*, Series A, 307:405-437 (1982); and D.E. LENNARD, "Ocean Thermal Energy Conversion—Past Progress and Future Prospects," *IEE Proceedings*, vol. 134, part A, no. 5, pp. 381-391 (May 1987).

Current and future petroleum and mineral resources in the ocean environment and the technologies necessary to recover them are addressed in GERARD J. MANGONE (ed.), *The Future of Gas and Oil from the Sea* (1983); ELISABETH MANN BORGESSE, *The Mines of Neptune: Minerals and Metals from the Sea* (1985); DAVID CRONAN, "A Wealth of Sea-floor Minerals," *New Scientist*, 106:34-38 (June 6, 1985); and JAMES M. BROADUS, "Seabed Materials," *Science*, 235:853-860 (Feb. 20, 1987).

Discussions of the use of the ocean as a site for waste disposal, and the problems of marine pollution, include IVER W. DUEDALL *et al.* (eds.), *Wastes in the Ocean*, 6 vol. (1983-85), on industrial and sewage, radioactive, and energy wastes, dredged-material disposal, and deep-sea and nearshore waste disposal; R.B. CLARK, *Marine Pollution*, 2nd ed. (1989); WESLEY MARX, *The Oceans: Our Last Resource* (1981); DAVID K. BULLOCH, *The Wasted Ocean* (1989); and a complete issue of *Oceanus*, vol. 33, no. 2 (Summer 1990). (Ed.)

Olympic Games

Just how far back in history organized athletic contests were first held remains a matter of doubt, but it is reasonably certain that they occurred in Greece, at least, some 3,500 years ago.

However ancient in origin, by the end of the 6th century BC at least four of the Greek sporting festivals, sometimes known as classical games, had achieved major importance. They were the Olympic Games, held at Olympia; the Pythian Games at Delphi; the Nemean Games at Nemea; and the Isthmian Games at Corinth. Later, similar festivals were held in nearly 150 cities as far afield as Rome, Naples, Odessus, Antioch, and Alexandria.

The Olympic Games in particular were to become famous throughout the Greek world. There are records of the champions at Olympia from 776 BC to AD 217. The Games, held every four years, were abolished in AD 393 by the Roman emperor Theodosius I, probably because of their pagan associations. For the first 100 or 200 years, Olympic champions came from a dozen or more Greek

cities, the majority from Sparta and Athens, but in the next three centuries, athletes were drawn from 100 cities in the Greek empire. And in the final 100 years or so before the games were discontinued, champions came from as far from Olympus as Antioch, Alexandria, and Sidon.

In 1887 the 24-year-old Baron Pierre de Coubertin conceived the idea of reviving the Olympic Games and spent seven years preparing public opinion in France, England, and the United States to support his plan. At an international congress in 1894, his plan was accepted and the International Olympic Committee was founded. The first modern Olympic Games were held in Athens in April 1896, with 13 nations sending nearly 300 representatives to take part in 42 events and 10 different sports. The revival of the Olympic Games led to the formation of many international bodies controlling their own amateur sports and to the creation of National Olympic Committees in countries throughout the world.

EARLY HISTORY

Greece. Of all the games held throughout Greece, those staged at Olympia in honour of Zeus are the most famous. Held every four years between August 6 and September 19, they occupied such an important place in Greek life that time was measured by the interval between them—an Olympiad. Although the first Olympic champion listed in the records was one Coroebus of Elis, a cook, who won the sprint race in 776 BC, it is generally accepted that the Games were probably at least 500 years old at that time. According to one legend they were founded by Heracles, son of Alcmena. The Games, like all Greek games, were an intrinsic part of a religious festival. They were held at Olympia in the city-state of Elis, on a track about 32 metres (35 yards) wide. The racing length was one stade, a distance of about 192 metres (210 yards). In the early Olympics a race, called a stade, covered one length of the track. Horse racing, which became part of the ancient games, was held in the hippodrome, south of the stadium.

At the meeting in 776 BC, there was apparently only one event, the stade, but other events were added over the ensuing decades. In 724 BC a two-length race, *diaulos*, roughly similar to the 400-metre race, was included, and four years later the *dolichos*, a long-distance race possibly to be compared to the modern 1,500- or even 5,000-metre event, was added. Wrestling and the pentathlon were introduced in 708 BC. The latter was an all-around competition consisting of five events—the long jump, javelin throw, discus throw, foot race, and wrestling.

Boxing was introduced in 688 BC, and in 680 a chariot race. In 648 the pancratium (Greek *pankration*), a kind of all-strength, or no-holds-barred, wrestling, was included. Kicking and hitting were allowed; only biting and gouging (thrusting a finger or thumb into an opponent's eye) were forbidden. Between 632 and 616 BC events for boys were introduced. And from time to time further events were added, including contests for fully armed soldiers, for heralds, and for trumpeters. The program must have

been as varied as that of the modern Olympics, although the athletics (track and field) events were limited; there was no high jumping in any form and no individual field event, except in the pentathlon.

Until the 77th Olympiad (472 BC) all of the contests took place on one day; later they were spread, with, perhaps, some fluctuation, over four days, with a fifth devoted to the closing-ceremony presentation of prizes and a banquet for the champions. Sources generally agree that women were not allowed as competitors or, except for the priestess of Demeter, as spectators. In most events, the athletes participated in the nude.

The Olympic Games were originally restricted to free-born Greeks. The competitors, including those who came from the Greek colonies, were amateur in the sense that the only prize was a wreath or garland. The athletes underwent a most rigorous period of supervised training, however, and eventually the contestants were true professionals. Not only were there substantial prizes for winning, but the Olympic champion also received adulation and unlimited benefits from his city. Athletes became full-time specialists—a trend that in the modern games has caused a long and bitter controversy over amateurism.

Rome. Greece lost its independence to Rome in the middle of the 2nd century BC, and the support for the competitions at Olympia and other places fell off considerably in the next century. The Romans looked on athletics with contempt—to strip naked and to contend in public was degrading in the eyes of the Roman citizen. The Romans realized the value of the Greek festivals, however, and Augustus, who had a genuine love for athletics, staged athletic games in a temporary wooden stadium erected near the Circus Maximus. Nero was also a keen patron of the festivals in Greece. By the 4th century AD, Rome, with its population of more than 1,000,000, had well over 150 holidays for games. There was chariot racing in the hippodrome and horse racing in the Circus Maximus, with room for more than 250,000 spectators. In an amphithe-

The first
Olympic
champion

Early
profes-
sionalism

atre with accommodation for 50,000, animals and human beings were maimed and slaughtered in the name of sport.

Indeed, public games were held in abundance, but for the Romans athletic events occupied a secondary position. The only ones that really interested them were the fighting events—wrestling, boxing, and the pancratium. The main difference between the Greek and Roman attitude was that the Roman festivals were described as *ludi* (games), the Greek as *agōnes* (contests). The Greeks originally organized their games for the competitors, the Romans for the public. One was primarily competition, the other entertainment; and it is not unreasonable to suggest that the Greeks took an “amateur” view of sport, the Romans a professional one.

REVIVAL OF THE OLYMPICS

The architect of the modern Olympics was Baron Pierre de Coubertin, born in Paris on New Year's Day, 1863. As a young man he was intensely interested in literature and in education and sociology. Family tradition pointed to an army career or possibly politics, but at the age of 24 Coubertin decided that his future lay in education. At the same time he had the idea of reviving the Olympic Games, and he propounded his desire for a new era in international sport when on November 25, 1892, at a meeting of the Union des Sports Athlétiques in Paris, he said:

Let us export our oarsmen, our runners, our fencers into other lands. That is the true Free Trade of the future; and the day it is introduced into Europe the cause of Peace will have received a new and strong ally. It inspires me to touch upon another step I now propose and in it I shall ask that the help you have given me hitherto you will extend again, so that together we may attempt to realise, upon a basis suitable to the conditions of our modern life, the splendid and beneficent task of reviving the Olympic Games.

The speech did not produce any appreciable activity, but Coubertin was not fainthearted. At a conference on international sport in Paris in June 1894 at which Coubertin raised the possibility of the revival of the Olympic Games, there were 79 delegates representing 49 organizations from nine countries. Coubertin himself wrote that except for his co-workers Dimitrios Vikélas of Greece, who was to be the first president of the International Olympic Committee, and Professor William M. Sloane of the U.S. from the College of New Jersey (later Princeton University), no one had real interest in the revival of the Games. Nevertheless, and to quote Coubertin again, “a unanimous vote in favour of revival was rendered at the end of the Congress chiefly to please me.”

It was at first agreed that the Games should be held in Paris in 1900. Six years seemed a long time to wait, however, and it was decided to change the venue—what better site than Athens, the capital of Greece—and the date, to April 1896. A great deal of indifference, if not opposition, had to be overcome, including a refusal by Athens to stage the Games at all. But Coubertin and his newly elected International Olympic Committee of 14 members won through, and the Games were opened by the King of Greece in the first week of April 1896.

ORGANIZATION OF THE MODERN OLYMPICS

The International Olympic Committee. At the Congress of Paris in 1894, the control and development of the modern Olympic Games was entrusted to the International Olympic Committee (ioc; Comité International Olympique), with headquarters to be established in Switzerland. It is responsible for maintaining the regular celebration of the Olympic Games; seeing that the Games are carried out in the spirit that inspired their revival; and promoting the development of amateur sport throughout the world. The original committee in 1894 consisted of 14 members and Coubertin, and membership since then has been self-perpetuating.

Convinced that the downfall of the ancient Olympic Games had been caused by outside influences that undermined the spirit of the Games, Coubertin felt that the revived Games would go the same way unless they were in the hands of people whose concern was to keep the spirit of amateur sport alive and who were responsible in

no way to any outside influences. Thus ioc members are regarded as ambassadors from the ioc to their national sports organizations. They are in no sense delegates to the committee and may not accept from the government of their country, or from any organization or individual, any instructions that in any way affect their independence.

The ioc is a permanent organization that elects its own members. Each member—the present membership is about 70—must speak French or English and be a citizen of or reside in a country that has a National Olympic Committee. With a very few exceptions, there is only one member from any one country. Members were originally elected for life, but anyone elected after 1965 must retire at 75.

The ioc elects its president for a period of eight years, at the end of which he is eligible for reelection for further periods of four years each. Juan Antonio Samaranch (Spain) was elected in 1980. Previous presidents were Dimitrios Vikélas (1894–96, Greece), Baron Pierre de Coubertin (1896–1925, France), Count Henri de Baillet-Latour (1925–42, Belgium), J. Sigfrid Edström (1946–52, Sweden), Avery Brundage (1952–72, United States), and Michael Morris, Lord Killanin (1972–80, Ireland).

The executive board of 11 members holds periodic meetings with the international federations and National Olympic Committees. The ioc as a whole meets annually, and a meeting can be convened at any time that one-third of the members so request.

National Olympic Committees. Each country that desires to participate in the Olympic Games must have an Olympic committee accepted by the ioc. By 1988 there were 167 such committees.

A National Olympic Committee is composed of at least five national sporting federations, each affiliated to an appropriate international federation. The ostensible purpose of these National Olympic Committees is the development and promotion of the Olympic movement and of amateur sport. National Olympic Committees arrange to equip, transport, and house their country's representatives at the Olympic Games. According to the rules of the committee, they must be not-for-profit organizations; must not associate themselves with affairs of a political or commercial nature; and must be completely independent and autonomous and in a position to resist all political, religious, or commercial pressure.

A person who has ever competed in sports as a professional, who has ever coached sports competitors for payment, or who is engaged in or connected with sport for personal profit is not eligible to serve on a national committee. The rules provide that

exceptions to these categories may be made by the Executive Board of the I.O.C. on the recommendation of the National Olympic Committee concerned.

National Olympic Committees that do not conform to ioc rules and regulations forfeit their recognition and their right to send participants to the Olympic Games.

IOC awards. In individual Olympic Games events, the award for first place is a gold (silver-gilt, with six grams of fine gold) medal, for second place a silver medal, and for third place a bronze medal. Solid gold medals were last given in 1912. Diplomas are awarded for fourth, fifth, sixth, seventh, and eighth places. All competitors and officials receive a commemorative medal.

The ioc presents two noncompetitive awards, the Olympic Cup and the Olympic Order. The former was instituted by Baron de Coubertin in 1906. It is awarded to an association or institution that has a general reputation for merit and integrity, that has eminently served the cause of amateur sport, and that has made a substantial contribution to the Olympic movement. The first recipient of the Olympic Cup was the Touring Club de France.

The Olympic Order, created in 1974, is intended for living persons, excluding active members of the ioc. There are two degrees of award—gold and silver—to be made “to any person who has illustrated the Olympic ideal through his action, has achieved remarkable merit in the sporting world, or has rendered outstanding services to the Olympic cause, either through his own personal achievement or his contribution to the development of sport.” The first gold

Independence of International Committee members

Presidents of the ioc

First games of the modern cycle

Olympic Order

medal was awarded posthumously to Avery Brundage, for 20 years president of the IOC. Among the silver awards that have been made were those to Jesse Owens, winner of four gold medals at the 1936 Olympics, and to Dan Ferris, for more than 50 years a prominent administrator in U.S. and world track and field. Bronze medals had also been awarded but were discontinued in 1981.

Five previous awards were suspended in 1974: the Olympic Diploma of Merit, first awarded in 1905; the Sir Thomas Fearnley Cup and the Mohammed Taher Trophy, first awarded in 1951; the Count Alberto Bonacossa Trophy, established in 1955; and the Tokyo Trophy, first awarded in 1967.

The Games and participants. The Olympic Games (Summer) are held every four years. There is no age limit for competitors, unless one has been established by a sport's international federation. No discrimination is allowed on grounds of race, religion, or political affiliation. The Games are contests between individuals and not between countries. Separate Winter Games have been held since 1924.

The Olympic Games celebrate an Olympiad, or period of four successive years. The first Olympiad of modern times was celebrated in 1896, and subsequent Olympiads are numbered consecutively, even though no Games take place (as was the case in 1916, 1940, and 1944).

In 1986 the IOC voted to alternate the Summer and Winter Games every two years, beginning in 1994. The Winter Games would be held in 1992 and again in 1994 and thereafter would be held every four years; the Summer Games would maintain their original four-year cycle.

The maximum number of entries permitted for individual events is three per nation. The number is fixed (but can be varied) by the IOC in consultation with the international federation concerned. In team events, only one team per country is allowed. In general, a National Olympic Committee may only enter a citizen of the country concerned.

Problems of eligibility. To be allowed to compete, a competitor must meet the eligibility rules as defined by the international body of the particular sport and also by the rules of the IOC.

In recent years there has been a tendency away from the strict definition of amateur status. In 1971 the IOC decided to eliminate the term amateur from the Olympic Charter. Subsequently the eligibility rules were amended to permit "broken-time" payments to compensate athletes for time spent away from work during training and competition. The IOC also legitimized the sponsorship of athletes by National Olympic Committees, sports organizations, and private businesses. In some sports, including track and field, figure skating, and skiing, athletes must place income from commercial endorsements and sponsorships in a restricted trust fund, which is controlled by their national federation.

In 1986 the IOC adopted rules that permit the international federation governing each Olympic sport to decide whether to permit professional athletes in Olympic competition. Professionals in ice hockey, tennis, soccer, and equestrian sports were permitted to compete in the 1988 Olympics, although their eligibility was subject to some restrictions, and professionals from sports other than track and field were eligible for Olympic track and field events.

It now appears to some of those who have been closely associated with the Games that they have become too vast, too nationalistic, too expensive, and too commercial. It is felt that no longer is the important thing "to take part" but that winning a gold medal is the only thing that matters. The primary consideration appears no longer to be the competitors, more than 95 percent of whom cannot win gold medals, but the public. Entertainment now seems to supersede the enjoyment of competition, and the demand for entertainment may well be the death of amateur sport.

Programs and events. An official Summer Olympic program must include at least 15 of the following sports: archery, athletics (track and field), basketball, boxing, canoeing, cycling, diving, equestrian sports, fencing, field hockey, football (soccer), gymnastics, handball (team handball), judo, modern pentathlon, rowing, shooting, swim-

ming, table tennis, tennis, volleyball, water polo, weight lifting, wrestling, and yachting. Women can participate in all of the sports except boxing, football, judo, modern pentathlon, water polo, weight lifting, and wrestling. An Olympic program may also include up to two demonstration sports and in addition must include national exhibitions and demonstrations of fine arts (architecture, literature, music, painting, sculpture, photography, and sports philately).

The particular events included in the different sports are a matter for agreement between the IOC and the international federations. For many years there were 24 events for men in track and field. In 1976, however, the men's 50,000-metre walk was excluded (on the grounds that the total number of competitors in the Games must be reduced), while women's rowing events were included for the first time. It appears that although the IOC feels that in some way there must be a limit placed upon the total number of competitors, it is unwilling to take the severe action of excluding certain sports.

The Olympic Village. The Olympic Village was first introduced at Los Angeles in 1932. The organizing committee provides the village so that competitors and team officials can be housed together and fed at a reasonable price. The villages are located as close as possible to the main stadium and other facilities and have separate accommodations for men and women. Only competitors and officials may live in the village, and the number of team officials is limited.

Ceremonies. *The Olympic flag.* In the stadium and its immediate surroundings, the Olympic flag is flown freely together with the flags of the nations taking part. The Olympic flag presented by Baron Coubertin in 1914 is the prototype: it has a white background and in the centre there are five interlaced rings—blue, yellow, black, green, and red. The blue ring is on the left next to the pole. These rings represent the five continents joined together in the Olympic Movement. The Olympic motto is *Citius—Altius—Fortius* ("Faster—Higher—Stronger").

The opening ceremony. The form of the opening ceremony is laid down by the IOC in great detail, from the moment when the chief of state of the host country is received by the president of the IOC and the organizing committee at the entrance to the stadium, to the end of the proceedings when the last team files out. The rules provide that participants are not permitted to carry cameras into the arena, but this provision is always ignored.

When the head of state has reached his place in the tribune, he is greeted with the national anthem of his country, and the parade of competitors begins. The Greek team is always the first to enter the stadium, and, except for the host team, which is always last, the other nations follow in alphabetical order as determined by the language of the organizing country. Each contingent, dressed in its official uniform, is preceded by a shield with the name of its country, while an athlete carries its national flag. At the 1980 games, some of the countries protesting the Soviet Union's involvement in Afghanistan carried the Olympic flag in place of their national flag. The competitors march around the stadium and then form up in the centre of the ground facing the tribune.

The president of the organizing committee then delivers a brief speech of welcome, followed by another brief speech from the president of the IOC, who asks the chief of state to proclaim the Games open.

A fanfare of trumpets is sounded as the Olympic flag is slowly raised; pigeons are released, symbolically to fly to the countries of the world with the news that the Games are open.

The Olympic flame is then carried into the stadium by the last of the runners who have brought it from Olympia, Greece. The runner circles the track, mounts the steps, and lights the Olympic fire that burns night and day during the Games. In 1968 a woman carried the flame into the stadium, and in 1976 the flame was borne jointly by a male and a female athlete. In 1984, at the Games in Los Angeles, a female runner brought the flame into the stadium but passed it to a male, who ran up the steps to light the Olympic fire.

The
Olympic
flame

Victory ceremony. Medals are presented during the Games at the various venues and usually soon after the conclusion of the event. The competitors who have won the first three places proceed to the rostrum, with the winner (gold medalist) in the centre, the silver medalist on his or her right, and the bronze medalist on the left. The medals, attached to a chain or ribbon, are hung around the necks of the winners by a member of the IOC, and the flags of the nations concerned are raised to the top of the flagpoles while an abbreviated form of the national anthem of the winner is played. The spectators are expected to stand and face the flags, as do the three successful athletes.

Closing ceremony. The closing ceremony takes place after the final event, which is usually the equestrian Prix des Nations. Since the Melbourne Olympics in 1956, the closing ceremony has been a less formal affair, and after certain formalities have been observed, the athletes taking part stage their own demonstrations.

The ceremonies include a parade of athletes, six from each nation, marching eight or 10 abreast without distinction of nationality, and signifying the friendly bonds of Olympic sport. The president of the IOC calls the youth of the world to assemble in four years to celebrate the Games of the next Olympiad. A fanfare is sounded, the Olympic fire is extinguished, and to the strains of the Olympic anthem the Olympic flag is lowered and the Games are over.

The awarding of the Olympic Games. The honour of holding the Olympic Games is entrusted to a city and not to a country. The choice of the city lies solely with the IOC. Application to hold the Games is made by the chief authority of the city, with the support of the national government.

Applications must state that no political meetings or demonstrations will be held in the stadium or other sports grounds or in the Olympic Village, and it must be promised that every competitor shall be given free entry without any discrimination on grounds of religion, colour, or political affiliation. This involves the assurance that the national government will not refuse visas to any of the competitors. At the Montreal Olympics in 1976, however, the Canadian government refused visas to the representatives of Taiwan because they were unwilling to forgo the title of the Republic of China, under which their National Olympic Committee was admitted to the IOC. This Canadian decision, in the opinion of the IOC, did great damage to the Olympic Games, and it was later resolved that any country in which the Games are organized must undertake strictly to observe the rules. Enforcement would be difficult and even the use of severe penalties by the IOC might not guarantee elimination of infractions.

HISTORY OF THE MODERN GAMES

Since the revival of the Games, growth in the numbers of competitions, of competitors, and of participating countries has been almost continuous. The history of the modern Games may be conveniently divided into four periods: (1) from the revival in 1896 to the outbreak of World War I, (2) the period between the two World Wars, (3) from the resumption of the Games in 1945 through the 1968 Games, and (4) from the 1972 games onward.

First period: 1896–1912. It took some time for the Games to find their continuing pattern. Of the five celebrations in the first period, the first three—Athens in 1896, Paris in 1900, and St. Louis, Missouri, in 1904—were somewhat haphazard affairs. The entries were unlimited and hardly ever “national” in the sense of representing each nation’s best performers. The actual events included varied considerably, and it is not possible to determine with any degree of confidence which of the events were really of Olympic significance. Women competed at golf and lawn tennis in the Paris Games and at archery in the St. Louis Games.

The Games of 1908 in London were the first to be organized by the various sporting bodies concerned and were not regarded as an appendage to a world fair and controlled by the promoters. Though the holding of a Franco-British Exhibition at Shepherd’s Bush, London, made possible the construction of a new stadium—the famous White City,

with a capacity of 66,000—the governing bodies of sport were in control. Twenty-two nations sent more than 2,000 athletes (but only 36 women) to compete in more than 100 events in 17 different sports. Archery and lawn tennis were included in the 1908 program.

At Stockholm in 1912, the number of nations increased to 28, the number of competitors exceeded 2,500, and for the first time three swimming events for women were included. Because of World War I, no Games were held in 1916.

Second period: 1920–36. This period saw the golden age of athletes—from the Finnish domination of middle- and long-distance running to the performances in the sprints, especially that of Jesse Owens. In this period, too, there were five celebrations. In less than two years after the Armistice in November 1918, Belgium organized the first post-World War I Olympics, opened at Antwerp by King Albert I. Twenty-nine nations, including many new ones, sent more than 2,500 competitors to take part in more than 150 events in 19 sports. Women competitors were still a mere handful (about 60). Four years later, in Paris, the number of countries increased to 44, with more than 3,000 competitors for 137 events, a decrease because of a reduction in the excessive number of shooting and yachting events. More than 100 women took part, competing in fencing as well as swimming and lawn tennis. After 1924 a question of eligibility in lawn tennis caused the IOC to omit the sport from future Games.

In 1928 in Amsterdam, women’s track and field competitions (five events) and one event for women in gymnastics were introduced. Again there were 3,000 athletes, from 46 countries, but the number of women (290) was more than double that at Paris (136). Four years later the Games for the second time crossed the Atlantic, to Los Angeles, and there was a falling off in the number of competitors—less than 1,500 from 37 countries. The long journey from Europe and the heavy cost during a major depression were responsible for the decreases. The return to Europe for the Berlin Games produced 4,000 athletes in 1936.

Third period: 1948–68. In this period there was a significant rise in the number of women competitors and the number of events open to women. Sports other than track and field, such as swimming, came into prominence. Most of all an increase in television coverage of both Winter and Summer Games increased the audience. Because of World War II, no Games were held in 1940 or 1944. London was given the task of organizing the first postwar Games in 1948 with a bare three years available. This was accomplished despite difficult postwar conditions, with rationing of various materials and supplies still in effect and with expenditures limited. The number of competing countries was 59, with 4,000 competitors, of whom 385 were women. Track and field events for women were increased to nine by the addition of the 200-metre run, the broad (now long) jump, and the shot put.

Finland was host to the 1952 Games, at Helsinki. The number of countries participating rose to 69, competitors totalled within 100 of 6,000, and women topped the 500 mark. In 1956 for the first time the venue was in the Southern Hemisphere. The Games in Melbourne were celebrated in November and December, and for the first time one of the sports had to take place in another country. Because of quarantine regulations that prohibited the importation of horses to Australia, the equestrian events were decided in Stockholm. Again the distance from Europe reduced the competitors in Melbourne by 1,500.

In Rome four years later, however, the number of competitors passed the 5,000 mark, the number of nations rose to more than 80, and the number of events rose to 150. Originally Rome was to have staged the 1908 Games.

The Games were in Asia for the first time in 1964, at Tokyo, again in a city where the previous award (in 1940) had not been fulfilled. Once more there were record figures: 94 countries, 162 events, and 5,500 competitors.

There was considerable criticism when Mexico City was awarded the 1968 Games. Controversy surrounded charges that the altitude, more than 2,300 metres (7,500 feet), would adversely affect the majority of distance runners, who would not have been able to spend many months liv-

Increase of women’s events

First Asian Games

London, 1908

ing in a comparably rarefied atmosphere. The number of competitors rose to more than 6,500 from 125 countries. Women numbered 800, the total events 172.

The
Munich
tragedy

Fourth period: 1972 onward. This period has been marked by political violence and dissension. In Munich in 1972 there were nearly 200 different events, with 8,000 competitors from 124 countries. Tragedy struck the Games when Arab (Palestinian) terrorists invaded the Olympic Village and killed two and seized nine Israeli athletes as hostages for the release of 200 Arab prisoners in Israel; all nine, five of their captors, and a West German policeman were slain when police rescue attempts failed.

In Montreal in 1976 the number of entries exceeded those of Munich, but the last-minute withdrawals by countries protesting the presence of the New Zealand team because of their rugby affiliation with South Africa, whose apartheid policies were held to be objectionable, reduced the actual competitors by more than 400.

Moscow
Games
boycott

The games of the XXII Olympiad at Moscow in 1980 were marred by the lack of participation of some 60 eligible nations in protest against the Soviet Union's invasion of Afghanistan in December 1979. A total of 5,923 competitors representing 81 nations did take part, but the Games were further diminished by the intrusion of two other issues—alleged bias in judging by eastern European officials and the use of anabolic steroids by athletes to improve performance. The latter issue was exacerbated just before the Games when seven athletes caught using the drugs in 1979 were made eligible for the Olympics against the rules of the International Amateur Athletic Federation.

Preparations for the 1984 Games at Los Angeles were complicated by the fears of some over the physiological effects of the infamous Los Angeles smog on athletes, by jurisdictional disputes over security by various law enforcement agencies, by legal suits over scheduling of endurance events for women athletes, and by the decision of the Soviet Union and a number of its allies not to send teams to participate in the Games.

Nearly 10,000 athletes from 160 countries participated in the 1988 Games at Seoul. The program included 26 sports, with 237 separate events. The use of steroids and

other drugs continued to be a major issue; 10 athletes, five of them medalists, were disqualified for using banned substances.

The 1992 Summer Olympics were scheduled for Barcelona.

The Winter Olympic Games. While some skating events were included in the 1908 and 1920 Games, the Winter Games were accepted as a celebration comparable to the Summer Games and given the official blessing of the IOC in 1924. The first Winter Games were held at Chamonix, France, and consisted of 16 events. There were 16 participating countries, and the participants numbered less than 300. Subsequent Winter Games were held at St. Moritz, Switzerland (1928); Lake Placid, New York (1932); Garmisch-Partenkirchen, Germany (1936); St. Moritz (for a second time; 1948); Oslo (1952); Cortina d'Ampezzo, Italy (1956); Squaw Valley, California (1960); Innsbruck, Austria (1964); Grenoble, France (1968); Sapporo, Japan (1972); Innsbruck (for a second time; 1976); Lake Placid (for a second time; 1980); Sarajevo, Yugoslavia (1984); and Calgary, Alberta (1988). The 1992 Winter Olympics were scheduled for Albertville, France, and the 1994 Winter Games were scheduled for Lillehammer, Norway.

Principles of Optics

Originally, the term optics was used only in relation to the eye and vision. Later, as lenses and other devices for aiding vision began to be developed, these were naturally called optical instruments, and the meaning of the term optics eventually became broadened to cover any application of light, even though the ultimate receiver is not the eye but a physical detector, such as a photographic plate or a television camera. Within the present century optical methods have been applied extensively to regions of the electromagnetic radiation spectrum not visible to the eye, such as X-rays, ultraviolet, infrared, and microwave radio waves, and to this extent these regions are now often included in the general field of optics.

In the present article the image-forming properties of

lenses, mirrors, and other devices that make use of light are considered. The wave and quantum nature of light, its velocity, wavelength, polarization, diffraction, and interference may be found in **LIGHT**. The interrelations between light and electricity, which are involved in light sources and detectors, are treated in **ELECTRONICS: Electron tubes**. The analysis of light into its component colours by prisms and gratings forms the basis of the extensive field of spectroscopy, the principles of which are discussed in **ANALYSIS AND MEASUREMENT: Spectroscopy**. For information about the reception of light by the retina of the eye and the interpretation of images by the brain, see **SENSORY RECEPTION: Vision**.

Geometrical optics

GENERAL CONSIDERATIONS

The optical image. An optical image may be regarded as the apparent reproduction of an object by a lens or mirror system, employing light as a carrier. An entire image is generally produced simultaneously, as by the lens in a camera, but images may also be generated sequentially by point-by-point scanning, as in a television system or in the radio transmission of pictures across long distances in space. Nevertheless, the final detector of all images is invariably the human eye, and, whatever means is used to transmit and control the light, the final image must either be produced simultaneously or scanned so rapidly that the observer's persistence of vision will give him the mental impression of a complete image covering a finite field of view. For this to be effective the image must be repeated (as in motion pictures) or scanned (as in television) at least 40 times a second to eliminate flicker or any appearance of intermittency.

Historical background. To the ancients, the processes of image formation were full of mystery. Indeed, for a long time there was a great discussion as to whether, in vision, something moved from the object to the eye or whether something reached out from the eye to the object. By the beginning of the 17th century, however, it was known that rays of light travel in straight lines, and in 1604 Johannes Kepler, a German astronomer, published a book on optics in which he postulated that an extended object could be regarded as a multitude of separate points,

each point emitting rays of light in all directions. Some of these rays would enter a lens, by which they would be bent around and made to converge to a point, the "image" of the object point whence the rays originated. The lens of the eye was not different from other lenses, and it formed an image of external objects on the retina, producing the sensation of vision.

There are two main types of image to be considered: real and virtual. A real image is formed outside the system, where the emerging rays actually cross; such an image can be caught on a screen or piece of film and is the kind of image formed by a slide projector or in a camera. A virtual image, on the other hand, is formed inside an instrument at the point where diverging rays would cross if they were extended backward into the instrument. Such an image is formed in a microscope or telescope and can be seen by looking into the eyepiece.

Kepler's concept of an image as being formed by the crossing of rays was limited in that it took no account of possible unsharpness caused by aberrations, diffraction, or even defocussing. In 1957 the Italian physicist Vasco Ronchi went the other way and defined an image as any recognizable nonuniformity in the light distribution over a surface such as a screen or film; the sharper the image, the greater the degree of nonuniformity. Today, the concept of an image often departs from Kepler's idea that an extended object can be regarded as innumerable separate points of light, and it is sometimes more convenient to regard an image as being composed of overlapping patterns of varying frequencies and contrasts; hence, the quality of

Lens
theories

a lens can be expressed by a graph connecting the spatial frequency of a parallel line object with the contrast in the image. This concept is investigated fully under *Optics and information theory* below.

Optics had progressed rapidly by the early years of the 19th century. Lenses of moderately good quality were being made for telescopes and microscopes, and in 1841 the great mathematician Carl Friedrich Gauss published his classical book on geometrical optics. In it he expounded the concept of the focal length and cardinal points of a lens system and developed formulas for calculating the position and size of the image formed by a lens of given focal length. Between 1852 and 1856 Gauss's theory was extended to the calculation of the five principal aberrations of a lens (see below), thus laying the foundation for the formal procedures of lens design that were used for the next 100 years. Since about 1960, however, lens design has been almost entirely computerized, and the old methods of designing lenses by hand on a desk calculator are rapidly disappearing.

By the end of the 19th century numerous other workers had entered the field of geometrical optics, notably an English physicist, Lord Rayleigh (John William Strutt), and a German physicist, Ernst Karl Abbe. It is impossible to list all their accomplishments here. Since 1940 there has been a great resurgence in optics on the basis of information and communication theory, which is treated at length below.

Light rays, waves, and wavelets. A single point of light, which may be a point in an extended object, emits light in the form of a continually expanding train of waves, spherical in shape and centred about the point of light. It is, however, often much more convenient to regard an object point as emitting fans of rays, the rays being straight lines everywhere perpendicular to the waves. When the light beam is refracted by a lens or reflected by a mirror, the curvature of the waves is changed, and the angular divergence of the ray bundle is similarly changed in such a way that the rays remain everywhere perpendicular to the waves. When aberrations are present, a convergent ray bundle does not shrink to a perfect point, and the emerging waves are then not truly spherical.

In 1690 Christiaan Huygens, a Dutch scientist, postulated that a light wave progresses because each point in it becomes the centre of a little wavelet travelling outward in all directions at the speed of light, each new wave being merely the envelope of all these expanding wavelets. When the wavelets reach the region outside the outermost rays of the light beam, they destroy each other by mutual interference wherever a crest of one wavelet falls upon a trough of another wavelet. Hence, in effect, no waves or wavelets are allowed to exist outside the geometrical light beam defined by the rays. The normal destruction of one wavelet by another, which serves to restrict the light energy to the region of the rectilinear ray paths, however, breaks down when the light beam strikes an opaque edge, for the edge then cuts off some of the interfering wavelets, allowing others to exist, which diverge slightly into the shadow area. This phenomenon is called diffraction, and it gives rise to a complicated fine structure at the edges of shadows and in optical images (see *LIGHT*).

The pinhole camera. An excellent example of the working of the wavelet theory is found in the well-known pinhole camera. If the pinhole is large, the diverging geometrical pencil of rays leads to a blurred image, because each point in the object will be projected as a finite circular patch of light on the film. The spreading of the light at the boundary of a large pinhole by diffraction is slight. If the pinhole is made extremely small, however, the geometrical patch then becomes small, but the diffraction spreading is now great, leading once more to a blurred picture. There are thus two opposing effects present, and at the optimum hole size the two effects are just equal. This occurs when the hole diameter is equal to the square root of twice the wavelength (λ) times the distance (f) between the pinhole and film—i.e., $\sqrt{2\lambda f}$. For $f = 100$ millimetres and $\lambda = 0.0005$ millimetre, the optimum hole size becomes 0.32 millimetre. This is not very exact, and a 0.4-millimetre hole would probably be just

as good in practice. A pinhole, like a camera lens, can be regarded as having an f -number, which is the ratio of focal length to aperture. In this example, the f -number is $100/0.32 = 310$, designated $f/310$. Modern camera lenses have much greater apertures, in order to achieve light-gathering power, of around $f/1.2$ – $f/5.6$.

Resolution and the Airy disk. When a well-corrected lens is used in place of a pinhole, the geometrical ray divergence is eliminated by the focussing action of the lens, and a much larger aperture may be employed; in that case the diffraction spreading becomes small indeed. The image of a point formed by a perfect lens is a minute pattern of concentric and progressively fainter rings of light surrounding a central dot, the whole structure being called the Airy disk after George Biddell Airy, an English astronomer, who first explained the phenomenon in 1834. The Airy disk of a practical lens is small, its diameter being approximately equal to the f -number of the lens expressed in microns (0.001 millimetre). The Airy disk of an $f/4.5$ lens is therefore about 0.0045 millimetre in diameter (ten times the wavelength of blue light). Nevertheless, the Airy disk formed by a telescope or microscope objective can be readily seen with a bright point source of light if a sufficiently high eyepiece magnification is used.

The finite size of the Airy disk sets an inevitable limit to the possible resolving power of a visual instrument. Rayleigh found that two adjacent and equally bright stars can just be resolved if the image of one star falls somewhere near the innermost dark ring in the Airy disk of the other star; the resolving power of a lens can therefore be regarded as about half the f -number of the lens expressed in microns. The angular resolution of a telescope is equal to the angle subtended by the least resolvable image separation at the focal length of the objective, the light-gathering lens. This works out at about four and a half seconds of arc divided by the diameter of the objective in inches.

The Rayleigh limit. As noted above, when a perfect lens forms an image of a point source of light, the emerging wave is a sphere centred about the image point. The optical paths from all points on the wave to the image are therefore equal, so that the expanding wavelets are all in phase (vibrating in unison) when they reach the image. In an imperfect lens, however, because of the presence of aberrations, the emerging wave is not a perfect sphere, and the optical paths from the wave to the image point are then not all equal. In such a case some wavelets will reach the image as a peak, some as a trough, and there will be much destructive interference leading to the formation of a sizable patch of light, much different from the minute Airy disk characteristic of a perfectly corrected lens. In 1879 Rayleigh studied the effects of phase inequalities in a star image and came to the conclusion that an image will not be seriously degraded unless the path differences between one part of the wave and another exceed one-quarter of the wavelength of light. As this difference represents only 0.125 micron (5×10^{-6} inch), it is evident that an optical system must be designed and constructed with almost superhuman care if it is to give the best possible definition.

REFLECTION AND REFRACTION

Reflection. The use of polished mirrors for reflecting light has been known for thousands of years, and concave mirrors have long been used to form real images of distant objects. Indeed, Isaac Newton greatly preferred the use of a mirror as a telescope objective to the poor-quality lenses available in his time. Because there is no limit to the possible size of a mirror, all large telescopes today are of this type.

When a ray of light is reflected at a polished surface, the angle of reflection between ray and normal (the line at right angles to the surface) is exactly equal to the angle of incidence. It can be seen that a convex mirror forms a virtual image of a distant object, whereas a concave mirror forms a real image. A plane mirror forms a virtual image of near objects, as in the familiar looking glass. Plane mirrors are often used in instruments to bend a beam of light into a different direction.

Airy disk

Law of
reflection

The law of refraction. When a ray of light meets the surface of separation between two transparent media, it is sharply bent or refracted. Because rays are really only directions and have no physical existence, the passage of light waves through a surface must be considered if refraction is to be understood. Refraction effects are based on the fact that light travels more slowly in a denser medium. The ratio of the velocity of light in air to its velocity in the medium is called the refractive index of the medium for light of a particular colour or wavelength. The refractive index is higher for blue light than for light at the red end of the spectrum.

In Figure 1, AA' represents a plane wave of light at the instant that A' meets the plane refracting surface $A'B$ separating two media having refractive indices n and n' , respectively. During the time taken by the light to travel from A to B in material n , light travels from A' to B' in material of refractive index n' , forming the new wave BB' in the second material, proceeding in direction BC . Hence, the relationship $n'/n = AB/A'B' = \sin I/\sin I'$ can be obtained; and dividing numerator and denominator by BA' gives

$$\frac{n'}{n} = \frac{AB/BA'}{A'B'/BA'} = \frac{\sin I}{\sin I'} \tag{1}$$

The angles I and I' are called the angle of incidence and angle of refraction between the refracting surface and the incident and refracted waves, respectively.

Figure 1: The law of refraction. Plane light wave at position AA' in medium of index n and BB' in medium of index n' (see text).

Returning now to the convention of considering the movement of light in terms of rays because entering and emerging rays are always perpendicular to the light waves they represent, angles I and I' also denote the angles between the entering and emerging rays and the normal (perpendicular) line to the refracting surface at B .

Equation (1), known as the law of refraction, is generally written: $n' \sin I' = n \sin I$.

Dispersion. The difference between the refractive indices of a transparent material for a specific blue light and a specific red light is known as the dispersion of the material. The usual choices of blue and red lights are the so-called “F” and “C” lines of hydrogen in the solar spectrum, named by Fraunhofer, with wavelengths 4861 and 6563 angstroms (the angstrom unit, abbreviated Å, is 10^{-8} centimetre), respectively. It is generally more significant, however, to compare the dispersion with the mean refractive index of the material for some intermediate colour such as the sodium “D” Fraunhofer line of wavelength 5893 angstroms. The dispersive power (w) of the material is then defined as the ratio of the difference between the “F” and “C” indices and the “D” index reduced by 1, or,

$$w = \frac{n_F - n_C}{n_D - 1}$$

Hundreds of different types of optical glass are currently available from manufacturers. These may be represented

Figure 2: Relationships between refractive indices and dispersive powers of several representative optical glasses and plastics.

graphically on a plot of mean refractive index against dispersive power (Figure 2).

At first lenses were made from selected pieces of window glass or the glass used to make blown tableware. In the early 1800s, the manufacture of clear glass that was intended specifically for lenses began in Europe. The glass was slowly stirred in the molten state to remove striations and irregularities, and then the whole mass was cooled and broken up into suitable pieces for lens making. Subsequently, the pieces were placed in molds of the approximate size of the lens, slowly remelted to shape, and carefully annealed; *i.e.*, allowed to cool slowly under controlled conditions to reduce strains and imperfections. Various chemicals were added in the molten state to vary the properties of the glass: addition of lead oxide, for example, was found to raise both the refractive index and the dispersive power. In 1884 it was discovered that barium oxide had the effect of raising the refractive index without increasing the dispersion, a property that proved to be of the greatest value in the design of photographic lenses known as anastigmats (lenses devoid of astigmatic aberration). In 1938 a further major improvement was achieved by the use of various rare-earth elements, and since 1950 lanthanum glass has been commonly used in high-quality photographic lenses.

The cost of optical glass varies considerably, depending on the type of glass, the precision with which the optical properties are maintained, the freedom from internal striae and strain, the number of bubbles, and the colour of the glass. Many common types of optical glass are now available in quite large pieces, but as the specifications of the glass become more stringent the cost rises and the range of available sizes becomes limited. In a small lens such as a microscope objective or a telescope eyepiece, the cost of the glass is insignificant, but in large lenses in which every millimetre of thickness may represent an additional pound in weight, the cost of the glass can be very high indeed.

Lenses can be molded successfully of various types of plastic material, polymethyl methacrylate being the most usual. Even multi-element plastic lenses have been manufactured for low-cost cameras, the negative (concave) elements being made of a high-dispersion plastic such as styrene.

Total internal reflection. When a ray of light emerges obliquely from glass into air, the angle of refraction between ray and normal is greater than the angle of incidence inside the glass, and at a sufficiently high obliquity the angle of refraction can actually reach 90° . In this case the emerging ray travels along the glass surface, and the sine of the angle of incidence inside the glass, known as the critical angle, is then equal to the reciprocal of the refractive index of the material. At angles of incidence greater than the critical angle, the ray never emerges, and total internal reflection occurs, for there is no measurable

Plastic lenses

Dispersive power

loss if the glass surface is perfectly clean. Dirt or dust on the surface can cause a small loss of energy by scattering some light into the air.

Light is totally internally reflected in many types of reflecting prism and in fibre optics, in which long fibres of high-index glass clad with a thin layer of lower index glass are assembled side-by-side in precise order. The light admitted into one end of each fibre is transmitted along it without loss by thousands of successive internal reflections at the interlayer between the glass and the cladding. Hence, an image projected upon one end of the bundle will be dissected and transmitted to the other end, where it can be examined through a magnifier or photographed. Many modern medical instruments, such as cystoscopes and bronchoscopes, depend for their action on this principle. Single thick fibres (actually glass rods) are sometimes used to transmit light around corners to an otherwise inaccessible location.

RAY-TRACING METHODS

Graphical ray tracing. In 1621 Willebrord Snell, a professor of mathematics at Leiden, discovered a simple graphical procedure for determining the direction of the refracted ray at a surface when the incident ray is given. The mathematical form of the law of refraction, equation (1) above, was announced by the French mathematician René Descartes some 16 years later.

Snell's construction is as follows: The line AP in Figure 3A represents a ray incident upon a refracting surface at P , the normal at P being PN . If the incident and refracted rays are extended to intersect any line SS' parallel to the normal, the lengths PQ and PR along the rays will be

Figure 3: Graphic refraction procedures (see text).

Snell's construction

proportional to the refractive indices n and n' . Hence, if PQ and the indices are known, PR can be found and the refracted ray drawn in.

A convenient modification of Snell's construction can readily be used to trace the path of a ray through a complete lens. In Figure 3B, the incident ray BP strikes a refracting surface at P . The normal to the surface is PC . At any convenient place on the page two concentric circles are drawn about a point O with radii proportional to the refractive indices n and n' , respectively. A line OE is now drawn parallel to the incident ray BP extending as far as the circle representing the refractive index n of the medium containing the incident ray. From E a line is drawn parallel to the normal PC extending to F on the circle representing the refractive index n' . The line OF then represents the direction of the desired refracted ray, which may be drawn in at PB' . This process is repeated successively for all the surfaces in a lens. If a mirror is involved, the reflected ray may be found by drawing the normal line EF across the circle diagram to the incident-index circle on the other side.

Trigonometrical ray tracing. No graphical construction can possibly be adequate to determine the aberration residual of a corrected lens, and for this an accurate trigonometrical computation must be made and carried out to six or seven decimal places, the angles being determined to single seconds of arc or less. There are many procedures for calculating the path of a ray through a system of spherical refracting or reflecting surfaces, the following being typical: The diagram in Figure 4 represents a ray lying in the meridian plane, defined as the plane containing the lens axis and the object point. A ray in this plane is defined by its slope angle, U , and by the length of the

Figure 4: Trigonometrical ray tracing (see text).

perpendicular, Q , drawn from the vertex (A) of the surface on to the ray. By drawing a line parallel to the incident ray through the centre of curvature C , to divide Q into two parts at N , the relation is stated as $AN = r \sin U$, and $NM = r \sin I$. Hence

$$Q = r(\sin U + \sin I). \quad (2)$$

From this the first ray-tracing equation can be derived,

$$\sin I = \frac{Q}{r} - \sin U. \quad (3a)$$

Applying the law of refraction, equation (2), gives the second equation

$$\sin I' = \frac{n}{n'} - \sin I. \quad (3b)$$

Because the angle $PCA = U + I = U' + I'$, the slope of the refracted ray can be written as

$$U' = U + I - I'; \quad (3c)$$

and, lastly, by adding primes to equation (2),

$$Q' = r(\sin U' + \sin I').$$

Having found the Q' of the refracted ray, transfer to the next surface can be performed by

$$Q_2 = Q_1 - d \sin U',$$

in which d is the axial distance from the first to the second refracting surface. After performing this calculation for all the surfaces in succession, the longitudinal distance from the last surface to the intersection point of the emergent ray with the lens axis is found by

$$L' = \frac{Q'}{\sin U'}.$$

Corresponding but much more complicated formulas are available for tracing a skew ray, that is, a ray that does not lie in the meridian plane but travels at an angle to it. After refraction at a surface, a skew ray intersects the meridian plane again at what is called the diapiant. By tracing the paths of a great many (100 or more) meridional and skew rays through a lens, with the help of an electronic computer, and plotting the assemblage of points at which all these rays pierce the focal plane after emerging from the lens, a close approximation to the appearance of a star image can be constructed, and a good idea of the expected performance of a lens can be obtained.

PARAXIAL, OR FIRST-ORDER, IMAGERY

In a lens that has spherical aberration, the various rays from an axial object point will in general intersect the lens axis at different points after emerging into the image space. By tracing several rays entering the lens at different heights (*i.e.*, distances from the axis) and extrapolating from a graph connecting ray height with image position, it would be possible to infer where a ray running very close to the axis (a paraxial ray) would intersect the axis, although such a ray could not be traced directly by the ordinary trigonometrical formulas because the angles would be too small for the sine table to be of any use. Because the sine of a small angle is equal to the radian measure of the angle itself, however, a paraxial ray can be traced by reducing the ray-tracing formulas to their limiting case for small angles and thus determining the paraxial intersection point directly. When this is done, writing paraxial-ray data with lowercase letters, it is found that the Q and Q' above both become equal to the height of incidence y , and the formulas (3a), (3b), and (3c) become, in the paraxial limit:

Paraxial rays

$$i = \frac{y}{r'} - u \quad (4a)$$

$$i' = \frac{n}{n'} i \quad (4b)$$

$$u' = u + i - i'. \quad (4c)$$

The longitudinal distance from the last surface to the intersection point of the emerging paraxial ray with the lens axis becomes $l' = y/u'$.

Because all paraxial rays from a given object point unite at the same image point, the resulting longitudinal distance (l') is independent of the particular paraxial ray that is traced. Any nominal value for the height of incidence, y , may therefore be adopted, remembering that it is really an infinitesimal and y is only its relative magnitude. Thus, it is clear that the paraxial angles in equation (4) are really only auxiliaries, and they can be readily eliminated, giving the object-image distances for paraxial rays:

$$n'(l' - r)u' = n(l - r)u \quad (5)$$

and

$$\frac{n'}{l'} = \frac{n}{l} + \frac{n' - n}{r}. \quad (6)$$

Magnification: the optical invariant. It is frequently as important to determine the size of an image as it is to determine its location. To obtain an expression for the magnification—that is, the ratio of the size of an image to the size of the object—the following process may be used: If an object point B lies to one side of the lens axis at a transverse distance h from it, and the image point B' is at a transverse distance h' , then B , B' , and the centre of curvature of the surface, C , lie on a straight line called the auxiliary axis. Then, by simple proportion,

$$m = \frac{h'}{h} = \frac{l' - r}{l - r} = \frac{nu}{n'u'}.$$

Hence,

$$h'n'u' = hnu, \quad (7)$$

and the product (hnu) is invariant for all the spaces between the lens surfaces, including the object and image spaces, for any lens system of any degree of complexity. This theorem has been named after the French scientist Joseph-Louis Lagrange, although it is sometimes called the Smith-Helmholtz theorem, after Robert Smith, an English scientist, and Hermann Helmholtz, a German scientist; the product (hnu) is often known as the optical invariant. As it is easy to determine the quantities h , n , and u for the original object, it is only necessary to calculate u' by tracing a paraxial ray in order to find the image height h' for any lens. If the lens is used in air, as most lenses are, the refractive indices are both unity, and the magnification becomes merely $m = u/u'$.

The Gauss theory of lenses. In 1841 Gauss published a now famous treatise on optics in which he demonstrated that, so far as paraxial rays are concerned, a lens of any degree of complexity can be replaced by two principal, or nodal, points and two focal points, the distances from the principal points to their respective focal points being the focal lengths of the lens, and, furthermore, that the two focal lengths are equal to one another when the refractive indices of object and image spaces are equal, as when a lens is used in air.

The principal and focal points may be defined as follows: Figure 5 shows a lens system of any construction, with a bundle of rays entering from the left in a direction parallel to the lens axis. After refraction by the lens each ray will cross the axis at some point, and the entering and

Figure 5: The Gauss theory (see text).

emerging portions of each ray are then extended until they intersect at a point such as Q . The locus of all the points Q is a surface of revolution about the lens axis known as the equivalent refracting locus of the lens. The point where this locus crosses the axis is called the principal point, P_2 , and the central portion of the locus in the neighbourhood of the axis, which is virtually a plane perpendicular to the axis, is called the principal plane. The point where the emerging paraxial ray crosses the axis is called the focal point F_2 , the distance from P_2 to F_2 being the (posterior) focal length f . A similar situation exists for a parallel beam of light entering from the right, giving the anterior principal point P_1 , the anterior focal point F_1 , and the front focal length f . For a lens in air it can be shown that the two focal lengths are equal in magnitude but opposite in direction—i.e., if F_2 is to the right of P_2 , then F_1 must lie to the left of P_1 , as in the case of an ordinary positive lens (one that gives a real image). In a negative lens (one that gives a virtual image), F_2 lies to the left of P_2 , and the posterior focal length f is negative.

The relation between the distances of object and image from a lens can be easily stated if the positions of the two principal points and the two focal points are known. (In using these expressions, distances are considered positive or negative depending on whether they are measured to the right or to the left from their respective origins.) For a lens in air: (a) If the conjugate distances measured from the respective focal points are x and x' , and if m is the image magnification (height of image divided by height of object), then $m = -x'/f = f'/x$ and $xx' = -f^2$. (b) If the conjugate distances measured from the respective principal points are p and p' and if m is the image magnification, then $m = p'/p$ and $1/p' = 1/p + 1/f$. The Lagrange equation (7) requires modification for a distant object because in that case the object height h is infinite, and the slope angle u is zero. If the off-axis distance h is divided by the object distance L , and u is multiplied by L , equation (7) becomes $h' = (n/n')f'\phi$, in which ϕ is the angle in radians subtended by the distant object at the lens. This formula provides a means for defining focal length and for measuring the focal length of an unknown lens.

The thin lens. In a thin lens such as a spectacle, the two principal planes coincide within the lens, and then the conjugate distances p and p' in the formula above become the distances of object and image from the lens itself.

The focal length of a thin lens can be computed by applying the surface-conjugate formula (6) to the two surfaces in succession, writing the l of the first surface as infinity and the l of the second surface equal to the l' of the first surface. When this is done, the lens power (P) becomes

$$P = \frac{1}{f'} = (n - 1) \left(\frac{1}{r_1} - \frac{1}{r_2} \right).$$

If a number of thin lenses are assembled together in contact, assuming that the combination is still virtually a thin lens, then the power ($1/f'$) of the combination will be equal to the sum of the powers of the separate lenses. Thus, if a thin negative lens is placed in close contact with a thin positive lens of equal power, the combination will have zero power and will no longer act like a lens. This is the basis of a process used by optometrists to ascertain the power of an unknown lens by combining it with one of a series of known lenses from a trial case.

Chromatic aberration. Because the refractive index of glass varies with wavelength, every property of a lens that depends on its refractive index also varies with wavelength, including the focal length, the image distance, and the image magnification. The change of image distance with wavelength is known as chromatic aberration, and the variation of magnification with wavelength is known as chromatic difference of magnification, or lateral colour. Chromatic aberration can be eliminated by combining a strong lens of low-dispersion glass (crown) with a weaker lens made of high-dispersion glass (flint) glass. Such a combination is said to be achromatic. This method of removing chromatic aberration was discovered in 1729 by Chester Hall, an English inventor, and it was exploited vigorously in the late 18th century in numerous small telescopes. Chromatic variation of magnification can be eliminated by

Determina-
tion of focal
length

Lagrange
theorem

achromatizing all the components of a system or by making the system symmetrical about a central diaphragm. Both chromatic aberration and lateral colour are corrected in every high-grade optical system.

Longitudinal magnification. If an object is moved through a short distance δp along the axis, then the corresponding image shift $\delta p'$ is related to the object movement by the longitudinal magnification (\bar{m}). Succinctly,

$$\bar{m} = \delta p' / \delta p = m^2,$$

in which m is the lateral magnification. The fact that the longitudinal magnification is equal to the square of the transverse magnification means that m is always positive; hence, if the object is moved from left to right, the image must also move from left to right. Also, if m is large, then \bar{m} is very large, which explains why the depth of field (δp) of a microscope is extremely small. On the other hand, if m is small, less than one as in a camera, then \bar{m} is very small, and all objects within a considerable range of distances (δp) appear substantially in focus.

Image of a tilted plane. If a lens is used to form an image of a plane object that is tilted relative to the lens axis, then the image will also be tilted in such a way that the plane of the object, the plane of the image, and the median plane of the lens all meet. This construction can be derived by the use of the lateral and longitudinal magnification relations just established above. With a tilted object the magnification at any point is given by the ratio of the distances of image and object from the lens at that point in the image, and, consequently, m varies progressively from one end of the image to the other. This arrangement is frequently used in view cameras equipped with "swings" to increase depth of field and in enlargers to rectify the convergence of parallel lines caused by tilting the camera, for example, in photographing tall buildings. The rule finds extensive application in photogrammetry and in the making of maps from aerial photographs.

OPTICAL SYSTEMS

System components. An optical system consists of a succession of elements, which may include lenses, mirrors, light sources, detectors, projection screens, reflecting prisms, dispersing devices, filters and thin films, and fibre-optics bundles.

Lenses. All optical systems have an aperture stop somewhere in the system to limit the diameter of the beams of light passing through the system from an object point. By analogy with the human eye, this limiting aperture stop is called the iris of the system, its images in the object and image spaces being called the entrance pupil and exit pupil, respectively. In most photographic lenses the iris is inside the objective, and it is often adjustable in diameter to control the image illumination and the depth of field. In telescope and microscope systems the cylindrical mount of the objective lens is generally the limiting aperture or iris of the system; its image, formed behind the eyepiece where the observer's eye must be located to see the whole area being observed, called the field, is then the exit pupil.

The pupils of a lens system can be regarded as the common bases of oblique beams passing through the system from all points in an extended object. In most systems, however, the mounts of some of the lens elements cut into the oblique beams and prevent the beams from being perfectly circular, and the pupils are then not fully filled with light. This effect is known as vignetting and leads to a reduction in illumination in the outer parts of the field of view.

A common feature of many optical systems is a relay lens, which may be introduced to invert an image or to extend the length of the system, as in a military periscope. An example of the use of a relay lens is found in the com-

mon rifle sight shown diagrammatically in Figure 6. Here the front lens A is the objective, forming an inverted image of the target on the cross wire or reticle at B . The light then proceeds to the relay lens C , which forms a second image, now erect, at D . Beyond this image is the eyepiece E to render the light parallel so that the image may be seen sharply by the observer. Unfortunately, the oblique beam from the objective will usually miss the relay lens, and so a field lens must be inserted at or near the first image B to bend the oblique beams around and redirect them toward the relay lens. The power of the field lens is chosen so that it will form an image of the objective lens aperture on the relay lens aperture. The iris and entrance pupil of this system coincide at the objective; there is an internal pupil at the relay lens, and the exit pupil lies beyond the eyepiece as shown in Figure 6.

Mirrors. Mirrors are frequently used in optical systems. Plane mirrors may be employed to bend a beam of light in another direction, either for convenience or to yield an image reversed left for right if required. Curved mirrors, concave and convex, may be used in place of lenses as image-forming elements in reflecting telescopes. All of the world's largest telescopes and many small ones are of the reflecting type. Such telescopes use a concave mirror to produce the main image, a small secondary mirror often being added to magnify the image and to place it in a convenient position for observation or photography. Telescope mirrors are commonly made parabolic or hyperbolic in section to correct the aberrations of the image. Originally telescope mirrors were made from polished "speculum metal," an alloy of copper and tin, but in 1856 Justus von Liebig, a German chemist, invented a process for forming a mirror-like layer of silver on polished glass, which was applied to telescope mirrors by the German astronomer C.A. von Steinheil. Today most mirrors are made of glass, coated with either a chemically deposited silver layer or more often one made by depositing vaporized aluminum on the surface. The aluminum surface is as highly reflective as silver and does not tarnish as readily.

A large astronomical mirror presents many problems to the optical engineer, mainly because even a distortion of a few microns of the mirror under its own weight will cause an intolerable blurring of the image. Though many schemes for supporting a mirror without strain have been tried, including one to support it on a bag of compressed air, the problem of completely eliminating mirror distortion remains unsolved. A metal mirror, if well ribbed on the back, may be lighter than a glass mirror and therefore easier to handle, but most metals are slightly flexible and require just as careful support as glass mirrors. Since temperature changes can also cause serious distortion in a mirror, astronomers try to hold observatory temperatures as constant as possible.

Light sources. Many types of optical instruments form images by natural light, but some, such as microscopes and projectors, require a source of artificial light. Tungsten filament lamps are the most common, but if a very bright source is required, a carbon or xenon arc is employed. For some applications, mercury or other gas discharge tubes are used; a laser beam is often employed in scientific applications. Laser light is brilliant, monochromatic, collimated (the rays are parallel), and coherent (the waves are all in step with each other), any or all of these properties being of value in particular cases.

Detectors. The image formed by an optical system is usually received by the eye, which is a remarkably adaptable and sensitive detector of radiation within the visible region of the electromagnetic spectrum (see LIGHT). A photographic film, another widely used detector, has the advantage of yielding a permanent record of events. Since about 1925 many types of electrical detectors of radiation, both within the visible region and beyond it, have been developed. These include photoelectric cells of various kinds in which either a voltage or a resistance is modified by light falling on the device. Many new types of detectors are sensitive far into the infrared spectrum and are used to detect the heat radiated by a flame or other hot object. A number of image intensifiers and converters, particularly for X-ray or infrared radiation, which have appeared

since World War II, embody a radiation detector at one end of a vacuum tube and an electron lens inside the tube to relay the image on to a phosphor screen at the other end. This arrangement produces a visible picture that may be observed by eye or photographed to make a permanent record.

Television camera tubes detect real images by electronic scanning, the picture on the viewing tube being a replica of the image in the original camera. The combined application of electronics and optics has become common (see below). An extreme example of electro-optics appears in some space cameras, in which the film is exposed, processed, and then scanned by a tiny point of light; the light passing through the film is picked up by a photocell and transmitted to Earth by radio, where it is made to control the brightness of another point of light scanning a second piece of film in exact synchronism with the scanning spot in the camera. The whole system thus produces a picture on Earth that is an exact replica of the picture photographed in space a few minutes earlier.

Projection screens. The simplest screen for the projection of slides or motion pictures is, of course, a matte white surface, which may be on a hard base as in outdoor theatres or on a stretched cloth indoors. A theatre screen is often perforated to transmit sound from loudspeakers placed behind it.

Improved screen materials have been developed to increase the brightness of the picture to suit the particular shape of the auditorium. A screen covered with tiny beads tends to send the light back in the general direction of the projector, and is suitable for use at one end of a long, narrow auditorium. Another type of screen is covered with fine embossed vertical grooves; this tends to distribute the light in a horizontal band across the audience with little or no vertical spread. A real advantage of these highly reflective screens is that they tend to reflect ambient room light away from the viewer as by a mirror, so that the pictures appear almost as bright and clear by day as in a darkened room.

Reflecting prisms. Reflecting prisms are pieces of glass bounded by plane surfaces set at carefully specified angles. Some of these surfaces transmit light, some reflect light, while some serve both functions in succession. A prism is thus an assembly of plane reflectors at relatively fixed angles, which are traversed in succession by a beam of light.

The simplest prism is a triangular block of glass with two faces at right angles and one at an angle of 45° . The face at 45° deflects a beam of light through a right angle. The common Porro prism used in a pair of binoculars contains four 45° reflecting surfaces, two to reverse the beam direction in the vertical plane and two in the horizontal plane (Figure 7). These reflecting faces could be replaced by pieces of mirror mounted on a metal frame,

Prism
binoculars

Figure 7: Porro prism.

but it is hard to hold mirrors rigidly and harder still to keep them clean. Some microscopes are equipped with a 45° deflection prism behind the eyepiece; this prism may provide two or three reflections depending on the type of image inversion or left-for-right reversal required.

Prisms containing a semireflecting, semitransmitting surface are known as beam splitters and as such have many

uses. An important application is found in some colour television cameras, in which the light from the lens is divided by two beam splitters in succession to form red, green, and blue images on the faces of three image tubes in the camera.

Dispersing devices. There are two forms of dispersing element used to spread out the constituent colours of a beam of light into a "spectrum," namely a prism and a grating. The prism, known to Newton, is the older; it separates the colours of the spectrum because the refractive index of the glass is lowest for red light and progressively increases through the yellow and green to the blue, where it is highest. Prism spectroscopes and spectrographs are made in a variety of forms and sizes, but in all cases the blue end of the spectrum is greatly spread out while the red end is relatively compressed.

Prism
and
grating

A diffraction grating is a ruled mirror or transparent plate of glass having many thousands of fine parallel grooves to the inch. It separates the colours of the spectrum by a process of diffraction. Each groove diffracts, or scatters, light in all directions, and in the case of light of one particular wavelength, there will be one direction in which the light wave from one groove lags behind the light wave from the next groove by precisely one or more whole wavelengths. This results in a strong beam of diffracted light in that direction and darkness in all other directions. Since each spectral colour corresponds to a different wavelength, the grating spreads out the spectrum into a fan where it can be observed or photographed. The red rays are bent most and the blue rays least, the opposite of the situation with a prism.

Although a prism or grating is the essential dispersing element in a spectrograph, a fine slit and additional lenses or focussing mirrors must be used to form a sharply defined spectrum. Prism spectroscopes are, of course, limited to those wavelengths for which the prism material is transparent; a reflecting grating can be used for any wavelength that the material will reflect.

Filters and thin films. A colour filter is a sheet of transparent material that modifies a light beam by selective absorption of some colours in relation to others. A neutral filter absorbs all wavelengths equally and merely serves to reduce the intensity of a beam of light without changing its colour.

Filters may be made from sheets of coloured glass, plastic, or dyed gelatin, and in some cases glass cells filled with liquid have been used. Since World War II, another type of filter depending on the interference of light has been developed in which one or more metallic or other types of films of controlled thickness have been deposited on a glass plate, the layers being so thin as to cause selective interference of some wavelengths in relation to others and thus act as a nonabsorbing filter. In this case the rejected colours are reflected instead of being absorbed.

Polarizing filters have the property of transmitting light that vibrates in one direction while absorbing light that vibrates in a perpendicular direction. These filters are used extensively in scientific instruments. In sunglasses and when placed over a camera lens, polarizing filters reduce unwanted reflections from nonmetallic surfaces. Polarizing spectacles have been used to separate the left-eye and right-eye beams in the projection of stereoscopic pictures or movies.

Fibre-optics bundles. As noted earlier, a thin rod or fibre of glass or other transparent material transmits light by repeated internal reflections, even when the rod is somewhat curved. An ordered bundle of rods or fibres is thus capable of taking an image projected upon one end of the bundle and reproducing it at the other end. A fibre-optics bundle can be fused together into a rigid channel, or it may be left flexible, only the ends being rigidly fastened together. Because a fibre bundle is exceedingly delicate, it must be handled with care; breaking a fibre would cause a black dot to appear in the reproduced image.

(R.K./Ed.)

Nonclassical imaging systems. Besides the familiar optical systems cited above, there are many nonclassical optical elements that are used to a limited extent for special purposes. The most familiar of these is the aspheric (non-

Aspheric surfaces

spherical) surface. Because plane and spherical surfaces are the easiest to generate accurately on glass, most lenses contain only such surfaces. It is occasionally necessary, however, to use some other axially symmetric surface on a lens or mirror, generally to correct a particular aberration. An example is the parabolic surface used for the primary mirror of a large astronomical telescope; another is the elliptic surface molded on the front of the little solid glass reflector units used on highway signs.

Another commonly used optical surface is the side of a cylinder. Such surfaces have power only in the meridian perpendicular to the cylinder axis. Cylindrical lenses are therefore used wherever it is desired to vary the magnification from one meridian to a perpendicular meridian. Cylindrical surfaces are employed in the anamorphic lenses used in some wide-screen motion-picture systems to compress the image horizontally in the camera and stretch it back to its original shape in the projected image.

To correct astigmatism in the eye, many spectacles are made with toric surfaces—*i.e.*, with a stronger curvature in one meridian than in the perpendicular meridian, like the bowl of a teaspoon. These surfaces are generated and polished by special machines and are made by the million every year.

Another nonclassical optical system is the bifocal or trifocal spectacle lens. They are made either by forming two or three separate surfaces on a single piece of glass or obtaining additional power by fusing a piece of high-index glass on to the front of the main lens and then polishing a single spherical surface over both glasses.

Two French scientists, Georges-Louis Buffon and Augustin-Jean Fresnel, in the 18th century suggested forming a lens in concentric rings to save weight, each ring being a portion of what would normally be a continuous spherical surface but flattened out. On a large scale, Fresnel lenses have been used in lighthouses, floodlights, and traffic signals, and as cylindrical ship's lanterns. With fine steps a few thousandths of an inch wide, molded plastic Fresnel lenses are often used as condensers in overhead projectors and in cameras as a field lens in contact with a ground-glass viewing screen.

Lenses have occasionally been made with one surface taking the form of a flattened cone. Such lenses produce a long, linear image of a point source, lying along the lens axis; for this reason they are commonly referred to as axicons. They have been used to produce a straight line of light in space for aligning machines and shafting, but since about 1965 the beam from a gas laser has generally been used instead.

Axicons

LENS ABERRATIONS

Seidel sums. If a lens were perfect and the object were a single point of monochromatic light, then, as noted above, the light wave emerging from the lens would be a portion of a sphere centred about the ideal image point, lying in the paraxial image plane at a height above the axis given by the Lagrange theorem. In practice, however, this condition is most unlikely to occur; it is much more probable that the emerging wave will depart slightly from a perfect sphere, the departure varying from point to point over the lens aperture. This departure is extremely small, being of the order of the wavelength of light that is only half a micron, so it would be impossible to show this departure on a drawing. It can be represented mathematically, however, in the following way: The coordinates of a point in the exit-pupil aperture will be represented by x_0 and y_0 , the y_0 coordinate lying in the meridian plane containing the object point and the lens axis. The departure of the wave from the ideal sphere is generally called OPD, meaning optical path difference. It can be shown that OPD is related to x_0 and y_0 by five constants S_1 through S_5 , and the quantity h'_0 ,

$$\text{OPD} = S_1(x_0^2 + y_0^2) + S_2y_0(x_0^2 + y_0^2)h'_0 + S_3(x_0^2 + 3y_0^2)h_0'^2 + S_4(x_0^2 + y_0^2)h_0'^2 + S_5y_0h_0'^3.$$

Each of these five terms is considered to be a separate "aberration," the coefficients S_1, \dots, S_5 , being called Seidel sums after the 19th-century German scientist L.P. Seidel, who identified the imperfections. These aberrations

are respectively spherical, coma, astigmatism, Petzval field curvature, and distortion. The symbol h'_0 refers to the height of the final image point above the lens axis, and hence it defines the obliquity of the beam.

The five Seidel sums can be calculated by tracing a paraxial ray from object to image through the lens and by tracing also a paraxial principal ray from the centre of the aperture stop outward in both directions toward the object and image, respectively. The angle of incidence i and the ray slope angle u of each of these paraxial rays at each surface are then listed and inserted into the following expressions for the five sums. The angle u'_0 represents the final emerging slope of the paraxial ray.

The calculation starts by determining the radius A of the exit pupil by $A = \sqrt{x_0^2 + y_0^2}$ and also the quantity K at each surface by

$$K = \frac{1}{2}y n \left(\frac{n}{n'} - 1 \right) (i - u').$$

The corresponding K_{pr} for the paraxial principal ray is also determined at each surface. Then, the five aberrations may be written

$$S_1 = \frac{1}{4A_4} \sum K i^2 \quad S_2 = \frac{1}{A^3 h'_0} \sum K i i_{pr}$$

$$S_3 = \frac{1}{2A^2 h_0'^2} \sum K i_{pr}^2 \quad S_4 = \frac{u_0'^2}{4A^2} \sum \frac{n - n'}{nn' r}$$

$$S_5 = \frac{1}{A h_0'^3} \sum [K_{pr} i i_{pr} + \frac{1}{2} h'_0 u_0' (u_{pr}^2 - u_{pr'}^2)].$$

To interpret these aberrations, the simplest procedure is to find the components x' , y' of the displacement of a ray from the Lagrangian image point in the paraxial focal plane, by differentiating the OPD expression given above. The partial derivatives $\partial \text{OPD} / \partial x_0$ and $\partial \text{OPD} / \partial y_0$ represent respectively the components of the slope of the wave relative to the reference sphere at any particular point (x_0, y_0) . Hence, because a ray is always perpendicular to the wave, the ray displacements in the focal plane can be found by

$$x' = f \frac{\partial \text{OPD}}{\partial x_0} \quad \text{and} \quad y' = f \frac{\partial \text{OPD}}{\partial y_0},$$

in which f is the focal length of the lens. The aggregation of rays striking the focal plane will indicate the kind of image that is characteristic of each aberration.

This procedure will be applied to each of the five aberration terms separately, assuming that all the other aberrations are absent. Obviously, in a perfect lens x' and y' are zero because OPD is zero. It must be remembered, however, that by using rays instead of waves, all fine-structure

Calculation of Seidel sums

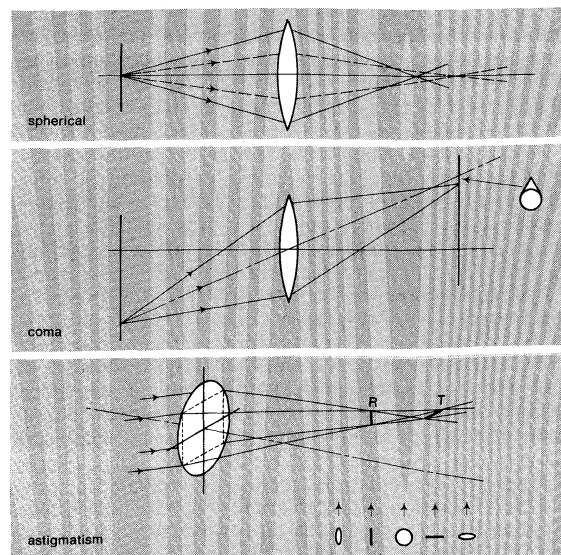

Figure 8: Lens aberrations.

effects caused by diffraction will be lost, and only the macroscopic image structure will be retained.

Spherical aberration. The first term in the OPD expression is $\text{OPD} = S_1(x_0^2 + y_0^2)^2$. Hence

$$x' = f \frac{\partial \text{OPD}}{\partial x_0} = 4fA^2S_1 \cdot x_0 \quad \text{and} \quad y' = f \frac{\partial \text{OPD}}{\partial y_0} = 4fA^2S_1 \cdot y_0.$$

These displacements can both be eliminated simultaneously by applying a longitudinal shift L to the focal plane. This changes x' by $-Lx_0/f$ and y' by $-Ly_0/f$; hence, if L is made equal to $4f^2A^2S_1$, both ray displacements vanish. The aberration, therefore, represents a condition in which each zone of the lens has a different focus along the axis, the shift of focus from the paraxial image being proportional to A^2 . This is known as spherical aberration (see Figure 8).

Coma. The S_2 term in the OPD expression represents the aberration called coma, in which the image of a point has the appearance of a comet. The x' and y' components are as follows:

$$x' = fh'_0S_2(2x_0y_0) \\ y' = fh'_0S_2(x_0^2 + 3y_0^2).$$

When this aberration is present, each circular zone of the lens forms a small ringlike image in the focal plane, the rings formed by successive concentric zones of the lens fitting into two straight envelope lines at 60° to each other (Figure 8). Because the brightness of this image is greatest at the tip, coma tends to form a one-sided haze on images in the outer parts of the field.

Astigmatism. If only the S_3 term is present, then

$$x' = 2fh'_0^2S_3(x_0) \\ y' = 2fh'_0^2S_3(3y_0).$$

For any one zone of the lens, x' and y' describe a vertical ellipse with major axis three times the minor axis. The images formed by all the smaller zones of the lens fit into this ellipse and fill it out with a uniform intensity of light. If the image plane is moved along the axis by a distance L , as in focussing a camera, then, at $L = 2f^2h'_0^2S_3$, the ellipse shrinks to a radial focal line (R). Twice this displacement yields a circle; three times this L gives a tangential focal line (T), which is followed by an ellipse with its major axis in the x direction, as in Figure 8, bottom. The usual effect of astigmatism in an image is the appearance of radial or tangential blurring in the outer parts of the field.

Petzval curvature. For the S_4 term taken alone,

$$x' = 2fh'_0^2S_4 \cdot x_0 \\ y' = 2fh'_0^2S_4 \cdot y_0.$$

The image of a point is now a small circle that contracts to a point at a new focus situated at a longitudinal distance $L = 2f^2h'_0^2S_4$ from the paraxial image. As the longitudinal displacement of the focus is proportional to the square of the image height h'_0 , this aberration represents a pure field curvature without any accompanying loss of definition (all lines remain sharp). It is named after the Hungarian mathematician József Petzval, who studied its properties in the early 1840s. The effect of Petzval curvature can be somewhat offset by the deliberate introduction of sufficient overcorrected astigmatism, as was done in all the pre-anastigmat photographic objectives. This added astigmatism is, of course, undesirable, and in order to design an anastigmat lens having a flat field free from astigmatism, it is necessary to reduce the Petzval sum S_4 drastically.

For a succession of thin lenses (1, 2, 3, ... etc.) in a system, the Petzval sum becomes simply $1/f_1n_1 + 1/f_2n_2 + 1/f_3n_3 + \dots$ etc., in which f is the focal length of each element and n is its refractive index. Therefore, to reduce the sum and minimize this aberration, relatively strong negative elements of low-index glass can be combined with positive elements of high-index glass. The positive and negative elements must be axially separated to provide the lens with a useful amount of positive power. The introduction of high-index barium crown glass with a low dispersive power in the 1880s initiated the development of anastigmat lenses.

Distortion. For the S_5 aberration,

$$x' = 0 \\ y' = fh'_0^3S_5.$$

When this aberration is present, the entire image point is displaced toward or away from the axis by an amount proportional to the third power of the transverse distance h'_0 of the image from the axis. This leads to the formation of an image of a square that is either a barrel-shaped or a cushion-shaped figure.

It is to be noted that the five Seidel aberrations represent the largest and most conspicuous defects that can arise in an uncorrected optical system. Even in the best lenses in which these five aberrations have been perfectly corrected for one zone of the lens and for one point in the field, however, there will exist small residuals of these aberrations and of many other higher order aberrations also, which are significantly different from the classical types just described. The typical aberration figures shown in Figure 8 are, of course, grossly exaggerated, and actually it requires some magnification of a star image to render these appearances clearly visible. Nevertheless, they are important enough to require drastic reduction in high-quality lenses intended to make sharp negatives capable of considerable enlargement.

Other
aberra-
tions

IMAGE BRIGHTNESS

General relations. All photometric concepts are based on the idea of a standard candle, lamps having accurately known candle power being obtainable from the various national standards laboratories. The ratio of the candle power of a source to its area is called the luminance of the source; luminances range from about 2,000 candles per square millimetre at the surface of the Sun down to about 3×10^{-6} candle per square centimetre (3×10^{-6} stilb) for the luminous paint on a watch dial. Ordinary outdoor scenes in daylight have an average luminance of several hundred candles per square foot. The quantity of light flux flowing out from a source is measured in lumens, the lumen being defined as the amount of flux radiated by a small "point" source of one candle power into a cone having a solid angle of one steradian. When light falls upon a surface it produces illumination (*i.e.*, illuminance), the usual measure of illuminance being the foot-candle, which is one lumen falling on each square foot of receiving surface.

It is often important to be able to calculate the brightness of an image formed by an optical system, because photographic emulsions and other light receptors cannot respond satisfactorily if the light level is too low. The problem is to relate the luminance of an object with the illuminance in the image, knowing the transmittance and aperture of the optical system. A small area A of a plane object having a luminance of B candles per square unit will have a normal intensity of AB candles. This source radiates light into a cone of semi-angle U , limited, for example, by the rim of a lens. The light flux (F) entering the cone can be found by integration to be

$$F = \pi AB \sin^2 U \text{ lumens.}$$

If the object luminance is expressed as B_L lamberts, the lambert being an alternative luminance unit equal to $1/\pi$ (*i.e.*, 0.32) candle per unit area, the flux (F) is

$$F = AB_L \sin^2 U \text{ lumens,}$$

because there are π times as many lamberts in a given luminance as there are candles per unit area.

A fraction t of this flux finds its way to the image, t being the lens transmittance, generally about 0.8 or 0.9 but less if a mirror is involved. The area of the image is $A'm^2$, in which m , the magnification, is given by

$$m = \frac{\sin U}{\sin U'}.$$

Hence, the image illuminance (E) is

$$E = (t\pi AB \sin^2 U) \div (A' \sin^2 U / \sin^2 U') = t\pi B \sin^2 U' \quad (8)$$

or $E = tB_L \sin^2 U'$.

Effect of
astigma-
tism

The image illuminance thus depends *only* on the luminance of the source and the cone angle of the beam proceeding from the lens to the image. This is a basic and most important relation underlying all calculations of image illuminance.

It is often more convenient to convert the angle U' into other better known quantities, such as the f -number of the lens and the image magnification. The relation here is

$$\sin U' = \frac{1}{2(f\text{-number})(1 + m/m_p)} \quad (9)$$

Definition
of
 f -number

The f -number of the lens is defined as the ratio of the focal length to the diameter of the entrance pupil; m is the image magnification; and m_p is the pupil magnification—i.e., the diameter of the exit pupil divided by the diameter of the entrance pupil. Combining equations (8) and (9) gives

$$\text{Image illuminance} = E = \frac{\pi t B}{4(f\text{-number})^2(1 + m/m_p)^2}$$

As an example in the use of this relation, if it is supposed that an $f/2$ lens is being used to project an image of a cathode-ray tube at five times magnification, the tube luminance being 5,000 foot-lamberts (1.7 candles per square centimetre), the lens transmittance is 0.8, and the pupil magnification is unity. Then the image illuminance will be

$$E = \frac{0.8 \times 5,000}{4 \times 4 \times 36} = 6.9 \text{ foot-candles.}$$

The image is very much less bright than the object, a fact that becomes clear to anyone attempting to provide a bright projected image in a large auditorium.

Distribution of illumination over an image. So far only the illumination at the centre of an image has been considered, but the distribution of illumination over a wide field is often important. In the absence of any lens, the small plane source already considered radiates in a direction inclined at an angle ϕ to the axis with an intensity $AB \cos \phi$. This light has to travel farther than the axial light to reach a screen, and then it strikes the screen at another angle ϕ . The net result is that the oblique illumination on the screen is smaller than the axial illumination by the factor $\cos^4 \phi$.

The same law can be applied to determine the oblique illumination due to a lens, assuming a uniform extended diffusing source of light on the other side of the lens. In this case, however, the exit pupil will not in general be a perfect circle because of possible distortion of the iris by that part of the optical system lying between the iris and the image. Also, any mechanical vignetting in the lens will make the aperture noncircular and reduce still further the oblique illumination. In a camera this reduction in oblique illumination results in darkened corners of the picture, but, if the reduction in brightness is gradual, it is not likely to be detected because the eye adapts quickly to changing brightness as the eyes scan over the picture area. Indeed, a 50 percent drop in brightness between the centre and corners of an ordinary picture is scarcely detectable.

Visual brightness. The apparent brightness of things seen by the eye follows the same laws as any other imaging system, because the apparent brightness is measured by the illuminance in the image that is projected on the retina. The angle U' in equation (8) inside the eye is determined by the size of the pupil of the eye, which varies from about one millimetre to about eight millimetres, depending on the brightness of the environment. Apart from this variation, retinal illuminance is directly proportional to object luminance, and objects having the same luminance appear equally bright, no matter at what distance they are observed.

From this argument, it is clear that no visual instrument, such as a telescope, can possibly make anything appear brighter than when viewed directly. To be sure, a telescope having a large objective lens accepts more light from an object in proportion to the area of the lens aperture, but it magnifies the image area in the same proportion; so the increased light is spread over an increased area of the retina, and the illuminance remains unchanged. Actually,

the telescopic view is always dimmer than the direct view because of light losses in the telescope due to glass absorption and surface reflections and because the exit pupil of the telescope may be smaller than the pupil of the eye, thus reducing the angle U' .

The case of a star being observed through a telescope is quite different, because no degree of magnification can possibly make a star appear as anything other than a point of light. Hence, star images appear brighter in proportion to the area of the telescope objective (assuming that the exit pupil is larger than the eye pupil), and the visibility of a star against the sky background is thus improved in proportion to the square of the diameter of the telescope objective lens.

Optics and information theory

GENERAL OBSERVATIONS

A new era in optics commenced in the early 1950s following the impact of certain branches of electrical engineering—most notably communication and information theory. This impetus was sustained by the development of the laser in the 1960s.

The initial tie between optics and communication theory came because of the numerous analogies that exist between the two subjects and because of the similar mathematical techniques employed to formally describe the behaviour of electrical circuits and optical systems. A topic of considerable concern since the invention of the lens as an optical imaging device has always been the description of the optical system that forms the image; information about the object is relayed and presented as an image. Clearly, the optical system can be considered a communication channel and can be analyzed as such. There is a linear relationship (i.e., direct proportionality) between the intensity distribution in the image plane and that existing in the object, when the object is illuminated with incoherent light (e.g., sunlight or light from a large thermal source). Hence, the linear theory developed for the description of electronic systems can be applied to optical image-forming systems. For example, an electronic circuit can be characterized by its impulse response—that is, its output for a brief impulse input of current or voltage. Analogously, an optical system can be characterized by an impulse response that for an incoherent imaging system is the intensity distribution in the image of a point source of light; the optical impulse is a spatial rather than a temporal impulse—otherwise the concept is the same. Once the appropriate impulse response function is known, the output of that system for any object intensity distribution can be determined by a linear superposition of impulse responses suitably weighted by the value of the intensity at each point in the object. For a continuous object intensity distribution this sum becomes an integral. While this example has been given in terms of an optical imaging system, which is certainly the most common use of optical elements, the concept can be used independent of whether the receiving plane is an image plane or not. Hence, for example, an impulse response can be defined for an optical system that is deliberately defocused or for systems used for the display of Fresnel or Fraunhofer diffraction patterns. (Fraunhofer diffraction occurs when the light source and diffraction patterns are effectively at infinite distances from the diffracting system, and Fresnel diffraction occurs when one or both of the distances are finite.)

Temporal frequency response. A fundamentally related but different method of describing the performance of an electronic circuit is by means of its temporal frequency response. A plot is made of the response for a series of input signals of a variety of frequencies. The response is measured as the ratio of the amplitude of the signal obtained out of the system to that put in. If there is no loss in the system, then the frequency response is unity (one) for that frequency; if a particular frequency fails to pass through the system, then the response is zero. Again, analogously the optical system may also be described by defining a spatial frequency response. The object, then,

The optical
system as a
communi-
cation
channel

Retinal
illumi-
nance

to be imaged by the optical system consists of a spatial distribution of intensity of a single spatial frequency—an object the intensity of which varies as $(1 + a \cos \omega x)$, in which x is the spatial coordinate, a is a constant called the contrast, and ω is a variable that determines the physical spacing of the peaks in the intensity distribution. The image is recorded for a fixed value of a and ω and the contrast in the image measured. The ratio of this contrast to a is the response for this particular spatial frequency defined by ω . Now if ω is varied and the measurement is repeated, a frequency response is then obtained.

Nonlinear optical systems. The analogies described above go even further. Many optical systems are nonlinear, just as many electronic systems are nonlinear. Photographic film is a nonlinear optical element in that equal increments of light energy reaching the film do not always produce equal increments of density on the film.

A different type of nonlinearity occurs in image formation. When an object such as two stars is imaged, the resultant intensity distribution in the image is determined by first finding the intensity distribution formed by each star. These distributions must then be added together in regions where they overlap to give the final intensity distribution that is the image. This example is typical of an incoherent imaging system—*i.e.*, the light emanating from the two stars is completely uncorrelated. This occurs because there is no fixed phase relationship between the light emanating from the two stars over any finite time interval.

A similar nonlinearity arises in objects illuminated by light from the Sun or other thermal light source. Illumination of this kind, when there is no fixed relationship between the phase of the light at any pair of points in the incident beam, is said to be incoherent illumination. If the illumination of the object is coherent, however, then there is a fixed relationship between the phase of the light at all pairs of points in the incident beam. To determine the resultant image intensity under this condition for a two point object requires that the amplitude and phase of the light in the image of each point be determined. The resultant amplitude and phase is then found by summation in regions of overlap. The square of this resultant amplitude is the intensity distribution in the image. Such a system is nonlinear. The mathematics of nonlinear systems was developed as a branch of communication theory, but many of the results can be used to describe nonlinear optical systems.

This new description of optical systems was extremely important to, but would not alone account for, the resurgence of optical research and development. This new approach resulted in the development of whole new branches of study, including optical processing and holography (see below). It also had an effect, together with the development of digital computers, on the concepts and versatility of lens design and testing. Finally, the invention of the laser, a device that produces coherent radiation, and the development and implementation of the theory of partially coherent light gave the added impetus necessary to change traditional optics into a radically new and exciting subject.

IMAGE FORMATION

Impulse response. An optical system that employs incoherent illumination of the object can usually be regarded as a linear system in intensity. A system is linear if the addition of inputs produces an addition of corresponding outputs. For ease of analysis, systems are often considered stationary (or invariant). This property implies that if the location of the input is changed, then the only effect is to change the location of the output but not its actual distribution. With these concepts it is then only necessary to find an expression for the image of a point input to develop a theory of image formation. The intensity distribution in the image of a point object can be determined by solving the equation relating to the diffraction of light as it propagates from the point object to the lens, through the lens, and then finally to the image plane. The result of this process is that the image intensity is the intensity in the Fraunhofer diffraction pattern of the lens aperture function (that is, the square of the Fourier transform of the

lens aperture function; a Fourier transform is an integral equation involving periodic components). This intensity distribution is the intensity impulse response (sometimes called point spread function) of the optical system and fully characterizes that optical system. Figure 9 shows the impulse response for a perfect optical system (no aberration) that is limited only by its aperture.

With the knowledge of the impulse response, the image of a known object intensity distribution can be calculated. If the object consists of two points, then in the image plane the intensity impulse response function must be located at the image points and then a sum of these intensity distributions made. The sum is the final image intensity. If the two points are closer together than the half width of the impulse response, they will not be resolved. For an object consisting of an array of isolated points, a similar procedure is followed—each impulse response is, of course, multiplied by a constant equal to the value of the intensity of the appropriate point object. Normally, an object will consist of a continuous distribution of intensity, and, instead of a simple sum, a convolution integral results.

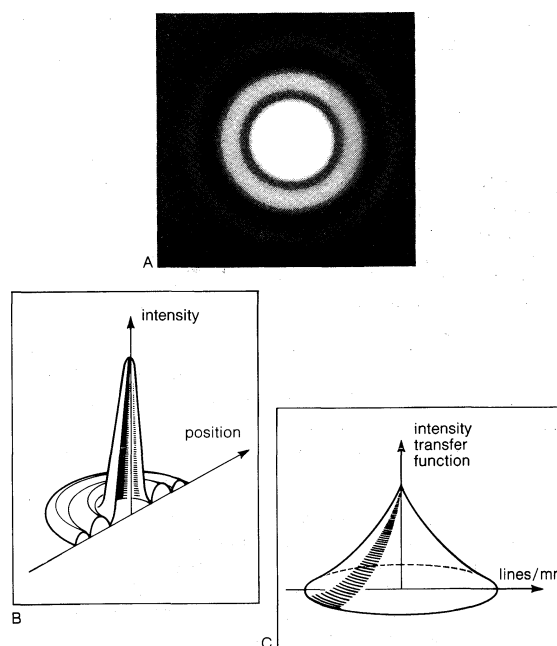

Figure 9: The intensity impulse response of a perfect (*i.e.*, no aberrations) optical system. (A) Photograph; (B) plot; (C) the transfer function of the same aberration-free system.

Transfer function. The concept of the transfer function of an optical system can be approached in several ways. Formally and fundamentally it is the Fourier transform of the intensity impulse response. The transfer function for the optical system for Figure 9B is shown in Figure 9C. Because the impulse response is related to the lens aperture function, so is the transfer function. In particular, the transfer function can be obtained from a knowledge of the aperture function by taking the function and plotting the resultant overlapping areas as the aperture function is slid over itself (*i.e.*, the autocorrelation of the aperture function).

Conceptually, however, the transfer function is best understood by considering the object intensity distribution to be a linear sum of cosine functions of the form $(1 + a \cos 2\pi\mu x)$, in which a is the amplitude of each component of spatial frequency μ . The image of a cosine intensity distribution is a cosine of the same frequency; only the contrast and phase of the cosine can be affected by a linear system. The image of the above object intensity distribution can be represented by $[1 + b \cos (2\pi\mu x + \phi)]$, in which b is the amplitude of the output cosine of frequency μ and ϕ is the phase shift. The transfer function, $\tau(\mu)$, for that frequency is then given by the ratio of the amplitudes:

Nonlinear
optical
systems

Intensity
distribution

Auto-
correlation

$$\tau(u) = \frac{b}{a} e^{j\phi(u)}.$$

If μ is now varied, the spatial frequency response of the system is measured by determining $\tau(\mu)$ for the various values of μ . It should be noted that $\tau(\mu)$ is in general complex (containing a term with $\sqrt{-1}$), although in the example of Figure 9 it is real and positive [$\phi(\mu) = 0$ for all μ].

The transfer function, like the impulse response, fully characterizes the optical system. To make use of the transfer function to determine the image of a given object requires that the object be decomposed into a series of periodic components called its spatial frequency spectrum. Each term in this series must then be multiplied by the appropriate value of the transfer function to determine the individual components of the series that is the spatial frequency spectrum of the image—a transformation of this series will give the image intensity. Thus, any components in the object spectrum that have a frequency for which $\tau(\mu)$ is zero will be eliminated from the image.

PARTIALLY COHERENT LIGHT

Image formation is concerned above with incoherent object illumination, which results in an image formed by the addition of intensities. The study of diffraction and interference, on the other hand, requires coherent illumination of the diffracting object, the resulting diffracted optical field being determined by an addition of complex amplitudes of the wave disturbances. Thus, two different mechanisms exist for the addition of light beams, depending upon whether the beams are coherent or incoherent with respect to each other. Unfortunately, this is not the whole story; it is not sufficient to consider only the two situations of strictly coherent and strictly incoherent light. In fact, strictly incoherent fields are only approximately obtainable in practice. Furthermore, the possibility of intermediate states of coherence cannot be ignored; it is necessary to describe the result of mixing incoherent light with coherent light. It was to answer the question How coherent is a beam of light? (or the equivalent one, How incoherent is a beam of light?) that the theory of partial coherence was developed. Marcel Verdet, a French physicist, realized in the 19th century that even sunlight is not completely incoherent, and two objects separated by distances of over approximately $1/20$ millimetre will produce interference effects. The eye, operating unaided in sunlight, does not resolve this separation distance and hence can be considered to be receiving an incoherent field. Two physicists, Armand Fizeau in France and Albert Michelson in the United States, were also aware that the optical field produced by a star is not completely incoherent, and hence they were able to design interferometers to measure the diameter of stars from a measurement of the partial coherence of the starlight. These early workers did not think in terms of partially coherent light, however, but derived their results by an integration over the source. At the other extreme, the output from a laser can produce a highly coherent field.

The concepts of partially coherent light can best be understood by means of some simple experiments. A circular uniform distant source produces illumination on the front of an opaque screen containing two small circular apertures, the separation of which can be varied. A lens is located behind this screen, and the resultant intensity distribution in its focal plane is obtained. With either aperture open alone, the intensity distribution observed is such that it is readily associated with the diffraction pattern of the aperture, and it may thus be concluded that the field is coherent over the dimensions of the aperture. When the two apertures are opened together and are at their closest separation, two-beam interference fringes are observed that are formed by the division of the incident wave front by the two apertures. As the separation of the apertures increases, the observed interference fringes get weaker and finally disappear, only to reappear faintly as the separation is further increased. As the separation of the apertures is increased, these results show that (1) the fringe spacing decreases; (2) the intensities of the fringe minima are never zero; (3) the relative intensity of the maxima above the

minima steadily decreases; (4) the absolute value of the intensity of the maxima decreases and that of the minima increases; (5) eventually, the fringes disappear, at which point the resultant intensity is just twice the intensity observed with one aperture alone (essentially an incoherent addition); (6) the fringes reappear with a further increase in separation of the aperture, but the fringes contain a central minimum, not a central maximum.

If the intensities of the two apertures are equal, then the results (1) through (5) can be summarized by defining a quantity in terms of the maximum intensity (I_{max}) and the minimum intensity (I_{min}), called the visibility (V) of the fringes—i.e., $V = (I_{max} - I_{min}) / (I_{max} + I_{min})$. The maximum value of the visibility is unity, for which the light passing through one aperture is coherent with respect to the light passing through the other aperture; when the visibility is zero, the light passing through one aperture is incoherent with respect to the light passing through the other aperture. For intermediate values of V the light is said to be partially coherent. The visibility is not a completely satisfactory description because it is, by definition, a positive quantity and cannot, therefore, include a description of item (6) above. Furthermore, it can be shown by a related experiment that the visibility of the fringes can be varied by adding an extra optical path between the two interfering beams.

The key function in the theory of partially coherent light is the mutual coherence function $\Gamma_{12}(\tau) = \Gamma(x_1, x_2, \tau)$, a complex quantity, which is the time averaged value of the cross correlation function of the light at the two aperture points x_1 and x_2 with a time delay τ (relating to a path difference to the point of observation of the interference fringes). The function can be normalized (i.e., its absolute value set equal to unity at $\tau = 0$ and $x_1 = x_2$) by dividing by the square root of the product of the intensities at the points x_1 and x_2 to give the complex degree of coherence, hence

$$\gamma_{12}(\tau) = \frac{\Gamma_{12}(\tau)}{\sqrt{I(x_1)I(x_2)}}.$$

The modulus of $\gamma_{12}(\tau)$ has a maximum value of unity and a minimum value of zero. The visibility defined earlier is identical to the modulus of the complex degree of coherence if $I(x_1) = I(x_2)$.

Often the optical field can be considered to be quasi-monochromatic (approximately monochromatic), and then the time delay can be set equal to zero in the above expression, thus defining the mutual intensity function. It is often convenient to describe an optical field in terms of its spatial and temporal coherence by artificially separating out the space- and time-dependent parts of the coherence function. Temporal coherence effects arise from the finite spectral width of the source radiation; a coherence time Δt can be defined as $1/\Delta\nu$, in which $\Delta\nu$ is the frequency bandwidth. A related coherence length Δl can also be defined as $c/\Delta\nu = \lambda^2/\Delta\lambda$, in which c is the velocity of light, λ is the wavelength, and $\Delta\lambda$ the wavelength bandwidth. Providing that the path differences in the beams to be added are less than this characteristic length, the beams will interfere.

The term spatial coherence is used to describe partial coherence arising from the finite size of an incoherent source. Hence, for the equipath position for the addition of two beams, a coherence interval is defined as the separation of two points such that the absolute value $|\gamma_{12}(0)|$ is some prechosen value, usually zero.

The mutual coherence function is an observable quantity that can be related to the intensity of the field. The partially coherent field can be propagated by use of the mutual coherence function in a similar way to the solution of diffraction problems by propagation of the complex amplitude. The effects of partially coherent fields are clearly of importance in the description of normally coherent phenomena, such as diffraction and interference, but also in the analysis of normally incoherent phenomena, such as image formation. It is notable that image formation in coherent light is not linear in intensity but is linear in the complex amplitude of the field, and in partially coherent light the process is linear in the mutual coherence.

OPTICAL PROCESSING

Coherent optical systems. Optical processing, information processing, signal processing, and pattern recognition are all names that relate to the process of spatial frequency filtering in a coherent imaging system—specifically, a method in which the Fraunhofer diffraction pattern (equivalently the spatial frequency spectrum or the Fourier transform) of a given input is produced optically and then operated upon to change the information content of the optical image of that input in a predetermined way.

The idea of using coherent optical systems to allow for the manipulation of the information content of the image is not entirely new. The basic ideas are essentially included in Abbe's theory of vision in a microscope first published in 1873; the subsequent illustrative experiments of this theory, notably by Albert B. Porter in 1906, are certainly simple examples of optical processing.

Abbe's ideas can be interpreted as a realization that image formation in a microscope is more correctly described as a coherent image-forming process than as the more familiar incoherent process. Thus, the coherent light illuminating the object on the microscope stage would be diffracted by that object. To form an image, this diffracted light must be collected by the objective lens of the microscope, and the nature of the image and the resolution would be affected by how much of the diffracted light is collected. As an example, an object may be considered consisting of a periodic variation in amplitude transmittance—the light diffracted by this object will exist in a series of discrete directions (or orders of diffraction). This series of orders contains a zero order propagating along the optical axis and a symmetric set of orders on both sides of this zero order. Abbe correctly discerned what would happen as the microscope objective accepted different combinations of these orders. For example, if the zero order and one first order are collected, then the information obtained will be that the object consisted of a periodic distribution, but the spatial location of the periodic structure is not correctly ascertained. If the other first order of diffracted light is included, the correct spatial location of the periodic structure is also obtained. As more orders are included, the image more closely resembles the object.

Coherent optical data processing became a serious subject for study in the 1950s, partly because of the work of a French physicist, Pierre-Michel Duffieux, on the Fourier integral and its application to optics, and the subsequent use of communication theory in optical research. The work was initiated in France by André Maréchal and Paul Croce, and today a variety of problems can be attempted by the technique. These include removal of raster lines (as in a TV picture) and halftone dots (as in newspaper illustration); contrast enhancement; edge sharpening; enhancement of a periodic or isolated signal in the presence of additive noise; aberration balancing in which a recorded aberrated image can be somewhat improved; spectrum analysis; cross correlation of data; matched and inverse filtering in which a bright spot of light in the image indicates the presence of a particular object.

Filtering. The basic system required for coherent optical processing consists of two lenses (Figure 10). A collimated beam of coherent light is used to transilluminate the object. The first lens produces the characteristic Fraunhofer diffraction pattern of the object, which is the spatial frequency distribution associated with the object. (Mathematically, it is the Fourier transform of the object amplitude distribution.) A filter that consists of amplitude (density) or phase (optical path) variations, or both, is placed in the plane of the diffraction pattern. The light passing through this filter is used to form an image, this step being accomplished by the second lens. The filter has the effect of changing the nature of the image by altering the spatial frequency spectrum in a controlled way so as to enhance certain aspects of the object information. Maréchal gave the descriptive title double diffraction to this type of two-lens system.

The filters can be conveniently grouped into a variety of types depending upon their action. Blocking filters have regions of complete transparency and other regions of complete opacity. The opaque areas completely remove

certain portions of the spatial frequency spectrum of the object. The removal of raster lines and halftone dots is accomplished with this type of filter. The object can be considered as a periodic function the envelope of which is the scene or picture—or equivalently the periodic function samples the picture. The diffraction pattern consists of a periodic distribution with a periodicity reciprocally related to the raster periodicity. Centred at each of these periodic locations is the diffraction pattern of the scene. Hence, if the filter is an aperture centred at one of these locations so that only one of the periodic elements is allowed to pass, then the raster periodicity is removed, but the scene information is retained (see Figure 10). The problem of

Figure 10: Two-lens coherent optical processing system, showing how the raster periodicity is removed but the scene information is retained (see text).

the removal of halftone dots is the two-dimensional equivalent of the above process. Because the two-dimensional spatial frequency spectrum of an object is displayed in a coherent optical processing system, it is possible to separate out information by means of its orientation. Other applications of blocking filters include band-pass filters, which again have a direct relationship to the band-pass filters in electronic circuits.

A second type of filter is an amplitude filter that will consist of a continuous density variation. These filters can be produced to achieve the enhancement of contrast of the object input or the differentiation of the object. They are often constructed by controlled exposure of photographic film or evaporation of metal onto a transparent substrate.

Certain optical processing techniques require that the phase of the optical field be changed, and, hence, a filter with no absorption but varying optical thickness is required. Usually, both the amplitude and the phase have to be modified, however, thus requiring a complex filter. In simple cases the amplitude and phase portions can be made separately, the phase filter being manufactured by using an evaporated layer of transparent material, such as magnesium fluoride. Current practice is to fabricate the complex filter by an interferometric method in which the required complex amplitude function is recorded as a hologram (see below).

The phase-contrast microscope can be considered to be an example of an optical processing system, and the concepts understood by reference to Figure 10. Only the simplest form will be considered here. The spatial frequency spectrum of the phase object is formed and the phase of the central portion of that spectrum changed by $\pi/2$ or $3\pi/2$ to produce positive or negative phase contrast, respectively. To improve the contrast of the image an additional filter covering the same area as the phase filter is used that is partially absorbing (*i.e.*, an amplitude filter). The restriction on this process is that the variations of the phase $\phi(x)$ are small so that $e^{i\phi(x)} \approx 1 + i\phi(x)$. With incoherent light, phase information is not visible, but many biological samples consist only of variations of refractive index, which results in optical path and hence phase, differences. The image in the phase-contrast microscope is such that the intensity in that image relates linearly to, and hence is a display of, the phase information in the object—*e.g.*, $I(x) \propto 1 \pm 2\phi(x)$ for positive and negative phase contrast, respectively.

One of the important motivations for the study of optical processing methods is to achieve some correction of aberrated images. Considerable technological advantage can be gained if photographs taken with an aberrated optical system in incoherent light can be corrected by subsequent processing. Within definable limits this can be

Amplitude filters

Correction of aberrated images

Examples of data processing

Blocking filters

accomplished, but the impulse response or the transfer function of the aberrated system must be known. The recorded image intensity distribution is the convolution of the object intensity with the intensity impulse response of the aberrated system. This record is the input to the coherent optical processing system; the diffraction pattern formed in this system is the product of the spatial frequency spectrum of the object and the transfer function of the aberrated system. Conceptually, the filter has to be the inverse of the transfer function in order to balance out its effect. The final image would then ideally be an image of the object intensity distribution. It is critical, however, that the transfer function has a finite value over only a limited frequency range, and only those frequencies that are recorded by the original aberrated system can be present in the processed image. Hence, for these spatial frequencies that were recorded, some processing can be carried out to get a flatter effective transfer function; both the contrast and the phase of the spatial frequency spectrum may have to be changed because the transfer function is, in general, a complex function. Prime examples are for images aberrated by astigmatism, defocussing, or image motion.

HOLOGRAPHY

Theory. Holography is a two-step coherent image-forming process in which an intermediate record is made of the complex optical field associated with the object. The invention of the wave-front reconstruction process (now called holography) was first described in 1948 by Dennis Gabor, a Hungarian-born physicist, with a specific application in mind—to attempt to improve the resolution of images formed with electron beams. The technique has, however, had most of its success to date when light beams are employed particularly in the visible part of the spectrum. The first step in the process is to record (often on high-resolution film) the interference pattern produced by the interaction of the light diffracted by the object of interest and a coherent background or reference wave. In the second step, this record, which is the hologram, is illuminated coherently to form an image of the original object. In fact, two images are usually formed—a real image (often called the conjugate image) and a virtual image (often called the primary image). There are two basic concepts that underlie this process: first, the addition of a coherent background (or reference) beam. Two optical fields may be considered, the complex amplitudes of which vary as the cosine of an angle proportional to the space coordinate and as the modulus (absolute magnitude) of the cosine of the angle, respectively. From a measurement of the intensity of these fields it is impossible to distinguish them because both vary as the cosine squared of the space coordinate. If a second coherent optical field is added to each of these two fields, however, then the resultant fields become $(1 + \cos x)$ and $(1 + |\cos x|)$, respectively. The measured intensities are now different, and the actual fields can be determined by taking the square root of the intensity. The amplitude transmittance of a photographic record is, in fact, the square root of the original intensity distribution that exposed the film. In a more general sense, an optical field of the form $a(x) \exp[i\phi_1(x)]$, in which $a(x)$ is the amplitude and $\phi_1(x)$ is the phase, can be distinguished from a field $a(x) \exp[i\phi_2(x)]$ by adding a coherent background; the phases $\phi_1(x)$ and $\phi_2(x)$ are then contained as cosine variations of intensity in the resulting pattern. Hence, the problem of recording the phase information of the optical field is circumvented. When the hologram is illuminated, however, the optical field that originally existed in that plane is recreated. To apply the second basic concept—that of an image-forming property—it is necessary to determine what the hologram of a point object is—in actuality it is a sine-wave zone plate or zone lens. If a collimated beam of light is used to illuminate a zone lens, then two beams are produced; the first comes to a real focus, and the other is a divergent beam that appears to have come from a virtual focus. (By comparison, the more classical zone plate has a multitude of real and virtual focuses, and a real lens has but one.) When the object is other than a point, the zone lens is modified by the diffraction pattern of the object; i.e., each

point on the object produces its own zone lens, and the resultant hologram is a summation of such zone lenses.

In Gabor's original system the hologram was a record of the interference between the light diffracted by the object and a collinear background. This automatically restricts the process to that class of objects that have considerable areas that are transparent (see Figure 11A). When the hologram is used to form an image, twin images are formed, as illustrated in Figure 11B. The light associated with these images is propagating in the same

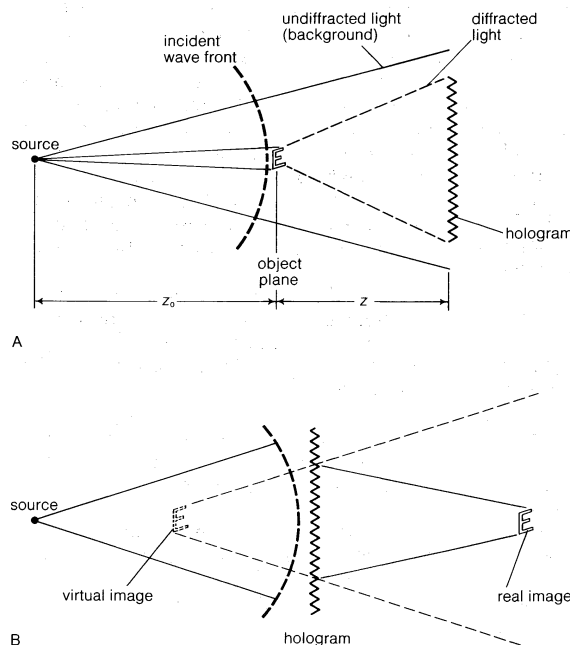

Figure 11: Holography.

(A) Formation of a hologram by light diffracted by an object with collinear background (Gabor's original method). (B) Image formation by illumination of the hologram.

direction, and hence in the plane of one image light from the other image appears as an out-of-focus component. This type of hologram is usually referred to as an in-line Fresnel hologram because it is the pattern of the object that interferes with the collinear coherent background. The deleterious effects of the second image can be minimized if the hologram is made in the far field of the object so that it is a Fraunhofer diffraction pattern of the object that is involved. This latter technique has found significant application in microscopy, particularly in the measurement of small particles, and in electron microscopy.

A more versatile method of recording the hologram is to add a second beam of light as a reference wave to produce the hologram. The hologram is now the record of the interference pattern produced by the light diffracted by the object and this separate reference wave. The reference wave is usually introduced at an angle to the diffracted beam, hence this method is often called off-axis (or side-band) holography. When the hologram is illuminated, the image-forming beams do not propagate in the same direction but are inclined to each other with an angle twice that between the diffracted beam and the original reference beam. Hence, the light associated with an image is completely separated from the other image.

A further technique that has some value and relates to the earlier discussion of optical processing is the production of the so-called generalized or Fourier transform hologram. Here the reference beam is added coherently to a Fraunhofer diffraction pattern of the object or formed by a lens (as in the first stage of Figure 10).

The process described so far has been in terms of transmitted light through the object. The methods involving the separate reference beam can be used in reflected light, and the virtual (primary) image produced from the hologram has all the properties of an ordinary image in terms of three-dimensionality and parallax. Normally, a recorded

The generalized hologram

Steps in the holography process

image is only a two-dimensional representation of the object. Full-colour holograms can be recorded by essentially recording three holograms simultaneously—one in red light, one in blue, and one in green.

Applications. *Image forming.* The applications mentioned here are in three groups: image-forming applications, non-image-forming applications, and the hologram as an optical element. It is notable that all three groups relate to the basic use of the process rather than specific holographic techniques. The first group involves those applications using image formation when, for a variety of reasons, normal incoherent or coherent image formation is not satisfactory. It is not sufficient merely to replace a normal image process by a holographic technique unless there is some significant gain—i.e., the required record can be obtained more easily or more accurately. Applications that fall into this category are holographic microscopy; particle-size analysis; high-speed photography of various types, particularly of gas flows; data storage and retrieval, including displays; image formation through a random medium; and non-optical holography, particularly acoustic holography.

Non-image forming. The second group of interest involves those applications that are not image forming. One of the very real and exciting applications of holography is to the nondestructive testing of fabricated materials. An interesting example of this method is for the testing of tires for the detection of flaws (debonds) that exist between the plies of the tire. The realm of interferometry is thus extended to whole new classes of objects. In a similar but separate development, interference microscopy has been used successfully.

Optical elements. The third and final group involves those applications that use the hologram as an optical element in its own right. This includes the building of accurate, specialized gratings and the application of holographic filters in coherent optical data processing.

Holography has been adapted to the conventional microscope, which is modified by the inclusion of a separate reference beam so that the light diffracted by the object in the microscope is made to interfere with the light from the reference beam. An increase in the depth of field available is achieved by this type of recording process. The image is produced when the hologram is illuminated again by a coherent beam.

The application of holography to particle-size analysis (e.g., to determine the size distribution of dust and liquid droplets) was really the first of the modern-day applications. In a sense, this, too, can be thought of as microscopy. The principles of Fraunhofer holography were developed to solve this particular problem. Because the particles are in motion, a hologram must be made instantaneously. A pulsed-ruby laser technique is therefore used. The hologram is formed between the light diffracted by the particles or droplets and the coherent background light that passes directly through the sample. In reconstruction, a series of stationary images are formed that can be examined at leisure. Hence, a transient event has been transformed into a stationary image for evaluation.

Data storage and retrieval is perhaps one of the more important applications of holography, which is in the process of development and refinement. Because the information about the image is not localized, it cannot be affected by scratches or dust particles. Recent advances in materials, particularly those that might be erasable and reusable, have added further interest in holographic optical memories.

Among the non-image-forming applications are interfer-

ometry, interference microscopy, and optical processing. Holographic interferometry can be done in several ways. The basic technique involves recording a hologram of the object of interest and then interfering the image produced from this hologram with the coherently illuminated object itself. A variation on this technique would be to form two holograms at different times of the same object as it undergoes testing. The two holograms can then be used together to form two images, which would again interfere. The interference fringes seen would be related to the changes in the object between the two exposures. A third technique uses a time-average hologram, which is particularly applicable to the study of vibrating objects.

There are two applications that come under the heading holographic optical elements—the use of holographic gratings and the use of holographic filters for coherent optical data processing.

NONLINEAR OPTICS

Nonlinear effects in optics are now quite readily observable using the highly coherent and highly energetic laser beams. These effects occur when the output of a system is not linearly related to the input (e.g., a nonlinear electronic amplifier can be built with a gain that increases with signal intensity). The most important nonlinear effect is probably frequency doubling. Optical radiation of a given frequency is propagated through a crystalline material and interacts with that material to produce an output of a different frequency that is twice the input frequency. For example, the 10,600 angstroms infrared output of a neodymium laser can, under suitable conditions, be converted into green light at 5300 angstroms in a crystal of barium strontium niobate.

(B.J.T.)

BIBLIOGRAPHY. There are many journals and hundreds of books covering the general field of optics; some of the more familiar books include A.C. HARDY and F.H. PERRIN, *The Principles of Optics* (1932); and F.A. JENKINS and H.E. WHITE, *Fundamentals of Optics*, 3rd ed. (1957). At a more advanced level are R.S. LONGHURST, *Geometrical and Physical Optics*, 2nd ed. (1967); L.C. MARTIN, *Technical Optics*, 2 vol. (1960–61); and MAX BORN and EMIL WOLF, *Principles of Optics*, 2nd ed. (1964). In the purely geometrical field, the following can be recommended: W.T. WELFORD, *Geometrical Optics* (1962), which is fairly elementary and provides an excellent introduction to the subject; and L.C. MARTIN, *Geometrical Optics* (1956), which is somewhat more advanced. Other useful works include R. KINGSLAKE (ed.), *Applied Optics and Optical Engineering*, 5 vol. (1945–69), a definitive work, with the first three volumes treating optical devices and theory and the remaining two volumes giving detailed treatment of the principal types of optical instruments; and A.E. CONRADY, *Applied Optics and Optical Design*, 2 vol. (1957–60), a full description of the theory and practice of lens design, providing detailed instructions for the design of many types of optical systems.

Recommended books on the subject of information theory are EDWARD L. O'NEILL, *Introduction to Statistical Optics* (1963); JOSEPH W. GOODMAN, *Introduction to Fourier Optics* (1968); ARNOLD R. SCHULMAN, *Optical Data Processing* (1970); KENDALL PRESTON, *Coherent Optical Computers* (1972); HENRY LIPSON (ed.), *Optical Transforms* (1972); GEORGE W. STROKE, *An Introduction to Coherent Optics and Holography*, 2nd ed. (1969); JOHN B. DEVELIS and GEORGE O. REYNOLDS, *Theory and Applications of Holography* (1967); and ROBERT J. COLLIER, CHRISTOPH B. BURCKHARDT, and LAWRENCE H. LIN, *Optical Holography* (1971). For particular topics, reference should be made to the *Journal of the Optical Society of America* (monthly); *Applied Optics* (monthly); and EMIL WOLF (ed.), *Progress in Optics* (1961–).

The Mathematical Theory of Optimization

Optimization is a technique for improving or increasing the value of some numerical quantity that in practice may take the form of temperature, air flow, speed, pay-off in a game, political appeal, destructive power, information, monetary profit, and the like. Techniques of optimization assume such varied forms that no one general description is possible. With the advent of modern technology more and more emphasis has been placed on optimization of various types, and special thinking has developed to the extent that it is meaningful to speak of a mathematical theory of optimization. Computer technology has been critically important in practical

applications, such as in the optimal control of rockets. Further advances in the optimization and control of complex systems will probably depend more on mathematical theory than on technological invention.

Optimization includes linear and nonlinear programming, cybernetics, and control theory, the various aspects of which are treated in this article. Game theory is often included as well, since early work on optimization was extended by the development of that branch of mathematics. For information about its basic concepts and methodology, see GAME THEORY. The present article is divided into the following sections:

Linear and nonlinear programming (mathematical programming)

GENERAL OBSERVATIONS

Mathematical programming may be described in terms of its mathematical structure and computational procedures or in terms of the broad class of important decision problems which can be formulated as the minimization (maximization) of a function of several variables that are subject to a system of side constraints. For example, a linear program is defined as the minimization of a linear "objective" function whose variables satisfy a system of linear inequalities.

The scope of mathematical programming

In practice, mathematical programming usually refers to such linear programs, the general study of nonlinear programs (those in which either the objective function or at least one of the constraint functions is nonlinear), integer programs (that is, linear programs with the additional restriction that some or all of the variables must be integer valued), stochastic programs (those programs involving random variables), and network flow theory (transportation or flow through networks). As such, mathematical programming overlaps, has contributed to, and has been influenced by operations research, mathematical economics, control theory, dynamic programming, and combinatorial theory.

The term programming had its origin in programming (i.e., planning, scheduling) the quantity and timing of the various activities of an organization such as a factory, an airline, the defense establishment, the national economy, or world trade. (It is not to be confused with "programming" as used for the task of preparing a sequence of instructions for a computer.) The goal is to find an optimum schedule.

A simple example, "the assignment problem," illustrates the essential difficulty. A factory has 70 men with different qualifications and it is desirable to assign them to 70 jobs. If a "value" can be attached to assigning a particular man to a particular job, then the problem becomes one of selecting out of 70! (which is the product of integers from 1 to 70) possible ways of permuting the assignments the one that yields the maximum total value to the fac-

tory. Because 70! is approximately 10^{100} , it would take an electronic computer executing 1,000,000 operations per second over 10^{87} years (or many times the projected life of the universe) to examine all the permutations. Such decision problems are common and have resulted in the development of clever formulation of the mathematical models, powerful mathematical methods of solution, and efficient computer algorithms (step-by-step procedures). The solution of linear programs is said to constitute 25 percent of all the time used by computers to solve scientific problems.

ORIGINS AND INFLUENCES

Although widely used now to solve everyday decision problems, linear programming was comparatively unknown before 1947. No work of any significance was carried out before this date, even though the French mathematician Jean-Baptiste-Joseph Fourier seemed to be aware of the subject's potential as early as 1823. A Russian mathematician, Leonid Vitalyevich Kantorovich, who published an extensive monograph in 1939, *Matematicheskie metody organizatsii i planirovaniya proizvodstva* ("Mathematical Methods for Organization and Planning of Production"), is credited with being the first to recognize that certain important broad classes of scheduling problems had well-defined mathematical structures. Unfortunately his proposals remained unknown both in the Soviet Union and elsewhere for nearly two decades. Meanwhile, linear programming had developed considerably in the United States and Western Europe. In the period following World War II, officials in the United States government felt that efficient coordination of the energies of a whole nation in the advent of atomic war would require the use of scientific planning techniques. The advent of the computer made such an approach feasible.

Intensive work began in 1947 in the United States Air Force. The linear programming model was proposed because it is simple, practical, and yet provided a sufficiently general framework for representing interdependent activities that must share scarce resources. The system (e.g., national economy) is viewed as made up of various activities (e.g., production, training, shipping, disposal, and storing).

The first linear programming model

Each activity is assumed to require a flow of inputs and outputs of various types of items (*e.g.*, men, materials) proportional to the level of the activity. Activity levels are assumed to be representable in terms of positive numbers or zero. The revolutionary feature of the approach, however, was the expressing of the goal, as that of minimizing (maximizing) an objective function (*e.g.*, maximizing sorties in the case of the air force or maximizing profits in industry). Before 1947 all practical planning was characterized by a series of authoritatively imposed rules of procedure and priorities. General objectives were never stated, probably because of the impossibility of performing the calculations necessary to minimize an objective function under constraints. In 1947 a method composed of successive tests for optimality at extreme points and intervening linear movement along polygonal edges called the simplex computational method was introduced which turned out to be indeed efficient. Interest in linear programming grew rapidly and by 1951 its use spread to industry. Today, it is almost impossible to name an industry that is not using mathematical programming in some form, although its use varies greatly, even within the same industry.

The current interest in linear programming by economists appears to be an anachronism. The French economist François Quesnay's attempt in his *Tableau économique* (1758) to interrelate the role of the landlord, the peasant, and the artisan was a crude example of a linear programming model. Léon Walras, another French economist, in 1874 proposed a sophisticated approach that had as part of its structure fixed technological coefficients (as assumed in linear programs). Oddly enough, until the 1930s, the linear-type model was little exploited.

Von Neumann in a 1937 paper analyzed a steadily expanding economy based on alternative methods of production and fixed technological coefficients. As far as mathematical history is concerned, the study of linear inequality systems excited virtually no interest before 1936. In 1911 a vertex-to-vertex movement along edges of a polyhedron (as is done in the simplex method) was suggested as a way to solve a problem that involved optimization, and in 1941 movement along edges was proposed for a problem involving transportation. Credit for laying much of the mathematical foundations should probably go to von Neumann. In 1928 he published his famous paper on *Game theory*. In 1947 he conjectured the equivalence of linear programs and matrix games, introduced the important concept of duality, and made several proposals for the numerical solution of linear programming and game problems. Serious interest by other mathematicians began in 1948 with the rigorous development of duality and related matters.

The general simplex method, already mentioned (see above *Origins and influences*) and to be discussed in detail (see below *The simplex method*), was first programmed in 1951 for the United States Bureau of Standards SEAC computer. Starting in 1952, the simplex method was programmed for use on various models of IBM (International Business Machines) computers and later for those of other companies. These programs turned out to be practical. As a result, commercial applications of linear programs in industry and government grew rapidly. New computational techniques and variations of older techniques continued to be developed.

At the present time there is much interest in solving large linear programs with special structures, for example, corporate models and national planning models that are multistaged, dynamic, and exhibit a hierarchical structure. It is estimated that certain underdeveloped countries have the potential of increasing their GNP (gross national product) anywhere from 10 to 15 percent per year if detailed growth models of the economy could be constructed, optimized, and implemented.

LINEAR PROGRAMMING THEORY

Basic ideas. A simple problem in linear programming is one in which it is necessary to find the maximum (or minimum) value of a simple function, such as $x_1 + 2x_2$, subject to certain constraints. An example of its application might be that of a factory producing two commodities.

In any production run, it produces x_1 of the first type and x_2 of the second. If the profit on the second type is twice that on the first, then $x_1 + 2x_2$ represents the total profit. The function $x_1 + 2x_2$ is known as the objective function.

Clearly the profit will be highest if the factory devotes its entire production capacity to making the second type of commodity. In a practical situation, however, this may not be possible; a set of constraints is introduced by such factors as availability of machine time, manpower, or raw materials. For example, if the second type of commodity requires a raw material that is limited so that no more than five can be made in any batch, then x_2 must be less than or equal to five; *i.e.*, $x_2 \leq 5$. If the first commodity requires another type of material limiting it to eight per batch then $x_1 \leq 8$. If 1 and 2 take equal times to make and the machine time available allows a maximum of ten to be made in a batch, then $x_1 + x_2$ must be less than or equal to 10; *i.e.*, $x_1 + x_2 \leq 10$.

Two other constraints are that x_1 and x_2 must each be greater than or equal to zero, because it is impossible to make a negative number of either; *i.e.*, $x_1 \geq 0$ and $x_2 \geq 0$. These conditions result in a simple linear program that can be stated in concise algebraic form. The problem is to find the values of x_1 and x_2 for which the profit is a maximum. Any solution can be denoted by a pair of numbers (x_1, x_2) ; for example, if $x_1 = 3$ and $x_2 = 6$, the solution is (3, 6). These numbers can be represented by points plotted on two axes; in Figure 1 the distance along

Figure 1: Constraint set bounded by the five lines $x_1 = 0$, $x_2 = 0$, $x_1 = 8$, $x_2 = 5$, and $x_1 + x_2 = 10$. These enclose an infinite number of points that represent feasible solutions.

the horizontal axis represents x_1 and that along the vertical represents x_2 . An infinite number of points exist corresponding to an infinite number of solutions, but because of the constraints the feasible solutions must lie within a certain region. For example, the constraint $x_1 \geq 0$ means that points representing feasible solutions lie on or to the right of the x_2 axis. The constraint $x_2 \geq 0$ means that they also lie on or above the x_1 axis. Application of all the constraints leads to the result that points representing solutions lie within the shaded area bounded by a polygon formed by intersection of the lines $x_1 = 0$, $x_2 = 0$, $x_1 = 8$, $x_2 = 5$, and $x_1 + x_2 = 10$. These form the constraint set. For example, to make three items of commodity 1 and four of 2 is a feasible solution since the point (3, 4) lies in this region. To find the best solution, the objective func-

tion $x_1 + 2x_2 = k$ is plotted on the graph for some value of k , say $k = 4$. This value is indicated by the broken line in Figure 1. As k is increased, a family of parallel lines are produced and the line for $k = 15$ just touches the constraint set at the point (5, 5). If k is increased further, the values of x_1 and x_2 lie outside the set of feasible solutions. Thus the best solution is that in which equal quantities of each commodity are made. The points (0, 0), (0, 5), (5, 5), (8, 2), and (8, 0) are the extreme points of the constraint set, and the problem involves finding the extreme point the coordinates of which yield the largest value for k .

The standard form of a linear program is expressed as an instruction to maximize (or minimize) a linear expression in n nonnegative variables, $\{x_j\}$, subject to m linear equations (see 1). In applications, the equations correspond to material balance of various items and the variables to levels of various activities (*e.g.*, production processes). Any system of linear inequalities can be reduced to this standard form by simple substitutions.

Definition
of a
feasible
solution

A set of x_j values that is nonnegative and satisfies the equations is a "feasible" solution and corresponds to a feasible but not necessarily optimal program. Such a solution is viewed as a point in n -dimensional space.

The constraint set—*i.e.*, the set of feasible solutions—has a property known as convexity. In general, a set S is convex if and only if it contains the entire line segment between any two of its elements. An element of a convex set S is called an extreme point if it does not lie on the line segment joining two other points of S . A line segment

in S is called an edge if no point on it lies also on a line segment in S that crosses it. The constraint set of a linear program has only a finite number of extreme points.

If a linear programming problem has a unique optimal feasible solution, then it is at an extreme point; if not unique, there is an optimal solution at an extreme point. Thus, the optimal feasible solution is within a finite set of extreme points.

The simplex method. There are certain difficulties involved in the simple graphical approach to solutions. First, the graphical method of solution illustrated by the figure is useful only for systems of inequalities involving two variables. Practical problems often involve hundreds of equations, thousands of variables, however, and a computer is required. Second, the number of extreme points can be quite large. For example, for n equal to 2,000 and a constraint set defined by restricting the sum of x_j and y_j to be 1 for all nonnegative values of the variables and for all n values of j (see 2), there are 2^n , or about 10^{600} , extreme points. It is thus necessary to restrict the number of extreme points to be examined. This is done by using the simplex method. It works in the following way. It is assumed that an extreme point is known. (If no extreme point is given, a variant of the simplex method, called Phase I, is used to find one or determine that there are no feasible solutions.) Using the algebraic specification of the problem, it is easy to test whether that extreme point is optimal. If the test for optimality is not passed, then a movement along some edge to an adjacent extreme point is sought along which the value of the objective function increases at the fastest rate. Sometimes one can move along an edge and make the objective function value increase without bound. If this occurs, the procedure terminates with a prescription of the edge along which the objective goes to positive infinity. If not, a new extreme point is reached having at least as high an objective function value as its predecessor. The sequence described is then repeated. Termination occurs when an optimal extreme point is found or the unbounded case occurs.

The simplex method solves the numerical example given above in the following way: The problem is put into canonical form by converting the linear inequalities into equations by introducing slack variables $x_3 \geq 0$, $x_4 \geq 0$, $x_5 \geq 0$, and the variable x_0 for the value of the objective function; the problem may then be restated as that of finding nonnegative quantities x_1, \dots, x_5 and the largest possible x_0 satisfying the resulting equations (see 3). One obvious solution of the resulting system of equations is found by setting $x_1 = 0$, $x_2 = 0$ (see 4), which corresponds to the extreme point at the origin in the figure. If x_1 (or x_2) were increased from zero while the other one x_2 (or x_1) is fixed at zero, the values of x_0 , x_3 , x_4 , x_5 could be made to satisfy the equations, and the objective value x_0 would increase as desired. The variable x_2 produces the largest increase of x_0 per unit change; so it is used first. Its increase is limited by the nonnegativity requirement on the variables. In particular, if x_2 were increased beyond 5, x_4 would become negative.

At $x_2 = 5$, this situation produces a new solution (see 5) and corresponds to the extreme point (0, 5) in the figure. The system of equations is put into equivalent form (see 6) by solving for the variables x_0 , x_2 , x_3 , x_5 , which are nonzero in the above solution in terms of those variables now at zero; *i.e.*, x_1 and x_4 . It is now apparent that an increase of x_1 while holding x_4 equal to zero will produce a further increase in x_0 . The nonnegativity restriction on x_3 prevents x_1 from going beyond 5. The new solution (see 7) corresponds to the extreme point (5, 5) in the figure. Solving for x_0 , x_1 , x_2 , x_3 in terms of the variables x_4 , x_5 (which are currently at zero value) yields a final equivalent system of equations (see 8). It is to be noted that no variable can be changed from its present value and yield a feasible solution with a higher value than $x_0 = 15$ (see 9). Hence, an optimal solution is determined (see 10).

The dual problem. Associated with each linear programming problem is a second linear programming problem known as its dual. In this association, the original problem is referred to as the primal. Von Neumann provided a

Slack
variables

$$(1) \quad \begin{cases} \text{maximize } p_1x_1 + \dots + p_nx_n \\ \text{subject to } a_{11}x_1 + \dots + a_{1n}x_n = b_1 \geq 0 \\ \quad \quad \quad a_{21}x_1 + \dots + a_{2n}x_n = b_2 \geq 0 \\ \quad \quad \quad \cdot \quad \quad \quad \cdot \\ \quad \quad \quad \cdot \quad \quad \quad \cdot \\ \quad \quad \quad a_{m1}x_1 + \dots + a_{mn}x_n = b_m \geq 0 \\ \quad \quad \quad x_1 \geq 0, \dots, x_n \geq 0 \end{cases}$$

$$(2) \quad x_j + y_j = 1, \quad x_j \geq 0, \quad y_j \geq 0 \quad \text{for } j = 1, \dots, n$$

$$(3) \quad \begin{cases} -x_0 + x_1 + 2x_2 & = 0 \\ x_1 & + x_3 & = 8 \\ x_2 & + x_4 & = 5 \\ x_1 + x_2 & + x_5 & = 10 \end{cases}$$

$$(4) \quad \begin{cases} x_0 = 0, x_1 = 0, x_2 = 0, x_3 = 8 \\ x_4 = 5, x_5 = 10 \end{cases}$$

$$(5) \quad (x_0, x_1, x_2, x_3, x_4, x_5) = (10, 0, 5, 8, 0, 5)$$

$$(6) \quad \begin{cases} -x_0 + x_1 & - 2x_4 & = -10 \\ x_1 + x_3 & & = 8 \\ x_2 & + x_4 & = 5 \\ x_1 & - x_4 + x_5 & = 5 \end{cases}$$

$$(7) \quad (x_0, x_1, x_2, x_3, x_4, x_5) = (15, 5, 5, 3, 0, 0)$$

$$(8) \quad \begin{cases} -x_0 & & - x_4 - x_5 & = -15 \\ & x_3 + x_4 - x_5 & = 3 \\ & x_2 & + x_4 & = 5 \\ & x_1 & - x_4 + x_5 & = 5 \end{cases}$$

$$(9) \quad x_4 \geq 0, x_5 \geq 0, x_0 = 15 - x_4 - x_5 \leq 15$$

$$(10) \quad x_1 = 5, x_2 = 5, x_3 = 3, x_4 = x_5 = 0$$

form for the primal problem (see 11) that yields an elegant statement of the dual problem (see 12).

An intimate relationship exists between a linear program and its dual. For any vector x^0 (see ANALYSIS: *Vector and tensor analysis*) satisfying the constraints of the primal and any vector y^0 satisfying the constraints of its dual, the primal objective value is never greater than the dual objective value, namely, $px \leq yb$. One implication of this relationship is that when the dual problem possesses at least one feasible vector, the primal objective function is bounded from above.

If the objective values satisfy $px^0 = y^0b$, then it is easy to show that x^0 and y^0 if feasible are optimal solutions of the primal and dual programs. If a vector x^0 is an optimal solution of the primal problem, there exists an optimal solution of the dual problem such that px^0 equals y^0b . Moreover, if $v^0 = b - Ax^0$ and $u^0 = p - y^0A$, then for optimal primal and dual feasible vectors x^0 and y^0 , the relations $y_i^0 v_i^0 = 0$ for $i = 1, \dots, m$ and $x_j^0 u_j^0 = 0$ for $j = 1, \dots, n$ hold and are referred to as complementary slackness conditions. Thus, if x_j^0 is positive in an optimal solution, then the j th inequality constraint of the dual holds as an equality; i.e., its slack, measured by u_j^0 , satisfies $u_j^0 = 0$.

NONLINEAR PROGRAMMING THEORY

A mathematical programming problem is nonlinear if the objective function $f(x)$ to be minimized, in which x is a vector, or any of the constraint functions are nonlinear.

Classification of the problems. One broad class of non-

linear programming problems is that concerning minimizing $f(x)$ subject to no constraints (the unconstrained problem); another is the linearly-constrained nonlinear programs that include as a special subclass quadratic programs concerned with the minimization of a quadratic function (see 13) subject to linear constraints. Another is the chemical equilibrium problem in which the Gibbs function, a measure of the free energy of a chemical system (see 14), is to be minimized subject to (linear) mass-balance equations (see 15) and nonnegativity conditions (see 16). The x_j in the problem represent the unknown number of molecules of different types in a system under constant temperature and pressure. In the mass-balance equations the b_i are the given number of atoms of various types; the a_{ij} are the number of atoms of type i in a single molecule of type j . The c_j in the Gibbs function are related to the constants in the law of mass action and are considered as constants only for dilute solutions.

Nonlinear programs are also classified according to whether defining functions have the appropriate convexity property. A function $F(x)$ defined on a convex set S is convex if (and only if) the set of points lying on or above its graph is convex. In analytic terms, convexity is equivalent to an inequality relation (see 17). The function $G(x)$ on S is concave if and only if $F(x) = -G(x)$ is convex. A useful property of any convex function $F(x)$ defined on the convex set S is that the set of all points in S such that $F(x) \leq 0$ is a convex set. (But the set of vectors x , such that $F(x) = 0$, is not necessarily convex.)

When a quadratic function has the property that its quadratic part (see 18) is nonnegative for all choice of values for x_i , x_j , then $Q(x)$ is a convex function. Linear functions are both convex and concave.

If $f(x)$ and $h_1(x), \dots, h_l(x)$ are convex functions, defined for each vector x appearing as the argument of the functions, then the problem of minimizing $f(x)$ subject to $h_j(x) \leq 0$ ($j = 1, \dots, l$) is called the convex programming problem. One important property of convex functions is the sufficiency of local conditions for identifying a minimum. If f is a convex function on the convex set S and x^0 is a point of S such that $f(x^0) \leq f(x)$ for all x in S that are sufficiently close to x^0 , then x^0 is also a (global) minimum of f on S ; that is, $f(x^0) \leq f(x)$ for all x in S . This property can be exploited in computational procedures aimed at calculating optimal solutions of convex programming problems.

Methods of solution. The question of identifying optimal solutions of nonlinear programs is often discussed assuming that the constituent functions are differentiable. The simplest such case is the unconstrained minimization of a differentiable function $f(x)$. If $x^0 = (x_1, \dots, x_n)$ is an optimal solution, then the gradient vector of f at x^0 vanishes (see 19). Geometrically, this means that the tangent plane to the graph of f at the point $[x^0, f(x^0)]$ is horizontal. For a convex function f , the vanishing of the gradient is enough to guarantee that the point x^0 is a (global) minimum of f . But in general, the vanishing of the gradient can occur at points that are not even local minima, namely, at saddle points and local maxima.

The equality-constrained minimization problem is of the form: minimize $f(x)$ subject to $g_i(x) = 0$ for $i = 1, \dots, m$ and $m < n$. If the functions f, g_1, \dots, g_m are differentiable, the attempt to isolate a (local) minimum point x^0 for this problem by finding numbers

$\lambda_1, \dots, \lambda_m$ such that $\nabla f(x^0) = \sum_{i=1}^m \lambda_i \nabla g_i(x^0)$ is called the

method of Lagrange multipliers (see 20). In this approach, one looks for unconstrained (local) minima of an associated Lagrangian function (see 21).

When all the constituent functions are differentiable, there is an analogous result on the necessary conditions of optimality for inequality-constrained minimization problems (see 22). These necessary conditions are closely related to the Kuhn-Tucker conditions. The mathematicians H.W. Kuhn and A.W. Tucker of the United States showed in a now classic, nonlinear programming paper that if a certain regularity condition holds, a relation is true between the gradient of f and the gradients of subsidiary

Convex
quadratic
program-
ming
problems

functions h_j at an optimal solution x^0 . In particular, if f and the functions h_j are convex, then a solution x^0 that satisfies stated conditions for some vector λ of multipliers is a global minimum.

Some methods for solving convex quadratic programming problems are closely related to the simplex method for linear programming and share with it the feature of terminating after only a finite number of iterations. Most of these methods make use of the Kuhn-Tucker conditions because the differentiability and regularity requirements are automatically satisfied. These characteristics are seldom found in nonlinear programming procedures in general. Instead of leading in a finite number of steps to an exact solution, they (at best) yield a point close to a point at which a local minimum is attained.

One of the historically important ancestors of nonlinear programming methods is the method of steepest descent due to the 19th-century French mathematician Augustin-Louis Cauchy. Its original application was to solving systems of nonlinear equations. For example, to solve the system of simultaneous equations $g_i(x) = 0$, ($i = 1, \dots, m$) a sum of squares of the functions appearing in the equations can be formed (see 23). An attempt can be made to obtain its unconstrained minimum. For every vector x , the functional value $f(x)$ is nonnegative because it is the sum of squares. Consequently, x^0 is a solution if and only if $f(x^0) = 0$.

The method is easily stated: From a starting point (trial solution) $x^{(1)}$, compute the direction of steepest descent, $-\nabla f(x^{(1)})$. Using a fixed step size, symbolized by the Greek letter sigma, σ , minimize the function f along the line segment of length σ issuing from $x^{(1)}$ in the direction of steepest descent. The point $x^{(2)}$ that minimizes $f(x)$ along this line segment becomes the new trial solution. In general, the preceding step is repeated from at each trial solution $x^{(k)}$ to obtain the next one $x^{(k+1)}$.

The method of steepest descent is valid under the assumption that the function f is continuously differentiable, and all points satisfying $f(x) \leq f(x^{(1)})$ lie within a fixed finite distance from the origin. The aim of the procedure is actually to locate a point x^* satisfying the necessary local conditions of optimality: $\nabla f(x^*) = 0$. Because such a point might be reached only in a limiting sense, it is customary to terminate the computational process when a point $x^{(k)}$ is reached at which the absolute value $|\partial f(x^{(k)}) / \partial x_j|$ is less than a prescribed value for $j = 1, \dots, n$. If the function f being minimized is convex, a point x^* at which $\nabla f(x^*)$ is zero must be a global minimum.

Another method deals with the linearly-constrained nonlinear programming problem: Minimize $f(x)$ subject to $Ax = b$, $x \geq 0$ in a manner that uses both linear programming and the Kuhn-Tucker conditions. It is assumed that the objective function $f(x)$ is continuously differentiable. It is then natural to replace f by its linear approximation at a feasible point and solve the associated linear program. For example, if $x^{(k)}$ is a feasible point, f can be replaced by its linear approximation (see 24). Assuming that $y^{(k)}$ is the solution of this linear program, a search can then be performed to minimize f along the line joining $x^{(k)}$ to $y^{(k)}$. The point $x^{(k+1)}$ at which the latter minimum is attained becomes the new trial solution at which the linear approximation to f can be formed for the repetition of the process. The computation can be interrupted if a point x^0 is reached at which the solution point y^0 of the associated

linear programming problem satisfies $\nabla f(x^0)(y^0 - x^0) \geq 0$. It can be shown that the point x^0 must be optimal when the objective function f is convex.

Of the many algorithms for the solution of nonlinear programming problems, none is known to be superior to the generalized reduced-gradient method. Its roots lie in the reduced-gradient method (for linearly-constrained nonlinear programs) and ultimately in the simplex method itself. (G.B.D./R.W.Co.)

Cybernetics

The presentation to follow deals only with the principles of cybernetics and includes reference to mathematical aspects such as information theory, automata theory, and cybernetic systems. The technological aspects of cybernetics are multifold and can be found in INFORMATION PROCESSING AND INFORMATION SYSTEMS and AUTOMATION.

DEFINITIONS OF THE TERM CYBERNETICS

The term cybernetics comes from the ancient Greek word *kybernētikos* ("good at steering") referring to the art of the helmsman. In the first half of the 19th-century, the French physicist André-Marie Ampère, in his classification of sciences, suggested that the still nonexistent science of the control of governments be called cybernetics. This term was soon forgotten until used by the United States mathematician Norbert Wiener as the title for his book published in 1948. In that book Wiener made reference to an 1868 article by the British physicist James Clerk Maxwell on governors and pointed out that "governor" is derived, via Latin, from the same Greek word that gives rise to the term "cybernetics." The date of Wiener's publication is generally accepted as the date of the birth of cybernetics as an independent science. Wiener defined cybernetics as "the science of control and communications in the animal and machine." This definition relates cybernetics closely first of all with the theory of automatic control and with physiology, particularly the physiology of the nervous system. Subsequently, the computer and the areas of mathematics related to it (e.g., mathematical logic) had a great influence on the development of cybernetics. The reason is that the computer can be used not only for automatic calculation, but also for all conversions of information, including various types of information processing used in control systems. This ability made two different views of cybernetics possible. The narrower view, common in the Western countries, defines cybernetics as the science of control of complex systems of various types (technical, biological, and social). In many countries (for example, in the United States), particular emphasis is given to those aspects of cybernetics that are used in the generation of control systems in technology and in living organisms. In addition to cybernetics, the science of computers and the general rules of information processing is being developed in the Western countries (English—computer science; French—*informatique*).

The broader interpretation of the subject of cybernetics common in the Soviet Union includes not only control but all forms of information processing. This definition includes therefore the Western computer science as one of the component parts of cybernetics.

PRINCIPLES

Information theory. It should be emphasized that the concept of information and its conversion is an important first concept of cybernetics no matter how its subject is defined. Information arises with any act of selection or limitation of possibilities of selection. For example, if it is known that a room can contain 100 men, then the message that the room at a given moment contains 50 men or that the number of people in the room is less than 40 carries information. The message that the number is less than 200 carries no information, because the first, fixed selection is in no way thus limited. In developing the principle of limitation of selection, Claude E. Shannon, an electrical engineer in the United States, introduced the method of changing the quantity of information.

Information is transmitted by signals. In pure cybernetics,

$$(22) \quad \begin{cases} \text{Minimize } f(x) \text{ subject to } h_j(x) \leq 0 \text{ for } j = 1, \dots, l, \\ \text{Then } x^0 \text{ is a locally minimizing solution only if there} \\ \text{exist multipliers } \lambda_0, \lambda_1, \dots, \lambda_l \text{ not all zero such that} \\ \lambda_0 \nabla f(x^0) = \lambda_1 \nabla h_1(x^0) + \dots + \lambda_l \nabla h_l(x^0) \text{ and} \\ h_j(x^0) \leq 0, \quad \lambda_j \geq 0, \quad \lambda_j \cdot h_j(x^0) = 0 \text{ for } j = 1, \dots, l. \end{cases}$$

$$(23) \quad f(x) = [g_1(x)]^2 + \dots + [g_m(x)]^2$$

$$(24) \quad F(y) = f(x^k) + \nabla f(x^k)(y - x^k)$$

The nature and types of signals

the physical nature of the signals is completely disregarded. It is important only that the signals can be differentiated from each other. The form of the set of possible signals and the nature of their changes are also significant. For example, a signal carrying information on the number of persons in a room cannot take on fractional values. The values of these signals change in jumps. On the other hand, a signal giving information of the temperature of the air in the room cannot change its value, say from 19° C to 20° C, without passing through all intermediate values. Signals of the first type are called discrete and of the second type, continuous. The same terms are used in relation to the information represented by these signals.

In describing continuous information within a certain accuracy, it can always be reduced to discrete information. The usual method of representation of discrete information is as a finite sequence of signals selected from a certain fixed finite set of signals called the (abstract) alphabet, for example the set of letters in the Latin alphabet, the set of decimal numbers, etc. One important but simple fact is the possibility of representing any discrete information in the form of sequences of signals of only two different types, as is done, for example, in the dots and dashes of the well-known Morse telegraph code. Problems of various forms of representation of discrete information make up the subject of a special division of theoretical cybernetics called encoding theory.

Automata as information converters. Encoding is the simplest form of information conversion. In the general case, these conversions are performed by so-called information converters, or data processors. An information converter, referred to in cybernetics as a machine or automaton (see AUTOMATA THEORY), is a device that converts a certain set of signals called the input signals to another set, the set of output signals. The input signals arrive at the converter through the input channels, the output signals leave through the output channels. Furthermore, in the general case, the processor can store signals in the form of a certain set of parameters, the different values of which determine the internal state of the processor, that is, the condition of its memory.

A processor is called continuous if all of the parameters that define it (memory, input, and output signals) are continuous. In the case of discrete processors, all of these signals must be discrete. Processors dealing both with continuous and with discrete signals are called hybrid processors.

The changes in output signals and in the internal state of any processor depend generally both on the input signals and on the internal state of the processor at a given time. For a processor without memory, the values of the output signals at any moment in time depend only on the values of the input signal at the same moment in time. If all of these dependences are fixed by fully defined, unambiguous functions (e.g., single-valued), the processor is called deterministic. If there are random dependences, the processor is called probabilistic.

Information processors in which no functional components and no internal structural parts other than those described above can be distinguished are called elementary. Nonelementary processors, also called cybernetic systems, consist of networks composed of elementary (or in any case simpler) processors. A network is constructed by connecting some (or all) of the output channels of the processors composing the network to some (or all) of their input channels. A portion of the input and output channels of the elementary processors may be appropriately connected to the input and output signals of the entire system.

The concept of elementariness or nonelementariness of a processor is relative and depends on the depth of penetration into the subject. For example, if interest is confined to the functions of the brain, not in its structure, it can be analyzed as an elementary processor (although it is characterized by a tremendous number of parameters). It is known, however, that the brain is an extremely complex system, composed of more elementary processors, the neurons. In turn, upon transition to the molecular level, the neurons themselves can be regarded as extremely complex cybernetic systems.

Study of systems. The study of systems and particularly of the complex probabilistic systems is one of the most important tasks in cybernetics. The specific feature of the cybernetic approach to the study of systems is that it abstracts itself from the actual nature of the elements of the system and the signals circulating in it. This allows a general mathematical apparatus and general methods of investigation to be developed, suitable for systems of varying nature and purpose. In the study of continuous cybernetic systems, a system of ordinary differential equations is particularly significant.

Theory of algorithms. In the discrete case, the *modus operandi* is the so-called theory of algorithms. An algorithm is an arbitrary, finite system of rules of any nature, allowing expressions in any alphabet to be converted to new expressions in the same (or any other) alphabet. So-called algorithmic languages are used for precise descriptions of the rules for these conversions (see AUTOMATA THEORY: *Classification of automata*).

It is extremely important that the presence in an algorithmic language of a relatively small number of means of expression can give it the property of universality. Universality of an algorithmic language means the possibility of expressing in this language any conversion of discrete information that can be defined using a finite number of rules, that is, expressed as a certain algorithm in any other algorithmic language.

The fact of existence of universal algorithmic languages means that it is possible to construct universal discrete information processors. To do this, it is sufficient to fix upon some concrete alphabet and to construct a memory device capable of storing any word (expression) in the alphabet and a device capable of performing all of the elementary rules of a certain universal algorithmic language.

Universal digital computers are such universal information processors if the limitations resulting from their finite memory volume are not considered. Until computers appeared, the only universal data processor was the natural information processor, the human brain.

The availability of technical universal data processors is highly significant for the development of cybernetics in at least two ways. First of all, this fact opens unlimited possibilities for the automation not only of the physical, but also of the mental activity of man, and this automation does not require that new technical devices be invented for each case. It is sufficient to study and describe the rules defining the type of activity to be automated and to program them; i.e., express them in one of the algorithmic languages used in existing computers.

Mathematical modelling. Second, the use of universal data processors—computers—gives cybernetics a method of scientific investigation of systems that is new in principle—so-called mathematical modelling. Until this method appeared, scientists actually had only two different methods of study: experimental and theoretical. In the former, experiments were performed only with the system itself, or with an actual, physical model of the system. In the second, it was necessary to be able to solve equations describing the system.

Mathematical modelling occupies an intermediate position between these two methods: there is no necessity to construct an actual physical model of the system. It is replaced by a mathematical model; i.e., a description of the system in some algorithmic language. There is also no need to solve complex mathematical problems related to this description (i.e., to solve systems of differential equations). The description of the system is simply entered into a computer that models the behaviour of the system (i.e., provides precise descriptions of the system) under various conditions defined according to the purpose of the research assignment.

This method allows the scientist to produce a full description of complex systems, the individual parts of which are studied by different people or even in different sciences. One example is the human organism. Its individual parts (circulatory system, digestive system, nervous system, glandular system, etc.) are studied by different specialists, even though the parts are closely related to each other.

To produce a mathematical model of the organism, first

The cybernetic approach to systems study

Modelling the human organism

of all it must be divided into individual parts and the state of each part described by some system of parameters. Among these parameters might be continuous quantities (for example, the percent content of sugar in the blood) or discrete quantities (for example, qualitatively differing levels of secretory function of the liver). The next step is description of the relationships between the separate parts. One of the most typical forms of relationship for this example is expressed by a sentence such as: When organ A shifts from state m_1 to state m_2 , and organ B shifts from state n_1 to state n_2 after k days (weeks, months), organ C will change its state from l_1 to l_2 with probability p . The specialists must describe all of the relations of this type with which they are familiar (called simple relationships) to form the required mathematical model. Operations with this model in the computer permit the establishment of the complex relationships (*i.e.*, the influence of organs on other organs not directly, but through still other organs). This type of model can be used to study versions of the development of various diseases, various methods of treatment, etc.

Mathematical modelling can in principle be performed in any universal data processor, including the human brain. The brain, however, being a very complex system itself, is comparatively poorly suited for such routine but laborious work as the modelling of complex systems. Consequently, only the appearance of the computer provided a qualitative jump and made it possible to perform effective study of really complex systems in various areas of knowledge. Actually, the concern is with coarse qualitative criteria, differentiating simple systems from complex; if the structure and behaviour of a system can be studied by a single man in a reasonable time, the system is called simple. If the efforts of many persons and the use of special technical equipment (computers) are required to draw the whole picture, the system is called complex.

Cybernetic systems. *Self-teaching mechanisms.* Complex tasks arise in so-called self-teaching systems, in which attempts to achieve a certain final goal lead to changes in the methods of its attainment, and the setting of various intermediate goals. One of the simplest examples of this type of system is the so-called Shannon's mouse. It is a moving automaton placed in a maze. The final purpose of the automaton is to find the "food" placed at some point in the maze.

Shannon's
mouse

At first, the mouse uses a simple trial and error algorithm, bumping into the walls until an exit is found. During the process of this type of search, it "learns" and memorizes the plan of the maze. After once reaching the goal (by chance), the mouse will use an entirely different, much more economical, and seemingly "intelligent" algorithm for reaching the goal in a subsequent experiment, based on "knowledge" of the layout of the maze.

Self-teaching is one type of self-improvement of control systems. In this case, the improvement occurs without changing the structure of the system. It is also possible, however, that the upper levels of a system may change the structure of lower levels in order to improve their functioning. This type of self-improvement is naturally called self-development.

Methods have been designed for the quantitative definition of self-improvement. In this case, in pure theory, the boundary between self-teaching and self-development disappears. In practice, however, the difference between these types of self-improvement is usually rather clear.

Biocybernetics. Many control systems in biology are constructed according to the principles of self-teaching and self-development. For example, in all probability, only a small portion of the organization of the human brain is determined genetically. Everything else is produced as a result of the effects of many, rather effective, mechanisms of self-improvement.

Highly complex examples of self-development can be found in the processes of biological evolution, as well as various social processes.

For systems of the high degree of complexity characteristic of living organisms and human society, an ever greater role is played not just by control processes, but by cognition processes. These systems have highly perfected

systems of sensors and effectors (for example, the eye and the hand), capable of recognizing complex patterns and performing widely varied actions. The central portion of the system has a multilevel structure; the upper links of the structure develop abstract concepts and recognize the deeper regularities existing both in the system itself and in its surroundings.

By the last quarter of the 20th century, cybernetics had achieved significant success in the solution of the problem of pattern recognition, automation (by computer) of the processes of logical conclusion, formation of new concepts, and other problems. This success has allowed the creation of universal robots controlled by computers and imitating rather complex forms of conscious behaviour. (Ed.)

Control theory

GENERAL BACKGROUND

As long as human culture has existed, control has always meant some kind of power over man's environment. Cuneiform fragments suggest that the control of irrigation systems in Mesopotamia was a well-developed art at least by the 20th century BC. There were some ingenious control devices in the Greco-Roman culture, the details of which have been preserved. Methods for the automatic operation of windmills go back at least to the Middle Ages. Large-scale implementation of the idea of control, however, was impossible without a high-level of technological sophistication, and it is probably no accident that the principles of modern control started evolving only in the 19th century, concurrently with the Industrial Revolution. A serious scientific study of this field began only after World War II and is now a major aspect of what has come to be called the second industrial revolution.

Although control is sometimes equated with the notion of feedback control (which involves the transmission and return of information)—an isolated engineering invention, not a scientific discipline—modern usage tends to favour a rather wide meaning for the term; for instance, control and regulation of machines, muscular coordination and metabolism in biological organisms, prosthetic devices; also, broad aspects of coordinated activity in the social sphere such as optimization of business operations, control of economic activity by government policies, and even control of political decisions by democratic processes. Scientifically speaking, modern control should be viewed as that branch of system theory concerned with changing the behaviour of a given complex system by external actions. (For aspects of system theory related to information, see below.) If physics is the science of understanding the physical environment, then control should be viewed as the science of modifying that environment, in the physical, biological, or even social sense.

Much more than even physics, control is a mathematically-oriented science. Control principles are always expressed in mathematical form and are potentially applicable to any concrete situation. At the same time, it must be emphasized that success in the use of the abstract principles of control depends in roughly equal measure on the status of basic scientific knowledge in the specific field of application, be it engineering, physics, astronomy, biology, medicine, econometrics, or any of the social sciences. This fact should be kept in mind to avoid confusion between the basic ideas of control (for instance, controllability) and certain spectacular applications of the moment in a narrow area (for instance, manned lunar travel).

EXAMPLES OF MODERN CONTROL SYSTEMS

To clarify the critical distinction between control principles and their embodiment in a real machine or system, the following common examples of control may be helpful. There are several broad classes of control systems, of which some are mentioned below.

Machines that cannot function without (feedback) control. Many of the basic devices of contemporary technology must be manufactured in such a way that they cannot be used for the intended task without modification by means of control external to the device. In other words, control is introduced after the device has been built; the same

Examples
of feedback
control

The role of computers in feedback control

effect cannot be brought about (in practice and sometimes even in theory) by an intrinsic modification of the characteristics of the device. The best known examples are the vacuum-tube or transistor amplifiers for high-fidelity sound systems. Vacuum tubes or transistors, when used alone, introduce intolerable distortion, but when they are placed inside a feedback control system any desired degree of fidelity can be achieved. A famous classical case is that of powered flight. Early pioneers failed, not because of their ignorance of the laws of aerodynamics, but because they did not realize the need for control and were unaware of the basic principles of stabilizing an inherently unstable device by means of control. Jet aircraft cannot be operated without automatic control to aid the pilot, and control is equally critical for helicopters. The accuracy of inertial navigation equipment (the modern space compass) cannot be improved indefinitely because of basic mechanical limitations, but these limitations can be reduced by several orders of magnitude by computer-directed statistical filtering, which is a variant of feedback control.

Control of machines. In many cases, the operation of a machine to perform a task can be directed by a human (manual control), but it may be much more convenient to connect the machine directly to the measuring instrument (automatic control); e.g., a thermostat (temperature-operated switch) may be used to turn on or off a refrigerator, oven, air-conditioning unit, or heating system. The dimming of automobile headlights, the setting of the diaphragm of a camera, the correct exposure for colour prints may be accomplished automatically by connecting a photocell or other light-responsive device directly to the machine in question. Related examples are the remote control of position (servomechanisms), speed control of motors (governors). It is emphasized that in such case a machine could function by itself, but a more useful system is obtained by letting the measuring device communicate with the machine in either a feedforward or feedback fashion.

Control of large systems. More advanced and more critical applications of control concern large and complex systems the very existence of which depends on coordinated operation using numerous individual control devices (usually directed by a computer). The launch of a spaceship, the 24-hour operation of a power plant, oil refinery, or chemical factory, the control of air traffic near a large airport, are well-known manifestations of this technological trend. An essential aspect of these systems is the fact that human participation in the control task, although theoretically possible, would be wholly impractical; it is the feasibility of applying automatic control that has given birth to these systems.

Biocontrol. The advancement of technology (artificial biology) and the deeper understanding of the processes of biology (natural technology) has given reason to hope that the two can be combined; man-made devices should be substituted for some natural functions. Examples are the artificial heart or kidney, nerve-controlled prosthetics, and control of brain functions by external electrical stimuli. Although definitely no longer in the science-fiction stage, progress in solving such problems has been slow not only because of the need for highly advanced technology but also because of the lack of fundamental knowledge about the details of control principles employed in the biological world.

Robots. On the most advanced level, the task of control science is the creation of robots. This is a collective term for devices exhibiting animal-like purposeful behaviour under the general command of (but without direct help from) man. Industrial manufacturing robots are already fairly common, but real breakthroughs in this field cannot be anticipated until there are fundamental scientific advances with regard to problems related to pattern recognition and the mathematical structuring of brain processes.

PRINCIPLES OF CONTROL

The scientific formulation of a control problem must be based on two kinds of information: (A) the behaviour of the system (e.g., industrial plant) must be described in a mathematically precise way; (B) the purpose of control

(criterion) and the environment (disturbances) must be specified, again in a mathematically precise way.

Information of type A means that the effect of any potential control action applied to the system is precisely known under all possible environmental circumstances. The choice of one or a few appropriate control actions, among the many possibilities that may be available, is then based on information of type B; and this choice, as stated before, is called optimization.

The task of control theory is to study the mathematical quantification of these two basic problems and then to deduce applied-mathematical methods whereby a concrete answer to optimization can be obtained. Control theory does not deal with physical reality but only with its mathematical description (mathematical models). The knowledge embodied in control theory is always expressed with respect to certain classes of models, for instance, linear systems with constant coefficients, which will be treated in detail below. Thus control theory is applicable to any concrete situation (e.g., physics, biology, economics) whenever that situation can be described, with high precision, by a model that belongs to a class for which the theory has already been developed. The limitations of the theory are not logical but depend only on the agreement between available models and the actual behaviour of the system to be controlled. Similar comments can be made about the mathematical representation of the criteria and disturbances.

Once the appropriate control action has been deduced by mathematical methods from the information mentioned above, the implementation of control becomes a technological task, which is best treated under the various specialized fields of engineering. The detailed manner in which a chemical plant is controlled may be quite different from that of an automobile factory, but the essential principles will be the same. Hence further discussion of the solution of the control problem will be limited here to the mathematical level.

To obtain a solution in this sense, it is convenient (but not absolutely necessary) to describe the system to be controlled, which is called the plant, in terms of its internal dynamical state. By this is meant a list of numbers (called the state vector) that expresses in quantitative form the effect of all external influences on the plant before the present moment, so that the future evolution of the plant can be exactly given from the knowledge of the present state and the future inputs. This situation implies, in an intuitively obvious way, that the control action at a given time can be specified as some function of the state at that time. Such a function of the state, which determines the control action that is to be taken at any instant, is called a control law. This is a more general concept than the earlier idea of feedback; in fact, a control law can incorporate both the feedback and feedforward methods of control.

In developing models to represent the control problem, it is unrealistic to assume that every component of the state vector can be measured exactly and instantaneously. Consequently in most cases the control problem has to be broadened to include the further problem of state determination, which may be viewed as the central task in statistical prediction and filtering theory. Thus, in principle, any control problem can be solved in two steps: (1) Building an optimal filter (so-called Kalman filter) to determine the best estimate of the present state vector; (2) determining an optimal control law and mechanizing it by substituting into it the estimate of the state vector obtained in step 1.

In practice, the two steps are implemented by a single unit of hardware, called the controller, which may be viewed as a special-purpose computer. The theoretical formulation given here can be shown to include all other previous methods as a special case; the only difference is in the engineering details of the controller.

The mathematical solution of a control problem may not always exist. The determination of rigorous existence conditions, beginning in the late 1950s, has had an important effect on the evolution of modern control, equally from the theoretical and the applied point of view. Most important is controllability; it expresses the fact that some

Basic task

Control-ability

kind of control is possible. If this condition is satisfied, methods of optimization can pick out the right kind of control using information of type B.

CONTROL OF LINEAR SYSTEMS

Systems with constant coefficients. The preceding considerations may be illustrated much more directly by taking the special case of linear systems with constant coefficients. The point of view and most of the results described below originated after 1950, but the beginnings of the theory are more than 100 years old dating from Maxwell's work published in 1868. In fact, this class of models is the only one for which a reasonably complete mathematical theory of control exists so far.

One may denote by $y(t)$ the number giving the value of the output of the plant at time t ; similarly, the number $u(t)$ denotes the value of the input to the plant at the same time. A classical way to describe the behaviour of the plant (information of type A) is to assume that the input and output are related by a linear differential equation with constant coefficients $\alpha_1, \dots, \alpha_n$ (see 25), which is called the open-loop equation of the plant. In this case the state vector is the list $(y(0), \dots, y^{(n-1)}(0))$ consisting of the output at time $t=0$ and the first $n-1$ derivatives with respect to time of the function $y(t)$ at $t=0$. Under these circumstances, the control law is a linear combination of the state variables, with coefficients β_1, \dots, β_n (see 26).

The fact that this control law is linear in the state is an assumption needed to assure the manageability of mathematical machinery for the problem. It is desirable to assume also that the coefficients β_1, \dots, β_n are all constants so that the same formula can be used at any time. [A minus sign in the control law (26) expresses the classical idea of negative feedback; in the general theory, this has become merely a notational convention.]

Substitution of the control law into the linear differential equation of the plant (25) leads to the closed-loop differential equation for the controlled output of the plant (see 27). Here the coefficients γ_i are the differences $\alpha_i - \beta_i$. So the effect of control is to replace the coefficients α_i of the open-loop equation with the γ_i of the closed-loop equation. Since the β_i in the control law are arbitrary, it follows that arbitrary changes can be effected in the dynamical behaviour of the plant by means of control. In particular, it is possible to make a plant stable by means of the control law because the criterion for stability is given by

The
criterion
for stability

$$(25) \quad \frac{d^n y}{dt^n} + \alpha_1 \frac{d^{n-1} y}{dt^{n-1}} + \dots + \alpha_n y = u(t)$$

$$(26) \quad -u(0) = \beta_n y(0) + \beta_{n-1} \dot{y}(0) + \dots + \beta_1 y^{(n-1)}(0)$$

$$(27) \quad \frac{d^n y}{dt^n} + \gamma_1 \frac{d^{n-1} y}{dt^{n-1}} + \dots + \gamma_n y = 0$$

$$(28) \quad \gamma_1 > 0, \quad \begin{vmatrix} 1 & \gamma_2 \\ \gamma_1 & \gamma_3 \end{vmatrix} > 0, \dots$$

$$(29) \quad \frac{dx}{dt} = Fx + gu(t), \quad y(t) = \langle h, x(t) \rangle$$

$$(30) \quad F = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & 1 \\ -\alpha_n & -\alpha_{n-1} & -\alpha_{n-2} & \dots & -\alpha_1 \end{bmatrix}, \quad g = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}$$

$$(31) \quad \det[g \quad Fg \quad F^2g \quad \dots \quad F^{n-1}g] \neq 0$$

the positiveness of the Routh-Hurwitz determinants (see 28). These conditions can of course always be met since the γ_i can be arranged to have any values.

It is necessary to comment on this seemingly overly general (but indeed correct) result from two points of view. First the result assumes that the plant description (see 25) is exactly true and that the state list $(y(t), \dots, y^{(n-1)}(t))$ is known at every time t . These assumptions are never exactly correct, but they can be approximated in many cases with sufficient accuracy by restricting the output $y(t)$ to small deviations about a given steady-state value and by constructing a statistical filter to estimate the derivatives of the function $y(t)$ with respect to t . Second, the model (see 25) does not represent the most general linear system with constant coefficients; in fact, this model, because of its special form, implicitly possesses the property of controllability that may not hold for the general model in the linear, constant coefficient class.

The most general system of this class (with one input and one output) is given by a pair of state-vector equations (see 29); the symbol x denotes the state vector (a list of n arbitrary numbers), F is an $n \times n$ matrix, g is an n -vector, h is an n -vector, and \langle, \rangle is the inner product; the symbols $u(t)$ and $y(t)$ have the same meaning as above. The equations of the plant discussed above (see 25) can always be transformed into the general case (see 29), but not necessarily vice versa.

Transforming the plant equations discussed above to the general form gives the canonical matrices F, g (shown in 30). If these expressions are substituted into the controllability criterion (see 31) for the general system (29), it is seen that the special model for the plant that was used above (25) is always controllable. Thus, it is clear that the true significance of the celebrated controllability concept can be grasped only after the control problem has been formulated in the state-vector style. In the classical development of control theory, too much emphasis was placed on special models for the plant (25); the advances since 1950 to a large extent resulted from a recognition that the most general model corresponding to the basic restrictive hypotheses of linearity and constant coefficients is given by the state-vector equations (29); this recognition eventually led to the discovery that for the general class there is a nontrivial controllability condition (31).

The explicit form of the controllability condition is of great practical and philosophical importance. It is a generic condition: it is satisfied by almost all systems of the linear, constant-coefficient class. Because the state-vector equations (29) accurately represent most physical systems making only small deviations about their steady-state behaviour, it follows further that in the natural world control in the small is, in principle, almost always possible. This fact of nature is the theoretical basis of practically all the presently existing control technology. On the other hand, little is known at present, in the scientific sense, about the ultimate limitations of control when the models in question are not linear. In particular, it is not known under what conditions control is possible in the large; that is, for arbitrary deviations from existing conditions. This lack of scientific knowledge should be kept in mind in assessing often exaggerated claims by economists and sociologists in regard to a possible improvement in human society by governmental control.

Optimal control. To reduce the arbitrariness of the control law (see 26), it is necessary to use information of type B. This is done, conceptually, in the following way. It is assumed (after a change of variables, if necessary) that the state $x=0$ represents the ideal condition of the plant to be controlled. Any given state $x(0)$ not equal to zero at time $t=0$ is regarded as an undesirable deviation, attributed to unavoidable disturbances acting on the system. The task of control is to restore the ideal condition $x(t)=0$ in the best possible way. The specification of a suitable optimality criterion is frequently dictated by mathematical expediency.

The long mathematical history of the calculus of variations has suggested that the most natural criterion to consider is the minimization of an integral from zero to infinity, which measures the deviation of $x(t)$ from zero as

Control
limita-
tions in
nonlinear
modelling

well as the cost of control. For example, the coefficients in the control law may be explicitly determined by minimizing a quadratic integral (see 32) by the choice of the function $u(t)$ with respect to solutions of the open-loop differential equation (see 25). The applied-mathematical technique for solution is well developed and requires the solution of a nonlinear differential equation of the Riccati type, which can be conveniently carried out by digital computer. It can be shown also that this general procedure includes older techniques based on semi-quantitative engineering analyses, for instance, the idea of maximizing the loop gain.

In many respects, optimization theory represents a satisfactory solution of the control problem (in some cases even outside the linear case), but basic difficulties remain in regard to the appropriate choice of the criterion represented by the quadratic forms in the performance index (see 32).

Optimal filtering and state estimation. At least in the linear case, the solution of the state-estimation problem can be accomplished by methods similar to that for optimal control; this follows from the well-known Duality Principle which states that the dual equations (matrices

$$(32) \quad \int_0^\infty [Q(x(t)) + R(u(t))] dt \quad (Q, R \text{ are quadratic forms})$$

and vectors replaced by their transposes) of control optimization are the equations for state estimation. The optimal filter is then a dynamical system similar to (25), in which the principal task is to determine a dual control law similar to (26).

In practice, the state estimation problem is much more important than the control problem; approximately 90–95 percent of practical controllers are devoted to state estimation, only about five percent being required for the implementation of the control law.

NONLINEAR CONTROL SYSTEMS

Whenever the controlled variable $y(t)$ is allowed to have large deviations from the steady state, the linear constant-coefficient model will cease to represent the plant accurately because of intrinsic nonlinearities involved in the description of most natural dynamical phenomena. Equally important are intentionally introduced nonlinearities that result from reasons of economy, simplicity and reliability of engineering, or from ignorance of the fact that the savings achieved by nonlinear control devices may be negated by factors resulting from the greater intrinsic difficulty of control. A good example of unavoidable nonlinearities in the object to be controlled is a space vehicle whose rockets, at the current state of technology, can only be controlled by turning them on or off. Continuously variable control action (which is desirable) in this case is technologically impossible; the high cost of rocket engines, however, justifies extremely sophisticated computer-based technology to achieve optimal control. The purpose of the computer is then simply one of switching the rockets on or off; the difficulty of the control lies in the extreme precision with which the time must be determined when this takes place.

When the basic mathematical data can be stated in the conventional optimization framework, effective methods are available for solving the optimal control problem even in the nonlinear case. The methods for doing this are an extension of the classical methods of the calculus of variations. These methods, however, have yielded little theoretical insight and their straightforward application becomes prohibitively expensive for large-scale systems.

Even less satisfactory is the status of the nonlinear optimal filtering and state estimation problem, which, as has been noted, is a critical part of the general solution of the control problem. Because of nonlinearity, the Duality Principle no longer applies; even the formulation of the problem is controversial.

Nonlinear systems do not represent a special case, but simply everything that is not subjected to the special assumption of linearity; in a sense “nonlinear” is synonymous with “unknown.” Scientific progress will undoubtedly occur by singling out special classes of systems subject to restrictive structural assumptions other than linearity.

linearity

Ōsaka-Kōbe Metropolitan Area

The Ōsaka-Kōbe metropolitan area is the second largest urban and industrial agglomeration in Japan. It is located on Ōsaka Bay at the eastern end of the Inland Sea. The cities of Ōsaka and Kōbe are at the centre of what is called by geographers the Hanshin Industrial Zone; as a result of the expansion of the urban area along the Inland Sea and northeast toward the city of Kyōto, the region is now included in the larger Keihanshin Industrial Zone. Neither of these zones is a political entity, but the larger of the two corresponds to the Kansai, one of Japan's traditional cultural areas. The Kansai, a region of ancient

cities, is the birthplace of the earliest Japanese state. It is an area of historically dense population that until well into the 20th century was the most industrialized and economically advanced part of Japan.

Ōsaka is the capital of Ōsaka *fu* (urban prefecture), an administrative division that includes the city of Ōsaka and large urban and rural areas. Kōbe is the capital and largest city of Hyōgo *ken* (prefecture) and one of Japan's chief ports. There are many satellite industrial and residential cities around the two central cities.

Physical and human geography

THE LANDSCAPE

River
deltas and
uplands

The city site. The city of Ōsaka is situated on the delta of the Yodo River. To the east of the central city, Ōsaka Castle, originally built by Toyotomi Hideyoshi, stands on a northern extension of the upland (about 65 feet [20 metres] above sea level) that rises in the southern part of Ōsaka urban prefecture to more than 3,000 feet. The metropolitan area spreads over the deltas of the Yodo, Yamato, and other rivers and into their diluvial uplands. The area is bounded by the Ikoma Mountains in the east, the Izumi Mountains in the south, and the Rokkō Mountains in the northwest. The southwestern boundary of Ōsaka Bay is formed by Awaji Island. On the northwestern shore of the bay is Kōbe, above which rises the granite peak of Mount Rokkō (3,058 feet). The coastline between the two cities has been altered by reclamation for port facilities and industries. Along the coast and in the uplands are the best residential areas of Kōbe and the cities of Ashiya, Nishinomiya, Ikeda, Itami, and Toyonaka. On the delta of the Kanzaki River, just west of Ōsaka, is the city of Amagasaki, a centre of heavy industry. To the north of Ōsaka are the cities of Toyonaka, Suita, and Ibaraki. Above them, on Senri Hill, are new towns developed since the 1960s. Northeast of Ōsaka, along the Yodo River, are the industrial and residential cities of Takatsuki, Moriguchi, Neyagawa, and Hirakata. To the east of Ōsaka are the cities of Kadoma, Higashiōsaka, and Yao. To the southeast are Fujiidera, Tondabayashi, Matsubara, and others, most of them old historical towns. To the southwest, on the coastal plain, are Sakai, Izumi-Ōtsu, Kaizuka, Kishiwada, and Izumi-Sano, some of them industrial and others residential. Urbanization extends to Nara, 25 miles (40 kilometres) east of Ōsaka, and to Kyōto, 25 miles northeast. A dense network of railways and roads winds throughout the area.

Climate. The region has a temperate climate. The annual mean temperature is about 60° F (16° C), and the annual rainfall averages 54 inches (1,370 millimetres). The temperature in August is often 86° F (30° C) or more, with no breeze from the sea at night. The January mean is about 40° F (4° C), and snow falls several times in winter. The rainy seasons are in June-July and September-October. In September the region is usually struck by one or two typhoons. The greatest typhoon disaster in the

area's history occurred in 1934, when 3,000 people were killed. During the rainy season of June-July 1938, huge landslides from the Rokkō Mountains buried wide areas of Kōbe, and floods took the lives of 870 persons.

The citizens of Ōsaka once took pride in its smoky atmosphere as a mark of industrial progress, calling it the "Capital of Smoke" ("Kemuri no miyako"); but by the mid-1970s the city's smog and air pollution were seen as harmful, and during the 1980s improvement of air quality became a priority. Other environmental problems receiving attention include water pollution and subsidence (sinking) of the earth in the Amagasaki region.

The city layout. The streets of central Ōsaka are laid out on a grid plan, but the rest of the city is a patchwork

Street
patterns

Lawrence Smith—Photo Researchers

Ōsaka Castle.

Central Kōbe and Rokkō Mountains, seen from Port Island.

Kurt Scholz—Shostal Associates

of planned grids and rambling streets. The north-south axis is Midō-suji ("Midō Street"), connecting Ōsaka railway station in the north and Namba station in the south. The east-west axis is Chūō Ōdōri ("Central Boulevard"), running from the Central Pier of the Port of Ōsaka in the west to the foot of the Ikoma Mountains in the east. Parallel to Midō-suji is the narrow Shinsaibashi-suji, the central shopping district. Dotombori, at the south end of Shinsaibashi-suji, is a crowded theatre and restaurant area.

The central business district is the northern part of the downtown area. Nakanoshima, an island formed by arms of the Yodo River, contains City Hall, the Central Civic Hall, the Bank of Japan, and the headquarters of the Asahi Press and several large businesses. Until World War II the traditional commercial centres had been Semba and Shimanouchi streets, where old-style white-walled shops with family quarters behind them had existed for centuries.

There are two large *sakariba* (amusement districts) in the city. Kita ("The North") is located just south of Ōsaka railway station, where the city's highest-priced land is found. Kita has a complex of high-rise office buildings and a large underground shopping centre. Minami ("The South") has many theatres and restaurants. Ōsaka's industrial areas are on the lower Yodo delta and in the eastern and northeastern parts of the city.

The street pattern of Kōbe is governed by its location between the mountains and the shore. Main streets run east and west, crossed by short north-south streets and occasional longer streets going up into the hills. The central shopping street, Motomachi, runs between the Sannomiya and Kōbe railway stations. The central business district is near the harbour.

The Ōsaka area has been settled and built upon since prehistoric times; kitchen middens and pottery shards have been found dating to at least 7000 BC. There are many ancient burial mounds from the Tumulus period (c. AD 250–c. 600), and the contents of some of these have helped document the presence of settlers from the Korean peninsula. The ancient villages of the rice farmers were on the marshy plains, while the palaces, shrines, and temples were located on higher ground. Medieval settlements were in the uplands. Some modern residential areas are on the sites of several former settlements. Thus, Tezukayama, a residential development in Ōsaka south of the old castle, is built over a number of ancient mounds.

The central part of Ōsaka is now primarily commercial; since 1920 there has been a migration from the city to the suburbs, helped along by private railway companies that have made suburban building land available along their rights-of-way. The Hankyū Electric Railway was particularly instrumental in developing the city of Toyonaka northwest of Ōsaka. Two of the large postwar housing developments are Senri New Town and Senboku New Town, started in 1961 and 1965, respectively.

About two-thirds of Ōsaka urban prefecture's dwellings are apartment houses. Much of Ōsaka and nearly all of

Kōbe were destroyed during World War II, and inner-city areas are now occupied mostly by Western-style multistoried buildings; traditional architectural styles can still be seen, however, in the Tekijuku, a school of foreign studies (18th century), and the Kōnoike (1708; rebuilt 1853) in Ōsaka, as well as in some residential houses in Kōbe. Examples of early Western-influenced architecture survive on Nakanoshima, including the Bank of Japan building (1903) and the Ōsaka Prefectural Library (1904). The redevelopment of the central business districts of both cities since the 1960s has produced many large, modern, and architecturally innovative buildings: notable examples include the office and hotel complex in front of Ōsaka railway station; the Semba Centre Building, which although only four floors in height extends about three-fifths of a mile along Chūō Ōdōri and is constructed under an elevated expressway and over a subway; and the convention centre built on the man-made Port Island in Kōbe Harbour.

THE PEOPLE

Demographic trends in the Ōsaka-Kōbe metropolitan region parallel two major national trends: sustained urban population growth through rural-urban migration and suburbanization. Thus, the region's population has been swollen for more than a century by a continuous stream of people moving in from rural areas; but the population of the city of Ōsaka—after reaching a peak of about 3,150,000 in the mid-1960s—has declined, as people have migrated from the city to the suburbs. In addition, the city's highest density is not in the centre but in the peripheral wards, because the population decrease has been greatest in the central wards. By contrast, the population of the city of Kōbe has increased steadily, although, like Ōsaka, there has been a loss of population in the inner city and high increases in peripheral wards.

The population of the Ōsaka-Kōbe metropolitan area—like the Kansai region in general—is the most ethnically diverse of Japan. Included are the country's largest concentrations of ethnic Koreans, most of whom are descendants of Koreans who migrated to Japan during the period (1910–45) when Korea was a Japanese colony and who retain Korean nationality; Okinawans, who legally are Japanese but who are treated as internal aliens; and *burakumin*, the term being a euphemism for descendants of an outcaste group that was once legally, though not genetically, distinct from the general Japanese population. All three groups are subject to discrimination in education, employment, marriage, and housing. In Kōbe there are also sizable communities of Chinese, Indians, and Westerners, whose presence contributes an international flavour to the city's culture.

THE ECONOMY

Industry. Ōsaka was once known as the Manchester of the Orient because of its great textile industry; now,

however, its leading industries are the manufacture of iron and steel, fabricated metals, electric machinery, machinery, and chemicals. Between Ōsaka and Kōbe are several other industrial cities. The largest, Amagasaki, is a centre of machinery, metallurgy, chemicals, cement, and paper production. The major industries in Kōbe are shipbuilding and steel production. Heavy industry and chemical plants are situated along the shore of Ōsaka Bay, while light industry and assembly plants are inland.

Commerce. In the past the merchants of Ōsaka greeted one another in the mornings with the query, "Are you making money?" Contemporary merchants and executives continue to greet each other by asking about the state of their businesses. The salutations reflect the traditional importance of commercial enterprise in Ōsaka. The city holds about one-seventh of the nation's wholesale trade.

Ōsaka is Japan's second largest financial centre. Together with Kōbe it is the leading port for foreign trade, handling about one-fifth of all exports.

Railways

Transportation. Ōsaka is an important junction point of the national railway network, handling traffic between the Tokyo region to the northeast and regions farther west and south. Following the privatization of the formerly government-controlled Japanese National Railways (JNR) in 1987, Ōsaka became the headquarters of the West Japan Railway Company (JR Nishi Nihon), which operates passenger service in western Honshu. The region is also served by Shinkansen "bullet" express trains and the national freight rail system, both of which also have become private entities. In addition, there are other privately owned railroads that provide suburban commuter and regional interurban passenger service between Ōsaka and Kōbe and their suburbs and to other major cities in central Honshu, particularly Kyōto and Nagoya. Rail lines also run inland from Kōbe to rural areas of Hyōgo prefecture north of the city. Ōsaka's subway system, started before World War II, underwent great expansion in the late 1960s and was expanded again in the early 1980s; Kōbe's first subway line was opened in the mid-1980s.

Because of heavy automobile traffic, Ōsaka's main streets are one-way. A network of surface and elevated expressways runs through the central parts of Ōsaka and Kōbe, linking the two cities together as well as joining them to the national expressway system. Ordinary highways also span the whole region. Kōbe and Ōsaka are both international and domestic ports; passenger ships, freighters, and car ferries sail to the islands of Shikoku and Kyushu and to various ports of the Inland Sea. Air service is provided by the Ōsaka International Airport, located north of the city near Itami. A considerable increase in both domestic and international air travel since the mid-1970s led to the need for a second regional airport; construction of the new facility—on a man-made island in Ōsaka Bay—began in 1987.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The city of Ōsaka is the capital of Ōsaka urban prefecture, which consists of 31 cities and 13 towns and villages. It is also the centre of the Kinki District (Kinki-chihō), which consists of the seven prefectures of Ōsaka, Kyōto, Hyōgo, Nara, Wakayama, Shiga, and Mie. Various prefectural and regional institutions have their main offices in Ōsaka.

Public utilities. Ōsaka's main source of water is the Yodo River; Kōbe has several reservoirs on the slope of the Rokkō Mountains. Sewage services are adequate in the central urban areas. Electricity is available everywhere, and gas is available in most city areas.

Health. Medical care in Ōsaka centres on the hospitals of Ōsaka University and of the Ōsaka City University and on several other medical institutions. Other hospitals and health centres are distributed throughout the region.

Education. In Ōsaka and Hyōgo prefectures there are more than 100 universities and junior colleges. Ōsaka University, Ōsaka University of Foreign Studies, Ōsaka University of Education, Kōbe University, and Hyōgo University of Education are national universities. Public municipal institutions include Ōsaka City University and the University of Ōsaka Prefecture. Kansai University in Ōsaka

and Kwansei Gakuin University in Nishinomiya are the oldest and largest private universities in the area.

CULTURAL LIFE

Ōsaka and Kyōto have long been leading centres of culture—Ōsaka, famous for its cuisine, has a more bustling, democratic tone than Kyōto, which is one of the great centres of Japanese culture. Traditional and modern Japanese drama and music are performed at theatres and halls in the metropolitan area, as are Western music, operas, and plays. There are numerous museums, galleries, and libraries. Ōsaka is the home of two national newspapers, the *Asahi* and the *Mainichi*.

Green space in the city of Ōsaka is scarce, but recreational opportunities abound. The important parks include Nakanoshima, Ōsaka Castle, Tsurumi Ryokuchi, Nagai, and Tennoji, the latter with a zoo and botanical gardens. The suburbs have many historical sites and large recreation areas. Beside the spacious man-made Hattori Ryokuchi and Meiji no Mori Minoo parks, there are the recreational areas of the Kii Peninsula on the Pacific, the beaches of the Inland Sea, the historical towns of Nara and Kyōto, and beautiful Lake Biwa, near Kyōto. At Kōbe, Mount Rokkō can be ascended by road or by cable car; there is a golf course at the top and ponds for swimming. There are four professional baseball teams in the metropolitan area, and the national high school baseball championships are played in the summer in Nishinomiya. The town of Takarazuka, northwest of Ōsaka, has been developed as an amusement centre; it houses the Girls Opera and Dancing Theatre. In 1970 the Japan World Exposition (Expo 70) was held near Senri New Town; Expo Memorial Park now holds the National Museum of Ethnology, the National Museum of Art, and a recreation area.

History

ŌSAKA

The plain of Ōsaka was settled in Paleolithic times and by c. AD 300 was a political centre. Among the many ancient burial mounds in the Ōsaka area is that ascribed to the semilegendary emperor Nintoku; the largest tomb of the Tumulus period, the 5th-century structure is surrounded by three moats and occupies some 80 acres (32 hectares). Ancient Naniwa—in what is now Ōsaka—was the site of palace or capital complexes intermittently from the early 5th to the mid-7th century, but in 710 it lost its position to Nara, the first "permanent" national capital.

When Kyōto became the Imperial capital in 794, land and water routes between Ōsaka and Kyōto were improved. The reclamation of the delta of the Yodo River allowed the building of new settlements, including Watanabe, which became a provincial capital and port during the Middle Ages. South of Ōsaka, on the eastern shore of the bay, is Sakai, which had emerged as a port town by the 14th century. There is evidence that, like some medieval European towns, it was self-governing in the 15th and 16th centuries, run by its leading merchants until they capitulated to the warlord Oda Nobunaga in 1569. These merchants grew wealthy from Sakai's lucrative domestic and foreign trade; under their patronage Sakai became a centre of the arts after Kyōto was devastated in the Ōnin War (1467–77). Sakai was also a centre of Christian proselytizing in the late 16th and early 17th centuries; the accounts of Jesuit missionaries tell of the wealth and cosmopolitan flavour of the city at that time.

In 1496—in the midst of a century of civil war—Renno, chief priest of the militant True Pure Land (Jōdo Shin) sect of Buddhism, selected a site near the mouth of the Yodo River for a fortress temple. Completed in 1532, this temple, Ishiyama Honganji, became the nucleus of a major town that was destroyed in 1580 by Oda Nobunaga, after a siege of many years. Oda's successor, Toyotomi Hideyoshi, built a great castle on the site with massive stone walls and broad moats; the castle town that developed around it was the origin of present-day Ōsaka. From this base Hideyoshi brought the whole of Japan under his control, and Ōsaka was the seat of national power until his death in 1598.

Ōsaka's
ancient
origins

The castle and town were badly damaged and depopulated during Tokugawa Ieyasu's siege of 1614–15, in which he eliminated Hideyoshi's heir and consolidated his power as shogun. Succeeding shoguns rebuilt the castle and town, and during the rest of the Tokugawa period (1603–1867) Ōsaka was a directly administered shogunal city. Unlike other towns of the period, Ōsaka was not a political centre and therefore was not dominated by the samurai (warrior) class. Instead, it became the country's main commercial city; feudal lords from all Japan established warehouses for their tax rice along the city's canals, and rice was traded actively. Many other goods were traded in Ōsaka—which had some 380 wholesale houses by 1679—and the city became an expanding commercial and manufacturing centre. These activities stimulated the rapid monetization of the regional economy.

As it grew more prosperous, Ōsaka became a centre of the cultural renaissance of the Genroku period (late 17th–early 18th century). New dramatic forms such as *bunraku* (puppet theatre) and Kabuki were created, and new genres of prose fiction arose, the styles and themes of which catered to the tastes of urban commoners and marked a shift in cultural arbitration away from the samurai class. During the 18th century, however, Ōsaka's position as cultural leader was lost to Edo (now Tokyo), but the city remained an educational centre, with schools in classical studies and in medicine. In the mid-19th century, when Japan was still closed to most Westerners, the Dutch language and Western science were studied by the Japanese in Ōsaka.

Ōsaka remained preeminent both as a port and as a centre of industry until World War II. Much of the city was destroyed by aerial bombardment during the war, however, and postwar economic growth was focused largely in the Tokyo–Yokohama metropolitan area. The revolution in China deprived Ōsaka of its important China trade until the early 1970s, while the increasing economic role of the national government tended to encourage industrial location in the Tokyo–Yokohama area.

KŌBE

The history of Kōbe is as old as that of Ōsaka. In ancient times the name Kōbe was applied to a small fishing village

separated by the Minato River from the town of Hyōgo, the chief port of the area. Hyōgo, also known as Ōwada and Muko, was an important port for trade with China and Korea as early as the 8th century. For many centuries it continued to be Japan's chief port for foreign trade, prospering especially during the 15th and 16th centuries, and the government maintained patrol boats there to control pirates in the Inland Sea. For a brief period during the 12th century Taira Kiyomori made it the capital instead of Kyōto.

During the Tokugawa period, Hyōgo served as the outer port of Ōsaka until in 1868 it was reopened to foreign trade. Soon it was outstripped and absorbed by Kōbe, which has a deeper harbour. The combined ports have been called the port of Kōbe since the establishment of the Kōbe customhouse in 1872. Hyōgo and Kōbe were incorporated as the city of Kōbe in 1889. The many foreigners who settled there in the 19th century gave it an international and cosmopolitan atmosphere.

The size of the city increased in the late 19th and early 20th centuries through the absorption of adjacent communities. During World War II, air raids destroyed much of the city. It was rebuilt quickly after the war, its size again increasing by annexation. Kōbe has become one of the largest cities in Japan. Its port facilities, which have undergone tremendous expansion since the war, have been combined administratively with those of Ōsaka since the early 1970s.

BIBLIOGRAPHY. Two publications by the Association of Japanese Geographers are useful: *Japanese Cities: A Geographical Approach* (1970), for the academic study of postwar urban Japan; and *Geography of Japan* (1980), especially ch. 12–18, which contains scholarly analyses of contemporary Japanese urban development. WILLIAM B. HAUSER, *Economic Institutional Change in Tokugawa Japan: Ōsaka and the Kinai Cotton Trade* (1974), analyzes Ōsaka's premodern economic role. *Osaka and Its Technology* (semiannual) includes essays on urban development and public works. A novel by JUNICHIRO TANIZAKI, *The Makioka Sisters* (1957, reissued 1983; originally published in Japanese, 3 vol., 1949), provides an excellent if romanticized view of life in the Ōsaka–Kōbe region before World War II. PAT TUCKER SPIER (ed.), *The River Without Bridges: An Encounter with the Japanese Buraku* (1986), discusses the civil rights of the *burakumin* in Ōsaka. (S.K./R.P.T.)

Incorporation of Kōbe

Pacific Islands

The Pacific Islands is an expression commonly accepted as including all of those islands in the Pacific Ocean that are collectively referred to as Melanesia, Micronesia, and Polynesia, also sometimes known as Oceania. This usage rules out the Australian island continent, the Asia-related Indonesian, Philippine, and Japanese archipelagoes, and the Ryukyu, Bonin-Volcano, and Kuril island arcs that project seaward from Japan. Neither does the term encompass the Aleutian chain connecting Kamchatka and Alaska nor such isolated islands of the Pacific Ocean as Juan Fernández off the coast of South America.

Although the Pacific Ocean makes up nearly one-third of the Earth's surface, the Pacific Islands discussed in this article add up to a little less than 500,000 square miles

(1,300,000 square kilometres) of land area. New Guinea, the largest island in the world after Greenland, represents 70 percent of this total, and New Zealand accounts for 20 percent. The remaining 10 percent of the land area of the Pacific is divided among more than 10,000 scattered islands.

The Pacific Islands lie mainly in the area bounded by latitudes 23° N and 27° S and longitudes 130° E and 125° W. Exceptions to this are New Zealand, which lies in the southern temperate zone, and Easter Island, which stands in isolation at longitude 109° W, almost halfway to South America. (Australia and New Zealand are treated in separate articles, and Hawaii is treated in the article UNITED STATES OF AMERICA.)

THE REGION

For convenient reference, the Pacific Islands are customarily divided into three ethnogeographic groupings. The great arc of islands located north and east of Australia and south of the Equator is called Melanesia (from the Greek words *melas*, "black," and *nēsos*, "island") after the predominantly dark-skinned peoples of New Guinea, the Bismarcks, Solomon Islands, Vanuatu (formerly the New Hebrides), New Caledonia, and Fiji. North of the Equator and east of the Philippines is another island arc that ranges from Palau (Belau) and the Marianas in the west through the Carolines and Marshalls all the way to Kiribati (formerly the Gilbert Islands). This is Micronesia, so named because of the smaller size of these islands and atolls. In the eastern Pacific, and largely enclosed within a huge triangle formed by Hawaii in the north, New Zealand to the south, and Easter Island far to the east, are the "many" (poly-) islands of Polynesia. Other components of this widely scattered collection are Samoa, Tonga, French Polynesia (including the Society, Tuamotu, and Marquesas Islands), and the Cook Islands. In this, the last section of the Pacific Ocean to be inhabited, the islanders share a cultural tradition that relates them closely to many Fijians. Fiji, indeed, is actually a transitional territory between Melanesia and Polynesia.

Since the 16th century, the Western world has shown an interest in the Pacific Islands that has been expressed in the activities of explorers, scientists, artists and writers, missionaries, commercial entrepreneurs, and imperialistic statesmen. The variety of the Pacific's environments, both physical and biotic, continues to be a laboratory for experimenting in social and cultural adaptation. Though insularity has often dominated this process, its effect has been offset by the opportunities for human contact and exchange in many directions across the ocean's expanse.

In the 20th century, the islands and their inhabitants have continued to attract international interest, although for new reasons, such as their strategic significance in the relationships of the world powers in Europe, Asia, and America. Attention has also centred on the problems created for Pacific islanders by nature's limitation of land and resources in the face of expanding populations and rising standards of living.

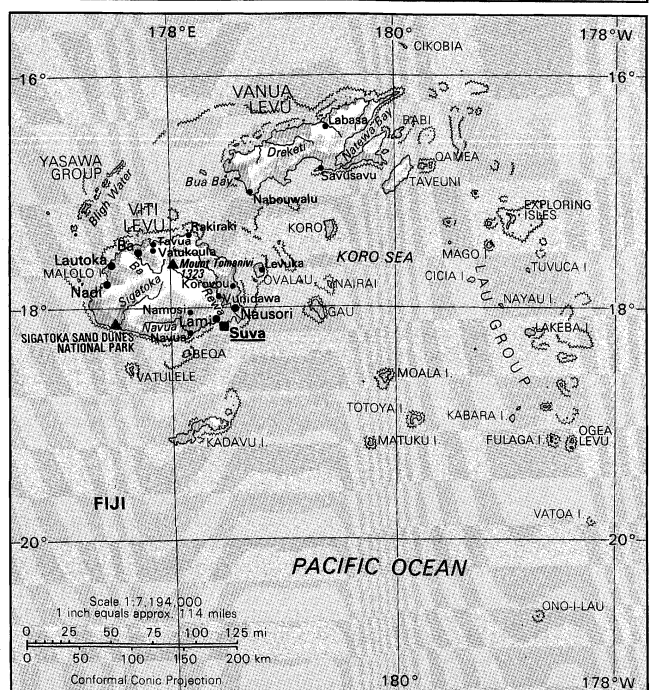

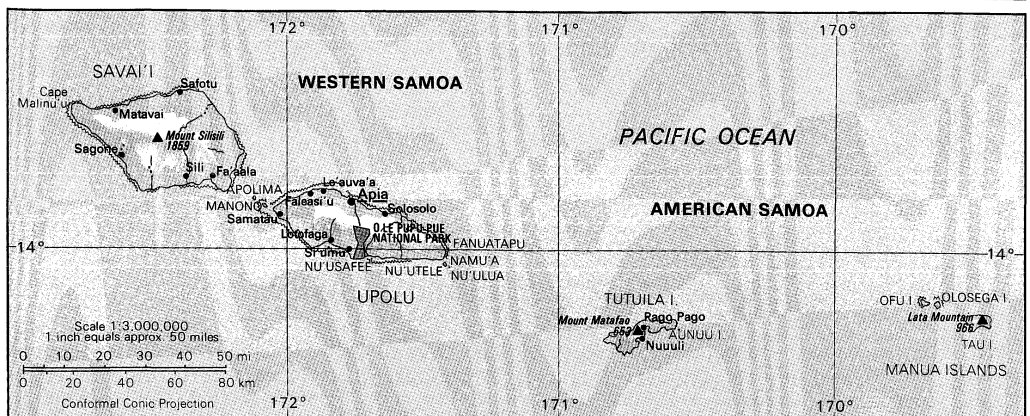

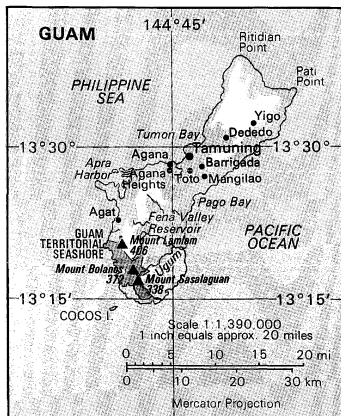

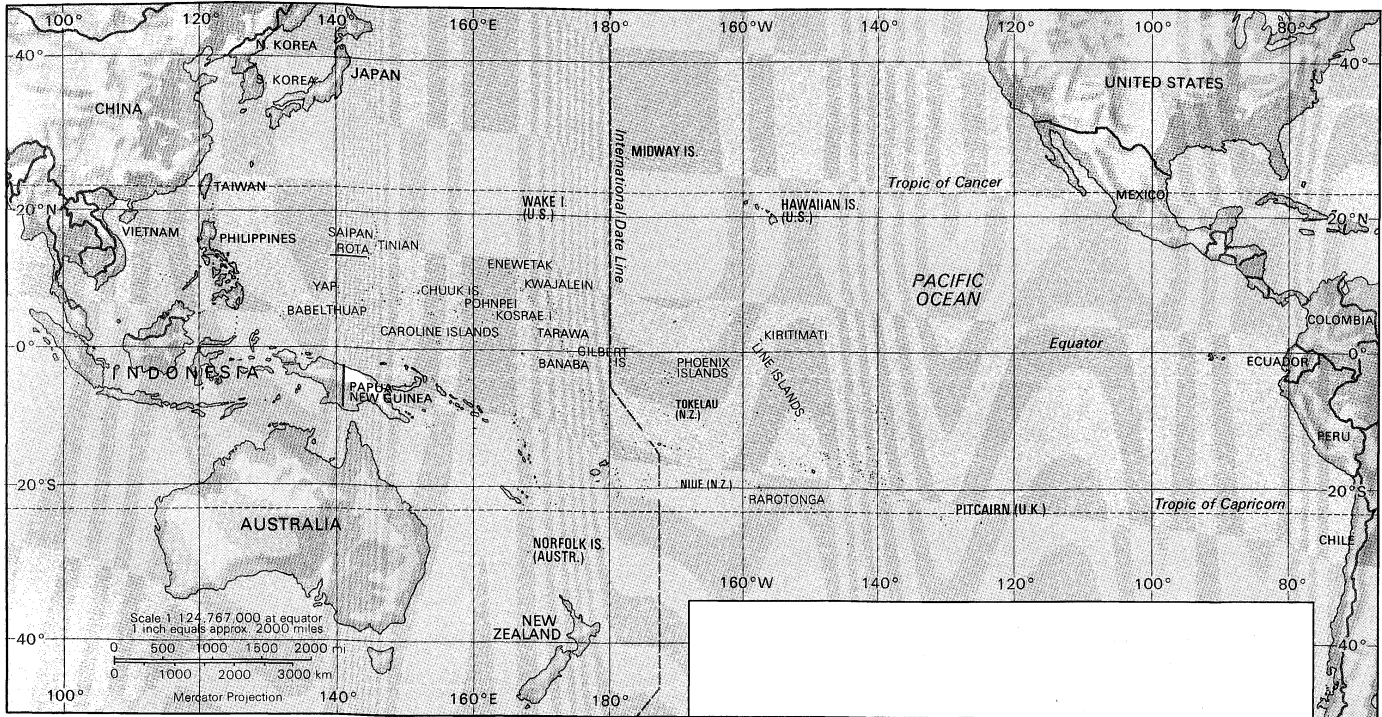

Physical and human geography

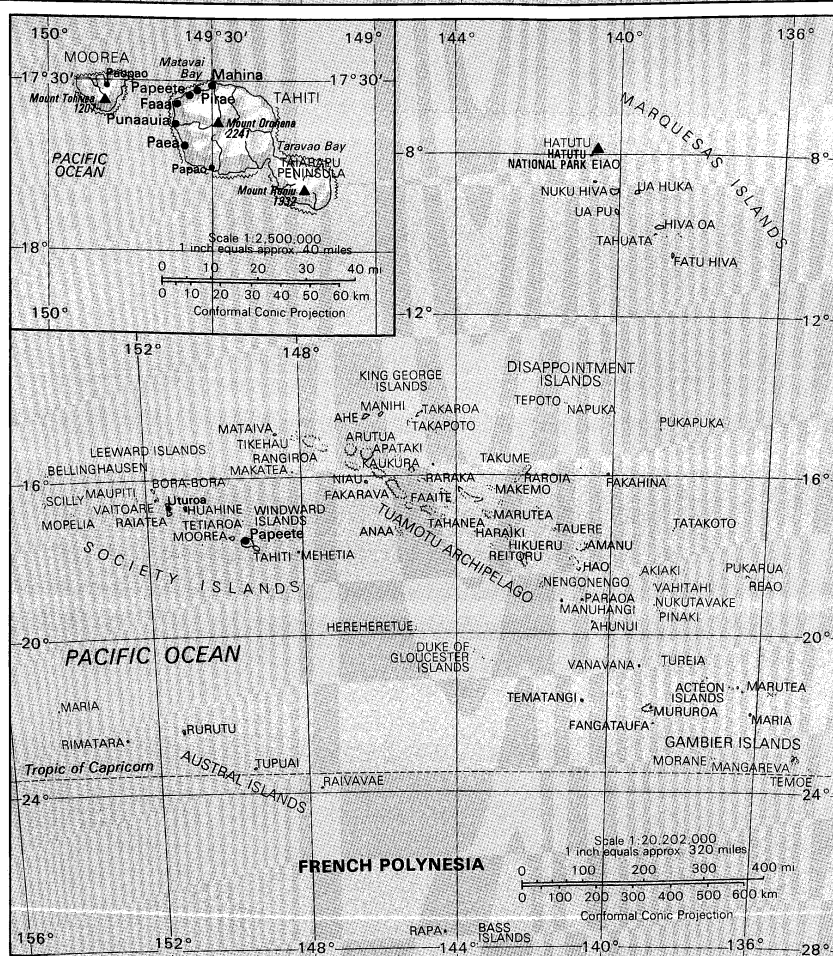

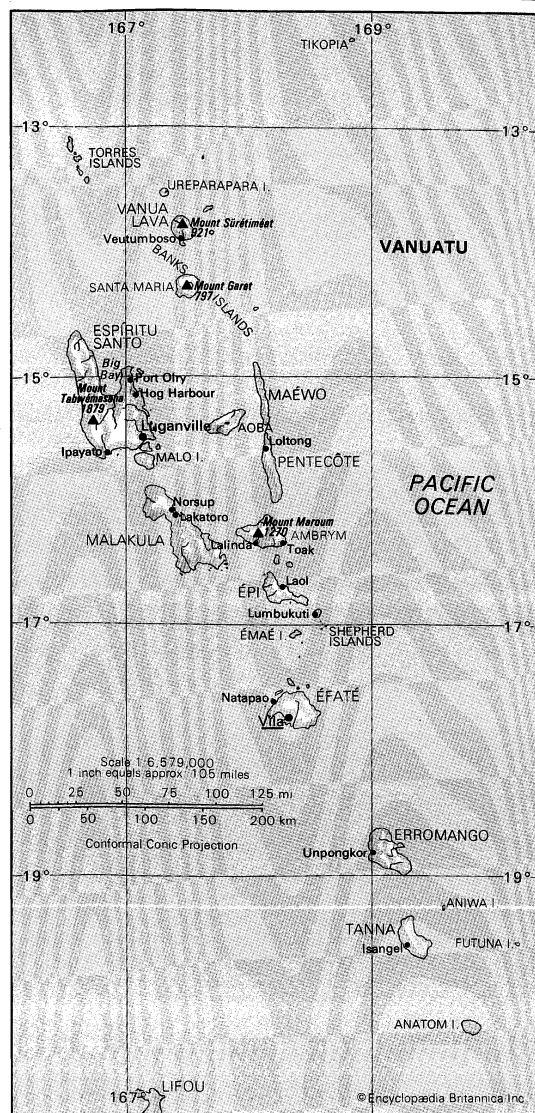

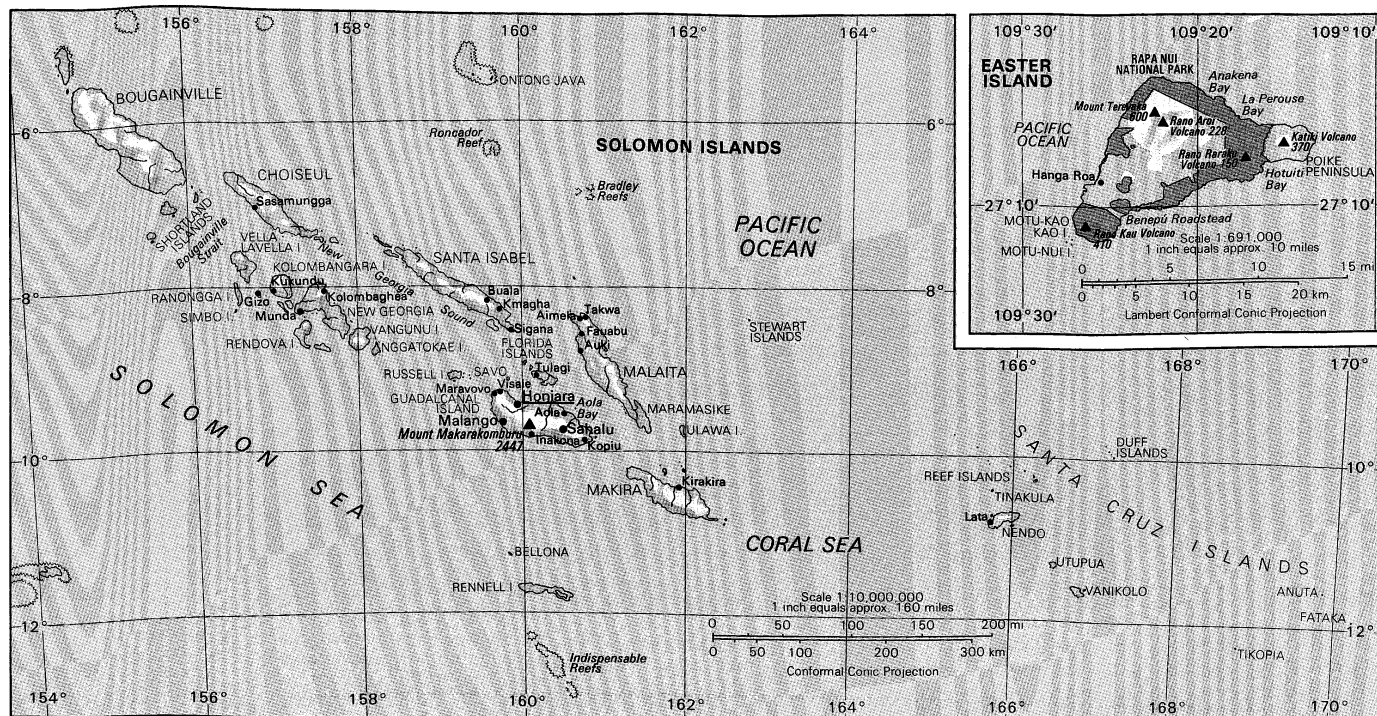

THE LAND

The island ecosystem. To know what it is like to live on a Pacific island, the intermixture of physical and biological characteristics of the particular island must be considered. Each of the myriad ecological systems in the Pacific is a unique complex of living organisms and their nonliving environment. Each is a functional system of interacting components that tends toward an equilibrium that is never quite achieved. The limited size of most Pacific islands makes it probable that almost any change, whether by human action or by some natural agency, will have repercussions elsewhere within the ecosystem. The landform, climate, soils, vegetation, and animal life all are elements to which people who live on an island must relate, for they, too, occupy a niche in the total ecological scheme.

Relief. The islands may be classified as either continental or oceanic. The former are associated with the ancient continental platforms of Asia and Australia, now partially submerged. Oceanic islands, located eastward in the deeper Pacific basin, are differentiated as high volcanic-based islands or low coral islands and atolls. A coral island may be single, or two or more coral islets may be

part of an atoll if connected by a reef ringing a lagoon. The "high-low" distinction is misleading as the two types occur in many combinations, and some coral islands have been elevated considerably by changes in the ocean level.

Continental islands. The islands of the broad western Pacific margin, formed mainly of metamorphosed rocks, sediments, and andesitic volcanic material, are separated from the basaltic volcanic islands of the central and eastern Pacific by deep ocean trenches along the eastern borders of Japan, the Marianas, New Guinea, Solomon Islands, Fiji, and New Zealand, a demarcation that is commonly called the Andesite Line. These continental islands, faulted and folded in mountainous arcs, tend to be higher and larger than those farther east and have rich soils that support almost every kind of vegetation. New Guinea, 1,500 miles long and with a maximum width of nearly 500 miles, is a good example. Its snowcapped mountains rise to about 16,400 feet (5,000 metres), its interior is dissected by high plateaus and extensive river systems, and its slopes and coastal margins contain dense forests and vast swamps.

High oceanic islands. Extensive volcanic mountain ranges in the central and eastern Pacific rise abruptly from the ocean deep, their cores of dense black basalt built up from lava flows from the fractured seafloor. Where summits stand in high relief above sea level, they represent most of the islands that constitute Polynesia and Micronesia. Small to intermediate in land area, nowhere do they match the extent of continental islands. Hawaii's snow-topped Mauna Kea reaches 13,796 feet, though most oceanic islands have peaks of somewhat less than 5,000 feet. Topography is extremely rugged, with sharp ridges, deep canyons, high cliffs, and waterfalls abounding. Human communities occupy the more congenial lower slopes, floodplains, and wide strands. The islands, rich in iron and magnesium oxides, are densely forested but lack the mineral wealth of continental islands.

Low coral islands. Most Pacific islands are coral formations, although all rest on volcanic or other cores. In the shallow waters of the tropics, both continental and oceanic islands attract coral growth in the form of fringing reefs, partially submerged platforms of consolidated limestone, with coral organisms at the ocean edge feeding on materials carried in by waves and currents. Coral-building polyps and algae secrete calcium carbonate from seawater, forming skeletal frameworks that adhere to land surfaces or to the rock remains of coralline ancestors. Many islands have been gradually submerged through a combination of sinking, caused by geologic action, and flooding, caused by the melting of ice caps. As islands were flooded, coral growth continued outward, producing barrier reefs farther from shore and separated from it by a lagoon.

A coral atoll results when still further flooding reduces an island to a submarine condition. The usually irregular reef continues to build up in the warm shallows. It en-

Small offshore coral atoll at the eastern end of Guadalcanal Island, Solomon Islands.

circles a clear-surfaced lagoon of moderate depth and in time supports a number of islets, known locally as motu, built up from reef debris to 20 or 30 feet above sea level. Atolls exist in all shapes and sizes. Kwajalein Atoll in the Marshalls is the world's largest, being about 80 miles long and 20 miles wide, with a lagoon area of 655 square miles. Openings, or passages, which commonly occur on the leeward side of Pacific atolls, permit access to the lagoon by ocean shipping. The only source of fresh water is rain.

Successive elevations of an island above sea level by geologic action have created a variety of "raised" coral formations. The northern half of Guam, for example, is a coralline limestone plateau rising to 850 feet, while the mountains in the southern half of the island, formed by volcanic activity, reach elevations up to 1,300 feet. Nauru and Banaba (Ocean Island) are raised coral islands that stand at elevations of about 210 and 265 feet, respectively. They have deeper soil and a more adequate water supply than atoll islets, as well as surface deposits of phosphate rock (derived from guano) that have been mined commercially.

Soils. Pacific island soils develop through the action of

Coral
atolls

temperature, rainfall, and organic matter on the original rock materials. This process is further influenced by factors of time and land relief. Coral island soils are the least mature and are deficient in organic materials and low in fertility. The mineral-bearing soils of the continental islands are more complex and, being favoured by a longer period of weathering, are richer than those of the volcanic-based high islands. The most productive soils on high islands occur in the lower valley slopes, alluvial floodplains, and deltas and in some instances are further enriched by volcanic ash deposits of recent age. Tropical temperatures and rainfall have produced laterite soils from which nutrients have been leached. These soils, of only moderate fertility, decline rapidly after two or three years of crop use. Fertilizers must then be added, or else the land must be abandoned to allow it to recover by natural processes while other land is cleared and planted in its place.

Climate. To describe the climate as tropical and oceanic is to stress the influence of the lower latitudes and the tremendous expanse of the sea. Humidity and temperature tend to be high and are generally uniform throughout the year. Regional differentiation in climate is linked principally to rainfall patterns. Here, factors of altitude and longitude, as well as latitude, come into play as they relate to the various systems of air circulation prevailing in the Pacific.

Across the eastern and central Pacific, air currents, moving from the north and south toward the Equator, trend westward and form the northeast and southeast trade winds. These brisk winds bring light to moderate showers interspersed with brief but often heavy downpours or clear skies. The windward sides of high islands are cloudier and wetter than the drier leeward coasts. Seasonal shifts in wind direction frequently presage stormy weather. Where the trade winds meet near the Equator lie the doldrums, a region often of little or no wind, considerable clouds, and high humidity. The trade winds merge or give way to the monsoon winds in the far western Pacific, where the alternate cooling and heating of continental Asia produces a seasonal reversal of winds. From about November to March, the northwest monsoon from Asia brings rain to the northerly slopes of the western Carolines, New Guinea, and the Solomons. In summer the southeast monsoon reverses the process.

Monsoon
winds

Typhoons, or hurricanes, occur frequently in western Micronesia from July to November and are active south of the Equator from Australia to the Society Islands four to six months later. These winds of gale force are accompanied by torrential rains and high waves and cause extensive damage to crops and buildings, especially on low-lying coral islands. Atolls in the equatorial region, however, have suffered droughts lasting as long as two or three years. In 1982–83 the entire western Pacific was devastated by extreme aridity caused by an anomalous meteorologic and oceanographic phenomenon known as El Niño. The unusually warm ocean conditions at the same time brought about extensive flooding in the easternmost parts of the Pacific basin.

Plant and animal life. Most island vegetations reveal Asian ancestries stemming from Indonesia and New Guinea. Generic variety declines eastward across the Pacific, providing evidence that seeds and fruits carried by ocean currents, birds, winds, and island voyagers encountered mounting obstacles to acceptance. The easternmost islands were host to limited plant dispersal movement from South America. Plant adaptation to local differences in moisture, soil, salinity, and temperature resulted in countless new, endemic species. Plant introductions from other world sources during the past century have, however, markedly altered island vegetations.

The seacoast, or strand, vegetation is the most widespread of Pacific zonal types. Depending on the availability of moisture, this relatively unfavourable setting supports shrubs, herbs, woody vines, and trees that have a high tolerance for the salt spray that is borne by ocean winds. Mangrove thickets proliferate in brackish swamps. On coral islands, coconut and pandanus trees flourish. Breadfruit, banana, and papaya may also be grown farther inland, as may marsh taro (*Cyrtosperma*), a root crop

cultivated in pits dug to groundwater level and enriched with plant debris.

On high islands primary forests still survive in valley bottoms, on intermediate slopes, and on lowland plains. The ever-present rain forest is a community of huge trees that overlook smaller trees and shade-tolerant ferns, vines, and shrubs. Species differentiate enormously. Yam, taro (*Colocasia*), cassava (manioc), and sweet potato, in addition to those crops already noted, are important staples in high-island economies. Secondary forests and grasslands have replaced virgin forests destroyed by fire and by shifting cultivation. Grasslands are also associated with areas of poor soil and little rain, as on leeward slopes.

Bats, rats, and, in New Guinea, wallabies, flying opossums, and spiny anteaters were the only mammals to precede humans into the Pacific, after which pigs, dogs, poultry, goats, deer, and cattle were introduced. Most islands have some snakes and lizards, but crocodiles are restricted to the west. Seabirds, such as terns, frigates, albatross, petrels, and boobies, supplemented by migratory ducks, plovers, and curlews, are found almost everywhere. While oceanic islands support only a few land birds, New Guinea has unusual species such as the cockatoo, hornbill, bird of paradise, and cassowary.

Unusual
bird species

The abundant marine life is infinitely valuable for human subsistence. Reefs and lagoons provide lobsters, shrimps, clams, oysters, snails, eels, octopuses, turtles, and innumerable species of fish. In deeper waters beyond the reefs are found skipjack and yellowfin tuna (which are fished commercially), swordfish, marlin, and many other sport fishes. Sharks predominate as predators. Schools of whales and porpoises are seen frequently at sea. Insects are the most numerous of island fauna; the more pestiferous include centipedes, cockroaches, lice, houseflies, and the malaria-carrying *Anopheles* mosquito, which exists in Melanesia from coastal New Guinea to Vanuatu. Scorpions are also found.

THE PEOPLE

Humans in the Pacific have had to adapt to island environments just as other species have done. The technologies and organizational systems introduced into the Pacific by migrants were established in habitats that varied from receptive to hostile. The earliest arrivals, as food-gathering peoples, probably provoked little disruption of the environment. Their successors, practiced in horticulture and skilled in sea transport, were more able to fashion and control local environmental conditions after their own customs. Later, Western practices, part of an advanced technology and civilization, threatened the balance of the inherently vulnerable island ecosystems.

Aboriginal groupings. Natives of the Pacific tend to identify themselves by their home island or their mother tongue, saying, for example, that they are from Nauru or that they speak Fijian. Occasionally, however, they may invoke another, and larger, identity, claiming to be Polynesian, Micronesian, or Melanesian. As a geographic designation this representation has value, but as a mark of racial, linguistic, or cultural affiliation it is apt to be misleading. While Melanesians appear to be more Australoid and Micronesians more Mongoloid, with Polynesians demonstrating characteristics of both physical types, a great deal of racial intermixture has taken place throughout the Pacific since the first immigrants arrived in the southwestern islands. The linguistic pattern is also complex. Some valid generalizations about cultural practices and institutions in the three regions may nevertheless be made, although it must be remembered that overlap among the traditionally ascribed areas is common and that there are exceptions to every statement.

General-
izations
about the
traditional
regions

Polynesia. Polynesians are the most homogeneous in speech, custom, and physical appearance, although western Polynesians (Samoans and Tongans) are moderately distinct from the rest. Accomplished as cultivators and fishermen, they have directed their principal energies to nonmaterial pursuits. Epic mythology, copious genealogies, sophisticated social etiquettes, hereditary aristocracies, and elaborated religious formality, with varying degrees of emphasis, characterized society in pre-European Polyne-

sia. A kinship system that recognized the worth of both maternal and paternal family ties supported group solidarity in community enterprises. Secular leaders, regarded as lineal descendants of deified ancestors, served gods and humans alike. The social-religious-political hierarchies encouraged and rewarded aesthetic creativity in wood and stone sculpture, featherwork, tapa (bark cloth), and tattooing, according privileges to the artists commensurate with those accorded warriors, navigators, herbalists, and seers.

Micronesia. Eight or 10 cultural-linguistic areas in Micronesia attest to its greater heterogeneity. Palau, Yap, and the Mariana Islands, in western Micronesia, suggest affinities with Melanesia, Indonesia, and the Philippines. The customary siting of island farmsteads and hamlets near the shore reflects the prevailing interest in fishing, canoeing, and interisland trade. Except in Kiribati (the Gilbert, Phoenix, and Line Islands), matrilineal clans and lineages, requiring marriage outside each group, influence property inheritance, succession to traditional titles, and intracommunity competition. Local political autonomy was formerly overshadowed by loose confederations and tribute allegiance in western Micronesia, as well as in Pohnpei, Kosrae, and the Marshall Islands, where class stratification is still observed. Indigenous religions lacked formality and were largely of personal or family concern. Art is mainly decorative and is manifest in mat work, shell ornaments, loom weaving, tattooing, and functionally crafted wood and shell artifacts.

Melanesia. This is a region of unending contrast. "Beach" populations, who maintain advantages from coastal trading and cultural exchanges, may be compared with more traditional and isolated "bush" populations in the interiors of the larger islands. Polynesian influence touches Fiji and a few outlying islands to the northwest. The massive extent of New Guinea, with its thousands of indigenous tribes, requires separate consideration.

Melanesians are all cultivators, with a penchant for pig raising. Descent groups, usually patrilineal, are the basis for community organization. In most Melanesian societies, leadership depends on the local "Big Man," who, aided by his many relatives, gains support within his own village and enhances his influence in others nearby by hosting more and bigger feasts than his rivals and amassing wealth through ceremonial exchanges of valuable goods. Opportunities for upward mobility are better for the sons of an established "Big Man," assuming they can prove themselves. Head-hunting and raiding of neighbouring tribes continue in the interior of New Guinea. The animistic religion of Melanesians, a mixture of magic, sorcery, totemism, and ancestor worship, is dominated by elaborate initiations, secret societies, and men's clubhouses. Although males dominate most cultural activities, the roles of women are substantial in certain religious and exchange systems. Art forms associated with these activities include dance masks, sculptured figures, body scarification, and carved mortuary standards.

For a detailed treatment of these cultural areas, see below *Traditional cultures of the Pacific Islands*.

Interaction with Western societies. During almost five centuries of contact with, first, Europeans and, then, Americans and Asians, island societies fluctuated between change and disorganization on the one hand and stability and reintegration on the other. Relatively balanced ecosystems of prehistoric times were disrupted when islanders, reacting to the novelty and authority of Western civilization, redirected traditional skills to serve new economies and, under pressure from missions and alien governments, adopted practices and beliefs that were strange to them. From this initial confusion there emerged reasonably stabilized island societies that, while preserving the traditional ethos, reflected a fusion of specific elements from both cultures. European, American, and Asian residents continued to maintain their own cultural identities in social enclaves. Meanwhile, influence toward change was exercised by an increasing mixed-blood population, reflecting the needs of culturally marginal individuals.

The direct impact of World War II stimulated many island communities to seek greater participation in Western society. Their efforts were expressed in chiefly two ways.

The first was in a proliferation of mystical cults. Occurring principally in Melanesia, where they are called cargo cults, these cults blended traditional and Christian elements in systems aimed at materialistic bounty, but they provided solutions largely in fantasy. The second, a more rational effort toward economic betterment and political nationalism, was promoted by both native and part-native persons, many of whom had been educated overseas and who lived in the more urbanized centres. Opposed to assimilation, most islanders argued for more independent status within the structure of a Westernized "Pacific way."

Killing epidemics of introduced diseases contributed to population decline until around 1900, when they were checked by modern medical treatment and health education. Many island populations almost trebled during the next five decades. Family planning programs and economic pressures have not been very effective in slowing the rate of population growth. Many islanders have migrated to the port towns and island capitals, reacting to overpopulation in the smaller outlying islands or, more often, seeking gainful employment or further education. The urban centres are built around business, school, hospital, mission, and administration facilities; government is the largest single employer.

In some island states, more than half of the population live in the towns. Poor housing and sanitation, underemployment, scarcity of land for residential use, and decline of the extended family structure are common features of island urbanism. Alcoholism and crime are widespread, and suicide among young men has increased. Meanwhile, communities in the outer islands are less able to function, economically or socially depleted as their populations are by the exodus of able-bodied, middle-aged adults who have left for the towns. The urban centres link the hinterland communities by sea and air transport and by radiotelephone networks; they also serve as a point of departure for overseas destinations such as Guam, Nauru, New Caledonia, American Samoa, and Hawaii, where employment opportunities in the private sector are greater. Although most of those who migrate are unskilled, a significant number have technical and professional talents that are needed in the island centres, and their migration constitutes an undesirable drain on their communities.

THE ECONOMY

Agriculture and natural resources. Coconut products, including copra, from which oil is extracted, form the principal export from most islands. Agricultural production depends as much on native family enterprise as it does on plantation systems, which predominate in the larger islands. Perishable fruits, such as pineapples, bananas, and citrus fruits, require markets close at hand unless they are

locally processed or can be assured of prompt delivery to overseas destinations. Sugar, exported mainly from Hawaii and Fiji, requires careful management, costly machinery, and specialized labour. Experiments in growing coffee, cacao, spices, and other cash crops have been undertaken to stimulate diversification and to minimize the hazards of a one-crop economy. Timber and wood by-products are processed commercially on some islands.

Marine resources, although almost unlimited, require skilled labour and capital facilities for commercial exploitation. Deep-sea fishing, mostly for tuna, is conducted throughout the Pacific, mainly by Korean, Taiwanese, Japanese, and American fishing fleets. Canneries employing islanders are operated in American Samoa, Fiji, and Solomon Islands. Local cooperatives have been successful in marketing fresh fish.

Fiji, Papua New Guinea, Irian Jaya (a province of Indonesia comprising the western half of the island of New Guinea and its offshore islands), and Solomon Islands have profited from either gold or gold and copper discoveries, and New Caledonia is rich in nickel ores. Oil reserves and their exploitation are restricted to Irian Jaya, although prospecting in Papua New Guinea and Solomon Islands is encouraging. Natural phosphates on Nauru continue to be mined, but those on Banaba were depleted in 1979. In 1979 the South Pacific Forum, an organization of independent and self-governing countries, established the Forum Fisheries Agency (FFA) to facilitate mutual co-operation and assistance in fisheries and policing the 200-nautical-mile Exclusive Economic Zone (EEZ) of each member state. This group of 16 entities in 1987 concluded a multilateral treaty with the United States, whereby the United States agreed to pay \$60,000,000 in license fees and assistance to the fishing industry in return for permission for American fishing fleets to operate in the EEZs of the FFA member states. The latter are free to negotiate further agreements with other nations on the Pacific Rim.

Trade. Pacific islanders, as producers of agricultural, marine, and mineral commodities, face problems of market demand, labour supply, management skills, and transport that restrict them to an insignificant role in world export trade. Neither do the small, scattered populations present an attractive consumer market to overseas entrepreneurs. The combination of limited exportable products, heavy dependency on food imports, high cost of fuel imports, and overreliance on foreign aid makes each island state's economy extremely vulnerable.

More than half of the exports from the Pacific Islands are sent to Japan, the United States, Australia, New Zealand, and members of the European Economic Community (EEC). Imports are received mainly from the United States, Australia, New Zealand, France, Japan, and Singapore. Almost all island groups import far more, in dollar amounts, than they export. External financial aid for economic development is received primarily from Australia, New Zealand, the United States (for Guam, American Samoa, and the U.S. interests in Micronesia), France (for New Caledonia, Wallis and Futuna, and French Polynesia), and from international organizations (the Asian Development Bank, the United Nations Development Programme, and the EEC). Most grants-in-aid are made on a bilateral basis; few are negotiated on a multilateral or regional basis. Most employment opportunities for islanders are in government service agencies, except where mining or agricultural production contributes significantly to national income.

In the 1970s tourism opened up new employment opportunities and sources of revenue. By 1980 Guam, the Northern Marianas, Fiji, French Polynesia, and New Caledonia, among others, had followed Hawaii's earlier lead in attracting visitors by air and sea to enjoy the tropical scenery, handicrafts, and friendly hospitality of the Pacific Islands. Australians made up the largest group of tourists traveling to destinations south of the Equator, while Japanese made up the majority of vacationers to the north. However, the increasing ability of international airlines to bypass midway island stops, the devastation of hotel facilities by more frequent hurricanes, the fluctuating currency values in Pacific Rim countries, and political dis-

orders in Fiji and New Caledonia slowed the growth of the tourist industry. In some cases island labour was mostly restricted to the menial services, and management posts and industry profits were more often enjoyed by expatriate personnel and foreign-based corporations. The degree of government and private involvement and investment in tourist accommodations and entertainment varied with each island state. Some island populations, indeed, were more concerned with safeguarding their traditional cultures than deriving income from their commercialization.

Transportation and communication. Most islanders, by resorting to some combination of road, canoe, motorboat, interisland freighter, local air service, or international airline, can travel within a week or two to such distant cities as Sydney, Auckland, San Francisco, Vancouver, Tokyo, Manila, Hong Kong, or Singapore. Because of infrequent or irregular travel schedules, inhabitants of more remote islands may need two months or more to make such a journey. More than a score of shipping and airline companies offer carriers to move outbound and inbound cargo and passengers through such island centres as Guam, Port Moresby, Honiara, Nouméa, Suva, Pago Pago, Papeete, and Honolulu. This readier access, in both directions, has developed largely because islanders have demanded better facilities for travel and commercial expansion.

Radio, radiotelephone, cable, and satellite services have greatly improved communications. Two-way radio transmission is used, even in distant islands, to inform central authorities of emergencies and other critical needs. Radio broadcasts and news publications in English, French, and indigenous languages (such as Samoan, Fijian, and Tok Pisin [Melanesian Pidgin]) keep the island public informed about local and world events. Commercial television or videotaped programs from the metropolitan nations are available in urbanized centres.

ADMINISTRATIVE INSTITUTIONS

By the mid-20th century, overpopulation in a region of fragmented land areas, widely scattered communities, poor communications, inadequate resources, and rising costs of living posed a fundamental dilemma. Political responsibility for the situation rested largely with the five metropolitan nations (Australia, France, New Zealand, the United Kingdom, and the United States) administering the possessions, protectorates, and trusteeships that perpetuated a colonial heritage that was no longer popular. The amelioration of social and economic conditions seemed to await changes in the political environment, while the question of the five nations' willingness to share their territorial interests with the emerging native elites remained undecided.

Changing administrations. Two United Nations trust territories were the first to achieve sovereignty as independent nations—Western Samoa in 1962 and Nauru in 1968. The first continued to rely on New Zealand in foreign affairs, while Nauru ended its trusteeship ties with Australia, New Zealand, and the United Kingdom. New Zealand, a Commonwealth member with a self-conscious Maori Polynesian population surviving inside its borders, continued an active relationship with other Polynesian groups—the Cook Islands, Niue, and Tokelau. Cook Islanders in 1965 and Niueans in 1974 became self-governing in free association with New Zealand, from which they required only support in certain aspects of external affairs and financial aid.

In 1975 Australia, a Commonwealth country with territorial interests in Melanesia, relinquished its hold on Papua, which it had acquired from Great Britain in 1906, and its trusteeship in northeastern New Guinea, which the United Nations had granted in 1946. The fully independent nation of Papua New Guinea was thereby created. British Fiji and Tonga gained their independence from the United Kingdom in 1970. Other British colonies achieved freedom in subsequent years—the Solomon Islands in 1978; the Ellice Islands, renamed Tuvalu, also in 1978; the Gilbert Islands, which then became Kiribati, in 1979; and the New Hebrides, which Britain administered jointly with France until 1980, when the island group assumed nationhood as Vanuatu.

territories—French Polynesia, New Caledonia, and Wallis and Futuna. Each of these territories enjoys a degree of local autonomy and is represented in the French parliament by elected delegates. Popular movements toward greater self-government or independence are active in both French Polynesia and New Caledonia.

The United States dominates the Pacific region north of the Equator. Hawaii, formerly a territory, became the 50th U.S. state in 1959. Other U.S. territories are Guam and American (eastern) Samoa, both of which have been under civilian administration since 1950–51, after a half-century of naval rule. The Trust Territory of the Pacific Islands, covering much of Micronesia, was granted by the United Nations Trusteeship Council to the United States in 1947 as a strategic-area trusteeship.

Micronesians in the trust islands have negotiated in separate groups with the United States about their status. In 1975 the Northern Mariana Islands elected commonwealth status with the United States, and the commonwealth took partial effect in 1976. A constitution became effective two years later. Three other political entities have emerged in the remaining islands—the Republic of Palau (Belau), the Federated States of Micronesia (Kosrae, Pohnpei, Truk, and Yap), and the Republic of the Marshall Islands. Constitutional governments were established in the Federated States of Micronesia and the Marshall Islands in 1979, and Palau followed suit in 1981. Each of these has negotiated a Compact of Free Association with the United States, which in 1986 proclaimed that the trusteeship was terminated for the Republic of the Marshall Islands, the Federated States of Micronesia, and the Commonwealth of the Northern Mariana Islands. The U.S. government notified the United Nations Security Council of this action, but no response came from the council. Neither was the compact with the Republic of Palau approved by the constitutionally required 75 percent majority of Palauans.

Two Pacific island territories are politically peripheral to contemporary Oceania. Western New Guinea, which was formerly a part of the Dutch East Indies, became a province of Indonesia in 1963 and was called Irian Barat until 1973, when it was renamed Irian Jaya. Easter Island has been a dependency of Chile since 1888, and development of its Polynesian population is strongly oriented toward the interests of Chile.

Regional cooperation. The average Pacific island state is too small and limited in human and natural resources to function well on the world stage and has sought the advantages of joint action through regional cooperation among governments, churches, educational institutions, businesses, workers' unions, and cultural organizations. The total number of regional bodies in the Pacific Islands is over 200. The first significant attempt at regional cooperation came in 1947, when the major powers that had dependencies in the region agreed to form the South Pacific Commission (SPC) to provide research and consultative services in health, social, and economic development to island governments. Members now include the five metropolitan powers—Australia, France, the United Kingdom, New Zealand, and the United States—and 22 island states and dependent territories.

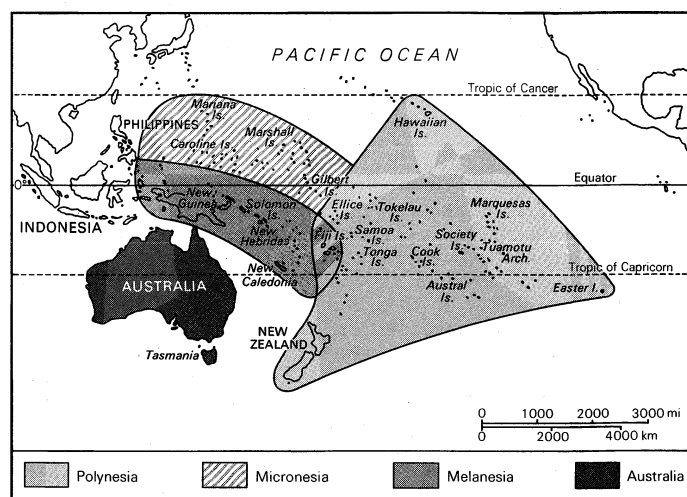

Proposals to add a political dimension to the SPC's activities have never been approved, and by the mid-1980s its image as a metropolitan body had seriously weakened its impact in the region. In part to meet this political need, the South Pacific Forum was organized in 1971 by leaders of the independent and self-governing island countries, including Australia and New Zealand; it was essentially an association of Pacific states in the British Commonwealth. In 1973 the forum established the South Pacific Bureau for Economic Cooperation (SPEC) to promote regional alliances in trade, shipping and air services, telecommunications, and external aid. The SPEC has also provided liaison with other regional organizations, such as the EEC and the United Nations Economic and Social Commission for Asia and the Pacific. The forum has taken strong positions in support of the Law of the Sea and its 200-nautical-mile Exclusive Economic Zone concept and of the acceleration of the decolonization process in French Polynesia and New Caledonia, and in 1985 at

its annual meeting in Rarotonga its members adopted the South Pacific Nuclear Free Zone Treaty.

By the late 1970s Australia and New Zealand had become the primary sources of regional aid, while France and the United States pursued their strategic interests in the Pacific. Regional cooperation has depended to a great extent on the pragmatic advantages to be gained by the smaller independent states made vulnerable by limited resources. (L.E.M.)

History and cultural development

The prehistory of the Pacific Islands, the period before written materials begin, extends back at least 33,000 years, a date provided in 1985 by sites in the Bismarck Archipelago. It is probable that human settlement significantly antedates the limit of radiocarbon determination of 40,000 years. Migration extended into the 2nd millennium AD and led to the populating of every habitable island. Since the arrival of Europeans in the early 16th century, the prehistoric world has been transformed, to varying extents, at first by contact with passing explorers and then, from the late 18th century, by the influence of more permanent visitors: castaways, beachcombers, missionaries, and traders. In the 19th and 20th centuries settlers, labourers and other immigrant communities (predominantly Indian and Chinese), and European administrators arrived. Missionaries, settlers, and immigrants remain significant segments of the population in the islands today, even though European governments, with the exception of the French, have withdrawn from the region.

The culture areas of the Pacific.

Both the prehistorical and historical periods present problems in the evidence of human activity. Archaeology has provided dates for the earliest settlement, but, until more sites are uncovered, sampling error makes certainty difficult. Linguistics, using a chronology of sound changes, traces the time and place of dispersion of language groups; but many of the languages of Oceania are as yet unstudied and unclassified. Genetics, using the distribution of leukocyte antigens in present blood-group samples, can establish, between contemporary human groups, connections that reveal past migrations, but systematic sampling has not yet been carried out.

The period of Oceanic history for which documentary evidence is available also presents difficulties. The documents are chiefly of European origin and are, therefore, the products of people who may not accurately have recorded a culture different from their own—a culture they perceived and understood only imperfectly. This distortion can be corrected to some extent by using the findings of social anthropology and the oral traditions of the Pacific island people, but these sources are difficult because, by definition, they are contemporary. They may not describe the past accurately because they serve contemporary purposes; they do not record the past for its own sake. But

The distortion of later Oceanic history

the main historiographic problem of Oceania is its diversity. Some 10,000 islands scattered across 500,000 square miles of ocean, a variety of cultures, hundreds of mutually unintelligible languages, and diverse historical experiences make it hard to generalize.

PREHISTORIC TIMES AND THE PROLIFERATION OF CULTURE

The influence of physical geography. The physical diversity means that contact between islands has never been easy because of the distances involved; it also means that the physical environment is not only isolated but varied. The large continental islands of Melanesia—such as New Guinea, New Caledonia, and Viti Levu (Great Fiji)—have a different physical basis of life and a wide variation in climate and fertility; moreover, their rugged terrain has made for social isolation. The smaller volcanic high islands, such as Samoa and Tahiti, have greater homogeneity and are very fertile, supporting life well above the subsistence level. The coral atolls, the low islands of Oceania, support a narrower range of vegetation; they are more exposed to bad weather and support an existence closer to subsistence, except for the rich marine life in the lagoons.

Physical environment does not determine the kind of society that exists, but it does set limits to it. The large islands of Melanesia produce marked differences between people of the coast and those of the interior. Their long coastlines have acted as a filter for many different arrivals in Oceania. The valleys have perpetuated differences. Thus Melanesia is characterized by many small groups of people, divided from each other by language and custom. Political and social organization has been small in scale. The margin above subsistence has not been great enough to allow for elaborate ceremonial. The high volcanic islands of Polynesia offered no such barriers to social and political unity. Their fertility allowed the development of elaborate social, religious, and political ceremonial. The low islands also allowed homogeneity and wide social groupings, but their land resources offered no great margin for ceremonial life. These contrasts within Oceania were obvious to early European visitors, but they conceal a similarity: whether small, with leadership a matter of acquiring influence rather than hereditary position, or larger, with chiefs surrounded with awe and reverence, Oceanic societies all rested on the principle of reciprocity. Every gift or service had to be returned.

Origins of Oceanic peoples. Jules-Sébastien-César Dumont d'Urville, an early 19th-century French navigator and explorer, classified the islanders as Melanesian, Micronesian, and Polynesian. The apparent differences among the islanders were regarded as evidence of separate waves of ethnically different people out of Southeast Asia (a discredited variant theory traced the Polynesians to South America). Recent research suggests that the differences arose within the islands themselves, through the intermixture of an original settlement of non-Austronesian-language speakers from Southeast Asia with a later wave of Austronesian speakers. The earlier wave of settlement occurred in Melanesia at least 33,000 years ago and probably, since New Guinea and Australia were then linked by land, at dates contemporaneous with Australian dates of settlement, extending back to the limit of radiocarbon determination of 40,000 years. Secure dates in the interior of New Guinea approach 30,000 years ago.

The later Austronesian speakers, who are associated with the pottery called Lapita ware (from the site at which it was first discovered in New Caledonia), established themselves in the Bismarck Archipelago about 4,000 years ago and then spread to Fiji, Tonga, and Samoa, which have been regarded as the Polynesian homeland. They then dispersed to Micronesia and eastern Polynesia. New evidence, however, has led to disagreement among prehistorians about the Lapita complex: it may have arrived in Fiji with a later wave of seafaring immigrants. There is also disagreement about the speed with which the Lapita culture, distinctively linked with the Polynesians, moved from Southeast Asia through Melanesia into Fiji and thence to eastern Polynesia; the theory of rapid spread has

been challenged on the basis of the length of time needed for a Polynesian homeland to develop in the Fiji-Samoa-Tonga region. Nevertheless, the known evidence of the Lapita culture outside the Bismarcks is dated after 3,500 years ago. In Fiji and western Polynesia the date is before 1000 BC; in eastern Polynesia it is about 500 BC. Allowing for new evidence to appear and for arguments as to its significance, there are still grounds for supposing that, from a Polynesian homeland region (Fiji-Samoa-Tonga), eastern Polynesia was settled by the Lapita culture bearers. It is possible that the Marquesas were settled as early as the 2nd century BC, rather than AD 300, a date at which settlements may have occurred in Hawaii. The Society Islands were occupied by at least the 9th century AD.

DEVELOPMENT OF DISTINCTIVE CULTURES

Oceanic societies, at the time of European discovery, were Neolithic. They had developed a technology based on stone, bone, and shell; they cultivated tubers and tree fruits, all of which were of Southeast Asian origin, with the exception of the sweet potato, which derives from South America and which culture had spread through most of Polynesia in pre-European times but only marginally into Melanesia. This Neolithic cultivation was associated with three domesticated animals: the pig, dog, and chicken, also of Asian ancestry. The coastal people had developed techniques of fishing and considerable skills as sailors; navigation between the closer islands was well-developed. Some skills were lost: pottery, for example, disappeared in the Samoas and the Marquesas shortly after initial settlement. And with the control of the environment that Oceanic technology offered, there is evidence of overpopulation, settlement spreading into less-favoured areas of the islands and being fortified, as in the Marquesas. (For a further discussion of the indigenous cultures, see below *Traditional cultures of the Pacific Islands*.)

THE PERIOD OF EUROPEAN EXPLORATION

The 16th and 17th centuries. The Oceanic world was not a static one, but changes were slow compared with those that attended European discovery. Vasco Núñez de Balboa was the first European to sight the Pacific, in 1513; seven years later Ferdinand Magellan rounded South America and sailed across the ocean, missing the main island groups but probably encountering Pukapuka in the Tuamotu Islands and Guam. After his death in the Philippines, his expedition encountered some of the Carolines. These northern islands were further explored by the Spaniards as they established a galley trade between Manila and Acapulco. The next major Spanish discoveries were made by Álvaro de Mendaña de Neira and Pedro Fernández de Quirós. In 1567 the former set out from Peru to discover the great southern continent that was believed to exist in the South Pacific. He found the Solomons but failed to find them again on his second journey, during which he died. In 1606 his chief pilot, Quirós, after finding part of the Tuamotu Archipelago, found the northern Cooks, Tikopia, and the New Hebrides. One of his companions, Luis Váez de Torres, found southeastern New Guinea and then the strait (later named for him) between that island and Australia, although the discovery was unknown to later sailors. These Spanish expeditions were motivated by the search for riches, by zeal to extend religion, and, in the case of Quirós, by an interest in discovery for its own sake. But with the voyage of Torres, the Spanish effort was ended.

Thereafter, the Dutch, who were already established in Indonesia, entered the Pacific. They too looked for a southern continent. In 1615–16 the Dutch navigator Jakob Le Maire came from the east through the Tuamotus to find Tonga, New Ireland, and New Hanover. In 1642 Abel Janszoon Tasman, sailing from Batavia (now Jakarta), the Dutch headquarters in the East Indies, saw New Zealand, Tonga, some of the Fijis, and New Britain. The Dutch were primarily interested in commerce; they found none. Tasman thought that New Zealand was part of the great southern continent. The effect of these visitors on Oceania was transitory. They stayed for periods of at most a few months. Their contacts with the islanders were those

Sighting by
Balboa

of simple barter, but the demands they made upon food supplies often caused hostilities in which some European and many islanders' lives were lost, as on Guadalcanal and in the Marquesas during Mendaña's visits.

The 18th century. During the early 18th century the extent of Oceania was further revealed. The English pirate William Dampier visited New Hanover, New Britain, and New Ireland in command of a Royal Navy ship. Dampier was the forerunner of scientific exploration, and he proved that those islands were separated from each other and from Australia. In 1722 the Dutch admiral Jacob Roggeveen crossed the Pacific from east to west on a voyage of exploration that also had commercial objects. He found Easter Island, more of the Tuamotu Archipelago, the northern islands of the Society group, and some of the Samoan islands. These voyages were not essentially different from earlier ones, but they foreshadowed the scientific interest of the later 18th century. The execution of that interest was delayed by European wars. But in 1765 the English admiral John Byron (grandfather of the poet), who was sent by the British Admiralty in search of the supposed southern continent, found more of the Tuamotus and the southern Gilberts. In 1767 Samuel Wallis and Philip Carteret followed, but their ships were separated as they entered the Pacific. Wallis found Tahiti, more of the Tuamotus, and the Society Islands, while Carteret found Pitcairn and rediscovered the Solomons of Mendaña, although he did not so identify them. This was left to the French following Louis-Antoine de Bougainville's visit in 1768, during which he also found some of the New Hebrides and Rossel Island in the Louisiade Archipelago.

The explorers contributed greatly to Europe's knowledge of the Pacific. Dampier's *A New Voyage Round the World* and Bougainville's description of the "noble savage" in Tahiti were particularly influential. The interest their journeys created was in part responsible for the instructions given to the greatest of all 18th-century explorers of Oceania, James Cook. After three voyages he left others little to do but fill in occasional details of Oceania. Cook was sent in 1769 to observe the transit of Venus at Tahiti and then to search for the great southern continent. Cook found some of the Society Islands, but he also circumnavigated New Zealand, and he defined the limits of eastern Australia. During his second voyage (1772–75), he proved that there was no southern continent, but he also made further discoveries in Oceania: in the Tuamotus, the Cooks, the Marquesas, Fiji, New Caledonia, the New Hebrides, and Norfolk Island. His third voyage (1776–79) was mainly concerned with the North Pacific, during which he found some of the Tongan group, Christmas Island, and Hawaii. He had completed the main work of discovery with an exactitude hitherto unknown. Although his contacts with islanders were not in essence different from those of his predecessors, his relations with them were nevertheless more prolonged and more humane. And his exploration of eastern Australia, through the account of his naturalist, Joseph Banks, was of great importance in Oceania, for it led to European settlement close to the islands.

EARLY EUROPEAN SETTLEMENT

Itinerants. With the establishment in 1788 of the Australian settlement, Oceania became a source of supply. In 1793 pigs from Tahiti were landed at Sydney, and until 1826 the trade, although subject to fluctuations due to the competition of other cargoes and Tahitian wares, was important. The competition among Europeans for sandalwood, pearl shell, and bêche-de-mer (sea cucumber), valuable cargoes that attracted ships from the Australian colony, further involved Oceania with the European world. In 1804 sandalwood was found in Fiji, and for the next 10 years it attracted European traders. The sealing industry drew seal hunters to New Zealand, and fur traders, in the 1790s, wintered in Hawaii. All of these contacts began to affect Oceanic societies because they were sustained and prolonged. Together with the castaways and beachcombers who had begun to live in the islands from the days of first European contact and who increased in numbers with commercial shipping, these European contacts began to transform Oceania. Castaways, such as HMS *Bounty*

mutineers who went to Tahiti in 1789, began to alter the political state of the islands they lived in by supporting with their muskets the chiefs who befriended them.

Missionary activity. Such Europeans had an important effect, but they were dependent upon the people they lived with for their survival. Very different were the missionaries, who traveled to Oceania with the deliberate intention of changing Oceanic society. In 1797 the London Missionary Society (LMS), now the Congregational Council for World Mission, sent a party to Tahiti. After some vicissitudes the missionaries converted the chief Pomare II, who controlled the area of Matavai Bay, where Europeans had called since Wallis' discovery. The LMS failed in its first attempts in Tonga and the Marquesas, although it was more successful in Huahine, the Tuamotus, the Cook Islands, and later in Samoa. Other missionary societies followed. In 1822 the Methodists began to work in Tonga; in 1835 they went to Fiji. In the 1840s Roman Catholic missionaries began working in New Caledonia, and the Church of England began to penetrate into Oceania from New Zealand. These missionaries encountered societies in Polynesia that already had a problem of law and order from the influence of European beachcombers and traders. Its solution was to create missionary kingdoms, in the case of British missionaries, or the establishment of direct political control, in the case of the French.

In Tahiti, Hawaii, and Tonga, native chiefs whose power was established by their access to European arms and support not only became kings but took missionary advisers and missionary-designed codes of law. In 1819 Pomare II of Tahiti promulgated such a code. In Tonga, Tautafa'ahu took the name of George in 1833, and in 1845, when he took the Tongan title of Tu'i Kanokupolu, he became "king" of Tonga; in 1862, under the influence of the Reverend Shirley Baker, he adopted a constitution. By attempting to enforce a scriptural code of law, these missionary kingdoms were an answer to the problems of European lawlessness in the islands. If the missionaries could not prevent the sale of arms, they could at least make sure that these passed into the hands of friendly chiefs. But the authority of these "kings" was challenged from two sides. By becoming Christian they had cut themselves off from the mana (a Polynesian religious concept sometimes described as an all-pervasive energy) that came from the old gods, and this produced nativist reactions. In Tahiti in 1830 there was a revolt against the new Christian order by supporters of the old ways; in Tonga in 1831 there was a similar reaction. In Samoa, where the holder of the Malietoa (district chief) title had embraced Christianity from Tahitian missionaries, there were heretical movements. If traditional beliefs thus resisted the chiefs and their missionary supporters, the European traders also resisted the political authority of the kings. Dissidents and heretics looked to these Europeans for leadership, and these Europeans looked to their own national governments for protection.

In Melanesia the story is somewhat different. In Fiji the missionaries who landed in 1835, accompanied by an envoy from George of Tonga, made no headway with the rising chief Cakobau, who was not converted until 1854, when his fortunes were at a low ebb and he needed Tongan support. Elsewhere in Melanesia, the absence of chiefs meant that missionary work had to be conducted with small groups of people and repeated every few miles. There was no wholesale conversion of the kind that had happened in Polynesia. The attempt of the LMS in the New Hebrides in the 1840s came to nothing. The Anglican Melanesian mission in the Solomons made slow progress in the 1850s. In New Guinea, mission work, divided into four spheres of influence in Papua, did not begin systematically until the 1870s. Micronesia was a backwater. The Spaniards had established missionaries in the Marianas in 1668, but the missionaries in the Carolines were killed in 1733. The main effort came from the Hawaiian Evangelical Mission in the 1850s. The general effect of mission activity was, nevertheless, the same as it was in Polynesia. It dissolved the old ties of society by attacking the supernatural sanctions that supported leadership and social mores. It altered the political structure of Oceanic soci-

Importance of Cook's travels

Missionary kingdoms

The *Bounty* mutineers

eties. It incidentally introduced both European goods and the desire for them. The missionaries themselves acted as intermediaries between Oceanic societies and other Europeans—as political advisers, as agents, and as interpreters.

Growth of trading communities. Beachcombers and castaways preceded missionaries in many of the islands, but the growth of trading communities was in part the result of the missionaries' work in restraining native violence. Those traders were initially pork traders in Tahiti, but European captains followed valuable cargoes from island to island. When the supply of sandalwood was depleted in Fiji by 1813, the traders then found it in Hawaii in the 1820s, in the New Hebrides in 1825, and in New Caledonia in 1840. Pearl shell attracted traders to the Tuamotus in 1807. The sandalwood trade declined as supplies were exhausted. Pearling declined as the native inhabitants took reprisals for the atrocities that had accompanied both trades. The demands of the Oceanians also changed the character of trade. Once native polities were established, the demand for muskets fell off; under missionary influence, the demand for alcohol was limited. What the islanders now wanted was clothing and hardware. The exchange traders were not guilty of the cruelties that those looking for sandalwood or pearls were apt to perpetrate, and exchange trading encouraged the growth of resident agents in the islands, a development that met the needs of the whalers who came ashore to refit their vessels. After 1840 it also met the needs of the staple trade of the islands—coconut oil, used for soap and candles. Copra trading, from which the oil came, became the mainstay of European trade because even islands that had no other resources had coconut palms.

European
trade
centres

Such commerce promoted the growth of the port towns and of resident trading communities. Papeete in Tahiti, Apia in Samoa, and Levuka in Fiji became European centres, including not only respectable traders but also lawless men who might be escaped convicts from New South Wales (Australia) or others escaping from the rules of settled societies. These were frontier towns and could be regulated only with difficulty by native kings or by visiting European captains.

Establishment of plantation societies. The problem became more urgent with the advent of permanent European settlers. In Fiji, for example, after Cakobau's first offer to cede the islands to Great Britain in 1858, Europeans arrived to establish plantations, at first of coconuts, then, during the American Civil War, of cotton, and afterward of sugar. The development in Samoa was similar. But planters needed land on a much larger scale than traders, and they needed labour in much greater quantities to work the plantations. Both land sales and labour recruitment caused friction, for "ownership" was not an Oceanic concept; thus, land titles were disputed or resented, and the recruitment of labour often caused the breakup of traditional societies if too many males left their communities and the creation of immigrant labour communities if they did not. By 1870 there were 2,000 such permanent European residents in Fiji. Politically the settlers had an interest in stability, and economically they needed security of title to land and a supply of labour. Neither requirement was satisfied by the missionary kingdoms. Nor was it satisfied by native governments that were not guided by missionaries. In Tahiti, Tonga, Samoa, and Fiji no native authority was able to keep order in the novel circumstances created by European enterprise; in any case, the native kings were themselves open to challenge within their own societies. Pomare II encountered revolt in Tahiti, Samoan politics were always a matter of rivalry between chiefs, and Cakobau's government was threatened by the Tongan chief Ma'afu, who had established his own confederacy in the Lau Islands of the Fiji group.

COLONIAL RULE

Involvement of foreign governments. Eventually the unstable internal conditions in the Pacific began to draw in European governments, all of which acknowledged some responsibility for the protection of their nationals and their property. The French government was the first to intervene, after the expulsion of two Roman Catholic

missionaries from Tahiti in 1836. In the same year two more were deported from Hawaii. In 1839 the Archbishop of Chalcedon suggested regular association between the Roman Catholic missions and the French navy, but the French government was also aware of the need for a good naval station for the fleet and for French commerce and for a place of penal settlement. Abel DuPetit-Thouars thus took possession of Tuahata and the southeast Marquesas in 1842 and in the same year persuaded the Tahitians to ask for a French protectorate, which was formally granted in 1843. In 1853 the presence of French missionaries in New Caledonia led to French annexation, possibly for fear of British action, certainly to establish a penal colony (to which convicts were transported until 1897). Other European nations intervened for different reasons. In 1857 August Unshelm, as agent for J.C. Godeffroy and Son, set up the company's depot at Apia, and Samoa became the greatest trading centre in the islands; and even when Godeffroy failed in 1879, the Deutsche Handel und Plantagesgesellschaft (German Trading and Plantation Company) took over, and Samoa remained the favourite colony of the colonial party in German politics. British nationals had trading and plantation interests in the islands; to give some protection to these interests, the British government had appointed consuls to those islands governed by recognizable rulers, but their powers to maintain order were limited and, except for the visits of warships, unenforceable. The United States also appointed consuls.

The rivalry between these officers and between European entrepreneurs, and the involvement of both in the internal politics of Oceanic societies, merely emphasized to metropolitan governments the disordered condition of the islands. In Tahiti the problem was resolved by French annexation. In Samoa, after a tripartite supervision set up by the Samoa Act of 1889 came to grief in European rivalries and Samoan factionalism over chieftainships, an agreement of 1899 divided the Samoa group between Germany and the United States; Britain received compensation elsewhere. Britain's main concern was in fact with the activity of its nationals: in Fiji, where it accepted the offer of cession of 1874, it did so primarily because native authority had broken down. But Britain also had been concerned with the labour trade by which the Queensland (Australia) plantations took islanders, who were sometimes recruited under doubtful or brutal conditions. In the 1860s this trade flourished in the New Hebrides, and violence there led the missionaries to protest. Then the labour trade moved north to the Solomons, where again there was violence, including the murder of the Anglican bishop in the Santa Cruz group, from which five men had been taken by recruiters. The British solution was the Western Pacific Order in Council (1877), which empowered the governor of Fiji to exercise authority over British nationals and vessels in a wide area of the western Pacific. The problem still remained, however, of non-British nationals in islands that had neither native kings nor European governors, especially those of Melanesia.

European government, like both mission and commercial enterprise, had been slower to penetrate Melanesia. Missionary activity did not begin in New Guinea until 1873. There was not much labour recruiting. The first main activity was the gold rush of 1877, but German traders had arrived on the northern coast in 1873, followed by the firm of Hensheim & Co. (a general trader) in 1875. Such foreign interest produced a demand in the Australian colonies for annexation for reasons quite unconnected with the internal situation in the islands. German interests were marked in Micronesia, French in the New Hebrides. A number of groups in Australia also looked on New Guinea as a rich possession. But the British government, notwithstanding Queensland's abortive attempt at annexation in 1883, would not annex unless the Australian colonies paid the cost of administration, the same argument it was applying to New Zealand's interest in the Cook Islands. When the Australian colonies agreed to pay, the British government acted. Southeast New Guinea was declared a protectorate in 1884 and annexed four years later; the Cooks became a protectorate in 1888 and were annexed in 1901. Germany annexed northeast New

Naval
stations
and penal
colonies

The annex-
ation of
Melanesian
islands

Guinea in 1884, including the Bismarck Archipelago; in 1886 it took possession of the northern Solomons (Buka and Bougainville). The British established a protectorate over the rest of the Solomons in 1893. In Micronesia the Germans, after an attempt to annex the Spanish possession of the Carolines in 1885, finally bought them from Spain with the Palaus and the Marianas (excepting Guam) in 1899. They had annexed the Marshalls in 1885 and, under a convention with Britain of 1886, the phosphate-rich island of Nauru. By that convention Britain's interest in the Gilberts was recognized, although no protectorate was declared until 1892. The Ellices were added to it, the group becoming the Gilbert and Ellice Islands. France declared a protectorate over Wallis and Futuna in 1887, and in the same year a convention set up a mixed British and French naval commission in the New Hebrides. Its authority was limited, and in 1906 a Condominium was agreed upon by which such difficult legal questions as land title were settled and a joint administration set up. The process of partition was completed by the United States, which took Guam in the Spanish-American War (1898), annexed the republic of Hawaii that same year, and obtained American (eastern) Samoa by agreement with Germany and Great Britain in 1899 and by deeds of cession (1900, 1904) from island chiefs.

Patterns of colonial administration. With the exception of Tonga, which remained an independent kingdom under British protection (from 1900) with a consul who was not to interfere in internal affairs, almost the whole of Oceania passed under the control of European powers and the United States between 1842 and the end of the century. Having acquired colonies, these powers governed Oceania with metropolitan institutions modified to a degree by local circumstances. Thus, Britain reproduced in the islands the pattern of crown colony government, which derived from its own political development: a governor who represented the king; an executive council of senior officials; and, where the European population justified it, a legislative council to advise the governor. Within this form of government, administration was adapted to local conditions. Thus, Sir Arthur Gordon, the first governor of Fiji, set up a system of native administration that incorporated the chiefs: the island was divided into provinces and districts that, on the information available to him, represented the old divisions of Fiji, and over each he tried to select the chief to take administrative office. Even in Melanesia, where chieftainship was not highly developed, the British attempted to appoint chiefs who were men of influence. The first administrator of British New Guinea was a former officer in Gordon's government, William MacGregor, who first tried appointed chiefs and then settled for village constables. The Australians, who took over British New Guinea in 1906 and rechristened it Papua, followed the British pattern. The first Australian governor, Sir Hubert Murray, although he introduced measures of native development, still preserved the British pattern of colonial government, as did New Zealand in the Cook Islands. Beneath the governor, district administration tried to incorporate both native leadership and the technical and professional direction of specialized departments (such as agriculture and health), as well as those departments that dealt with the questions raised by European settlement (such as land and labour).

Other nations had different patterns. The Germans, if only because domestic German politics made colonies an incident of European policy, tried to administer their colonies through commercial companies. In northeastern New Guinea, the German New Guinea Company was commissioned to administer the colony as a commercial enterprise. Only when it failed did the imperial government assume responsibility (1899). In the Marshalls, the German firms known as the Jaluit Gesellschaft became a chartered company under a government commissioner in 1885. In Western Samoa, in the first decade of the 20th century, the governor Wilhelm Solf attempted to control the importation of Chinese labour for the plantations and tried to enlist Samoan interest for the government, but he was subject to the pressure commercial interests were able to exert in Germany itself. In the French territories,

colonial rule meant assimilation to French institutions. The governor was analogous to the prefect of a French *département*, assisted by an administrative council and from time to time by a general council drawn from French citizens. Where such a council existed, its powers were limited to an optional section of the budget, the rest of which was obligatory. In effect, the governor ruled by administrative decree. In the U.S. territories there was also a marked assimilation to U.S. metropolitan forms of government. When Hawaii was annexed in 1898, the president of the republic became a U.S. governor. When eastern Samoa was given to the United States under the convention of 1899, President William McKinley, in 1900, placed it under the authority of the Department of the Navy, the commanding officer of the station also becoming governor and administering the islands with the help of his technical officers and the advice of a Samoan fono, or legislature. These colonial governments were adapted to local circumstances. In the Polynesian islands and in Fiji, Britain and Germany attempted to incorporate the authority of the chiefs into their governments, both as advisers and as local officials in the districts, as did the United States in American Samoa. But in both Hawaii and Tahiti the old system of rank had broken down under the impact of missionaries, traders, and settlers, so that it could not be used for administrative purposes but had to be replaced by appointed local officials. In Melanesia, where there was in general no chiefly authority that could be used because influence was acquired by criteria that made it fleeting, the colonial powers had no choice but to use appointed local headmen. The Germans and the British used appointed headmen in New Guinea and the Solomons, and the system was supervised by a patrol of European officers with an escort of armed native police. The patrols were brief and infrequent, however, and their effect was limited.

Colonial rule after World War I. This pattern of colonial rule in Oceania was altered by the outbreak of World War I in 1914. An Australian force took German New Guinea, and a New Zealand force took German (Western) Samoa; Japan took the Carolines, the Marshalls, the Palaus, and the Marianas. At the end of the war these German territories, together with Nauru, were retained by the occupying powers as mandates under the League of Nations. The professed aim of the administrators was to help the people of these territories to stand on their own feet under the strenuous conditions of the modern world.

This stress on Oceanic interests was not new, but it became an international standard. Still, the first step was the establishment of government control and of law and order before any other measures could be taken. In New Guinea, in the Solomons, and in many parts of Melanesia, the interior was rarely known, let alone controlled. So the attention of colonial government was concentrated on opening the interior. The government-sponsored exploration in 1933 of the grass valleys of New Guinea, which had been known for a decade by missionaries and miners, presented the Australian administration with the problem of 750,000 new people. Australia's resources for administering New Guinea were spread thinly. Health and education were left to the missions. By contrast, Fiji was more developed. With the importation of labourers from India to work the sugar plantations from 1879, and with the reforms in the indenture system (which came after a commission of 1909), the large Indian population of Fiji received the attention of the government in education and health matters, but the increase in this population raised the difficult question of the Fijians' future. They played a minor part in the economic life of the colony, and the trend of official policy was to preserve them within their villages under a separate system of administration, which was reorganized in 1944 as the Fijian Administration—to be virtually a state within a state. But the government's resources were not enough to introduce welfare measures, nor was it able to promote development on any great scale. A good deal depended on the missions and other private organizations. In Samoa, where the old society had retained its organization, there was resistance to change. The New Zealand administration of Western Samoa had

The British system

The Germans in Samoa

The role of the missions

begun with the objective of promoting the welfare of the native race, which meant health, education, and better use of the land. By recognizing Samoan councils it tried to ensure Samoan support, but the policies broke down in execution. In American Samoa the U.S. Navy provided welfare services as part of its routine work but could do little more than that when its principal concern had to be the smooth running of the naval base. In French Polynesia native policy aimed at making the people French citizens. The welfare services were directed from Paris, but they were limited by the resources available.

WORLD WAR II AND THE POSTWAR ERA

Impact of the war. Such limited resources and the competition between different objectives of colonial policy plainly restricted what could be done. The islands were affected directly by external events such as the Great Depression and the fluctuations in world markets for copra, sugar, and other products of Oceania. The principal achievements of the colonial powers were to check population decline by control of the introduced European diseases that had ravaged the islands and by increasing control of endemic diseases (such as malaria in Melanesia) and to hold a rough balance between European and indigenous interests. But welfare policies and island administration were both interrupted by World War II. The Japanese had been established in the north of Oceania, where they had treated their mandates as part of Japan itself. In 1941 they advanced into the rest of Oceania, reaching and controlling most of New Guinea and, at the peak of their advance, as much of the Solomons. New Caledonia, the New Hebrides, Fiji, and the islands of Polynesia were not occupied, but the effects of the war made colonial government there secondary to military operations. After the war the Trusteeship Council of the United Nations replaced the mandates; all of the colonial powers accepted that independence or self-government was the aim of their rule. The Oceanians themselves had been exposed to a more intensive European (and Japanese) impact; their horizons had widened. The colonial powers felt a greater urgency to promote development and to make available greater resources to achieve it.

Beginnings of self-government. Politically, colonial governments were reorganized to give indigenous people a part in government. In Western Samoa in 1947 the Legislative Council was given a Samoan majority and considerable powers. In American Samoa naval rule was replaced in

1951 by civilian control, and a legislature of two houses was set up, which by 1960 became a lawmaking body of Samoans. In French Polynesia and New Caledonia, elected assemblies were given considerable local autonomy in 1956; both territories chose to stay within the French Community in 1958. The trend toward a limited degree of internal autonomy and increased political participation by native residents continued in the 1960s in Fiji, the Cook Islands, and other Pacific dependencies.

THE INDEPENDENCE MOVEMENT

With the exception of some French, American, and Chilean territories, most of the Pacific Islands had achieved independence by 1980. Although most of these newly independent territories remained within the British Commonwealth, they represented a sizable addition to the ranks of microstates.

The speed of political development in the Pacific Islands was partly a matter of external pressure in the United Nations; but the colonial governments, with the exception of the French, were already moving toward self-government or independence. There were no mass nationalist movements, as in Africa and Asia, to whose demands colonial governments responded. The reaction to European rule usually took the form of nativistic movements or cargo cults in which rituals attempted to secure "cargo" diverted by Europeans. Occasionally, as with the Mau ("Strongly Held View") movement in Western Samoa in the 1920s and '30s, there was more overtly political action. In the French territories of French Polynesia and New Caledonia, for example, European-style political parties have demanded greater local autonomy and, as a minority, independence. In Fiji and Papua New Guinea, political parties formed when electoral machinery was established. The absence of mass nationalist movements owed something to the policies of colonial governments, which on the whole maintained the paramountcy of Oceanic interests; but it owed even more to the nature of Oceanic societies, in which kinship ties and a preference for consensus as "correct" behaviour led to "the Melanesian way" or "the Pacific way" as a style of politics. (F.J.W.)

TRADITIONAL CULTURES OF THE PACIFIC ISLANDS

General considerations

INDIGENOUS PEOPLES

Archaeological research has been undertaken in the Pacific Islands to trace the region's migration and settlement patterns. The region is vast, however, and understanding is both incomplete and uneven, despite collaboration among archaeologists, linguists, and physical anthropologists.

The area first penetrated by human immigrants was limited to New Guinea, Australia, and Tasmania, which are thought to have been connected in the Pleistocene Epoch (1,600,000 to 10,000 years ago) in what has been called the Greater Australian continent. Excavations in southeastern Australia reveal that people of modern type, *Homo sapiens sapiens*, had arrived there by 40,000 years ago. Migration eastward from New Guinea began by the end of the Pleistocene, but movement beyond the Melanesian region required sophisticated watercraft and did not occur until 4,000 to 3,000 years ago. Then, generations of voyagers ranged eastward into Polynesia (Fiji, Tonga, Samoa) and northward into eastern Micronesia, bearing with them distinctive physical, cultural, and linguistic characteristics.

Racial groups. The reconstruction of the racial history of Oceanian peoples has produced many theories and explanations. The opportunities for breeding groups to develop in isolation and evolve adaptive responses to special conditions were numerous, and just as important to the

racial diversity of the area is the hybridization produced by centuries of ebb and flow of migrating peoples. Such diversity is certainly the combined result of isolation or its lack, adaptation to differing environments, mating patterns, and natural selection.

Authorities disagree over whether early hominid forms known from fossil finds to have inhabited Indonesian, Melanesian, and Australian areas were progenitors of peoples found there in recent times. There is similarly a great diversity of opinion on just which groups may have been antecedent—the Australoid, Veddoid, or Negritoid peoples found in the insular projection of lands south of Asia. Some specialists once proposed commonality of origin or at least some link between the Negroid peoples of Africa and the darkly pigmented, sometimes frizzy-haired groups found in Melanesia. Blood-group research studies, however, show no evidence for such claims. In general, notions of a series of massive migrations, of relatively "pure" racial types from the Asian continent, and their miscegenation with antecedent peoples, seem to most specialists to be simplistic. Blood-group genetic research has contributed to a better understanding of certain populations, however, particularly the Negritos of the Philippines, who are thought by some researchers to be descended from late Pleistocene peoples who inhabited the islands of Southeast Asia and who are called Proto-Malays.

The racial composition of Pacific peoples is a composite

Earliest
occupation
dates

Main
racial
elements

of Mongoloid, Caucasoid, and Negroid elements; Negrito peoples have survived or been reported in remote areas of Melanesia, Australia, and Tasmania in addition to the Philippines. The Australian Aborigines may be described as a subcontinental isolate, although there is some evidence of genetic markers that point to ancient ties with New Guinea populations. Generalizations about the normative racial type of a particular culture area may be misleading. There are general tendencies, of course, but there are also such ranges of characteristics within virtually all areas that a representative of one area could easily be assimilated in one or more other areas.

Hair form among certain Melaneseans is kinky, and many Polynesians have wavy to straight hair; but kinky hair is also to be found in Polynesia, as is curly to straight hair in Melanesia. The epicanthic eye fold, which distinguishes Mongoloids, is found in abundance in Micronesia, but it occurs elsewhere as well. Recognizing the difficulties of generalization, then, it may still be noted that Tongans, Fijians, Samoans, and Hawaiians are often tall and inclined to corpulence. Pigmentation generally tends to be darker among Melanesian groups than is normal in Polynesia or Micronesia. In some of the Melanesian islands, such as the Solomons and New Britain, colour is virtually blue-black in some individuals. The ruggedness of Australian Aborigine facial characters exceeds that of other regions of the Pacific Islands. The people of the New Guinea Highlands are of relatively short stature and have facial features of distinctive quality.

Migration sequences. The influxes of population into Australia and Tasmania continued until at least the final phase of the Pleistocene (12,000 to 10,000 years ago). Tasmania was then cut off by the rise in sea level as the polar ice caps partially melted and the Bass Strait was formed. New Guinea, because of its size and location, continued to receive migrants well past the end of the last ice age. Migration to Micronesia and Polynesia appears not to have begun until 4,000 to 3,000 years ago: the islands of these areas were thus the last habitable portions of the Earth to be populated.

Chronological sequences based on pottery styles, types of fishhooks, and other dating techniques suggest that human presence in Micronesia was earlier than the oldest radioactive-carbon date yet found there of approximately 3,500 years ago. The evidence points to the entry of people into central Polynesia from eastern Melanesia. In due course, migrations radiating from both western and eastern central Polynesian island groups are thought to have settled the more distant reaches of Polynesia. The Marquesas were reached by people from Samoa as early as AD 300. Some authorities have suggested that settlement may have been even earlier. Hawaii was first reached midway to late in the 1st millennium AD by voyagers from the Marquesas, who were followed several centuries later by those from the Societies. The Societies also appear to have been the point of origin for the Polynesians who settled the Cook Islands, and people from either the Society or Marquesas islands reached New Zealand prior to AD 1000. Although the validity of the radioactive-carbon dates that have been recorded for Easter Island, indicating human presence by 400, has been questioned, the dates are in accord with the time of settlement of the Marquesas (whence Easter Island probably was reached).

The watercraft used by the ancient migrants from Asia were probably crude rafts or coracles; it is likely that the highly sophisticated sailing vessels so distinctive of the cultures of the islands developed over a long period of time. However simple the early craft, those that were used thousands of years later to explore and settle the far reaches of Micronesia and Polynesia were impressive indeed. These were great double-hulled vessels capable of carrying a hundred or more voyagers and their provisions for a voyage lasting a month or longer, as well as carrying domesticated animals and plants for propagation in a new homeland.

The issue of deliberate versus accidental voyages of discovery in the Pacific has prompted an impressive array of arguments from specialists on both sides. There is considerable evidence that some islands were, indeed, populated

by seafarers who, because of a storm or mere random sailing, came unexpectedly upon their new home. There is also a great deal of evidence, however, of the navigational skills and abilities of Oceanian peoples and of certain deliberate voyages of discovery. It is also clear that return voyages were made to points of origin.

Language groups. The study of Oceanian languages sometimes requires generalizations that are no more than statements of probabilities. Many of the languages have yet to be studied, and some are beyond study because they are extinct. Nevertheless, linguists offer the following characterization.

The languages of Polynesia, Micronesia, Melanesia, and Indonesia may be divided into two major groups: the Austronesian (sometimes called Malayo-Polynesian) and the non-Austronesian (also called Papuan). Virtually all of the latter group are found on New Guinea and islands to the east and west of it. Some 750 or more Papuan languages have been identified. The number of Austronesian languages probably exceeds 600. Their geographic distribution extends from Easter Island to Madagascar and from Hawaii and Taiwan to New Zealand, and they are spoken in New Guinea, except for the south coast area. There are even some Austronesian languages found in Southeast Asian mainland communities.

Most of the more than 200 languages of Australia, although in some instances quite different from each other, are thought to be related to one another—more than 85 percent being closely related. Common structural features strongly suggest a single original linguistic stock. Attempts to trace the Australian languages to those of other areas, even to contiguous ones, have proved fruitless; this probably indicates the great antiquity of the languages of Australia and the long isolation of the Aboriginal population (see also *LANGUAGES OF THE WORLD: Austronesian languages; Papuan languages; and Australian Aboriginal languages*).

Effect of European contact on population trends. The nature and number of the various island peoples at the time of the arrival of Europeans are uncertain. The period of European exploration was spread over several hundred years, beginning in the 16th century and becoming intense by the 18th and 19th. It was 1788, for example, before colonists from Europe settled in Australia. The number of Aborigines at that time is not known, and their widely dispersed and seminomadic hunting-and-gathering groups are estimated to have been organized into several hundred to nearly a thousand tribes. Tribal groups were generally associated with a given territory in which they eked out an existence from a relatively inhospitable land. Theirs was a simple yet highly functional material culture, which contrasted with a complex social system and a rich ceremonial life, featuring ancestor worship and totemic beliefs. They had rudimentary, impermanent shelters, went unclothed but for personal adornment, and foraged, hunted, and fought with simple but efficient implements and weapons. Some have estimated an Australian Aborigine population of 300,000 at time of European contact, but this is at best a guess. It is thought that the population had over time stabilized in relation to the ecology of the subcontinent and that, as a food-gathering and hunting culture, it was in balance with the environment. Like many other Oceanian peoples, the Australian Aborigines suffered severe population loss as a result of contact with the Western world.

DIVERSITY OF PACIFIC CULTURE PATTERNS

The people and cultures of present-day Oceania differ greatly from those of the days when the areal classification into Polynesia, Melanesia, Micronesia, and Australia was devised. The Aborigines of Australia are few in number, and many are of mixed race. The Tasmanian Aborigines fared even worse and became extinct in the late 19th century. Other Pacific peoples, such as those living in the Mariana Islands and on Easter Island, often are more Spanish and Chilean, respectively, than they are Micronesian or Polynesian. On some islands there are substantial populations of East Indian, Chinese, Japanese, or European-North American origin. With few exceptions, such as in remote areas of New Guinea, the peoples of the Pacific

Aborigine
culture

Islands have been exposed intensively to Western civilization and have adapted their ways to it either by choice or by necessity. Only certain features of their traditional cultures remain. There are, in greatly varying numbers, native inhabitants of all regions who manifest the physical types commonly associated with their culture areas. In some places, however, the native population is in the minority. It is, therefore, no longer accurate to say that the people of the Hawaiian Islands possess a Polynesian culture or that those of New Caledonia are Melanesian culturally. Nevertheless, the fourfold typology of Oceanian peoples and their cultures continues to be used with reference to the contemporary inhabitants as well as to the traditional people of Oceania and their ways of life.

Mana
and tapu

Social structure. Highly stratified social structures are typical of the aboriginal cultures of Polynesia and Micronesia. Hereditary chieftainship was closely related to supernatural beliefs that incorporated concepts of power (mana) and avoidance (tapu). Features of these two culture areas include an elaborate mythology, specialist craftsmen, distinctive artistic styles produced in part by isolation, pandemic and sometimes savage warfare, strong bonds of kinship and a related emphasis on genealogies, and, in places, strong trading or tributary relationships between island communities.

Melanesian societies are, because of their great diversity, less easily characterized. They were in general less concerned with social rank based on birth than with prestige gained through manipulation of resources. Root-crop agriculture (principally yams, sweet potatoes, and taro) was practiced as in many parts of Micronesia and Polynesia, and the resources of the sea were widely exploited. Ancestor worship and a rich ceremonial life were combined to produce a wealth of religious practices; they marked life-crisis situations and incorporated both venerative and propitiative behaviour. In many areas complicated and highly ritualistic trading relationships were developed, and there were usually distinct differences between coastal and inland societies. Personal adornment was often elaborate; warring raids, in which heads were taken and cannibalism was sometimes practiced, were common; stone tools were polished; and animism was featured in supernatural beliefs. Melanesia's domesticated animals were those found elsewhere in the Pacific region, but pigs were vastly more important in the pursuit of personal prestige.

Technological development. Most of the people of the Pacific, prior to contact with the Western world, were at the Neolithic stage of technological development; that is, they worked stone by grinding rather than by chipping and flaking as in the Paleolithic stage. Some areas also had various other cultural features of the Neolithic such as agriculture, animal husbandry, pottery, and watercraft.

Seashells were used generally both as ornaments and as cutting tools. Shark, snake, and lizard skins were used as heads for drums. Bird, whale, and human bone, as well as fish vertebrae, were used for ornamental purposes and for tools, implements, and weapons. Basalt, obsidian, jadeite, chalk, coral stone, and other lithic materials are irregularly distributed throughout the Pacific Islands. Where these materials were available craftsmen produced a bounty of objects—adz blades, ornaments, images, and weapons—by skillfully chipping and grinding. Native woods of both hard and soft varieties were used to produce finely executed weapons, drums, masks, images, and building ornamentation. Great logs of pine were felled in New Zealand to produce flotillas of war vessels that could carry more than 100 men. Other islanders, without suitable timber for such canoes, scoured the beaches for driftwood logs or devised canoes from smaller trees, fastening planks together with cordage and caulking the seams with gum. Polynesian ironwood provided a source for some of the most intricately carved and heaviest of weapons. Ebony, bamboo, tree fern, and palm all added to the lumber supply of the carver. Feathers of colourful birds were woven into garments and effigies in some places. Headdresses of feathers appeared in many parts of the Pacific region, but only the Hawaiians devised beautiful feather helmets. The kiwi, the tropic bird, the parrot, and the cassowary were but a few of the birds that added their plumage to

the artisan's kit. Fibres and barks were used abundantly, particularly orchid fibre, hibiscus, banana, flax, pandanus and ti leaves, and coconut-husk fibre. Pigments such as turmeric were obtained from plants. Earth and burned coral provided others. Pacific island craftsmen also used resins, gums, seaweed, spider webs, flying-fox fur, human hair, dog skin, kangaroo fur, boar tusks, vegetable seeds, shells, and teeth from humans, dogs, fish, and fruit bats (see also OCEANIC ARTS).

The environment in which the traditional island native lived provided the setting for his culture. If there was little suitable land for agriculture, he had only tree crops such as coconut or pandanus; yam growing could thus not become a factor in social prestige nor could tapa making become a fine art. Although environment did not absolutely determine the nature of the culture that evolved in a given location, it served as a limiting factor; the technology of a people was in direct consonance with the surrounding region. The peoples who lived on continental islands (that is, on islands geomorphologically connected with a continent) had at their disposal a variety of minerals, a diversified flora and fauna, and, usually, a good freshwater supply. By contrast, the resident of a small coral atoll was preoccupied with securing an adequate supply of potable water and had fewer species of plants and animals. The type of island, its age, composition, and elevation, as well as its location and climate, were vital factors in the development of a particular culture. Oceanian peoples had to adapt to a broad range of extremely diversified environments—tiny Micronesian atoll, humid New Guinea forest, or arid Australian desert. (R.W.Fo.)

Environmental
limitations

Melanesian cultures

Melanesian is an old anthropological category that has been rendered somewhat obsolete by developments in pre-history and linguistics. It groups together the dark-skinned, frizzy-haired populations of the southwestern Pacific and characterizes them culturally in terms of Neolithic root-crop economies, highly developed systems of exchange, generally small-scale and nonhierarchical polities, and diversity in social structure. As a culture area, Melanesia can be reexamined in the light of modern evidence.

The vast continental island of New Guinea and the islands that form an arc from its eastern end down toward the southeast—the Bismarck Archipelago, the Solomon Islands, the New Hebrides (the state of Vanuatu), and New

Caledonia—represent a meeting ground of two cultural traditions and populations. The earliest, for which the term Papuan provides the best label, is ancient: Papuans occupied the Sahul continent (now partly submerged) at least 40,000 years ago. As hunting-and-gathering peoples whose ways of life were adapted to tropical rain forest, they occupied the equatorial zone that, after sea levels rose at the end of the Pleistocene glacial period, became the vast island of New Guinea.

Modern descendants of these early populations speak languages belonging to a number of different families. They are categorized as Papuan (see *LANGUAGES OF THE WORLD: Papuan languages*).

Perhaps partly through indirect contact with developments in Southeast Asia, Papuan peoples developed one of the earliest agricultural complexes in the world (perhaps 9,000 years old, contemporaneous with the dawn of agriculture in the Middle East). Evidence indicates that they domesticated root crops and sugarcane and may have kept domestic pigs. By 5,000 years ago agricultural production in parts of the New Guinea Highlands was marked by systems of water control in agriculture and associated pig husbandry, both of which became intensified over subsequent millennia.

About 4,000 years ago seafaring peoples bearing a Southeast Asian cultural tradition must have been moving in areas north of New Guinea; by 3,500 years ago they had occupied parts of the islands of the Bismarck Archipelago. Their presence is marked by the appearance of the distinctive pottery and associated tools and ornaments of shell that define the Lapita culture. They apparently spoke a language of the Austronesian family (see *LANGUAGES OF THE WORLD: Austronesian languages*) related to languages of the Philippines and the Indonesian archipelago. This early language is labeled Proto-Oceanic: from it are descended the languages of central and eastern Micronesia and Polynesia; the languages of the Solomons, Vanuatu, and New Caledonia; and many of the languages of coastal eastern New Guinea, adjacent islands, and much of the Bismarck Archipelago.

The speakers of Proto-Oceanic, who had a maritime orientation and sophisticated seagoing technology, probably had a system of hereditary chiefs with political-religious authority and elaborate cosmogonies and complex religious systems that were not unlike those recorded in western Polynesia.

Earliest
Melanesian
settlement

The Bismarck Archipelago east of New Guinea was already occupied by speakers of Papuan languages (whose earliest settlement has been dated to 30,000 years ago). The dark-skinned, woolly-haired populations anthropologists have classed as Melanesian that now occupy the Bismarck Archipelago and the arcs of islands extending to the southeast (the Solomons, Vanuatu, New Caledonia) represent the mixing of cultural traditions and biological heritages of Papuan and Austronesian peoples. The mixing may have taken place largely within the zone of the Bismarcks prior to the settlement of the islands to the southeast (although the exact process and relative contributions of these historical populations is debated). A great deal of economic interchange took place between a Southeast Asian complex based on root- and tree-crop cultivation and on maritime technology and the already well-developed Papuan agricultural and technological systems. It is probable that an interchange of other cultural traditions, from social organization to religion, took place as well. Some Austronesian-speaking communities—perhaps ones that retained their maritime orientation—appear to have remained relatively isolated from intermarriage and cultural interchange.

Linguistically, in the interchange between Papuan and Austronesian peoples the latter were clearly dominant. Almost all languages spoken by dark-skinned peoples in the Pacific east of the Bismarcks are classed as Oceanic Austronesian, although some (especially those of the eastern tip of New Guinea and adjoining islands, but perhaps also those of the Santa Cruz Islands, southern Vanuatu, New Caledonia, and the Loyalty Islands) reflect extensive Papuan borrowings. The languages spoken by dark-skinned peoples of the southeastern Solomons and north-

ern and central Vanuatu are closely related to the languages of Polynesia and central and eastern Micronesia.

The zone east of New Guinea can be characterized as island, or seaboard, Melanesia, to contrast it with the Papuan-speaking zone of the continental island of New Guinea itself. "Melanesian" has sometimes been used in a narrow sense to label the dark-skinned peoples speaking Austronesian languages, in contrast to "Papuans." More commonly, "Melanesian" has been used in a more inclusive sense, to label both.

Little evidence has been found to identify the earliest settlers of the zone of island Melanesia south and east of the Bismarcks. It seems likely that the Solomons chain was settled by Papuan-speaking populations following the early occupation of the Bismarcks. The islands to the southeast of the Solomons—the Santa Cruz group, Banks Islands, New Hebrides, New Caledonia, and the Loyalties—are separated by much larger gaps of open sea, and they may well have been unoccupied prior to the arrival of Austronesian-speaking peoples in the Bismarcks. The pioneer settlers of large zones of island Melanesia may have been speakers of Austronesian languages who represented the genetic and cultural fusion described above, and others, contemporaneous with them, who had remained relatively isolated from intermarriage and cultural interchange with Papuan speakers. In the period from 3,500 to 3,000 years ago the latter established coastal communities and associated trade systems in the southeastern Solomons, New Hebrides, New Caledonia, and Fiji. Long-distance trade, particularly of shell ornaments and obsidian, suggests that these widely spread communities characterized by the Lapita pottery tradition were linked politically. The settlement of eastern Micronesia by speakers of Oceanic languages, perhaps from the Solomons, apparently took place in this period. Fiji apparently was initially colonized by Lapita-making peoples and later was settled by dark-skinned, culturally Melanesian peoples after Fiji had been a springboard to the settlement of western Polynesia. The spread of this Lapita tradition from Fiji into Samoa and Tonga fits closely with the evidence of the initial breakup of a linguistically reconstructed Proto-Polynesian.

Long-
distance
trade

Although the prehistory of most of island Melanesia remains little-documented, some evidence suggests that the cultural, linguistic, and political fragmentation that prevailed at the time of European penetration, with a half-dozen languages and cultures often represented on a single island, is partly a product of devolution in the past 2,000 years. More hierarchical regional political systems and concomitant trade systems seem to have fragmented and devolved, with progressive involution, the replacement of trade by exchange, the disappearance of political hierarchy (except in some coastal zones), and the separation of language or dialect groups as results. The causes of these transformations, perhaps including internecine warfare and the spread of diseases (of malaria in particular), remain unclear. These changes were accelerated by European penetration, which further disrupted trade systems, intensified intercommunity warfare by supplying firearms, thinned populations by introducing diseases and indentured labour, and eroded traditional authority systems. The island Melanesia described by anthropologists reflects both long-term devolution and recent disruption.

Although the mix of Austronesian and Papuan cultural elements varies in different parts of island Melanesia, in many ways the classification of these peoples and their cultures along with Papuan-speakers as Melanesians—in contrast to the Micronesians and Polynesians—does violence to the ethnological, linguistic, and archaeological evidence. The Melanesians of northern Vanuatu and the southeastern Solomons speak languages very closely related to those of Polynesia and eastern Micronesia. Culturally, they are in many ways more closely related to these other Austronesian-speaking peoples than to the Papuans of interior New Guinea. The Melanesians' religious systems, for example, incorporate such concepts as *mana* and, in the Solomons, *tapu*.

A further complexity is that the region has emerged not only into the modern world but also into the community of nations: Papua New Guinea, Solomon Islands, Van-

uatu, and Fiji constitute separate nation-states; western New Guinea (Irian Jaya) is a province of Indonesia; and the indigenous peoples of New Caledonia and the Loyalty Islands are locked in a struggle for independence with French settlers and the French government.

SOCIAL AND POLITICAL LIFE

Settlement patterns. In many areas, local groups were not concentrated in villages but were dispersed through territories in scattered homesteads and hamlets. In many cases these were occupied for short periods until the groups moved on to follow cultivation cycles. Where communities were in danger of surprise attack, they tended to cluster more closely; in interior areas they were usually sited on ridges and peaks.

In parts of the Sepik plains of New Guinea, huge villages (some with populations of more than 1,000 people) represented the aggregation of descent-based local groups. In the agricultural heartland of northern Kiriwina, in the Trobriands (Massim), villages of up to 200 people were arrayed around a central dance ground; villages at least as large were packed together on coral platforms in the lagoons of northern Malaita (Solomons). In general, larger villages settled over a span of generations were characteristic of coastal environments, and smaller, shifting settlements were characteristic of interior areas.

Residential separation of the sexes was common. Men's clubhouses, a focus of ritual and military solidarity, were common in many areas of New Guinea and island Melanesia. The men's huge cult-houses of the Sepik River basin and on the southern Papuan coast are examples. In the montane, sparsely settled interior zone of New Guinea, men's longhouses were built as defenses against the threat of raiding and as centres of cult activities. Women and children occupied domestic dwellings; in some regions women were isolated during menstruation and childbirth.

Gender relations. In many parts of New Guinea and island Melanesia, male-female relationships were polarized. In New Guinea a zone of extreme polarization extended from the Papuan coast (Marind-anim, Asmat) along the southern face of the Highlands (Anga speakers, Papuan plateau) and the high central mountains (Mountain Ok peoples) down into the Sepik. Men's cult secrecy, ritualized male homosexuality, elaborate men's initiation rituals, and the celebration of warfare were accompanied by belief in the dangers emanating from women's bodies and by separation of the sexes. Peoples throughout this zone were preoccupied with growth and with the physical fluids and substances (menstrual blood, semen, vaginal fluids) that are agents of reproduction and growth, all regarded as sources of power and danger.

These concerns were echoed in the eastern Highlands with a physical separation of the sexes, men's initiations and cult rituals, the use of sacred flutes, ritualized nose- or penis-bleeding (ostensibly in imitation of menstruation), and accompanying myths of an ancient female power that fell into the hands of men. In the Sepik basin complexes of what has been called "pseudo-procreative" ritual accompanied male cult activities.

In the central and western Highlands, where populations were dense and sweet potato and pig production were intensive, the risk of pollution by the female body and the array of male ritual activities were subordinated to the politics of extracting female labour, acquiring prestige and power through exchange, and mobilizing armed strength. Although cosmological beliefs reinforced the separation of male and female realms, women were actually a danger more as potential spies from enemy groups than as sources of polluting substances and essences.

In the Massim, in contrast, the powers of women, reproductive and productive, were represented both in the realities of social relations and in ideologies of descent and cosmic processes. In the Trobriands, women played prominent parts in some rituals. Matrilineages (in much of the Massim called *susu*, meaning "breast" or "breast milk") provided symbols of cosmic reproduction as well as physical and social reproduction.

While some polarization of the sexes emerges in accounts from the Solomons and Vanuatu, sexual segregation and

concerns with pollution by females seem to have more to do with the preservation of symbolic boundaries than the inherent dangers of women's bodies and essences. In everyday domestic politics, women had relatively high status in many island Melanesian communities. Their complementary but central role was widely given cultural recognition. In many areas both paternal and maternal links provided bases of ritual status or local group affiliation, and women were accorded importance in ritual and as healers, elders, and ancestors.

Kinship and local groups. The societies of precolonial New Guinea and island Melanesia were characteristically organized in local groups based on kinship and descent and linked together by intermarriage. In the usual absence of centralized political institutions, such local groups were relatively autonomous political units. In most areas the local groups were relatively small, with between 20 and 100 members; in densely settled areas of the New Guinea Highlands, and parts of the Sepik plains, kinship- and descent-based local groups were considerably larger.

Although domestic groups or individuals held rights over gardens and cultivated trees, in transmission, alienability, and the distribution of rights, the dominant pattern was the holding of corporate title to land by a local group. That is, title to land was inherited and held collectively by (some of) the descendants of those who initially cleared it. Use rights might then be extended to others. In patrilineal systems, for example, rights might be given to individuals related to the land through mothers or grandmothers, or to outsiders. In coastal zones, corporate title might be held to reefs or fishing grounds.

In many areas the relationship between people and land was conceptualized in terms of chains of descent—in male line (patrilineal descent), female line (matrilineal descent), or some combination of male and female links (cognatic descent)—from founding ancestors. Patrilineal descent systems prevail in most of lowland New Guinea; matrilineal descent systems, in much of the Massim and the Bismarck Archipelago and in much of the Solomons and the Banks Islands. New Caledonia and northern Vanuatu have primarily patrilineal descent systems. Considerable variation is found within these areas, however.

Societies of the central and western Highlands of New Guinea have been described as segmentary patrilineal descent systems. While some of them emphasize chains of descent connecting the living to ancestors, most seem unconcerned with such connections. They use father-son links as the main mechanism of group recruitment but are open to the attachment of refugees and individuals connected through women. The segmentary structures (of phratries, or clans above the level of local groups) characteristically use brother-brother and father-son links to represent what were once in fact relatively unstable political alliances. With intergroup warfare, the sheer size of local groups was a key to survival, and groups crystallized and dispersed according to the tides of warfare.

In patrilineal (and Highlands filiation-based) systems, political leadership within local groups, expressed in warfare and exchange, provided an arena for competition among men. Where matrilineal descent systems had developed, arenas for men's assertion of and competition for leadership and status parallel to the descent-based local groups tended to develop: examples are the secret societies of New Britain and the Banks Islands and the overseas exchange systems of the Massim.

The matrilineally organized societies of island Melanesia represent several variations on the themes of descent and residence. In parts of the Bismarck Archipelago, matrilineal moieties were localized on the basis of uxorilocal postmarital residence (that is, residence with the wife's kin after marriage), with communities containing members of each moiety. In parts of the Massim, matrilineal clans or subclans were at least partly localized on the basis of avunculocal postmarital residence: after childhood in his father's settlement, a boy moved to his mother's brother's village, where he later lived with his wife. In other parts of the Massim, notably Dobu, postmarital residence alternated between the husband's matrilineage village and the wife's matrilineage village. In other areas (such as

Land-
holding

Extreme
sexual
polar-
ization

Matrilineal
descent
patterns

parts of the Solomons), postmarital residence lay with the husband's kin, so that matrilineages were only indirectly localized by virtue of coresidence of several lineages in the same village. (Such a juxtaposition of two or more matrilineages or matriclans in the same village, or contiguous villages, is common in matrilineal descent systems in Melanesia; in patrilineal descent systems, local communities more commonly comprised members of a single descent group and in-marrying wives.)

Ties of intermarriage were important in creating and maintaining connections between descent- or kinship-based local groups. Marriages negotiated with enemies made at least temporary allies of them. Particularly where marriage entailed a transfer to her husband's group of rights to a wife's fertility as well as to her labour, these transfers of rights were validated by bridewealth in the form of valuables or pigs or both. (The custom is resilient in much of modern Melanesia despite Christianity and capitalist economic relationships.) Polygyny was relatively widespread, at least for prominent leaders, who could use the productive and reproductive labour to accumulate surplus pigs and root crops. In some areas, as in the Trobriands, polygynous marriages of high-ranking leaders were instruments of political alliance and of tributary relationships between descent-based local groups. (In the Trobriands, because a matrilineal subclan was obligated to cultivate and ceremonially present yams for the husbands of its absent female members, a leader with many wives became a centre of yam distribution.) Where polygyny was not practiced, leaders could use the financing of the bridewealth of followers to create a labour force.

The stability of marriage bonds varied widely from society to society. The dissolution of marriages was constrained, particularly in patrilineally structured societies, by rights acquired through bridewealth. Marriage tended to be less stable in some matrilineally organized societies.

Ties of kinship created through marriage alliances between local groups crosscut and were complementary to divisions based on unilineal descent. In the patrilineally organized societies of lowland New Guinea and island Melanesia, a person's connection to the mother's group and ancestors was often recognized in acts of kinship support, in ritual, and in the parts played by the groups in marriages, mortuary ceremonies, and other exchanges. In the matrilineally organized societies of island Melanesia, ties to the father's matrilineal relatives were similarly expressed. The complementary parts played by maternal and paternal subclans in Trobriand (Massim) mortuary rites were particularly complex. In some areas, secondary land rights were extended on the basis of such "complementary filiation" (so that a person could acquire interests in, or cultivate, land of the father's matrilineage or mother's patrilineage). Such secondary ties could be the basis for succession to corporate title when groups died out, dwindled, or were dispersed by warfare.

Throughout Melanesia, obligations toward kin constituted the ultimate moral imperative. Systems of exchange were constructed out of kinship obligation. Rights deriving from birth commonly had to be validated by prestations or the fulfillment of obligations. One case was the payment of a midwife by a father in matrilineally organized Mota (Banks Islands): unless he paid the fee, and thus validated his status as father, the person who paid in his stead acquired rights over the child.

Warfare and feuding. Large-scale armed confrontations between warriors were common in parts of New Guinea and some parts of island Melanesia. Ethnographers have often stressed the pageantry and ritual posturing involved and have inferred that few lives were lost; these accounts also often emphasize that territory was not gained or lost. But further evidence from the New Guinea Highlands and other parts of the island suggests that warfare, or in some areas clandestine raiding, had a high cost of human life (among the Mae Enga of the western Highlands, as many as 15 percent of male deaths occurred in war, and even today a resumption of armed combat takes a substantial toll of life). Moreover, it is now clear that victorious groups often did displace their enemies from territories, as in many parts of New Guinea (such as the Sepik and

the southern and eastern Highlands). Homicidal raiding of neighbouring peoples was widespread and was associated with head-hunting in such regions as the southern New Guinea coast (Asmat, Marind-anim) and the western Solomons (Roviana, Vella Lavella) and with cannibalism in others (southern Massim, New Caledonia). The cultural orientations of many Papuan and island Melanesian peoples were shaped by a warrior ethic—an ethos of bravery and violence, vengeance and honour—and by the religious imperatives that promoted aggression.

In other areas, such as Malaita in the Solomons and much of Vanuatu, large-scale combat was rare, but blood feuding was endemic. Where deaths were attributed to sorcery, a common pattern in both Papuan- and Austronesian-speaking areas, accusations of sorcery commonly triggered vengeance murders. So, in some areas, did seduction, adultery, theft, or ritual insult. Chains of blood feuding led neighbouring villages or clans into vengeance killings; feuding was laid to rest only when murders were finally balanced out or death compensation was paid.

Political leadership. Both in Papuan-speaking New Guinea and Austronesian-speaking island Melanesia, leaders of local groups characteristically emerged on the basis of success in prestige economy, warfare, or both. This mode of leadership, based on status achieved through entrepreneurial success and the influence and obligations attendant to it, has been elevated in anthropological stereotypes of the "Big Man" as prototypical Melanesian leader.

The stereotype needs critical examination. With warfare and feuding endemic in much of precolonial Melanesia, the importance of warrior leaders in many societies had waned or been eclipsed by leadership in competitive feasting and other exchange by the time anthropologists arrived. A second problem in the stereotype, at least for Austronesian-speaking Melanesia, is that it seems likely that early Oceanic-speaking peoples had hereditary chiefs. Thus, the emergence of entrepreneurial (or warrior) leaders to whom others deferred by virtue of their deeds, not their rank, may well have been a concomitant of the process of political devolution.

The most serious problem in the Big Man stereotype is that in many parts of island Melanesia, at the time of first European penetration, societies were led by hereditary chiefs. This was true of parts of Austronesian-speaking coastal New Guinea (e.g., Mekeo, Motu), parts of the Solomons (e.g., Buka, Shortlands, Small Malaita), parts of Vanuatu (Aneityum), and most of New Caledonia. In other areas leadership was based on conceptions of rank but with succession to leadership based on a complex relation between hereditary right and demonstrated ability (indeed, such a relation was important in much of Polynesia as well). Bronisław Malinowski's "Paramount Chief" in northern Kiriwina, in the Trobriands, has become recognized as a hybrid figure, not quite a chief in a classical sense but of an exalted rank that set him apart from the *mumi* of the Siuai of Bougainville or the *ngwane-inoto* of northern Malaita, on whom the Big Man stereotype was modeled. In much of precolonial island Melanesia, particularly in coastal areas, leaders seem to have fallen into this middle zone, with rank and achievement operating together to confer leadership and each reinforcing the other. The power of such local leaders depended partly on monopolies over trade or prestige exchange systems, or regional domination based on war, both of which were disrupted by European penetration. The stereotypical image of the Big Man is partly a result of the fact that ethnographic accounts were gathered in the colonial period and by observers operating in a tradition that discounted and disguised historical processes.

ECONOMIC SYSTEMS

Production and technology. The ancient root-crop cultivation systems of Papuan and Austronesian cultural traditions depended on swidden horticulture, a practice of shifting cultivation whereby rain-forest gardens are cleared, planted, harvested, and then left fallow for periods of up to a generation. Ground stone tools (and in some coral-island areas, shell tools) and fire were used to clear forest; digging sticks were used for cultivation.

Endemic

stereotype

"Complementary
filiation"

Results of
intensified
cultivation

The primary plant domesticates were taro and yams (*Dioscorea*), with plantains, sago, pandanus, leafy greens such as *Hibiscus manihot*, and sugarcane being other important domesticates. In swampy areas of New Guinea, sago production continues to support dense populations. Sweet potatoes, a New World domesticate that reached New Guinea through the Moluccas no earlier than the 16th century, allowed an intensification of production and dense settlement of higher altitudes (where *Pueraria*—a root vegetable—and taro had been cultivated earlier). The progressive expansion of intensified cultivation in the great highland valleys of New Guinea, accelerated in recent centuries, has resulted in the progressive transformation of montane forest hunting territories (also used for foraging and swidden cultivation) into *Imperata* grass, further accelerating reliance on pig husbandry and intensified production, particularly of sweet potatoes.

In island Melanesia either yams or taro typically has been the major staple crop. The two have quite different productive regimens (as well as symbolic meanings), and focus on one or the other (which often is difficult to account for on ecological grounds) tends to structure community life. Yams are planted and harvested seasonally, and the tubers, if unblemished and dry, keep for several months. Hence, communities that focus on yam production tend to have an annual cycle and to emphasize communal labour and common enterprise. Taro corms rot quickly after harvest, and taro has no seasonal cycle; the shoots are replanted after the corms have been cut off, so that both harvest and planting are continuous throughout the year. Cultivation by individual families, and more flexible local group structures, are promoted by the regimen of taro production.

In New Guinea and parts of island Melanesia agriculture was intensified by water control, mounding and composting, or terracing. Terraced and irrigated taro fields were found in parts of the New Hebrides and New Caledonia; the mounded and composted gardens of parts of highland New Guinea, associated with water control, allowed intensification of production and continuous use of land.

Root- and tree-crop production was augmented by the raising of domestic pigs, fishing (on coasts or in interior rivers, lakes, and streams), and hunting of marsupials and birds (and, sometimes, gathering of insects and grubs). Gathering of wild vegetable foods, including tubers, greens, nuts (notably the canarium almond, which was extremely important in areas such as northern Malaita in the Solomons), and fruits, augmented diets or provided emergency rations. Food crops were complemented by a range of cultigens used for purposes other than food. The areca nut and accompanying betel pepper, for example, were widely chewed as a stimulant and were a crucial medium of sociality in large zones of Melanesia; kava (*Piper methysticum*) served a similar purpose in parts of Vanuatu and in Fiji; and plants such as ginger and *Cordyline fruticosa* were used in ritual, magic, and medicine.

Although swidden horticulture typified the region, many peoples of montane New Guinea relied heavily on hunting and gathering and had low-intensity food production systems. Competition for hunting territories was apparently a major factor in warfare and raiding, particularly among the peoples of the ecologically marginal zones of the southern regions of the Highlands.

Exploitation of the
coastal
zone

In island Melanesia, coastal zones offered rich environments for the exploitation of fish, shellfish, and sea turtles. As sources of shell used for valuables and ornaments, of salt and lime, and of marine food products, the coastal zones contributed goods that coastal dwellers could trade and barter with peoples of the interior. In some areas, trade of root crops for marine products was institutionalized. In northern Malaita, in the Solomons, the coastal dwellers, who lived on islets and coral platforms dredged from the lagoon floor, bartered fish for root vegetables at regular markets. Other Solomons coastal communities specialized in manufacturing and exporting shell beads, which were widely used as valuables. Similar arrangements occurred in the Admiralty Islands and other areas of island Melanesia.

In addition to manufacturing ground stone adzes and axes, peoples of New Guinea and the islands to the east

commanded a broad range of Neolithic technology. Bags and nets for fishing, hunting, and trapping were made from bush fibres, and bark cloth was widely manufactured. Giant bamboo served a multitude of purposes, providing cooking vessels, water containers, torches, and carving knives. Canoes, ranging from small dugouts to elaborate composite seagoing canoes, were manufactured. Weapons included bows and arrows, spears, and clubs.

Although this technology was virtually universally distributed through the zone, particular peoples specialized in particular forms of production. Specialization in part followed the distribution of resources, such as clay for pottery, chert or greenstone for tool blades, or trees for canoes or weapons. But systems of trade and regional exchange seem to have depended on political and cultural imperatives as well as resources.

Trade and exchange systems. The regional trading systems of the islands around the eastern end of New Guinea were particularly elaborate. In the Massim—what is now Milne Bay province of Papua New Guinea (taking in the D'Entrecasteaux Islands, the Louisiades, and nearby islands)—the trade of pottery from the Amphletts, canoe timber and greenstone blades from Murua (Woodlark), carved platters and canoe prow boards, and other specialized products was complemented by a flow of yams and pigs from resource-rich areas to smaller, ecologically less-favoured islands. Some islanders, such as those from Tubetube in the southern Massim, did little producing and specialized instead as middlemen and traders. Similar interdependencies and specializations, with some communities acting as export traders and middlemen, occurred in the Vitiav Straits between New Guinea and New Britain. Through chains of intermediary trading partnerships among neighbouring peoples, trade systems in New Guinea connected communities that were separated by scores of miles of rugged mountains. Such networks carried salt, shell, and other objects from coasts to interiors and forest products, such as blackpalm, from interiors to coasts. They connected specialist communities, such as those extracting salt, collecting ochre, or making blades, to communities far away.

Trade
networks

Both Papuan-speaking and Austronesian-speaking zones of Melanesia had highly elaborated exchange systems, in which surpluses of pigs and root crops were used in prestige feasts and ceremonial valuables (usually shell beads or other shell objects, but also including dolphin and dog teeth and a range of other material objects) were exchanged. Elaborations of ceremonial exchange, in mortuary feasts and homicide-compensation payments, bridewealth presentations, and various forms of competitive feasting, were foci of community production, social cooperation, status rivalry, and political conflict. In some areas, at least, competitive exchanges were a surrogate for warfare (and in some instances they seem to have grown out of homicide compensation).

In New Guinea the most highly developed exchange systems were those of the western Highlands: the Enga *tee*, the Hagen *moka*, and other mass exchanges of pigs and shell. Cycles of pig production were orchestrated so that vast surpluses of sweet potatoes were required to feed expanded herds; mass pig kills, or the presentation of live pigs to the leaders of rival clans, were a focus of political rivalry and community productive labour.

In island Melanesia the best-known prestige exchange system was the kula of the Massim, documented by Malinowski. As he described it, the kula entailed the endless circulation of valuables through a network of communities on islands forming a giant ring. Through the network passed intrinsically useless valuables: shell-bead necklaces passed around the ring in a clockwise direction and were exchanged for arm shells, which moved counterclockwise. The exchanges were made between partners in neighbouring communities or, in the most exciting, dangerous, and prestigious exchanges, between neighbouring islands. Research in different parts of the kula zone has shown the exchange to have been considerably more complex than Malinowski was able to see from his vantage point in the Trobriands (as well as highly resilient in the face of Westernization and economic change). Early European

penetration did much to change the nature of exchanges and to stabilize a system that was highly unstable because of intercommunity warfare.

Complex systems of prestige feasting, often with a strong competitive element, have been described for many parts of island Melanesia, including Goodenough Island (in the Massim) and the Solomons (Bougainville, Malaita). In precolonial northern New Hebrides, status rivalry was played out through complex graded societies in which men moved to progressively higher grades by sponsoring feasts and presenting valuables and pigs.

Although strung shell beads and other valuables were best known as exchange tokens in the prestige economy, in some parts of Melanesia they served very much like money—as media of economic value and exchange. They were used to buy and sell pigs, fish, craft products, and even land. The *tambu* of the Tolai of New Britain are well known, and similar valuables were used on Malaita and in some other areas as generalized instruments of value, with standard “denominations” and standard “prices” for commodities.

RELIGION

The past in
the present

In Austronesian-speaking Melanesia a strong orientation to ancestors and the past was common, but it was a past manifested in the present, with ancestral ghosts and other spirit beings as everyday participants in social life. (While beliefs in gods and powerful spirits were held in the region, such beings figured more in myths than in everyday life and practical religion.)

Human effort in the uncertain projects of war, gardening, and the pursuit of prestige was thought to succeed only when complemented by support from invisible beings and forces, which were manipulated by magical formulas and elicited through prayer and sacrifice. The presence and effects of invisible ghosts and spirits were manifested in dream, revealed in divination, and inferred from human success or failure, prosperity or disaster, health or death. In such a world, religion was not a separate sphere of the transcendental but a part of everyday life; and religion and magic were not clearly distinguishable. The most sacred rituals often entailed the performance of magic, and performance of magic for personal, manipulative ends might be accompanied by prayer or even sacrifice. Although ghosts and spirit beings were not usually moral agents in their intervention in human life, there were some well-documented exceptions (such as Manus, in the Admiralties). Spirit beings were viewed in parts of island Melanesia as policing the punctilious observance of rules regarding pollution or exogamy and the correct performance of ritual. The concepts of *tapu* (sacred, forbidden, off-limits) and *mana* (efficacy or potency), well known for Polynesia, are fairly widely distributed in Oceanic Austronesian-speaking island Melanesia: *mana* is found in many Solomons languages and some languages of northern Vanuatu, and *tapu* or *tabu* is found widely in the Solomons and the Austronesian languages of the New Guinea area.

Island Melanesian societies lacked full-time religious specialists, so those who acted as priests or officials or as community magicians, intermediating with ghosts and spirits, were in everyday life indistinguishable from their fellows. Some forms of everyday magic—for gardening, fishing, attracting valuables or lovers—were widely known, although knowledge of magic often constituted a form of property. Other forms, for powers of fighting or theft, tended to be closely guarded, and malevolent magic for destructive ends was secretly held and generally used in clandestine fashion (although in a few cases, as among the Mekeo of coastal New Guinea, sorcerers acted as agents of chiefs). In many Melanesian societies sorcery was seen as the major cause of death or illness. Belief in witchcraft occurred in some areas.

Religions of Papuan-speaking New Guinea remain diverse. In much of New Guinea, ghosts and other spirit beings are much less important participants in everyday life than among Austronesian speakers, although there are many exceptions. Thus, the vast *tambaran* houses of the Sepik, with their elaborate rituals and developed beliefs in spirit beings (as described for such peoples as Abelam and

Plains Arapesh) contrast sharply with the relatively secular pragmatism of much of the Highlands. Among such montane peoples as Telefomin, Bimin Kuskusmin, and Baktamin, highly complex male initiatory cults progressively reveal cosmic secrets to initiates. In New Guinea as in island Melanesia, fear of sorcery is widespread; and, among such peoples as the Fore of the Highlands, accusations of sorcery are a major cause of hostility between groups and of blood feuding. Some highland peoples, such as Chimbu, Kuma, and Hewa, believe that witches—humans acting in the grip of forces or agencies beyond their conscious control—prey on the living, taking possession of them or draining their bodily substances.

In some areas, such as the Sepik and the lagoons of northern Malaita in the Solomons, where traditional religious systems and associated cult practices remain, the old religions are giving way under the combined pressures of Christianity and capitalist development. A striking phenomenon of the early colonial period was the emergence of cargo cults in coastal New Guinea and island Melanesia. The movements, such as the Vailala Madness of the Gulf Division and the cargo cults of the Rai coast, were based on the revelations of local prophets that the ancestors were withholding European material goods from indigenous peoples. Cult doctrines included the iconoclastic destruction of old ceremonial objects and the moral, social, and logistical preparation for the arrival of vast quantities of Western “cargo,” expected to be delivered by ship or plane. Cargo cults were widespread in New Guinea, the Bismarcks, and parts of the Solomons and New Hebrides (the John Frum Movement of Tanna is well known). Some of the movements were highly political and explicitly anticolonial in character, with a spectrum connecting millenarian movements, such as the Vailala Madness, at one end and political movements with mystical overtones, such as the postwar Maasina Rule movement in the Solomons, at the other.

ART

Melanesian art is highly varied. In much of highland New Guinea the body itself becomes a focus for art, with face and body painting, wigs and headdresses, and elaborate costumes. In lowland New Guinea, ebullient art traditions like the painting and carvings of such Sepik peoples as Iatmul and Abelam have become widely known. The curvilinear art of the Massim, of which Trobriand prow boards and dancing shields are examples, has also attracted interest. The *malanggan* carvings of New Ireland are equally spectacular and well-known and are relatively well-documented anthropologically. The latter, in contrast to the Sepik and Massim carvings, are ephemeral art; the fretwork *malanggan*, like some of the fern bole carvings of Vanuatu, were created for ceremonies and abandoned or destroyed afterward.

The art of
the Massim

In some cultural traditions of Melanesia, carvings and other art forms had strong religious significance. Masks were a focus of creativity in several regions; they were often used in elaborate ceremonials, with masked figures impersonating mythical beings or perpetuating or dramatizing cult secrets. Many peoples, however, as in the Solomons, the Huon Gulf, and the Admiralties, decorated virtually every object not immediately discarded, however utilitarian.

Music and dance have been less well-documented, partly because (until the era of tape recording and film) they were less easy to preserve than material objects, and partly because Christianization of much of the area led to the early abandonment of many forms of music and dance. Although it is difficult to generalize, dancing often was focused primarily on displaying the bodies and costumes of the dancers (and sometimes the collective strength of the group they represented). Complex dance forms have been recorded from some areas, however. Music ranges from dirges at wakes and love songs to highly complex forms such as the polyphonic panpipe music, with as many as eight contrapuntal voices, played by orchestras on Malaita in the Solomons. Also characteristic of the region are the genres of epic narrative, myth, folktale, and oratory, redolent with metaphor and mythic allusion. These traditions,

Diversity
in New
Guinean
religions

too, have often been lost because of the incursions of Christianity and the unavailability, until modern times, of effective recording devices.

EFFECTS OF EUROPEAN CONTACT

The indigenous peoples of much of the Melanesian region are now part of the world economic system and are subjected to pressures of Christianization and Westernization. In some areas such forces have operated for more than a century. In some interior areas, however, particularly in New Guinea, Western penetration came much later—in the 1930s or even after. But today the most remote regions have become accessible, and they have been transformed.

Papua New Guinea, Solomon Islands, and Vanuatu are now sovereign states and members of the United Nations; the indigenous Kanak peoples of New Caledonia have become a minority in a French overseas territory, battling for independence. The indigenous peoples of western New Guinea (Irian Jaya), since incorporation into Indonesia, have been subjected to massive disruption, dislocation, political repression, and the forced accommodation of large settler populations under national transmigration policies.

With Melanesians now serving as diplomats, businessmen, bishops, doctors, lawyers, and professors, many generalizations about Melanesia as a region marked by "primitive societies" have become anachronistic. Some general observations still seem possible, however. One is that classless societies have become class-stratified societies, with politicians, public servants, and entrepreneurs constituting an emerging elite. Moreover, at least in the English-speaking areas, the elites increasingly share a common (Westernized and consumerist) culture and common political and economic interests and ideologies that cut across boundaries not only between cultures and language groups but also between nations.

Internally, the countries of modern Melanesia show increasing polarization between metropolitan centres and village hinterlands. Squatter settlements on urban peripheries and movement into towns are increasingly found, and both serve as links between the villages and urban life. The more remote villages are poor and have little access to the educational, medical, and economic services of the state. It is in the marginal areas that the traditional culture tends to be the most resilient.

Cash cropping and various modes of capitalist enterprise, as well as dependence on imported goods, have penetrated ever farther into the Melanesian village hinterlands, with some areas (notably parts of highland New Guinea) attaining a measure of prosperity by Western standards through the production of coffee or other high-value crops. Roads and airfields now connect once-isolated hinterlands to regional networks.

Among the new elite, cultural nationalist ideologies have tended to focus on "custom" and "the Melanesian way"; cultural revivalism has become a prominent theme. Art festivals, cultural centres, and ideologies of *kastom* have cast in a more positive light the traditional cultural elements, such as ceremonial exchange, dance and music, and oral traditions, that had long been suppressed by the more conservative and evangelistic forms of Christianity. The emphasis on traditional cultures as sources of identity has been expressed in the perpetuation or revival of old genres of exchange. In Papua New Guinea the kula exchange of arm shells and necklaces continues in the Massim, carried on through the medium of air travel and among politicians, professionals, and public servants as well as by villagers in canoes. Members of the new elite conspicuously pay bridewealth in shell valuables.

Christianity has been a powerful force of change within the region for many decades. Much of island Melanesia and coastal New Guinea has been Christianized for two or three generations or longer. In the colonial period, missions were a major force of education and local economic change. Many of the leaders of postcolonial Melanesia have come from mission schools and backgrounds, and some have been trained as ministers or evangelists. In terms of their orientations and their leaders, the Melanesian postcolonial states are among the most Christian nations on earth.

Different Christian denominations, and even individual

missionaries, have in varying degrees been sympathetic to and knowledgeable about local languages and cultures. Missionary work, in conjunction with the imposition of colonial rule, has helped Melanesians to transcend and to liberate themselves from customary practices that exacted a heavy cost in violence, cruelty, and exploitation; but it has also destroyed much cultural richness, and the process continues in remote regions of Papua New Guinea.

(R.M.Ke.)

Micronesian cultures

Seven major high-island cultures can be distinguished in Micronesia: those of the Chamorros, most of whom live on the four southern islands of the Marianas; the Palauans; the Yapeese; the Trukese, inhabiting about 12 high islands of varying size in the large Truk Lagoon; the Pohnpeians; the Kosraeans; and some of the inhabitants of the isolated island of Nauru, which is geologically a raised atoll (without exposed volcanic rock).

The inhabitants of most of the low islands or atolls in Micronesia are culturally distinct from the high islanders, though in contact with them. In the east are found two culturally distinctive groups of atolls, the Marshalls and the Gilberts (politically constituted as the Republic of the Marshall Islands and the Republic of Kiribati, respectively), ranging from the northwest to the southeast over about 1,400 miles. The culture of Banaba (formerly Ocean Island), a raised atoll, is quite similar to that of the Gilberts and will be treated herein as a variant of Gilbertese culture. Three atolls within sailing distance of Pohnpei—Mokil, Pingelap, and Ngatik—show closer cultural relationships to the people of Pohnpei than to any other large population but are clearly distinct from them. The Hall Islands, atolls to the north of Truk, and the Mortlock (Nomoi) Islands, atolls to the south, are culturally closest to Truk. The remaining low islands to the west of Truk also show linguistic and cultural relationships to Truk, with the differences becoming more and more marked as distance increases. The low islands between Namonuito and Yap were once part of a ceremonial exchange system called the Yapeese Empire by anthropologists. Linguistically and culturally, however, these low-island people were closer to the Trukese than to the Yapeese.

The cultural diversity of Micronesia is indicated by the number of mutually unintelligible languages in the area. The following all have mutually unintelligible languages: Nauru, the Gilberts, the Marshalls, Kosrae, Pingelap, Mokil, Pohnpei, Ngatik, the Mortlocks, Truk, the Puluwat area, the Woleai area, Yap, the Palau, and the Marianas. The languages of the islands from the Marshalls and the Gilberts through the Woleai area in the above list appear to be somewhat more closely related to each other than to the remaining languages and have been referred to as Nuclear Micronesian. The languages of the Palau, Yap, and the Marianas are relatively distinct from each other and from other Micronesian languages, although they are clearly Austronesian in their general affiliation. The Chamorro language, spoken in the Marianas, has undergone much influence from Spanish and probably also from the Philippine Tagalog language after more than four centuries of Western contact.

Traditional Micronesian cultures were characterized by a belief in the stability of society and culture. People suffered occasional natural disasters, such as typhoons or droughts, but their goal after encountering one of these was to reconstitute the previous state of affairs. Wars occurred in most areas from time to time, mainly at the instigation of competing chiefs. At stake was the control of land (a very limited resource in the tiny islands of Micronesia) and followers, but there were usually few casualties.

Living in small communities on small territories, Micronesians learned to adjust to their neighbours and remain on good terms with most of them most of the time and to develop techniques of reconciliation when fights did break out. In general, Micronesians valued good manners. Even today, Micronesian adults and children are likely to impress the outsider as unusually quiet, polite people.

Micronesians traditionally depended on the cultivation of

Diversity
of the
Micro-
nesian
peoples

Newly
class-
stratified
societies

plant crops and on fishing in shallow reef waters. Because both arable land and reef were in short supply for the relatively dense population, the Micronesian had a strong practical basis for his attachment to his locality and lands. Land rights were usually held through some sort of lineage or extended family group, often backed up by traditions of ancestral origins on the land.

Local
loyalties

The strong local loyalties of the Micronesians may also be partly explained by the difficulty of traveling to any place very far from home, especially for the high islanders who lacked oceangoing canoes. Of the high-island peoples, only the Yapepe practiced very much navigation in the open seas at the time of their discovery by Europeans, sailing to Palau and to some of the atolls in the central Carolines. The remaining high-island peoples mostly sailed around their home islands without losing sight of land, although they were visited from time to time by low islanders. The low islanders had reason to visit the high islands, with their more fertile soil and greater elevation; they could obtain food and other items not found on their home islands or seek refuge after a typhoon or drought. Low islanders also had reason to visit other low islands in search of mates outside the limits of the incest taboo and for help after typhoons. Some of the low islanders, especially in the storm-swept central Carolines area between Truk and Yap and in the Marshalls, were skilled navigators of oceangoing canoes.

The populations of the Micronesian islands appear to have been in good balance with the natural resources at the time of their discovery by the Europeans. Because the climate is equable and varies little during the year, moderate amounts of labour were sufficient for comfortable survival, and much leisure was available for activities such as dancing, feasting, romantic affairs, and visiting friends and relatives. Some kinds of subsistence activities, especially fishing, were regarded as something like play. The period of youth was often prolonged, since the older people could afford to indulge their children. This positive attitude toward the enjoyment of leisure was especially characteristic of the high islanders, with their more fertile soil and more secure life.

SOCIAL AND POLITICAL LIFE

Settlement patterns and housing. Micronesians preferred to live in dispersed, extended-family homesteads, in contrast to some Melanesians and Polynesians. In atolls the inhabitants generally preferred the lagoon side of the larger islands for ease in launching canoes and for protection from typhoons. On the high islands, people again wanted access to the lagoon, although easily defensible sites were sometimes also preferred, such as the top of a steep, cleared slope.

The
"Venice"
of
Pohnpei

One ancient "city" in Micronesia is the archaeological site of Nan Matol or Metalanim on Pohnpei. This is a sort of tiny Venice, containing about 100 artificial islands, separated by shallow canals, covering one-third of a square mile in all, including water. The islands were used for royal, priestly, and noble residence and for ritual, and the total population may have been several hundred to 1,000. There is a similar site on the islet of Lelu (Lele) in Kosrae.

The typical Micronesian community had one or more meetinghouses. These served both as social gathering places and as places to plan community affairs. The number and elaborateness of the meetinghouses are greatest in Yap and Palau. Palauan meetinghouses were built by the men's clubs, suggesting some Melanesian influence. In Palau, Yap, and the western atolls, meetinghouses were used mostly by men, while farther east, women and children also entered them freely much of the time.

Houses in most areas were built on slightly raised platforms made of coral rock and gravel on the low islands and volcanic rock and dirt on the high islands. They generally had thatched roofs with low eaves and poor ventilation. The smoke from a small hearth may have been used to control mosquitoes, although plaited mosquito sleeping bags were also used at times. This form of construction may have also provided good protection against heavy rainstorms. Some of the houses in the Marianas appear to have been constructed on stone pillars. The *latte* stones of

this area—double rows of stone pillars with capstones—are now thought to have been piles for raised houses, perhaps for chiefs and wealthy men, since the *latte* sites are relatively few for the reported population. Other houses may have been built on wooden piles that have since disappeared.

Canoe houses were another important form of building throughout Micronesia. Those big enough to store the larger canoes were on the scale of meetinghouses and often were used as such in some areas.

Small buildings for the isolation of menstruating women were common in the western Carolines and continued in use in Yap until recent times.

Family and kinship. The majority of Micronesians before European contact lived in some form of extended-family group. In most areas the organization of this group probably had considerable flexibility, some newlywed couples living with the husband's family, others with the wife's relatives. Major determinants in the choice of residence were the relative availability of agricultural land and the need for additional labourers on one or the other side of the family. In much of the area the wife's family was considered the ideal place of residence; but frequently exceptions were allowed in practice, and children often had rights to use land on their father's mother's side. In Yap, on the other hand, patrilocal residence and patrilineal inheritance of land were considered ideal.

As in other parts of Oceania, the adoption of children of relatives was frequent. This was, in part, a way of caring for illegitimate and orphaned children; in part, a way of relieving young adults of the chores of child care and providing old people with young children to do minor work for them; in part, a way of ensuring more equitable distribution of land rights; and, in part, a way of providing heirs for specialized knowledge when the proper natural heir was lacking or unsatisfactory.

Matrilineages existed in most of Micronesia, with the exception of Yap, and they were traditionally exogamous—*i.e.*, members did not marry within the same lineage. While matrilineage membership was considered basically unalterable in some communities, there was probably some flexibility everywhere. If a lineage grew too large, it tended to split into two parts, one of which would adopt a new name and no longer observe exogamy with the other. If outsiders came into a community, they would often be taken into an existing lineage as honorary or fictive members and eventually might merge with the patron group and observe rules of exogamy with them.

Descent
based on
matri-
lineage

Marriage in Micronesia varied in formality. In the west, in Palau and Yap, marriages were marked by formal payments from the groom's family to the bride's. In the area from the central Carolinian atolls to the Marshalls, marital relationships were usually rather loose and informal, although people of high rank may have had public ceremonies with some exchange of wealth. In this area considerable premarital and extramarital sex was traditionally expected; marriage for ordinary people consisted simply of openly living together and being spoken of by the community as spouses. Apparently, there was more formality to marriage and more control of premarital sex in the Gilberts. Polygyny was generally permitted to some extent in Micronesian societies, although it was not very common. It was more likely to be practiced by high-ranking men and was sometimes restricted to chiefs.

Birth order has traditionally been widely important in Micronesian societies. The seniority of the eldest child is recognized in representing the family or lineage in public and in inheriting political office. The eldest child generally directs the use of lineage or family lands. Younger siblings generally exhibit formal respect to older siblings.

Brother-sister avoidance relationships are well-developed in parts of Micronesia, perhaps most strongly in the central Carolines from Truk through the atolls to the west. In this area women were traditionally expected to avoid speaking to their brothers, to crouch in their presence, and in other ways to show respect. In Pohnpei, farther to the east, a similar relationship existed between a man and his next younger sister but did not extend with the same force to other sisters.

Social
stratifi-
cation

A certain amount of hereditary social stratification was found universally in Micronesia, but its degree varied considerably from some of the smaller Carolinian atolls, which had nominal hereditary chiefs with little special power or wealth, to the high island of Yap, which had several ranked endogamous castes. Other cultures that showed relatively marked social stratification were Palau, Pohnpei, Kosrae, the Marshalls, and the Gilberts. It seems likely that the Marianas may have also had distinct social classes before the Spanish conquest. In all the above areas there appear to have been some chiefs who were supported principally by tribute from their subjects; who were the object of considerable deference; who could punish offenses (especially against themselves and their own relatives) by fines, destruction of property, or death; and whose principal wives were chosen mostly from other high-ranking families. Often they also had subordinate chiefs and officials.

The hierarchical principle was not well-developed in most of these societies. The notion of crime to be punished by the state was weakly developed. Palau and Pohnpei had an abundance of nominal political titles, the principal significance of which might be called recreational and dramatic. In both these societies individuals were able to rise above their initial hereditary status through personal achievement, thus introducing much flexibility into the system of social stratification.

On the high islands of Truk and on many low islands, especially in the central Carolines and the smaller communities in the Marshalls and Gilberts, social relationships were egalitarian. The local chief was expected to work for his living like anyone else. He received ceremonial deference but traditionally had little power to order people to do anything or punish them for offenses. His principal function was to preside at meetings and define and state the community consensus as it developed.

Social hierarchy and political organization. Throughout most of Micronesia the maximum independent autonomous political unit was the high island or the atoll, often subdivided into more than one unit. Satawan Atoll in the Mortlocks had four separate communities aboriginally, each with its own chief; sometimes they fought each other. The Palaus had two confederations of villages or districts aboriginally, each independent of the other, and the villages themselves had considerable autonomy. Pohnpei had five petty states at the time of first European contact, although there were traditions of a unified rule for the whole island at an earlier period. Truk was extremely fragmented politically, with several independent communities on each of the six larger high islands. The Marshalls and the Gilberts had larger political units, integrating groups of separate atolls under a high chief, although the fullest development of these expansionist states was achieved after the introduction of firearms by Europeans.

The low islands between Truk and Yap have been described as belonging to the "Yapese Empire." The so-called empire consisted mainly of a chain of trading and ceremonial relationships with one of the petty states of Yap. The Yapese exerted no military force against the low islanders but did claim the ability to punish them by sending typhoons, disease, and famine if they should fail to fulfill their obligations. According to widely accepted myths, the low islanders originated from the Yapese, although they are culturally and linguistically closer to the Trukese.

In most of the area from the Palaus in the west to the Marshalls in the east, the community was considered to be owned in some sense by a clan, the head of which was also the chief of the community. Other clans had land rights by their relation to former chiefs or to the men of the ranking clan: their women had married men of the chiefly clan, or their men had rendered the chiefly clan service in the past. The chiefly clans in some cases claimed their position by virtue of ancient military conquest and in others by virtue of being the first human beings to occupy the land. The aboriginal pattern of political and community organization in the Marianas has been obscured by the early Spanish conquest, which exterminated most of the population and concentrated the remainder under close Spanish military and religious control. Chieftainship in the Gilberts was by patrilineal succession.

Socialization and education. Micronesians were indulgent with infants. Children were inducted into adult life gradually through observation and participation; there was little in the way of formal schooling or initiation ceremonies in most of the Micronesian societies. Several forms of bodily ornamentation by mutilation were practiced, mostly performed around puberty or in early adulthood. The most widespread of these was tattooing, practiced by both sexes. This and other forms of bodily mutilation were generally done on individual initiative, to demonstrate bravery and increase sexual attractiveness.

Training in cultural specialties, such as medicine, magic, esoteric mythology, canoe and house building, and navigation, was often delayed until young adulthood or middle age. It was usually given by an older relative, although sometimes outsiders could receive it by payment of food and goods. The most formal training in esoteric knowledge appears to have been given by the specialists known as *itang* (in Truk). Each *itang* had himself been trained under an older expert adept in traditional history, oratory, war strategy and tactics, and magic. At the end of his training he was formally awarded the title or degree of *itang* and thenceforth could serve as an orator, ambassador, counselor, and executive officer for a chief.

ECONOMIC SYSTEMS

Production and technology. The islands of Micronesia were probably first settled by small groups of immigrants with few technical specialists among them. The prehistoric Micronesians had basically a subsistence technology with a few part-time specialists producing luxury items, such as personal ornaments and the shell and stone valuables that were used, mostly in the western Carolines, for ceremonial payments.

Subsistence everywhere was based primarily on fishing and horticulture, with fishing somewhat more important in the low islands and horticulture more important in the high islands. Domestic animals were limited to dogs and chickens, found only in some areas.

Rice was grown in the Marianas but later was largely replaced by corn (maize), introduced from Mexico by the Spanish conquerors. Coconuts and coconut palms were used everywhere, both as food and for other purposes, such as thatch, lumber, and cordage. Some form of taro, either the true taro (*Colocasia*) or the giant swamp taro (*Cyrtosperma*), was probably cultivated everywhere except on some of the drier low islands in the east, where the

Empire

groundwater tended to be too brackish. The breadfruit tree, which produces a large starchy fruit in abundance in the early summer, was also widely distributed. Bananas were an important food crop on the high islands. Tropical yams (*Dioscorea*), which produce large starchy tubers, are found today on a number of the high islands but are of greatest importance as a cultivated crop on Pohnpei, where they have high prestige and provide an important source of food in the winter. The sweet potato and cassava, introduced by Europeans, now serve as alternate subsistence foods on some of the high islands. On some of the drier atolls in the Marshalls and the Gilberts, the pandanus tree is a major subsistence crop. The edible fruit of some cultivated varieties contains starch and sugar that can be made into a flour and stored. Other varieties have large edible nuts. Some varieties of pandanus are cultivated for their leaves, used principally in making plaited mats and sometimes for thatch.

Many kinds of fishing were practiced traditionally. Often there was a division of labour, with men using techniques requiring canoes in deep water, such as seines and line fishing, and women wading in the waters of the fringing reefs. Deep-sea trolling with sailing canoes was practiced mostly by low islanders. The low islanders also at times made expeditions to certain small, uninhabited reefs and low islands to fish and collect turtle and seabird eggs.

Cutting tools were made from stone and shell. Iron was introduced by Europeans, although some iron tools may have been obtained from Oriental sources in western Micronesia.

Simple pottery has been found only in the western high islands of Micronesia: the Marianas, Palau, and Yap. Suitable clay apparently exists in Truk, Pohnpei, and Kosrae, but if pottery was ever introduced to these islands, it was not widely used.

All Micronesians, even the high islanders, relied often on water travel, although the high islanders used canoes principally in the sheltered coastal waters of their home islands. Micronesian canoes had a single hull with one outrigger. Canoes used in protected waters were often simple dugout canoes, but the oceangoing canoes, found especially in the central Carolinian atolls, the Marshalls, and the Gilberts, had sides built up of irregular planks that were caulked and sewn together with cord made from coconut-husk fibre.

Some of the atoll dwellers regularly went on trips requiring several nights in the open sea. Extra provisions were usually taken along as gifts and for emergency needs if the canoe were blown off course. In historic times vessels blown off course have ended up in a variety of islands inside and outside of Micronesia. Conversely, vessels from other areas of the Pacific and from the Orient have been blown to Micronesia. It seems clear that, prehistorically, there was communication in chain fashion from the Ellice Islands (now the state of Tuvalu) and western Polynesia through the Gilberts, the Marshalls, and the Carolines to Palau and the southeast atolls and beyond them into the northern Moluccas in Indonesia. Probably there was also deliberate communication across the larger gap between the central Carolinian atolls and the Marianas; in the latter there is a long-established population of cultural Carolinian immigrants retaining their original language.

Property and exchange. The most important property among the Micronesians was land. Land-tenure customs varied considerably from island to island, even among those with related cultures. Land was owned primarily by extended-family groups or lineages. Individuals acquired use rights to particular plots through their kin connections, acknowledging the rights of the group by periodic offerings of first fruits to the kin-group head. Often a community chief and sometimes a superior chief received offerings from each household or larger kin group holding land under his jurisdiction. In some areas, especially in eastern Micronesia, strong chiefs confiscated land from those who fell out of their favour, awarding it to loyal followers.

Because land was a scarce resource in much of Micronesia, various mechanisms developed to govern its distribution. In most areas matrilineal inheritance of land rights was practiced, and, if necessary, children of the men of the

lineage could also inherit use rights to the land worked by their fathers or receive a share outright if the lineage had more than it needed. In general, land was not sold, but it might be given in payment for medicine and nursing services or as compensation for an injury.

In the larger high islands, interior areas not under regular cultivation were considered community property and were used for collecting wild food and for temporary gardens. In the atolls all land was owned by one or another family group, even the smallest islets with only a few coconut trees.

Large feasts were common throughout Micronesia. The people assembled large quantities of food and offered it to the chief, and he in turn redistributed much of it to the people. Sometimes kin groups or communities held alternating semicompetitive feasts in which each tried to outdo the other. Feasts were held to commemorate important transitions in the life cycle, especially marriage and death. A kind of delayed exchange might take place at these feasts, certain relatives being obliged to make presentations of food and goods in return for past or anticipated services.

Substantial payments were sometimes made to practitioners of traditional medicine, especially when the practitioner was not a close relative. Such payments consisted of food and other goods. The precise amount was generally left to the family of the patient, with the understanding that a stingy family might not get the most energetic and effective treatment.

In Palau and Yap, shell and stone valuables were used in transactions at life crises and for certain other specific compensations, such as payment for injuries. These are often called money, but their use was much more limited and specific than that of most money. The best known of them were the large stone disks that the men of Yap manufactured on Palau and carried home in sailing canoes.

A certain amount of trade developed between the low islanders and high islanders, the low islanders providing handicraft products that the high islanders could have made if they had needed to, and the high islanders providing things obtained more easily there. This trade was especially well-developed between the low islanders of the central Carolines and the high islanders of Yap and Truk. The most important high-island export was turmeric, used for medicinal and cosmetic purposes, which formed a bright orange body paint when mixed with coconut oil. The low islanders provided shell beads, plaited pandanus mats, and coarse cloth woven from banana or wild hibiscus fibre and used for women's wraparounds and for men's loincloths. Trade was often with particular partners who regarded themselves as distant relatives. An important function of the trade was to provide the low islanders with aid and a temporary dwelling place when their islands were devastated by the periodic typhoons.

RELIGION AND ART

After 1900 Christianity became well-established in most major centres in Micronesia. Traditional religions were no longer practiced in their full original form, although in Yap and some atolls of the central Carolines, traditional religion continued to be practiced until the middle of the 20th century. Missionaries and travelers have left descriptions of certain aspects of the island religions, but there is no complete and systematic account.

The basic patterns of religion were probably similar throughout most of Micronesia. The Micronesians were polytheists, believing in several high gods, a large number of spirits attached to specific localities or performing specific functions, and a number of ancestors and deceased neighbours who could sometimes make contact with their living descendants and friends. Practices connected with these three major categories of supernatural beings tended to be distinct and to be handled by different specialists, although a figure might gradually shift from one category into the other.

Micronesians generally believed in at least three vertically arranged levels of the universe: the earth proper, the underworld, and heaven or the sky world. Some Micronesians may have believed in multiple heavens, as did

Feasts as
exchange
rituals

Travel
on the
open sea

people in Polynesia and Indonesia, but the details of their beliefs are now unclear.

Micronesian origin myths generally tell of the origin of particular islands or descent groups or the initial discovery or later conquest of an island by the ruling descent group. The notion of the supernatural creation of the whole human species or of the whole world is either not found or little emphasized in Micronesian mythology.

Ceremonies for the high gods appear to have been principally seasonal offerings of first fruits, performed often in private by a specialist priest with a few helpers. Special appeals to the high gods were probably also made at times of community crisis, such as wars or typhoons, but human sacrifice apparently was not practiced. The priests were very likely relatives of the ruling chiefs. The lesser spirits were called on by magicians for specific purposes, most notably for the diagnosis and cure of disease but also for such purposes as success in fishing, control of weather, success in love, and prowess in athletic contests, battle, canoe building, and other difficult pursuits.

Communi-
cation
with
spirits

Ancestral spirits were often contacted in dreams and in the trances of spirit mediums, as were the high gods and other nonhuman spirits. They would give people information about the causes of disease, deaths, and other misfortunes and would sometimes prescribe new medicines or new varieties of magic. At times, the spirit mediums would also order their human protégés to perform songs and dances for the entertainment of the spirits, to win their goodwill and ensure the prosperity of the community.

Micronesia has little permanent visual art. The best known consists of the painted bas-relief scenes on the timbers and gables of the men's houses in Palau. Stylized wooden masks and human figures have been found in the Mortlock Islands, southeast of Truk. Decorative lashings of light and dark sennit twine are found in important buildings. Painting and decoration of canoes is common, following traditional patterns for each island. Patterns were woven into clothing. Wooden bowls were carved and painted with aesthetic intent.

Much of the most-developed traditional art of Micronesia was ephemeral: body painting and ornamentation with garlands of flowers, singing, dancing, and the recital of myths, tales, and poetry. Oratory was also an important traditional art and still survives. A good orator was expected to make mythological and historical allusions and to use special figures of speech. (J.L.Fi./R.C.Ki.)

EFFECTS OF EUROPEAN CONTACT

Micronesia has the most complicated colonial history in the Pacific. Guam, the southernmost of the Mariana Islands, became the first inhabited Pacific island to be visited by a European when Ferdinand Magellan landed there in 1521, and the Marianas became the first European colony when Spain took control of the island chain in 1668. In 1670 the indigenous Chamorro people rebelled, and a quarter-century of sporadic warfare followed. That conflict, along with diseases introduced by Europeans, reduced the local population from perhaps as many as 100,000 to 4,000. Most of the Chamorro people were moved to Guam. Much of Chamorro culture was destroyed, but the language survived.

Spain attempted to expand its rule as far east as Pohnpei but did not succeed. The Germans claimed the Marshall Islands in 1885 and the island of Nauru in 1888. In 1892 Britain entered the scene in eastern Micronesia and added the Gilbert Islands to its colonial empire.

The Spanish-American War brought an end to Spain's presence in the Pacific. Upon Spain's defeat in 1898 the United States seized Guam because of the strategic coaling station that Spain had developed there. In the following year Germany purchased Spain's claims to the Caroline Islands (Palau, Yap, Pohnpei, Truk, and Kosrae) and the northern Marianas. The copra industry was greatly expanded under German rule, and its administration was one of indirect rule.

World War I changed the face of Micronesia. Japan replaced Germany in the northern Marianas, the Carolines, and the Marshall Islands. In 1920 the islands became a mandated territory under the authority of the

League of Nations. Japan initiated an aggressive program of economic development, and Japanese, Okinawan, and Korean immigrants eventually came to outnumber the islanders by a ratio of two to one. Sugar, fishing, and other industries were developed, and the copra industry was greatly expanded.

After World War I Nauru, which had been held by Germany, also became a League of Nations mandate, with Australia having administrative responsibility. Guam remained under the firm direct rule of the U.S. Navy, and the Gilberts continued as part of the larger British crown colony of the Gilbert and Ellice Islands with a system of indirect rule.

World War II again altered the political map of Micronesia. After its attack on Pearl Harbor in late 1941, Japan occupied the Gilberts, Guam, and Nauru, and for the only time in its history all of Micronesia was under one colonial master. The war inflicted great suffering, and major military engagements took place between Japanese and American forces in parts of the Gilberts, the Marshalls, Truk, Palau, Guam, and the northern Marianas. At the end of the war the economy was a shambles, a great amount of property had been destroyed, there were food shortages, and many people had been displaced.

After the war Guam was returned to the United States, and British colonial rule was resumed for the Gilberts. Nauru became a trust territory of the United Nations, similar to the old mandate system, and Australia resumed administrative responsibility. The United States replaced Japan in the former mandated islands, and this portion of Micronesia became the United Nations' Trust Territory of the Pacific Islands (TTPI).

The decolonization of the Pacific began when the Polynesian state of Western Samoa became independent in 1962. Nauru was the first Micronesian country to become a sovereign nation when it gained independence in 1968. Because of its rich phosphate deposits, its people have one of the highest per capita incomes in the world. Large sums are invested in trust funds around the world in preparation for the eventual exhaustion of its mineral wealth, which is expected to occur before the turn of the century. Nauruans are almost totally dependent on imports. Little traditional culture remains; housing, foods, and clothing are almost entirely Western.

The Gilbert Islands, along with Kiritimati (formerly Christmas) Island, Banaba (formerly Ocean) Island, and most of the Line Island and Phoenix Island groups, now form the nation of Kiribati, having gained independence in 1979. The Gilberts form the core of the nation and have the vast majority of its population. Outside of Tarawa Atoll, the site of the nation's capital, much of the traditional culture and life-style prevails. Subsistence agriculture and fishing remain the mainstays of the outer island economy, and most buildings and dwellings are of traditional designs and materials.

Negotiations regarding the future political status of the TTPI began in 1969, and it soon became clear that the peoples with such diverse cultures and languages did not feel any real sense of kindred or national unity. Three island groups had strategic value to the United States and used it to their advantage to demand separate negotiations with the United States.

The northern Mariana Islands were the first to break away. The highly Westernized Chamorro peoples had little in common with other Micronesians, and in 1975 they voted to become the Commonwealth of the Northern Mariana Islands, an integral part of the United States. The islands have a well-developed tourist trade and a sophisticated economy. With commonwealth status, the Chamorros became American citizens, and the population is highly urbanized and concentrated on the island of Saipan, the capital.

Palau and the Marshall Islands became republics, and the remaining islands of the TTPI formed the Federated States of Micronesia (composed of the four states of Yap, Truk, Pohnpei, and Kosrae). Each approved a Compact of Free Association under which the United States handles matters of defense, and strategic access is denied to all other nations. In return, the United States provides

Micronesia
and the
League of
Nations

Strategic
islands

substantial subsidies to the nations, and their citizens have the legal status of "habitual resident," allowing them the right to live in and seek employment in the United States. The compacts have been approved by the United States for the Federated States of Micronesia and the Republic of the Marshall Islands.

Each of the Micronesian entities has its own capital and urban area, and in the case of the Federated States of Micronesia there is a capital in each constituent state. Approximately one-half of all islanders in the former trust territory are urban dwellers today. They are heavily dependent on imports, and, except on the outer islands, much of traditional life has been lost. (R.C.Ki.)

Polynesian cultures

The physical environment of the islands of the Polynesian triangle is not as favourable for human habitation as it might at first seem and certainly presented difficulties when the ancestors of the Polynesians entered the area from the west, well before the beginning of the Christian Era. The islands were devoid of much that was needed for human habitation. Most of the food and useful plants and all of the domestic fowl and animals had to be transported by the settlers. Since that time, the physical environment has continued to exert a marked influence on the nature and extent of the evolution of Polynesian cultures.

The popular image of Polynesian cultures suggests an almost blissfully simple and easy way of life, devoid of harsh extremes of any type, played out on islands of great beauty and natural abundance. But the image, a product of popular literature and the motion-picture and tourist industries, is wide of the mark. Traditional Polynesian cultures were complex, highly specialized, and diversified, and the environment was not always benign.

The principal characteristic of Polynesian cultures is an effective adaptation to and mastery of the ocean environment in which they have flourished. This mastery did not extend merely to the technology involved in ship building, to the techniques of navigation, and to other obvious nautical aspects of the culture but permeated social organization, religion, food production, and most other facets of the culture. The Polynesians could not only sail the seas, but socially they could cope with the human problems of shipwreck, split families, and the sudden loss of large portions of the social group. In short, the cultures were well-equipped to handle the numerous hazards that they had to face in the beautiful but actually quite hostile Pacific environment.

Another important characteristic of Polynesian cultures was a high degree of conservatism and traditional orientation and the rather detailed structuring that placed every person in a well-defined relationship to society and to the universe. This conservatism is apparent even in a rapid examination of Polynesian materials from islands separated by hundreds or thousands of miles, whose populations had been separated from the common Polynesian stock two or three millennia in the past. The similarity between such items as stone adzes and fishhooks is most remarkable. The same is true for kinship terms, plant names, and much of the rest of the technical vocabulary of the cultures, as well as for art motifs and medical preparations. The ornate and voluminous genealogies, chants, legends, songs, and spells that were passed down and elaborated through the generations show a profound reverence for the past.

The traditions of Polynesian cultures provided a definition of an individual's relation to his society and to all of nature. The creation myths told of the origin of the world, setting forth the order of precedence of Earth, sky, and sea and all the phenomena thereof, including man and woman. The genealogies fixed the individual tightly into the typically aristocratic Polynesian social order. Other legends interpreted natural phenomena, while historical accounts often described, with varying amounts of mythological embroidery, the migrations of a people before they arrived at the island on which they were located, their adventures on the way, and the development of the culture following settlement.

The Polynesians were unusually well-oriented, as would

be expected of a nautical culture, to the entirety of nature. Their languages abound with terminology for stars, currents, winds, landforms, and directions and include a large number of grammatical elements indicating, for example, direction of motion implied by verbs, including movement toward or away from the speaker, relative positions of objects with reference to the speaker, and direction of movement along a seashore-inland axis.

Polynesian cultures displayed a thoroughly realistic and practical exploitation of the environment but at the same time exhibited a profound interest in the supernatural. This interest was directly related to the general interest in systematization and structure, the supernatural being for the Polynesian another portion of reality, albeit less manageable, that had to be structured and coped with.

Violence and cruelty were ever-present elements of Polynesian cultures. This is reflected in their oral literature and in all aspects of traditional life. Custom controlled and repressed direct physical expression of aggression within the kin group and the tribe up to a point, but there were definite limits beyond which only violence could restore status or assuage injured pride. Punishments for transgressing rules of behaviour toward chiefs and high priests or for violating various rituals incorporated ritual sacrifice and cannibalism as major features. Intertribal warfare was extremely common, particularly when population pressure had built up and land and resources were limited.

Perhaps the most publicized, and accordingly overrated, aspect of Polynesian culture is its sensuality: as in many other aspects of life, the Polynesians generally took a very direct, realistic, and quite physical approach to gratification of the senses. But there was no abnormal focus or concentration on any aspect of sensual gratification such as is seen in many other cultures where, for example, eating, drinking, or sex have become the object of great cultural elaboration. This lack of elaboration may be due in part to limitations imposed by the environment. The flora of Polynesia did not, for example, provide a very good basis for elaboration of cuisine, as the number of edible plants was rather restricted, and there was a dearth of spices. In general, however, this balanced approach to sensual gratification seems to be just another reflection of the Polynesian straightforward approach to the world. Polynesian culture, for example, is generally thought to have been characterized by extreme sexual promiscuity, but such is not the case. Definite restrictions were placed on sexual behaviour, though the limits of acceptable behaviour were indeed wider than in many other cultures of the world. Children were permitted freedom of sexual expression; from puberty on, sexual activity was strongly encouraged, limited only by incest restrictions (which were not stringent) and considerations of social prestige. Parents would become concerned if daughters were not sought after for sexual favours, and premarital pregnancy only enhanced a girl's attractiveness. Public intercourse was engaged in during certain religious festivals and crisis rite ceremonies as a means to promote general fertility. There was, however, no pathological elaboration of sex for its own sake. Polynesian art, for example, is strikingly devoid of sexual content. There are occasional references made to sexual activity in native Polynesian oral literature, but many of these have to do with creative acts of the Polynesian gods, for the Polynesians saw the process of the creation of the universe as having taken place in a manner similar to human procreation. There is no corpus of Polynesian literature analogous to pornography.

Sexual
mores

SOCIAL AND POLITICAL LIFE

Settlement patterns and housing. Two major settlement patterns were present in Polynesia prior to European contact: the hamlet and the village. Their origin and development may depend to a large extent on geographic factors, such as the distribution of food-crop resources, on defense considerations, and on social organization.

The hamlet settlement pattern was found in the larger volcanic islands, where food resources were diversified and scattered over the range of environmental zones that developed on such islands. A typical hamlet settlement pattern was often found in the Marquesas Islands. There,

Polynesian
conserva-
tism

in prehistoric times as at present, the population spread over the floors and up the sides of the deep and narrow Marquesan valleys in clusters of perhaps four to five houses, often with gardens, taro patches, coconut trees, and breadfruit clustered in the immediate vicinity. The Marquesan houses were built on rectangular platforms, the height and composition of which depended on the prestige of the owner. Individuals of lower status might have a simple paved rectangle no more than a few inches high, while warriors, priests, or chiefs might live in houses perched on platforms seven to eight feet high and containing stones of several tons in weight. The house itself was built on a kind of a step running across the rear of the platform. Composed of a lashed and fitted wooden framework and with a thatched roof, the typical house was open all the way across the front and had square ends. The roof sloped from the high ridgepole directly to the platform floor in the rear. Inside, a polished coconut log often ran the length of the house, serving as a kind of community pillow. The floors were covered with mats, shredded leaves, or bark. Belongings were suspended in bundles from the rafters. Most of the household activity took place on the "veranda," or unroofed front portion of the platform, which was paved with smooth basalt stones from streambeds. Houses of chiefs and other individuals of high status often made use of cut stone slabs for decorating the platform. Many also had rectangular pits in the platforms for storing fermenting breadfruit paste (an important delicacy) and small caches in which were interred the carefully cleaned and packaged bones of important family members.

Among the clusters of houses in each major valley section was a large rectangular ceremonial plaza, or *tohua*, which served as the focal point for all tribal or subtribal ceremonies, as well as a point for daily social gatherings. This complex of structures, often 600 feet (200 metres) or more in length, was generally built upon a huge artificial terrace carved out of a slope. Surrounding the plaza atop the terrace were the houses of the tribal chiefs and priests, temples and other sacred structures, and long sheds for spectators. At one end was usually found a temple with a sacred banyan tree in which were suspended the packaged bones of the illustrious dead of the tribe.

In Samoa, on the other hand, the village settlement pattern was followed after AD 1000 or so. There, fortified villages, consisting of 30 or more houses arranged in a network of paths, grew up along the coast. The houses at the time of European contact were built on oval mounds faced with rough stone slabs, although earlier houses had been built on rectangular platforms much like those of the Marquesas. The typical Samoan house was and is today a large shedlike structure without walls, oval in floor plan, with a beehive-shaped, thatched roof supported by a series of stout wooden pillars. Rolled mats along the eaves were let down to protect the inhabitants from sun, rain, or the night air. These houses, arranged in orderly fashion along the paths and sunken roadways that crosscut the villages, were surrounded by a fortification wall of stone or by wooden palisades.

The Maori of New Zealand constructed large and impressive fortified villages (*pas*) on hilltops, surpassing those of all other Polynesian cultures. These forts were protected by ditches, palisades, trenches, and terraces. The interiors were partitioned off by additional defensive works so as to facilitate battle even after the outer defenses had been penetrated by an enemy assault. The houses within were of timber, rectangular in plan, and generally dug about one foot into the earth surface.

Other, unfortified Maori villages consisted of loose collections of houses arranged around a level area where ceremonies and meetings might take place. Forts were usually constructed in the vicinity of such villages for the use of inhabitants in time of war.

Family and kinship. The typical Polynesian family was extended; that is, it consisted of three or more generations, and it centred around a descent group. The extended family and the descent group were not the same. In most cases descent was preferably traced through males, with both females and males belonging to their father's descent

group, and the extended family consisted of a senior male, his sons and grandsons, and their spouses and unmarried children of both sexes. Residence was usually virilocal; females left their family of birth and joined their husbands' families upon marriage. Polynesian societies were noted for their flexibility, however, and there were many variations in the system of descent. In Hawaii, Tahiti, and elsewhere, and especially if it were to one's advantage, descent could be traced through females and one could become a member of one's mother's descent groups. Thus, while descent through males was preferred, the descent system was actually bilateral (through either parental sex). Adoption was very common and added to the flexibility of the social system. Siblings and cousins frequently adopted one another's children, and grandparents sometimes adopted their own grandchildren. These children behaved toward their adopted parents as they would their own.

The basic Polynesian kinship pattern is a very simple one: it distinguishes among generations, as might be expected in a society so strongly oriented on tradition and genealogy. There are sets of terms for the grandparents' generation, distinguishing by sex only; parents' generation, in which parents are distinguished from various categories of aunt and uncles; members of a person's own generation, in which the terms permit identification by sex, relative age, and sometimes marital potential (marriage of certain cousin categories is preferred in some Polynesian societies); and, finally, children's generation, in which age and sex are again distinguished.

In general, the kinship terminologies in use in the various societies in eastern and marginal Polynesia are relatively simpler than those in the west.

Social hierarchy and political organization. The two major types of settlement in Polynesian cultures—hamlet and village—were bound together by a web of kinship and territorial ties of varying degrees of importance.

There were two main and probably related types of kinship-based descent groups prevalent in Polynesian society. By far the most common and perhaps the most like the ancestral form of Polynesian social organization was the "ramage" type, in which the whole society might be represented in the form of a multibranched tree. There was a senior line of descent, in which descent passed from firstborn son to firstborn son and was traceable back to the mythological past. Branches off this main line were founded by junior sons, and these branches in turn produced further branches. Because the main line was the direct line to the gods and therefore carried the maximum traditional prestige and sanctity, it followed that each of the branches was ranked in terms of its proximity to the main line, and each individual in each branch could place himself in a prestige-ranking scale relative to other members of his household settlement and kin group.

The levels of the branches off the main line assumed different levels of importance in various Polynesian societies. In New Zealand, for example, four levels were recognized: (1) The *waka* were a group descended on both maternal and paternal sides (male preferred) from the crew of one of the original canoes in the traditional Maori migration to New Zealand. They occupied a given territory and had a chief who functioned only in times of crisis and members who recognized their common tradition and interest. (2) The *iwi* were component parts of the *waka* but were made up of individuals tracing descent from a single occupant of one of the canoes, through either maternal or paternal line (again, the male line was the prestige line). The *iwi* had a chief and was a more tightly knit kinship group occupying a defined section of land within the *waka* territory. (3) The *hapu*, a component unit of the *iwi*, was the principal Maori descent group, consisting of all descendants of a given ancestor, usually sited in a particular village and controlling the farming land around the village. The *hapu* had a chief responsible for all economic and civil affairs. (4) The *whanau*, or households of the *hapu*, formed the lowest unit within Maori society and usually consisted of three to four generations.

Each of the hierarchical kinship segments just mentioned could be ranked relative to the others, with the exception of the *iwi*. The *hapu* could all be ranked within any given

"Ramage"-
type
descent

Maori
fortified
villages

iwi on the basis of their chiefs' ancestry. Within the *waka*, each *iwi* could also be ranked in terms of the distance of its founding ancestor from the chief of the canoe.

This form of hierarchical branching-descent-group organization with territorial overtones was found in most Polynesian societies, with appropriate variations for local environmental conditions and cultural history.

"Descent-line"
kinship
groups

The other major form of kinship-based descent group found in Polynesia is that known as the "descent line." Descent-line organization appears to be the result of a breakdown in genealogical ties between the lower levels of a ramage organization. The descent line in Samoa, for example, consists of a group of people tracing descent in the male line from a common mythical ancestor. This group was known as a *sa*. There was no concern for genealogical relationship of one descent line to another, nor was there any concern for ranking based on distance from or proximity to any particular male line of descent. What were passed down through the descent line were titles, each of which had rank and prestige attached to it. Each descent line held a number of these titles, which enabled it to participate in certain ways in the village council (*fono*). A number of descent lines were represented in each village council, and each descent line was spread through a number of villages in a given area. Within a given village, the senior title, determined by mythological connections, gave its holder the position of chief.

A characteristic of the descent-line system is its flexibility. Depending so heavily on myth and tradition for validation of status and title, it was only natural that ambitious titleholders could advance the prestige of their titles at the expense of others by various kinds of prestige behaviour, such as displays of wealth and power. The traditions governing title seniority could then be judiciously tampered with to produce the realignment that would allow the advance in status to occur. New descent lines might also be founded with similar "rewriting" of oral tradition.

Stratification. The tendency toward social stratification is perhaps inherent in Polynesian society, with its great interest in and emphasis on status and the indicators and prerogatives thereof. There seems to have been a process of social evolution occurring in Polynesia that tended to be somewhat unidirectional, leading toward more sharply defined differences in status and development of social classes that were clearly defined in terms of rights, duties, behaviour, and general life-style.

The chief in ancient Polynesian society was the person of highest status, yet he was regarded by his people and generally conducted himself as merely "first among equals." In most of the more traditional of the societies, the chief could not appropriate the land of his followers, nor did he appear to be too interested in increasing his own group's holdings at the expense of neighbouring groups. In terms of his clothing and behaviour, there was little to distinguish him from other males. Nevertheless, he was the repository of sacred power for the group, a symbol of its tie with the past, and the vehicle whereby this tie would be perpetuated for coming generations. Even in the traditional Polynesian societies, however, it was possible for a man to rise in prestige by various achievements; by giving gifts, holding feasts, or displaying military prowess, for example. These activities seem to have contained the seed of change in the traditional social order.

The breakdown of
traditional
social order

Warfare. There was a group of Polynesian societies in which the more traditional social order, when breaking down, gave way to one in which chiefs and other individuals of high status no longer held office on the traditional genealogical basis but by virtue of having taken it, often by force, or as a result of some act that raised their prestige higher than that of the actual chief. In these societies the chiefs behaved more autocratically and set themselves off from the rest of the population by various kinds of privileges and behaviour. Changes in leadership were frequent, and kinship groups were split internally and reorganized in the course of internecine wars. Finally, out of this dynamic social situation emerged the most socially and politically advanced Polynesian societies (Hawaii, Tahiti, Tonga), with clear-cut social stratification and concentration of all power at the apex of the social pyramid—the

paramount chief—below whom were several levels of nobility usually selected on genealogical relationship to the chiefly line. The paramount chiefs and upper classes had absolute powers over the commoners, inflicting cruel physical punishments, such as human sacrifice, for all manner of affronts to their dignities (touching a chief's shadow, for example). Warfare was frequent, well-organized, and marked by acts of great cruelty. Religious and political powers were closely linked, with religious concepts and the gods themselves mirroring the cruelty and viciousness of the societies that had produced them.

Socialization and education. The Polynesian child was generally born into a large and warm family environment. Even before the child could walk, it was turned over for care to the other children of the household (siblings, cousins), who generally associated in a kind of amorphous play group with children of other families. It was in this context that the Polynesian child received a great deal of its socialization, first carried piggyback by an older sister and then running with a crowd. A particularly warm relationship existed between a child and its grandparents, often taking the form of rather gross bantering but providing the vehicle for inculcation of traditional lore, technical training, and even sexual advice.

There was little by way of formal education in Polynesian society, except for the training in special crafts and skills, such as canoe making or tattooing, and the sacred academies for training the priest-bards who were the repositories of the society's traditions, mythology, and genealogies.

Rites of passage varied in type and importance from society to society, but there were several that were generally held throughout Polynesia. The birth of a child was a matter of great significance, particularly if the child happened to be a firstborn son of a high-status descent group. Various procedures were called for to announce the birth to the community, to the ancestors, and to the gods, and to care for the welfare (both physical and supernatural) of the infant and mother by application of medical and magical techniques.

Circumcision was a major event in the male life cycle and was marked by elaborate rituals, which increased in importance with the status of the male. Polynesians generally have an unusual abhorrence of the uncircumcised, to the extent that in some societies it was believed such people would go to a very unpleasant netherworld after death. Although no such rite involving mutilation is reported for girls, some societies, such as the Marquesas, had orgiastic ceremonies in which adolescent girls made a more or less public debut, in a sexual sense.

There were other milestones in life that were marked with ceremonies in Polynesian cultures, such as the formal presentation of a royal heir, the completion of a tattooing operation or ear piercing in a high-status child, and the formal investiture of a priest or chief. The observances of these milestones were marked with a variety of rituals and quite often included human sacrifice, wanton killing of members of the population who might happen into the path of the ceremonial party, or killing of those who made mistakes in performance of the rituals.

Death, the terminal milestone, was universally celebrated with extravagant behaviour, increasing in extravagance in direct proportion to the status of the deceased. In many societies these ceremonies were marked by violence, with mourners mutilating themselves and others, and by human sacrifices, obtained from within the social group or without. Feasts were also common, as was orgiastic behaviour. The extravagance of funeral rites was surpassed, in some societies, by ceremonies to deify a departed chief or priest. These went on for prolonged periods, involving prodigious feasting and drinking, violence, and sexuality.

Distinctive
rites of
passage

ECONOMIC SYSTEMS

Production and technology. The Polynesians were above all mariners, but among the many seafaring peoples of the world they were quite unusual, for, far from having a disdain for the land and all that it involves, they were capable of and devoted to horticulture and arboriculture.

The sea provided most of the protein in the Polynesian

diet. Fishing was carried on not only on an individual basis, with spear, line, or net, but on a group basis with large numbers of men spreading and drawing in huge nets in bays or lagoons or driving fish toward shore, where they could be captured in nets held in shallow water. In some Polynesian societies (Marquesas and Samoa, for example) there were specialists who directed the mass fishing efforts and the elaborate religious rituals that went along with them. Sea mammals (porpoises and whales) were also taken, the former often being driven into shore by means of large, well-organized drives: when a school of porpoises was sighted in a bay, a fleet of canoes would seal off the bay entrance, and crew members would leap into the water carrying stones in their hands, which they beat together as they swam slowly toward shore. The sounds terrified the porpoises, and they beached themselves in a frenzy.

The Polynesian fishermen's exploits were not, however, confined to coastal waters, for they were just as much at home on the high seas. The waters around their island homes were explored for miles in all directions. The Easter Islanders, for example, used to travel east to Sala y Gómez reef to fish—a journey of some 300 miles (500 kilometres). Good fishing waters were located by reference to land bodies if visible or just by dead reckoning. Line fishing to depths of 90 feet was not uncommon to take the grouper. School tuna were taken in large quantities on the high seas by means of shiny pearl shell lures with bone points. The flesh of sharks and rays was a delicacy.

Mollusks and crustaceans were important as food, and mollusks also provided the shells from which a wide variety of tools and ornaments were made. Clams, cowries, and various snails and conches were collected, generally by women and children, along the reefs or shorelines and in the shallows. Shrimps were netted with fine nets, while lobsters were collected by men who dove and pried their spiny prey loose from underwater crannies. The octopus was lured from its hiding place by an ingenious lure made of leopard cowrie shells. Various types of seaweeds and algae were also collected and were highly prized for their salty taste. There was, in short, nothing edible in the sea that was not food for the Polynesians.

Gardens and groves produced the staples of the Polynesian diet and most of the condiments. The major native Polynesian crops were yams, sweet potatoes, taro, breadfruit, bananas, sugarcane, coconuts, and Tahitian chestnuts (*Inocarpus edulis*). These crops achieved different levels of importance in various Polynesian societies, depending on cultural factors and environmental conditions. The Hawaiians, for example, relied heavily on taro, building extensive irrigation systems to grow the variety that requires muddy soil and planting the "dry" variety in the uplands. Breadfruit was not of great importance in Hawaii, however. In the Marquesas and Tahiti, on the other hand, breadfruit was the major staple, although taro was by no means neglected. In these islands breadfruit was allowed to become overripe and was then beaten into a pulp and stored in large, well-drained pits in the ground, in neat hibiscus-leaf bundles. The breadfruit paste thus stored would ferment but remain edible and nutritious for years, its sour taste being highly prized for imparting flavour to the rather bland fresh breadfruit paste.

In the subtropical climate of Easter Island and in temperate New Zealand, the most important Polynesian food plants could not survive. On Easter Island, for example, the coconut did not survive, although legends maintain that germinating coconuts were brought by the earliest settlers. This deprived the Easter Islanders not only of a variety of condiments and a rich source of vitamins but also of the leaves that were used elsewhere in Polynesia for thatch and baskets and of the husk fibres that were used to make fishing line and netting. In New Zealand it was not only the coconut but also breadfruit, yams, and bananas that did not survive. The radically different flora and fauna of New Zealand, however, offered foods to replace, at least partially, those that it would not support.

Not only the coconut but most food plants in Polynesia also provided materials for other purposes. The breadfruit furnished wood for the hulls of dugout canoes, and the milky sap of the fruit itself was used in caulking the gaps

between the planks of larger canoes. The black mud of the taro patches was used to stain wood and stone carvings. The pandanus fruit was highly prized as a kind of chewing gum, as well as a major component of floral necklaces and headpieces, to which it contributed its strong and pleasant colour. Pandanus leaves, when bleached, became the raw material for fine mats. The candlenut was used for torches, its oil was a cathartic, and its wood furnished certain canoe parts.

Polynesian technology can be circumscribed by five items: wood, stone, vegetable fibre, shell, and bone. The canoes, houses, domestic utensils, weapons, religious sculpture, and a host of other incidental tools were fashioned from wood with stone or shell adzes; stone-flake knives; files made of coral, sea urchin, or rough stone; and drills of bone, stone, or shells. Fine carving was done with stone, shell, or animal teeth, particularly those of rats or sharks. Stone, generally fine-grained basalt, was the hardest material available to the Polynesians and was used to produce a variety of adzes.

The absence of metal for use in attaching or clamping wooden parts posed no obstacle to Polynesian construction. Wooden components were skillfully fitted together and lashed with cordage made of various types of vegetable fibre, such as hibiscus bark, pandanus-leaf fibre, coconut fibre, or banyan bark. Huge double canoes 100 to 150 feet in length, for example, were built of numerous small wooden components all held together only by fitting and lashing, yet they were able to withstand the pounding of wind and wave for thousands of miles.

Vegetable material also furnished a major source of clothing in the form of the beaten bark (tapa) of the paper mulberry tree or the banyan. This material was beaten out into small sheets that could then be assembled to produce loincloths, capes, skirts, and headdresses. Bark cloth was decorated by painting and watermarking and by attaching feathers, shells, teeth, and other ornaments. Fine mats were also used as apparel in western Polynesia.

Home furnishings also consisted mainly of vegetable material in the form of mats for sleeping and sitting, as well as for protection from the weather, and of baskets for holding personal belongings and food. Coconut shells and bottle gourds provided handy, durable containers for various items.

Pottery was in use in western Polynesia at the time of European contacts. It had been in use earlier in the Marquesas Islands, at the extreme eastern edge of Polynesia, but had disappeared from the technology.

Craft organizations are an interesting aspect of Polynesian culture. These organizations provided for the training of specialists in tasks requiring special knowledge and higher levels of manual skills—canoe construction, wood carving, and adz making, for example, as well as complicated operations, such as fishing and tattooing. When specialist groups existed, they were usually designated by name and would ply their craft for pay in the form of goods and services, as well as support for the period of their service.

Property and exchange. Personal property was a well-developed concept in prehistoric Polynesia. Each individual, regardless of rank, had his own tools, small canoes, clothing, ornaments, trophies, weapons, and other items and was generally free to dispose of them as he wished. Other types of property, however, were owned by extended families or descent groups in common and used for the common good. These included items too large to be produced or managed by a single man alone, such as a large double canoe or a fishing net several hundred feet in length, as well as facilities and land intended directly for community use, such as a tribal ceremonial ground, a refuge fortification, or a large breadfruit-paste storage pit.

The matter of ownership of land and the means of production were complicated and varied among Polynesian cultures depending on the type of social organization that they developed. In Polynesian societies of the more traditional type, land was vested in a corporate descent group. Among the Maori this group was the *hapu*, and its members usually inhabited one or a few villages located in close proximity to each other. The land of the *hapu* was viewed as being symbolic of the *hapu* chief's sanctity

The
absence of
metal

Maori
land-
holding
practices

Horti-
cultural
practices

and power and as almost a literal extension of his body. Yet, the land was apportioned out to the various family groups within the *hapu* and worked by them. The chief, regardless of his prestige (stemming from a close family tie to the tribe's mythological ancestors), could not evict a family of nonproducers or in any way cut them off from their source of livelihood. He could invoke supernatural powers in the form of a curse or of a ritual prohibition, but expropriation was quite uncommon. In return for this essentially inalienable right to his land, the good Maori was expected to provide certain quantities of produce for the chief on various occasions and also for the chief of the next highest element in Maori social organization, the *iwi*. If his offerings were not of sufficient size and quality, the Maori risked punishment and possibly even death in extreme cases but not expropriation. If the food offered was acceptable, however, the offerer would be assured of an appropriate amount of food of other types in return, demonstrating the chief's desire to live up to his own obligations.

A number of Polynesian societies were essentially similar to the Maori in their landholding practices, including those of the Tikopia, Pukapuka, Futuna, and Uvea (Wallis); but, in others, evolutionary changes in social organization began to exert pressure on the basic landholding descent group (as exemplified by the Maori *hapu*), which seems to have been the basic building block of Polynesian society. As a result, the descent group ultimately lost control of all rights to land, surrendering it to increasingly powerful and autocratic chiefs. Thus, in Hawaii, perhaps the most sociopolitically evolved of all the Polynesian societies, there was a large mass of completely landless commoners dwelling in territorial districts, each of which ran from the seashore to the island's centre, thus including a segment of each of the island's ecological zones.

Each of these territorial districts was ruled by a chief, whose position was somewhat like that of a lord in medieval Europe. The chief was responsible to the paramount chief of the island for supervising, among other things, the production of that district. The district chief or the paramount chief was free to shift at will the population of commoners within the district, regardless of their kin affiliation, although the chief and nobles themselves still relied heavily on their own kinship affiliations and prerogative. The district chief saw to the production of each household in his district and could evict the unlucky farmer who failed to meet his quota. Both he and the paramount chief could also make a variety of arbitrary demands from which the commoners had little or no protection, except to leave the district and submit to the authority of another district chief. The commoners were responsible for the timely production of certain specified quantities of food, which was collected and passed up to the district chiefs and ultimately to the paramount chief. At that level, certain types of food reserved for chiefs only would be set aside, and a redistribution of the remaining food would take place, with portions being passed back down the same channels that had been used to collect the food in the first place. Although kinship groupings, consisting of all individuals related through both male and female lines, still existed, their main functions seem to have been to serve as a channel for low-level exchange of food and other commodities and to assist in the organization of the massive food collections held periodically throughout the year for the nobility.

The Polynesian system of exchange of goods and services may be summarized by two terms: redistribution and reciprocity, both already mentioned in connection with the discussion of the landholding systems. The redistributive system was essentially a vertical system with goods moving up from the lower strata of the society to the chiefs and other high-ranking persons and then being apportioned and redistributed, so that all would share in more equal fashion in the productivity of every kinship group or region. This system involved a complex, shifting web of reciprocal obligations, which is very much at the heart of Polynesian culture, even today. Goods and services rendered, even if not requested, necessarily give rise to an obligation for a return in kind. There were no markets in

Polynesian cultures, nor was there any standard medium of exchange. All exchange was in the form of barter, often under the general supervision of some senior family or kin-group member. Thus, for example, a portion of the fish catches made on a minor fishing expedition by coastal residents would be passed inland to residents at central villages, who might return dry taro for the fish at some fixed ratio of units of taro to units of fish. The services of any of the numerous specialists in Polynesian cultures (tattooists, fishermen, wood-carvers, for example) was also paid for by barter, usually over and above the cost of the specialist's keep during his period of service. Early European visitors to Polynesia who were able to analyze the importance of reciprocal exchange and put it to their own use generally fared quite well among the Polynesians, although they sometimes found themselves overwhelmed by the increasing size of the obligations they had undertaken. Captain David Porter of the U.S. Navy, for example, in 1813 won the friendship of the chief of Taiohae, Nuku Hiva, with a gift of sperm whales' teeth but within a few months found himself fighting a tribal war essentially on behalf of the same chief, in order to live up to his obligations.

RELIGION AND ART

Religion and magic pervaded all aspects of Polynesian culture. All things, animate and inanimate, were believed to be endowed to a greater or lesser degree with mana, or sacred supernatural power. This power could be nullified by various human actions. Polynesian chiefs had great mana—so great, in fact, that in some islands if a commoner touched the chief's shadow the injury to the chief's mana could only be compensated by the death of the commoner. In many Polynesian cultures even today, it is still considered to be in very poor taste to step over a person's legs, pass one's hand over a person's head, or stand with one's head higher than that of a person of high rank. These actions are believed to sap a person's mana, rendering him profane.

It was not only people who had mana, however, but buildings, stones, tools, canoes, and all things. Polynesian life was infused with a wide variety of complicated rules designed to prevent damage to the mana inherent in various things. Groves, trees, temples, or tracts of land were considered sacred and could not be entered by ordinary people because they were pervaded by the mana of a high-status person or god. If anyone inadvertently stepped over a tool left on the ground, it was thus rendered profane and would often be discarded. Women were not permitted in canoes under normal conditions in the Marquesas because their presence defiled the canoe. In many societies, men preparing for war or for any other hazardous or demanding undertaking had to go through a period of purification—avoiding the company of women, eating certain foods only, and often going into seclusion so as to protect their powers from defilement. Some chants and songs were so sacred that every syllable had to be pronounced correctly. The penalty for major violations of these tapu, or prohibitions, was often death, swiftly executed and gruesome. Violations of lesser tapu, such as trespassing in a sacred grove or disturbing the bones of the dead, were believed to result in supernatural punishment, manifested in some form of illness or in bad luck or debilitation.

Mana was not the only force that the Polynesian had to be wary of, however. The universe, in their beliefs, was peopled with spiritual beings of various types, many of whom were malevolent. In addition, there was a host of gods of various degrees of importance, ranging from the great gods of the Polynesian pantheon, such as Tangaroa, Tu, and Lono, to strictly local gods who were deified priests or chiefs of great renown. All of these gods had to be worshiped in their own way, the most important by full-time priests of highest status, those of lesser importance by part-time priests. Worship of the gods involved sacrifices (including humans), chants and recitations, feasting (often with great prodigality), sexual orgies (to promote fertility), and elaborate rituals, often preceded by long fasting and abstinence.

Magic flourished in Polynesian society, with everyone

The sacred power of places

Economic redistribution in Hawaii

practicing various rituals for success in love, war, planting, or fishing, or to bring misfortune to rivals. There were also magical specialists who could be resorted to when the problem at hand was too great or complicated to be solvable by ordinary magic. Such magical practices have survived in Polynesian cultures right down to the present time.

The numerous restrictions and demands placed upon the average Polynesian by religious observance and by measures required to protect against supernatural forces were in many cases seen as oppressive by the Polynesians themselves, and, in one case, the whole system was simply abolished. This occurred in Hawaii in 1819, when the young king, Kamehameha II, assisted by the high priest, his adviser, and other leaders of the court, publicly and intentionally broke the main food and eating tapu at a festival, after which the high priest desecrated the images of the gods and burned the temple. While many factors played a part in the prelude to this dramatic act (not the least of which were the presence of Europeans and the desires of the royal women to be free from the burden of tapu), the principal factor motivating Kamehameha II seems to have been a real impatience and frustration at an increasingly constricting system that provided little obvious benefit in return for the great inconvenience. Although no other islands in Polynesia followed the Hawaiian example, there is evidence that the religious system was viewed as extremely frustrating in many other Polynesian cultures.

Polynesian art was highly developed and brilliant, but little of what is known to have existed has survived down to the present day. This is mainly due to the perishability of much of the material (bark cloth, basketry, featherwork) and the dispersion that took place during the era of European contact, when such items were bartered for firearms, liquor, iron tools, or trinkets.

Each Polynesian society developed its own particular area of artistic endeavour—monumental stone sculpture on Easter Island and the Marquesas; highly decorated bark cloth in western Polynesia; fine mats in Tonga. In this development, a vocabulary of art motifs, styles, and artistic principles was elaborated, which also differ somewhat from culture to culture. Certain types of motifs nevertheless are widely distributed in Polynesia. For example, a number of small geometric decorative elements, such as a toothed pattern or units of diagonally sloping lines, are found in most cultures in many media. Stylized floral and animal elements are also widely distributed. In eastern and marginal Polynesia, an anthropomorphic figure and an often grotesque anthropomorphic face with bulging eyes and protruding tongue are prominent in all types of plastic art, as well as in tattooing.

Architecture was developed almost everywhere in Polynesia, but only the ruined stone structures of the eastern Polynesian islands remain to bear witness to the Polynesians' considerable architectural skill. The stone temples of the Society Islands, Easter Island, and the Marquesas, even in their ruined state, display striking proportions and design; clever use of stones of different colours, shapes, and textures; and the evidence of sound combination of practical engineering with artistic objectives.

(R.C.Su./R.C.Ki.)

EFFECTS OF EUROPEAN CONTACT

Polynesian cultures have been radically altered by contact with the Western world. European explorers navigated much of the area in the latter quarter of the 18th century, and the first missionaries arrived in the late 1700s and early 1800s. The colonial partitioning began in 1842 when France annexed Tahiti. Eventually, Chile, Germany, New Zealand, the United Kingdom, and the United States held territory in the area. Germany lost its interests in the islands as a consequence of World War I.

The period between the two world wars was tranquil, although there was some open resistance to New Zealand's administration of Western Samoa under a League of Nations mandate. The missions' influence on the Polynesian peoples increased, and Christianity became an integral part of the islanders' lives. In many areas Christianity

in turn was influenced by local traditions and customs. Quite commonly, villages competed to build larger and more elaborate churches, and first-time visitors to Polynesia are often surprised at the intensity of the islanders' commitment to Christianity. Many Polynesians were recruited to missionize other parts of the Pacific, particularly Melanesia.

After World War II, sentiments for decolonization began to spread, and Western Samoa became the first independent Pacific nation when it gained sovereignty from New Zealand in 1962. Tonga freed itself as a protectorate of the United Kingdom in 1970, and the Ellice Islands, in the Gilbert and Ellice Islands Colony of Great Britain, achieved independence as Tuvalu in 1978. Ironically, the conservatism of Polynesian cultures is most manifest in these three independent nations. Three island groups had been monarchies—Tonga, Tahiti, and Hawaii—but monarchy survives only in Tonga, although Tonga also has a British-style parliament that gives special status to traditional nobles.

Having been a mandate of New Zealand, a Commonwealth nation, Western Samoa also has a parliamentary system, but only traditional chiefs (*matani*) may vote and run for election. Tuvalu also follows the parliamentary style of government. In Tonga, Samoa, and Tuvalu, the vast majority of people live in subsistence-based villages, where much of traditional culture survives.

The Cook Islands and its former colonial authority created a new political status in 1965 when the Cooks became self-governing in free association with New Zealand. In this innovative arrangement, the Cooks became self-governing with regard to internal affairs, and New Zealand agreed to manage external affairs as requested. New Zealand provides the government of the Cook Islands with a financial subsidy, and Cook Islanders enjoy dual citizenship. As the relationship has subsequently evolved, the Cook Islands has assumed control of most of its external or foreign affairs. Niue Island, another former dependency of New Zealand, followed suit in 1974 when it also became self-governing in free association with the former colonial power. Many of the people of the Cook Islands and Niue have become very Westernized, and many of their citizens as well as those of Western Samoa have immigrated to New Zealand. Indeed, Auckland, N.Z., has the largest concentration of Polynesians of any city or place in the world.

Six other Polynesian entities remain parts of or are territories of four Western powers. Of these, two—French Polynesia and the self-governing territory of Wallis and Futuna—are integral parts of France and vote in French national elections. French Polynesia includes several island groups, but a large majority of the people live in or near the capital city of Papeete on the island of Tahiti and are quite urbanized. Wallis and Futuna is small and remote, and much of its traditional culture survives in a diluted form. Tokelau, New Zealand's last dependency in the Pacific, has small islands and a very small population. Like Wallis and Futuna, it is remote, and much of its former way of life remains.

Two island groups are American: Hawaii and American Samoa. Hawaii is the 50th state of the United States. The city of Honolulu, with its large, Western-style commercial district and sprawling suburbs, dominates the island of Oahu, has most of the state's population, and has much in common with cities on the U.S. mainland. American Samoa is a territory of the United States, and it is far less traditional than Western Samoa. The capital town of Pago Pago is a blend of both American and Samoan life-styles. Rural villages, however, have much in common with their counterparts in Western Samoa.

Easter Island is the anomaly of the area. The aboriginal population was decimated by European-introduced diseases and by slavers in the 1860s and almost became extinct. In 1888 Easter Island was annexed by Chile, and its people are the only Pacific islanders controlled by a Latin-American power. Little remains of the traditional culture of Easter Island. The indigenous Polynesian language survives, but most people also speak Spanish. About one-third of Easter Island's small population is from Chile.

MAJOR POLITICAL UNITS OF MELANESIA

(As mentioned at the beginning of this article, Australia and New Zealand are treated separately, and Hawaii is treated in the article UNITED STATES OF AMERICA. Other political and geographic units of the Pacific not covered below are treated individually in the *Micropædia*.)

Fiji

Fiji is an independent nation consisting of an archipelago surrounding the Koro Sea in the South Pacific Ocean, about 1,300 miles (2,100 kilometres) north of Auckland, N.Z. It forms part of the Melanesian cultural area.

The archipelago consists of some 300 islands and 540 islets scattered over about 1,000,000 square miles (3,000,000 square kilometres). Of the 300 islands, about 100 are inhabited. The total land area is 7,056 square miles. The capital, Suva, is on the southeast coast of the largest island, Viti Levu ("Great Fiji"). Fiji includes within its borders Rotuma, an island of 18 square miles located 440 miles north of Suva; Rotuma has a Polynesian population and was administered from Fiji in colonial times.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* Fiji has a complex geologic history. Based on a submerged platform of ancient formation, the Fiji islands are largely the product of volcanic action, sedimentary deposit, and formations of coral. Viti Levu, the largest island, has an area of about 4,000 square miles and accounts for more than half of Fiji's land. A jagged dividing range running from north to south has several peaks above 3,000 feet (914 metres), the highest being Mount Tomanivi (formerly Mount Victoria) at 4,341 feet. The main river systems—the Rewa, Navua, Sigatoka, and Ba—all have their headwaters in the central mountain area. To the southeast and southwest, and to the south where the range divides, the mountains give way to plateaus, then lowlands. The coastal plains in the west, northwest, and southeast account for only 15 percent of Viti Levu's area but are the main centres of agriculture and settlement.

Vanua Levu, the second largest island, has an area of about 2,140 square miles. It is divided along its length by a mountain range with peaks rising to more than 3,000 feet. On the island's northern coast, away from the mouth of the Dreketi River, the coastal plains are narrow. Most of the other islands, including the Lomaiviti, Lau, and Yasawa groups, are volcanic in origin, but, like the major islands, they are bounded by coral reefs, offshore rocks, and shoals that make the Koro Sea hazardous for navigation.

Climate. At Suva the average summer high temperature is 85° F (29° C) and the average winter low is 68° F (20° C); temperatures typically are lower in elevated inland areas. All districts receive the greatest amount of rainfall in the season from November through March, during which time hurricanes are also experienced perhaps once every two years. While rainfall is reduced in the east of the larger islands from April to October, giving an annual average of 120 inches (3,050 millimetres) per year, it virtually ceases in the west, to give an annual rainfall of 70 inches, thus making for a sharp contrast in both climatic conditions and agriculture between east and west.

Plant and animal life. Almost half of Fiji's total area remains in forest, while dry grasslands are found in western areas of the large islands. Coconut palms are common in coastal areas, and almost all tropical fruits and vegetables can be grown. Much of the shoreline is composed of reefs and rocks, while mangrove swamps are found on eastern coasts. There are few white-sand swimming beaches and, because of the encircling reef, little surf.

Most animals, including pigs, dogs, cattle, and a few horses, are domesticated. Mongooses, introduced to prey on snakes and rats, are often seen.

The people. While the indigenous Fijian people are usually classified as Melanesian, they are larger in stature than Melanesians from Vanuatu, Solomon Islands, or New Guinea; their social and political organization is

closer to that of Polynesia; and there has been a high level of intermarriage between Fijians from the Lau Islands of eastern Fiji and the neighbouring Polynesian islands of Tonga. Almost all indigenous Fijians are Christian, mostly Methodist and Roman Catholic.

Since World War II, indigenous Fijians have been outnumbered by Indians, most of whom are descendants of indentured labourers brought to work in the sugar industry. A few, particularly in commerce and the professions, are descended from free migrants. Most of the Indians are Hindus, though a significant number are Muslims.

There are also significant minorities of Europeans, part-Europeans, Chinese, and Pacific islanders from outside Fiji. In the last group are the Polynesian population of Rotuma and the Banabans, who were forced to leave Banaba after destruction in World War II made it uninhabitable. Many Banabans settled on Rabi Island in Fiji.

English is the official language. The widely used Fijian language has many dialects; the one most commonly used is known as Bauan Fijian and comes from Bau, the district that enjoyed political supremacy at the advent of colonial rule. Most people speak at least two languages, including English and the language of their own racial community.

There is very little intermarriage between racial communities. The relative proportions of Fijians and Indians in the population have been changing in recent years because the Fijian birth rate is higher than the Indian and because of the accelerating outward migration of Indians, especially to Canada, Australia, and New Zealand. While Suva has a very mixed population, the sugar regions of Viti Levu and Vanua Levu have predominantly Indian populations. On the smaller islands, and in less-developed rural areas of the larger islands, Fijians live in traditional villages. The two largest urban centres are on Viti Levu: Suva, in the southeast, which has about one-fifth of the total population, and Lautoka in the northwest, which is the centre of the sugar industry and has a major port. Labasa on Vanua Levu is a centre for administration, services, and sugar production.

The economy. Fiji has an agriculture-based market economy, including a substantial subsistence sector dominated by indigenous Fijians who earn a supplementary cash income from copra, cocoa, kava, dalo (taro), pineapples, cassava, or bananas, or from fishing. The commercial sector is heavily based on sugar, which, for the most part, is produced by independent Indian farmers. Sugar production is concentrated on the western side of Viti Levu and

Indian farmers transporting a load of sugarcane near Natandola, Viti Levu, Fiji.

in the area around Labasa. The Fiji Sugar Corporation has a monopoly on milling and marketing. Sugar is by far Fiji's largest export and accounts for more than one-half of all exports.

Except for a few years early in the 20th century, the alienation of native land has been prohibited since 1874, thus leaving 83 percent of all land under Fijian ownership. Farmers of other races operate on leaseholds of up to 30 years under the Agricultural Landlord and Tenant Act. Fijian land ownership is in the hands of *matagali*, or clan groups, but may be administered through the Native Lands Trust Board.

Tourism is almost as large an earner of foreign exchange as sugar. Fiji is strategically located for air travelers from Australia, New Zealand, the United States, and Japan and is a major destination for tourist cruises. Tourism is based on the attractions of duty-free shopping and colourful handicraft markets as well as the usual attractions of tropical islands. Many hotels are located on small offshore islands or secluded beaches and offer accommodations in houses of local design and materials rather than in urban-style multistory buildings.

The third major export earner, though well behind sugar and tourism, is gold, which is mined at Vatukoula in northern Viti Levu. Copper deposits are known to exist at Namosi, inland from Suva, but mining is not viable.

Since large-scale systematic planting of pine forests began in the 1960s, a timber industry has developed for domestic use and export. Development plans have emphasized the need to reduce dependence on imported food, especially rice, meat, fish, and poultry products. There is substantial hydroelectricity generation, but fuel remains a major import together with manufactured goods (many for resale to tourists), machinery, and food. Australia, New Zealand, Japan, and the United States are the major sources of imports.

The economy has a strong service and light industrial component serving small neighbouring countries as well as Fiji; activities range from boat building (especially fishing boats and pleasure craft) to brewing and paint manufacture. The government offers incentives (including residence) for investors but insists on potential for job creation and training programs for local employees.

Sugar is sold on long-term contracts to New Zealand, Malaysia, and Singapore and, under the Lomé Convention (which gives former overseas territories access to the European market), to the European Economic Community. Regional trading agreements give Fiji special access to markets in Australia and New Zealand.

Transportation

The larger islands, and many smaller ones, are served by domestic air services. International airports are located at Nausori, near Suva (mostly for regional flights), and Nadi, on the western side of Viti Levu. A coastal highway circles Viti Levu, and minor roads to the interior give access to most areas of settlement. For many villagers, however, river punts with outboard motors provide the most efficient form of transport, while from more remote areas it may still be simplest to transport produce to market by floating it downriver on bamboo rafts. Regular bus services operate within and between the major towns.

Administration and social conditions. *Government.* Until the coup d'état of May 1987, Fiji was a dominion, a member of the Commonwealth, and a parliamentary democracy, acknowledging the British sovereign, through a governor-general, as head of state. There was a bicameral legislature of a Senate and a House of Representatives. Eight members of the Senate were appointed by the Great Council of (Fijian) Chiefs, seven by the prime minister, six by the leader of the opposition, and one by the Rotuman council. The House of Representatives had 52 members, 27 of whom were elected by adult suffrage by and from the separate racial communities. A further 25 members (10 Fijian, 10 Indian, and five General [those of other ethnic origin]) were elected by all voters combined on a national electoral role. The leader of the majority party became the prime minister.

In October 1987 Fiji officially left the Commonwealth and became a republic. The coup leader, then-Lieutenant Colonel Sitiveni Rabuka, appointed a civilian government

headed by a president with a largely ceremonial role. The government was composed of a prime minister and cabinet of appointed members, almost all of whom are ethnic Fijians.

Local government reflects the plurality of Fiji's social structure. There are elected multiracial councils in the larger towns, a separate Fijian administration incorporating a hierarchy of chiefs and councils for the control of rural Fijians, and direct administration elsewhere.

Before the first of two coups in 1987, Fijian military forces had a largely ceremonial role, though they bore much of the burden of rebuilding and organizing after natural disasters and of civilian development projects. Military forces continued to perform these services after the coup, with the added role of agricultural distribution, together with their major preoccupation with the enforcement of internal security policies.

Education and medical facilities. While the government provides some primary and secondary education, most schools are controlled through local committees run by and for a single racial or religious community. Entry to secondary schools is by competitive examination. Students pay fees but not the full cost of their education, which is subsidized by the government. The University of the South Pacific, near Suva, is a regional institution; Fiji and other Pacific Islands governments fund the budget, and foreign aid meets the costs of buildings and capital development. To extend the reach of the university, lessons are broadcast to distant regional centres by a satellite network. Fiji also provides for its own technical, agricultural, and medical education and teacher training. There are private medical practitioners in all large towns, a national network of clinics and small hospitals, and major hospitals in Suva, Lautoka, and Labasa.

Effects of urbanization. Rapid urbanization, especially on the fringes of Suva, has seen the emergence of squatter settlements and has caused some social problems. The disparities of income between urban and rural workers, contrasting life-styles within the urban areas, and high urban unemployment can be related to an escalating rate of crime and to the rapid growth of a trade union movement.

Cultural life. Fiji's mixed racial background contributes to a rich cultural heritage. Many features of traditional Fijian life survive; they are most evident in the elaborate investiture, marriage, and other ceremonies for high-ranking chiefs. These provide a focus for the practicing of traditional crafts, such as the manufacture of *masi*, or tapa cloth, made from the bark of the paper mulberry; mat weaving; wood carving; and canoe making. Drinking of yanggona (kava, made from the root of *Piper methysticum*) is a part not only of important ceremonies but of everyday life. Displays of "traditional" Fijian culture, music, and dancing make an important contribution to tourism; model villages and handicraft markets are popular.

Most Indian women continue to wear the sari together with traditional jewelry in gold and silver. Traditional marriage ceremonies are practiced, as are customs such as fire walking and ritual self-torture as part of important religious ceremonies. Cinemas showing imported Indian films are popular. Diwali, the Hindu Festival of the Lights, is celebrated every October and is a public holiday.

Fiji has two daily newspapers and a multilingual public radio broadcasting system. Videocassette players are common in the towns (many villages have no electricity).

For statistical data on the land and people of Fiji, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

When Fiji's first settlers arrived from island Melanesia at least 3,500 years ago, they carried with them a wide range of food plants, the pig, and a style of pottery known as Lapita ware. This pottery is generally associated with peoples who had well-developed skills in navigation and canoe building and were horticulturists. From Fiji the Lapita culture was carried to Tonga and Samoa, where the first distinctively Polynesian cultures evolved. Archaeological evidence suggests that two other pottery styles were subsequently introduced into Fiji, though it is not

The University of the South Pacific

Two
types of
settlement

clear whether these represent major migrations or simply cultural innovations brought by small groups of migrants. In most areas of Fiji the settlers lived in small communities near ridge forts and practiced a slash-and-burn type of agriculture. In the fertile delta regions of southeast Viti Levu, however, there were large concentrations of population. These settlements, which were based on intensive taro cultivation using complex irrigation systems, were protected by massive ring-ditch fortifications.

Traditional Fijian society was hierarchical, with tribal groups led by chiefs chosen according to rank based on descent as well as personal achievement. Tribes were divided into *mataqali*, or clans, and residential subclans. By alliance or conquest tribes might form confederations led by paramount chiefs; warfare was common.

The first Europeans to sight the Fiji Islands were Abel Janszoon Tasman, who passed the northeast fringe of the group in 1643, and Captain James Cook, who passed the southeastern islands in 1774. Captain William Bligh passed through the group in his open longboat after the mutiny on HMS *Bounty* in 1789 and returned to explore it in 1792.

Commercial interest in the group began with the discovery of sandalwood at the beginning of the 19th century, leading to a rush to Bua Bay at the southwestern end of Vanua Levu. A few beachcombers, useful as armourers and interpreters, were adopted by influential chiefs from this time. Within little more than a decade the accessible, commercial stands of sandalwood were depleted, but by the 1820s traders were again visiting the group to trade for edible varieties of the marine invertebrate called the sea cucumber, also known as *bêche-de-mer* or trepang. Whereas most of the sandalwood had been cut by gangs of foreigners, the *bêche-de-mer* harvest involved large numbers of Fijians in gathering, cleaning, and drying and in the provision of food and firewood. These opportunities for new wealth and power, symbolized by the acquisition of muskets, intensified political rivalries and hastened the rise of the confederation of Bau, led first by Naulivou, then by his nephew Cakobau. Bau is a tiny island off the southeast coast of Viti Levu, but by the 1850s it dominated western Fiji. Cakobau's main rival was the Tongan chief, Ma'afu, who led an army of Christian Tongans and their allies from eastern Fiji. After a short-lived alliance with Ma'afu, Cakobau became a Christian in 1854, thus bringing most Fijians under the influence of Methodist missionaries. Roman Catholic and Anglican missionaries arrived later but did not enjoy the same success.

By the 1860s Fiji was attracting European settlers intent on establishing plantations to capitalize on a boom in cotton prices caused by the American Civil War. The consequent disputes over land and political power within and between European and Fijian communities, and problems with labour introduced from other Pacific islands, contributed to violent confrontations and exacerbated the implicit instability of Fijian society and ensured that no Fijian chief could impose his rule on the whole group. European attempts at government were doomed by the greed and factionalism of their members and by the interference of European governments and consuls. Imperial intervention thus became inevitable. On Oct. 10, 1874, after negotiations had led to an offer of unconditional cession, Fiji became a British crown colony. The policies of the first governor, Sir Arthur Gordon, were decisive in shaping the history of Fiji. Gordon saw himself as the protector of the Fijian people and thus initiated policies that limited their involvement in commercial and political developments. Sales of Fijian land were banned; the Fijians were taxed in agricultural produce, not cash; and they were governed through a system of indirect rule based on the traditional political structure.

In order to maintain these policies yet encourage the economic development of the new colony, Gordon promoted the introduction of indentured Indian labourers and investment by the Colonial Sugar Refining Company to establish sugar plantations and processing mills. Indian migrants were encouraged to become permanent settlers at the conclusion of their contracts, even though little land was available for sale and the migrants' political rights

were circumscribed. After the termination of the indenture system in 1920, Indian agitation over political and economic grievances caused strikes and continual discontent and challenged the commercial and political domination of the small European community in the islands.

During World War II Fiji was occupied by Allied forces, and a battalion of Fijians saw service as scouts in the campaign for the Solomon Islands. Indians refused to serve because they were not offered the same wages and conditions as Europeans. Indians also refused to cut their cane at the low prices offered. These actions led to the taint of disloyalty being applied to Indians by the other races, and to the army, which was retained after the war, remaining exclusively Fijian except for a handful of European officers. Incipient racial awareness was heightened by the realization that from 1943 Fijians were outnumbered by Indians. As one response to perceived stagnation in Fijian society, the colonial authorities restructured the Fijian administration, reinforcing chiefly leadership and thus consolidating the conservatism of Fijian society.

Constitutional development toward independence, which began in the 1960s, was more a response to international and British pressures than to any demand from within Fiji. The steps taken were, in practice, a compromise between the principles of parliamentary democracy and the racial divisions within the country. The franchise, previously exercised by Europeans and some Indians, was extended to adults of all races, including Fijians, who until then had been represented by their chiefs. Fijian land rights, guaranteed by the Deed of Cession in 1874, were given constitutional protection, while Fijian chiefs were given an effective veto on all important matters affecting the status of Fijians and on changes to the constitution itself. Facing political reality, Indian leaders relinquished their earlier demands and accepted the communal and cross-voting system, thus giving away the common electoral role that they had sought since the 1930s.

The effect of the constitution was to give power to Fijian politicians so long as they remained in partnership with the General voters and, critically, so long as the Fijian vote remained unified. Despite race riots during by-elections in 1968, independence was achieved in a spirit of cooperation on Oct. 10, 1970, the 96th anniversary of cession.

From that time until April 1987, Fiji was governed by the Alliance Party, which was pledged to policies of multiracialism. Its electoral supremacy was challenged only briefly in 1977, when Fijian votes were attracted by Fijian nationalist candidates campaigning under a slogan of "Fiji for the Fijians"; only factionalism prevented the formation of an Indian-led government.

In 1987, however, the Indian-dominated National Federation Party joined in coalition with the new Labour Party (led by a Fijian, Timoci Bavadra), which had strong support from Fijian and Indian trade unionists. The coalition was successful in elections held in April. The new government, which had a majority of Indian members in the legislature, was greeted with widespread Fijian protest. After only a few weeks the new government's leaders were arrested and deposed in a coup d'état led by Lieutenant Colonel Sitiveni Rabuka, who demanded greater protection for Fijian rights and an entrenched Fijian dominance of any future government. The governor-general declared a state of emergency and assumed control of the government. With political leaders he then negotiated a compromise that would have maintained civilian rule pending a constitutional revision and new elections. The compromise prompted Rabuka to lead a second coup in September and reimpose military rule. Toward the end of 1987 he declared Fiji a republic and appointed a new civilian government with Ratu Sir Kamisese Mara, prime minister from 1970 to 1987, as prime minister. (B.K.M.)

For later developments in the history of Fiji, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

of the con-
stitution

Crown
colony
status

New Caledonia

New Caledonia (official name Territoire de la Nouvelle-Calédonie et Dépendances, or Territory of New Caledonia)

nia and Dependencies) is a French overseas territory in the southwest Pacific Ocean, about 900 miles (1,500 kilometres) east of Australia. It includes the island of New Caledonia (the Grande Terre, or mainland), where the capital, Nouméa, is situated; the Loyalty Islands; the Bélep Islands; and the Isle of Pines. These islands, which form more than 99 percent of the total land area of about 7,300 square miles (19,000 square kilometres), lie between latitudes 18° and 23° S and longitudes 163° and 169° E. The territory also includes a number of far-flung uninhabited islets: Huon and Surprise islands in the D'Entrecasteaux Reefs, the atolls of the Chesterfield Islands and Bellona Reef, Walpole Island, Beutemps-Beaupré Atoll, and Astrolabe Reefs. France also claims Hunter and Matthew islands, but the claim is disputed by Vanuatu. Although New Caledonia has a relatively small population, it has acquired significance as a remaining outpost of European sovereignty in a largely decolonized region.

The main island, with an area of 6,500 square miles, is by far the largest island and contains about 90 percent of the population. It is surrounded by a coral reef that extends from the Huon Islands in the north to the Isle of Pines in the south. Except for the central part of the west coast, which is bordered only by a fringing reef, it is a true barrier reef enclosing a large lagoon. There are numerous passages in the reef, usually at the mouths of rivers.

Metamorphic rock formations

Relief and drainage. Rugged mountain ranges, consisting principally of metamorphic rock formations, divide the island into an east coast, which in many places descends precipitously to the sea, and a west coast, which slopes more gradually and contains flat, undulating land. Ultrabasic, serpentine rock forms a continuous plateau over most of the southern third of the island, rising to a height of 5,308 feet at Mount Humboldt, and continues along the west coast as a series of discrete massifs. Outcrops from this formation form the islands of Art and Pott in the Bélep archipelago in the north and, in the south, the central part of the Isle of Pines, which is bordered by an emerged coral platform. These rocks have weathered to form the striking *terre rouge* (i.e., red soils that overlay the island's extensive deposits of nickel, chrome, and cobalt ore). In the northeast an outcrop of gneiss forms a 40-mile-long mountain range that includes the territory's highest mountain, Mount Panié, 5,341 feet. Elsewhere, the northern half of the island consists mainly of an irregular series of ranges formed from schists. Sedimentary rocks are limited to a narrow zone extending along much of the west coast inland between the serpentine massifs and the northern schist formations. They have weathered to produce broad, undulating plains with some steep-sided hills.

Numerous streams descend from the central mountain chain to the lagoon, often flooding rapidly after rainfall and drying out in dry weather, especially on the west coast. The Diahot River, the longest river in the territory, flows for about 60 miles toward the northern tip of the island along the western escarpment of the Mount Panié range.

The Loyalty Islands consist of three main islands—Ouvéa, Lifou, and Maré—and numerous small islands, the most important being Tiga. The Loyalty Islands form more than 10 percent of New Caledonia's total land area, and about 10 percent of the population lives there. In contrast to the mainland, these islands are raised coral plateaus, nowhere rising more than 330 feet above sea level. Surface water is lacking because of the porous nature of the calcareous rock formation.

Climate. The climate is subtropical with a year-round rainfall. The rainfall is higher on the east coast, where at higher elevations more than 120 inches (3,000 millimetres) may fall annually. On the west coast the rainfall is regularly less than 40 inches. The period from December to March is particularly rainy because of equatorial depressions, including frequent cyclones. Another period of heavy rainfall occurs in July and August; the driest months are September through November. Winds bearing northeast to southeast, including trade winds, predominate throughout the year and relieve temperatures in the hot season, which begins in November. Cyclonic winds are frequent late in the hot season.

The mean annual temperature at sea level ranges be-

tween 71° F (22° C) and 75° F (24° C). In the south of the mainland there are very few days when the temperature rises above 86° F (30° C), but their frequency increases to the north. The lowest temperature recorded in Nouméa is 55° F (13° C), but farther north on the west coast temperatures as low as 41° F (5° C) have been known to occur.

Plant and animal life. Geographic isolation, contrasting soils, and a wide range in altitudes have produced a rich indigenous flora. *Terre rouge* soils support a highly original maquis in which sclerophyllic (resistant to drying) shrubs with spectacular coloured flowers are dominant. Different forms of rain forest range from those growing on coral platforms, as in the Loyalty Islands, to montane forests above 3,000 feet on the mainland. The savanna woodlands of the west coast are dominated by a ti tree, the ubiquitous niaouli (*Melaleuca quinquenervia*), which is highly fire-resistant and the spread of which is stimulated by bushfires. Although it grows best in wet soils up to an altitude of 2,000 feet, it extends also onto well-drained slopes and crests and forms the dominant species of closed swamp forests growing on the seaboard plains of the Diahot valley. A once-widespread dry sclerophyll forest, dominated by the guaiacum (*Acacia spirorbis*), growing at low altitudes on the west coast, is now confined to relict sites. Mangrove swamps proliferate on the highly indented west coast.

Except for several species of bat, which were present before the arrival of Europeans, mammals are absent from the native fauna. There are no frogs and no venomous land reptiles, although scorpions and centipedes are present. There are no endemic malaria-carrying mosquito species. The kagu, a flightless bird, is the most unusual of some 100 endemic bird species and is now rare. A wide range of marine life is present in the lagoon.

Settlement patterns. About three-fifths of the population live in Nouméa, which since 1965 has expanded to embrace the adjacent municipalities of Dumbéa, Mont-Dore, and Païta. Nouméa has the facilities of a French provincial city, including numerous bars and restaurants, modern shops and supermarkets, a hospital, schools, a local newspaper, and radio and television facilities. About four-fifths of people of migrant origin, including Europeans, Polynesians, and Asians, live there as compared with one-quarter of the Melanesian population. About three-quarters of the Melanesians live outside Nouméa in small, widely dispersed villages with few modern facilities. They engage chiefly in subsistence agriculture based on the cultivation of the yam, taro, sweet potato, and banana. The population is almost entirely Melanesian in the Loyalty Islands, the Isle of Pines, and the Béliés and on the east coast and in the mountain ranges of the mainland.

The people. Melanesians and Europeans are the two principal ethnic groups, forming 43 and 37 percent of the population, respectively. Their differing cultures have given rise to two distinct ways of life, known as *kanak* and *caldoche*; people of mixed descent tend to ascribe to one or the other. The *kanak* identity is based on clan membership, a network of family alliances and specific land rights. The *caldoche* way of life is essentially integrated into a cash economy. The Polynesian minority comprises Wallis and Futuna Islanders (9 percent) and Tahitians (4 percent). Descendants of Indonesian and Vietnamese migrant workers form 4 and 2 percent of the population, respectively, and are essentially an urban group.

French is the official language but is not the mother tongue of most Melanesians and Polynesians. Some 30 Melanesian languages are spoken, most Melanesians being proficient in more than one.

The Roman Catholic Church claims about two-thirds of the population as adherents, including almost all European, Uvean, and Vietnamese and half of the Melanesian and Tahitian minorities. Two Protestant churches, the Evangelical Church in New Caledonia and the Loyalty Islands (Église Évangélique en Nouvelle-Calédonie et Îles Loyauté) and the Free Evangelical Church (Église Libre), serve one-fifth of the population. Their memberships are almost entirely Melanesian. There are also numerous minor Christian sects and small numbers of Muslims.

The Melanesian population is widely believed to have

The influence of red soils on flora

Religions

declined rapidly in the 19th century, but estimates for the period, including that for the 1887 census, were so poorly based that this remains an impressionistic view. In the 20th century the figure for Melanesians was fairly stable up to 1939 but doubled in the 40 years following World War II. Migration into and out of the territory plays an important role in determining the numbers of the non-Melanesian communities. The birth rate is higher among Melanesians and Uveans than among other groups, but infant mortality is high among Melanesians, and life expectancy is relatively low.

The economy. New Caledonia's economy is highly dependent on France. Exports, which consist largely of partly refined nickel and nickel ore, cover less than half the cost of imports but vary with the world market price of nickel. Half of the territory's trade is with France; other important trade partners are Japan, the United States, and Australia. The trade deficit is made up by the transfer of funds from France, chiefly as grants to the territorial budget and expenditures for health, education, and the maintenance of military and security forces, which accounts for about one-third of the gross domestic product (GDP). The administration, commerce, and transport and services sectors contribute three-quarters of the GDP, compared with 9 to 12 percent for mining and 2 percent for agriculture. Efforts to diversify the economy beyond the commercial and administrative sectors have met with little success. There is, however, considerable potential for tourism, relying on tourists from Australia, New Zealand, and Japan. Import replacement industries, such as the manufacture of soft drinks and beer, soap, cement, fencing wire, and fishing and pleasure boats, have had little impact on the economy because of the small local market.

Although the per capita GDP is one of the highest in the countries of the South Pacific, distribution between ethnic groups is unequal, Melanesian household revenues being on average only about one-quarter of that of European households. The distribution of land resources on the mainland also is very uneven. Although some 35,000 Melanesians live by cultivating the land, two-thirds of the land is in the hands of European families, very few of whom are engaged in agriculture or cattle raising.

Europeans also dominate trades, businesses, and professions and hold most of the high-ranking administrative posts in the government. Among the official unemployed, Melanesians are twice as numerous as Europeans; figures do not include the considerable number of "hidden" unemployed who have returned to their villages.

Taxes in the territory consist primarily of duties on imported goods, sales taxes, and taxes on business revenues. An income tax was introduced in 1982 but has been maintained at a deliberately low level. More than 90 percent of the total tax receipts come from within Nouméa.

Resources. The weathering of serpentine rock provides the territory with 20 percent of the world's known reserves of nickel ore, as well as large deposits of chromium, cobalt, iron, and magnesium. The export of nickel ore, which has been mined since 1875, and of partly refined nickel from the Société Le Nickel (SLN) foundry on the outskirts of Nouméa, is subject to cycles of booms and depressions determined by the needs of the world steel industry and competition from other producers. It is a large industry by world standards. A large chromium mine at Tiébaghi in the north of the mainland was reopened in 1982 after a long period of inactivity to export ore to China and the United States. Cobalt and iron-ore deposits, as well as deposits of gypsum on the west coast and of phosphates on outlying islands, are no longer worked. Noncommercial deposits of coal are found on the west coast. The search for oil has not been successful. Hydroelectric power from Yaté and Néaoua provides nearly half of the territory's energy needs; the remainder of the territory's power is produced with imported fuel oil. More than three-quarters of the energy produced is used in the refining of nickel.

Agriculture. Local agricultural products meet barely half of the territory's needs for meat, vegetables, and fruit. Commercial agriculture has not succeeded despite efforts to establish sugarcane, cotton, rice, coffee, and copra industries. The production of coffee and copra that began

in the 19th century was kept going after World War II chiefly through the efforts of Melanesian subsistence farmers to diversify into the cash economy, but very little is now exported. A project began in 1982 to restart a coffee industry chiefly on Melanesian land by using varieties of coffee plants that are tolerant to sunlight. In the late 1970s reforestation projects, consisting mainly of plantings of Caribbean pine, were established on Melanesian land on the Isle of Pines and on the mountains inland from Koné on the west coast of the mainland. Similar projects have not been continued. Cattle raising is important to the economy; pigs and horses also are raised but rarely for commercial purposes.

Transportation. The main island of New Caledonia and the inhabited outer islands are ringed by roads. Virtually the entire coast of the island of New Caledonia may be traveled by road, and crossroads penetrate the centre of the island.

The port of Nouméa handles the majority of ocean traffic; a new deep-water harbour was completed in 1974. Regular service is available for cargo and passengers.

The domestic airline, Air Calédonie, provides internal air service from Magenta Airport near Nouméa to the main and outer islands, as well as to France and other countries.

Administration and social conditions. As a French overseas territory, New Caledonia is fully integrated into the French Republic, is subject to its laws, and sends parliamentary representatives to Paris. Special legislation is required, however, to introduce laws for the government of the territory and in areas such as education, health, and labour. Authority over defense, internal security, immigration, justice, radio and telecommunications, and secondary and higher education is retained by the French government and is administered by its appointed representative, the high commissioner. The administration of health, social security, transportation, industry, and infrastructure is shared by the high commissioner and locally elected representatives. Municipal and regional government is administered by the state.

Health and educational facilities of a high standard are in principle available to all but are of a higher standard in Nouméa than elsewhere. The school system closely follows the syllabus of schools in France, and students of non-European origin tend to progress more slowly than children of French origin. Although all attend school, attendance being compulsory until the 16th birthday, relatively few non-Europeans gain higher qualifications. French is the only language of instruction in state-supported schools.

Cultural life. Nouméa, with its bars, restaurants, cinemas, an excellent library and museum, good bookshops, and radio and television, offers a touch of Europe. For the Europeans, sports tend to be closely related to the sea and include boating, fishing, windsurfing, and swimming or sunbathing at the city beaches of Anse Vata and the Baie de Citron; tennis and cycling are also popular. Although big-league soccer in France is closely followed, soccer playing has virtually been appropriated by Melanesian men and a version of cricket (first introduced by early British missionaries in the Loyalty Islands) by Melanesian women. Melanesian soccer and cricket teams compete annually in territory-wide competitions.

In many areas, Melanesian custom remains strong, particularly in relation to clan and family ties and obligations. Almost without exception Melanesians, regardless of their education or urbanization, return to their villages to take part in elaborate ceremonies and gift exchanges on such occasions as births, marriages, and deaths. "Tradition" has, of course, been modified, an important inclusion now being Christian ceremonies. In rural areas, women still tend to carry out the daily agricultural round of planting, weeding, and harvesting, as well as their domestic tasks of cooking, cleaning, and child rearing. Men perform the heavier tasks of clearing the ground for new gardens. All take part in the annual yam planting and harvesting, which is still something of a ceremonial and social occasion, and these events also sometimes draw urban workers back to their villages for a short period.

Local languages remain surprisingly strong, despite the fact that, through the educational system, French has be-

French
authority

Mineral
reserves

come the lingua franca. In the 1980s, due to increasing nationalist feeling, there has been a revival of interest among Melanesians in the traditional arts of sculpture, mat and basket weaving, singing, dancing, and wood carving. This has been encouraged by the French government.

State-owned radio and television stations relay programs to all parts of the territory. In Nouméa there are also several privately owned radio stations. There is one daily newspaper, *Les Nouvelles Calédoniennes*.

For statistical data on the land and people of New Caledonia, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Melanesians settled the territory more than 3,000 years ago and, except for rare Polynesian voyagers, probably were cut off from outside contact until the late 18th century. In 1774 Captain James Cook landed at Balade, on the east coast of the mainland, and he named the island New Caledonia for his native Scotland. Cook was followed there by the French navigator Antoine de Bruni, chevalier d'Entrecasteaux, in 1793. Regular contact with Europeans began in 1841 when sandalwood traders from Australia introduced islanders to the use of iron. The arrival of a Protestant mission from the London Missionary Society in the Loyalty Islands in 1841 and a Marist mission, which was set up at Balade with the aid of the French navy in 1843, marked the beginning of the Protestant and Roman Catholic churches in the territory.

France took possession of most of present-day New Caledonia in 1853 in ceremonies at Balade and the Isle of Pines with the aim of reserving the territory as a possible site for a penal colony. The French flag was not run up in the Loyalty Islands until 1864.

From the time of colonial settlement until as late as 1917, Melanesian uprisings were common and were constantly feared by the settlers and authorities alike. The insurrection of 1856–59 near Nouméa and the uprising of 1878–79, which extended along the west coast from Bouloupari to Poya, seriously endangered French occupation. Grievances centred around the confiscation of Melanesian lands, the foraging of settlers' cattle on the Melanesians' produce gardens, and, in 1917, the head tax, which had been imposed by the colonial government in 1899. The French suppressed each uprising (with the help of indigenous auxiliaries) by destroying villages and crops and demanding unconditional surrender, and insurgents were punished by deportation or execution and further confiscation of their lands. By 1860 French authority had been established over the southern third of the mainland, and in the next decade policies for the disposal of indigenous land, the regrouping of tribes, and the appointment of a system of tribal chiefs to represent the administration were established. By the end of the 19th century large areas of Melanesian land had been alienated and the inhabitants relegated to reserves. Forced labour, limitations on travel, and curfews were imposed from the early days of colonial rule and became the basis of a system of administrative law codified in 1887 as the *indigénat* ("native regulations"). In 1899 a head tax was levied on male Melanesians to oblige them to obtain employment with settlers and the government and, like the *indigénat*, remained in force until 1946.

Although the prime concern of the early colonial administration was the reception and control of about 22,000 French convicts sent to New Caledonia between 1864 and 1897, the need to attract free settlers and to provide a supply of cheap labour also were continuing preoccupations. Between 1864 and 1939 some 60,000 indentured labourers, as well as the convicts, were imported to construct public works and to work on plantations, ships, wharves, and mines and in commerce and domestic service. These included ni-Vanuatu (the indigenous population of Vanuatu) and Solomon Islanders (1865–1920), Vietnamese (1891–1939), Javanese (1896–1939), and Japanese (1892–1921). Only a small percentage of the survivors of these workers remained in the colony after the expiry of their contracts, and, although few ex-convicts left the territory, not many established families. New Caledonia was also

the unlikely home of 4,000 *déportés*, political exiles of the 1871 uprising of the Paris Commune, but few of the survivors stayed after being granted amnesty. Most of the free white settlers were either former members of the French administration and armed forces, settlers from Australia and New Zealand, or former sugar planters from Réunion. Two later waves of free settlers in the 1890s and 1920s were encouraged to migrate to help establish coffee and cotton industries, respectively. By 1936, however, there were only 15,000 residents of European origin among 29,000 native Melanesians. After World War II the European population gradually increased by migration, but the main influx of white and Polynesian settlers occurred in the years leading up to and including the nickel boom of 1969–72. For the first time the Melanesians became a minority in their own country, although they still were the largest single ethnic group.

Since the beginning of French settlement, political debate among the white settlers revolved around the rights of residents to administer their own affairs without endangering the flow of French financial aid. Between 1885 and 1956 a locally elected general council advised the governor on territorial affairs and voted a local budget. By 1953 French citizenship had been granted to all, regardless of ethnic origin. Melanesians then formed a coalition with Europeans to bring the party, the Caledonian Union (Union Calédonienne), to power on a ticket of full self-government in local affairs. Progress toward self-government was made in 1957 when a Territorial Assembly was created with powers to elect an executive to administer, under the presidency of a high commissioner, the affairs of the territory. In the 1970s the Caledonian Union became an increasingly Melanesian party as Europeans deserted it. Many Melanesians also left to form parties that campaigned in support of independence. In 1979 the Caledonian Union, which had converted to the cause of independence, formed an Independence Front in coalition with several minority Melanesian parties. The Socialist French government of 1981 took many steps to stem the growing political polarization and granted complete self-government in territorial affairs under the Lemoine Statute of 1984. The statute was rejected, however, by the Independence Front, which reconstituted itself as the Kanak Socialist National Liberation Front (Front de Libération Nationale Kanake et Socialiste; FLNKS). The FLNKS boycotted the elections held in November 1984 and took control of most of the territory outside Nouméa. Peace was gradually restored as the government proposed to grant the Melanesians independence in association with France in an arrangement through which French citizens would retain residential and other rights. The European community, with the strong support of non-Melanesian ethnic groups, vigorously rejected this proposal.

In 1985 the French government transferred most of the powers of self-government to four regional councils. In elections held in September 1985 the FLNKS won a majority of seats in all except the Nouméa region, which was won by the settler-dominated party, the Rally for Caledonia in the Republic (Rassemblement pour la Calédonie dans la République; RPCR). In 1986 France reduced the powers of the regional councils and held a referendum. The referendum was boycotted by the FLNKS and produced a large majority for continued ties with France. It was followed by a new statute for self-government, which altered the regional boundaries to limit FLNKS successes to the principal concentrations of Melanesians in the Loyalty Islands and on the east coast of the mainland.

For its part the FLNKS demonstrated its ability to direct the votes of the great mass of Melanesian voters in four electoral consultations since 1984. With the aid of the independent countries of the South Pacific that form the South Pacific Forum, the question of New Caledonia was listed on the agenda of the United Nations Committee of Decolonization. The lack of consensus on the subject in France was paralleled by the increasing polarization within the territory. (D.L.Sh.)

For later developments in the history of New Caledonia, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

The main influx of settlers

The French claim

Papua New Guinea

The Independent State of Papua New Guinea encompasses the eastern half of the island of New Guinea (the western half, Irian Jaya, belonging to Indonesia) and its offshore islands as well as the islands of the Bismarck Archipelago (New Britain, New Ireland, and the Admiralty Islands) and those of Bougainville and Buka. Together these islands cover 178,704 square miles (462,840 square kilometres) of the southwestern Pacific, stretching from just south of the Equator to the Torres Strait, which separates New Guinea from Cape York Peninsula, the northernmost extension of Australia.

The official languages of the country are all introduced: English, Tok Pisin (Melanesian Pidgin), and Hiri, or Pol-ice, Motu, the last being a simplified form of the language of the people who lived around what is now the capital, Port Moresby, when it was first established in 1884. The islands that constitute Papua New Guinea have been settled for tens of thousands of years by the mixture of peoples who are generally referred to as Melanesians, and one of the principal challenges facing those who govern the modern state is the difficulty of welding together hundreds of diverse, once-isolated regional societies into a viable modern nation-state.

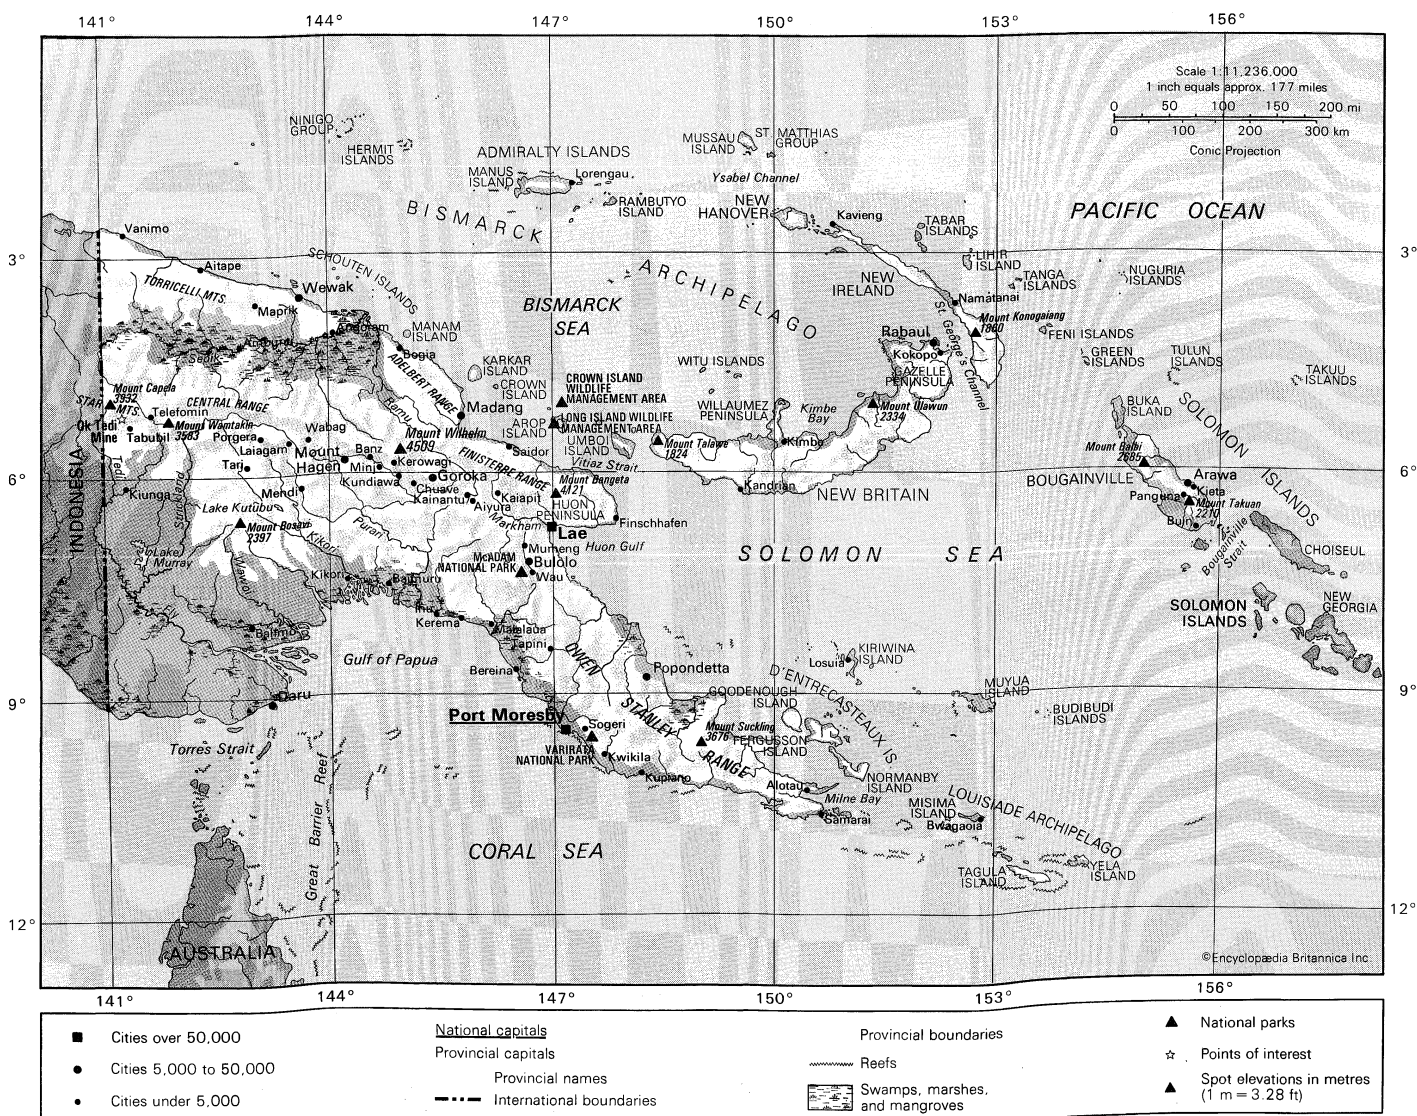

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* Papua New Guinea's magnificent and varied scenery reflects a generally recent geologic history in which movements of the Earth's crust resulted in the

collision of the northward-moving Australian Plate with the westward-moving Pacific Plate. The low-lying plains of southern New Guinea are geologically part of the Australian Plate. Indeed, New Guinea was separated physically from Australia only 8,000 years ago by the shallow flooding of the Torres Strait. The southern New Guinea plains, called the Fly-Digul shelf after the Fly and Digul rivers, are geologically stable but very sparsely populated by seminomadic sago gatherers.

Northward lies a belt of limestone country of varying width, most prominent in the Kikori River-Lake Kutubu area. This forms an extraordinarily harsh environment of jumbled karst, dolines, rock towers, and seemingly endless ridges of jagged rock, all covered in virtually impenetrable lowland rain forest. The discovery of mineral deposits about 1970 stimulated mining activity in the previously deserted region.

Farther to the north lie the Highlands, an east-west-trending zone of mountains with elevations in excess of 13,000 feet (4,000 metres) and enclosed upland basins whose floors are usually at 4,500 feet or higher. The basins contain lake deposits, formed in the recent geologic past by impeded drainage; soil wash from the surrounding mountains; and layers of volcanic ash, or tephra, deposited from nearby and recently active volcanoes. Such basins, therefore, are usually very fertile. Temperatures are much cooler than in the lowlands, and frosts occasionally cause serious damage to the sweet potato (*kaukau*), which is the staple diet of the area. Much of the natural vegetation of most of the upland basins has been removed by the inten-

sive agricultural technology of the Highlanders. Throughout the Highlands, carefully tended gridiron gardens with their drainage ditches or perfectly circular earth-covered mounds of compost dominate the landscape.

The mountains drop away sharply to the north, and the intensive cultivation of fertile soils gives way to swidden (slash-and-burn, or shifting) cultivation of taro and yams in the forests of the foothills. These thinly populated areas in turn give way to the sago swamps along the courses of the great Ramu and Sepik rivers, the latter area famous for its magnificent folk art but equally noted for its immense numbers of mosquitoes. In the slightly more elevated areas away from the main rivers, the high water table combines with the human activities of swidden cultivation and hunting (the burning of vegetation to drive animals toward hunters) to create extensive areas of poor grassland.

The most northerly zone consists of a complex, unstable volcanic arc stretching from the Schouten Islands off Wewak to the Huon Peninsula and through New Britain island, at which point it bifurcates, one arm sweep-

ing northwestward through New Ireland and the Admiralty Islands, the other proceeding southeastward through Bougainville and the Solomon Islands. The north coast, unlike the swampy south coast, drops sharply to the sea, and stands of mangrove and, in brackish waters, nipa palm are rather limited. This northern volcanic fringe contains some of the most fertile soils of the islands. Thus, despite the hazards of volcanic activity and frequent earth tremors, the area is generally well-populated. The island of Karkar and the Gazelle Peninsula of New Britain island are centres of particularly dense population where yams, taro, bananas, and fish are the basic foods. Elsewhere, previously little-used volcanic soils are the focus of large-scale resettlement and oil-palm-cropping schemes, especially in western New Britain.

Drainage. Steeply sloping mountain areas, exceptionally heavy rainfall, geologic instability in all except the most southerly areas, and rapid growth of both population and commercial enterprise combine to create some of the highest soil-erosion rates in the world, rivaling those of

Sweet-potato farming, Southern Highlands province, Papua New Guinea.

the Himalaya region. Consequently, while rivers are usually quite short in length, they carry extraordinarily high sediment loads, which have built up vast swampy plains and deltas, especially along the Sepik, the Fly, and the Purari river systems. Once they leave the Highlands, often through spectacular gorges, such rivers meander slowly across the sediment plains. For example, 512 miles (824 kilometres) from its mouth the Fly River is a mere 60 feet above sea level. Such high deposition rates create major problems for any proposed human use of these rivers, for transportation or hydroelectricity generation, for example.

Climate. Although all the climatic regions of Papua New Guinea are basically tropical, they are nevertheless varied. In the lowlands, mean annual maximum temperatures range between 86° and 90° F (30° and 32° C), and the minimums are between 73° and 75° F (23° and 24° C). Seasonal variation in temperature is slight, and the daily variation approximates the annual variation. Cooler conditions prevail in the Highlands, where night frosts are common above 6,500 feet; daytime temperatures there generally exceed 72° F (22° C) regardless of season.

Rainfall, rather than temperature, is the determinant of season. Precipitation is dependent on two wind systems, the southeast trades and the northwesterly turbulence zone (the monsoon), and on the three site characteristics of latitude, altitude, and exposure. The southeasterlies blow for approximately seven months (May to November) on the extreme southeast of the country (Milne Bay) and for gradually shorter periods northward, predominating for only three months in the Admiralty Islands. Conversely, northwesterlies are more common on the north coast and in the Bismarck Archipelago, but they affect Port Moresby for only three to four months of the year (December through March). The Highlands seem to have their own airflow systems, receiving rain throughout the year totaling between 100 and 160 inches (2,500 and 4,000 millimetres). With the northwesterlies, rain is frequently from convectional storms, and rain shadow effects are reduced. With the southeasterlies, however, exposure is particularly important. The Port Moresby coastal area is parched throughout the period of the southeasterlies, which flow parallel to the coast, yet where mountainous land lies athwart the airflow, as in New Britain or the southward-facing slopes of the Highlands, rainfall is extremely heavy, frequently exceeding 300 inches. Port Moresby receives less than 50 inches of rain annually, which occasions problems of water and hydroelectric power supply.

Plant and animal life. In most areas the coastline is

lined by mangrove swamp, succeeded inland by nipa palm (*Nipa fruticans*) in brackish waters. Farther inland, particularly along the valleys of the larger rivers in the north and along the deltas of the south coast, large stands of sago palm are scattered. Primary lowland rain forest covers much of the island up to approximately 3,300 feet above sea level. The forest is characterized by a large number of species, by the absence of pure stands of any one species, by fairly distinct layering of the forest into two or three levels, by the limited development of undergrowth, and by the small amount of human impact upon it. Dense undergrowth is usually a sign of human interference, except on soils that are particularly poor or where the low height of the forest allows sunlight to penetrate to the soil surface. In those lowland areas where drier conditions prevail, agriculture and hunting have often changed the delicately balanced natural ecosystem into grassland (for example, in the Sepik and Markham river valleys).
