Contributions of Niepce and Daguerre. Niepce, an amateur inventor living near Chalon-sur-Saône, a city 189 miles southeast of Paris, came to photography through his interest in lithography. In this process drawings were copied by hand onto the lithographic stone. To make the drawings Niepce relied upon his son's artistic skill, but, when his son entered military service, he was left without a draftsman. Not artistically trained, he devised a method by which light drew the pictures he needed. He oiled an engraving to make it transparent, then placed it on a plate coated with a light-sensitive solution and exposed the setup to sunlight. After a few hours the solution under the light areas of the engraving hardened, while that under the dark areas remained soft and could be washed away, leaving a permanent, accurate copy of the engraving. Using a type of asphalt, bitumen of Judea, which changes its solubility in oil of lavender according to its exposure to light, he succeeded from 1822 onward in copying oiled engravings onto lithographic stone, glass, and zinc and from 1826 onto pewter plates. In 1826/27, using a camera obscura fitted with a pewter plate, Niepce produced the first successful photograph from nature, a view of the courtyard of his country estate, Gras, from an upper window of the house. The exposure time was about eight hours, during which the sun moved from east to west so that it appears to shine on both sides of the building. The photograph was rediscovered in 1952 by the historian Helmut Gernsheim and is now preserved in the Gernsheim Collection at the University of Texas.

Niepce produced his most successful copy of an engraving, a portrait of Cardinal d'Amboise, in 1826. It was correctly exposed in about three hours, and in February

1827 he had the pewter plate etched to form a printing plate and had two prints pulled. The plate and prints are the oldest photomechanical reproductions still in existence. (The plate and one print are in the Science Museum, London; the other print is in the Gernsheim Collection.) Paper prints were the final aim of Niepce's heliographic (*i.e.*, sun-drawn) process, yet all his other attempts, whether made using a camera or engravings, were underexposed and too weak to be etched. Nevertheless, Niepce's discoveries showed the path that Daguerre and others were to follow with more success.

Daguerre was a professional scene painter. Between 1822 and 1839 he was co-proprietor of the Diorama in Paris, an auditorium in which he and his partner Charles-Marie Bouton displayed immense paintings, 45½ by 71½ feet (14 by 22 metres) in size, of famous places and historical events. The partners painted the scenes on translucent paper or muslin and by the careful use of changing lighting effects were able to present vividly realistic tableaux. The views provided grand entertainment in the illusionistic style, and the amazing *trompe l'oeil* effect was purposely heightened by the accompaniment of appropriate music and the positioning of real objects, animals, or people in front of the painted scenery.

Like many other artists, Daguerre made his preliminary sketches by tracing the images produced by a camera obscura. About 1826 he began unsuccessful experiments in recording the camera image "by the spontaneous action of light." Learning of Niepce's work, he wrote to him, and on Dec. 14, 1829, the two men formed a partnership for the express purpose of improving Niepce's invention of heliography. From then on Daguerre worked using the improved materials Niepce had adopted—silvered copper plates and iodine—without achieving any improved results until 1835, two years after the death of his partner. By accident Daguerre discovered that a latent image forms on a plate of iodized silver and that it can be "developed" and made visible by exposure to mercury vapour, which settles on the exposed parts of the image. Exposure times could thus be reduced from eight hours to 30 minutes. The results were not permanent, however; when the developed picture was exposed to light, the unexposed areas of silver darkened until the image was no longer visible. By 1837, though, Daguerre was able to fix the image permanently by using a solution of table salt to dissolve the unexposed silver iodide. That year he produced a photograph of his studio on a silvered copper plate, a photograph that was remarkable for its fidelity and detail. Contrary to his contract with Niepce, Daguerre now called the improved process after himself: *daguerreotype*.

The daguerreotype process

Niepce's heliographic process

"Still Life," daguerreotype by Louis-Jacques-Mandé Daguerre, 1837.

Collection de la Société Française de Photographie, Paris

In 1839 Daguerre and Niepce's son sold full rights to the daguerreotype and the heliograph to the French government, in return for annuities for life. On August 19 full working details were published. Daguerre wrote a booklet describing the process, *An Historical and Descriptive Account of the Various Processes of the Daguerreotype and the Diorama*, which at once became a best-seller: 29 editions and translations appeared before the end of 1839.

Contributions of Wedgwood and Talbot. In 1802 Thomas Wedgwood, son of the famous potter Josiah Wedgwood, reported his experiments in recording images on paper or leather sensitized with silver nitrate. Although he could record silhouettes of objects placed on the paper, he was not able to make them permanent and, to his disappointment, he failed to record a camera image. Nonetheless, the paper published by Sir Humphry Davy in the *Journal of the Royal Institution*, London, in June 1802, on the experiments of his friend Wedgwood, is the first account of an attempt to produce photographs.

Unaware of the work of Wedgwood and the French pioneers, Talbot, trained as a scientist at Cambridge University, was led to invent a photographic process because of his inability to draw landscapes. On a holiday trip to Italy in 1833, the idea came to him of recording by chemical means the images he observed in his camera obscura. By 1835 he had a workable technique: he made paper light-sensitive by soaking it alternately in solutions of common salt (sodium chloride) and silver nitrate. Silver chloride was thus produced in the fibres of the paper. On exposure to light the silver chloride became finely divided silver, dark in tone. Theoretically, the resulting negative could be used to make any number of positives simply by putting fresh sensitized paper in contact with the negative and exposing it to light. Talbot's method of fixing the print by washing it in a strong solution of sodium chloride was inadequate, however, and the process was not successful until February 1839, when the scientist Sir John F.W. Herschel suggested fixing the negatives with sodium hyposulphite (now called sodium thiosulfate) and waxing them before printing, which reduced the grain of the paper.

When news of Daguerre's process reached England in January 1839, Talbot rushed publication of his "photogenic drawing" process and subsequently explained his technique in complete detail to the members of the Royal Society—six months before the French government divulged working directions for the daguerreotype. There were many others who had similar techniques and who were to claim priority, but to Talbot and Daguerre were owed the two basic processes that were to establish photography as the most facile and convincing way to produce pictures.

First criticism. The two pioneer processes were different in several ways. Daguerreotypes were on metal; photogenic drawings were on paper. Each daguerreotype was unique; photogenic drawings could be duplicated. The aesthetic as well as physical character differed markedly. The daguerreotype rendered detail to a degree that was remarkable; the photogenic drawing, because of the fibrous structure of the paper supporting the silver image, gave a broader, somewhat diffused effect.

The first criticism of photography was necessarily based on a comparison with painting or drawing, since no other standards of picture making existed. Photography's remarkable ability to record a seemingly inexhaustible amount of detail was marveled at again and again. The critics regretted that, because of the great length of exposure, moving objects were not recorded or were rendered blurry and indistinct. The inability of the first processes to record colours was disappointing, but since the critics were already conditioned to black-and-white prints and drawings, this was not as serious a drawback as the harshness of the tonal scale. The technique of photography was at once recognized as a shortcut to art. No longer was it necessary to spend years in art school drawing from sculpture and from life, mastering the laws of linear perspective and chiaroscuro. As Daguerre boasted in a broadsheet in 1838, "with this technique, without any knowledge of chemistry or physics, one will be able to make in a few minutes the most detailed views."

PRE-WORLD WAR I HISTORY

Daguerre's process rapidly spread throughout the world. Before the end of 1839, travelers were bringing back to Paris daguerreotypes of famous monuments in Egypt, Israel, Greece, and Spain; from them engravings were made that were published in two volumes as *Excursions daguerriennes* between 1841 and 1843. Although his process was published "free to the world" by the French government, Daguerre took out a patent for it in England; the first licensee was Antoine-François-Jean Claudet. The first daguerreotypes in America were made on Sept. 16, 1839, just four weeks after the announcement of the process. Exposures were at first of excessive length—a daguerreotype of King's Chapel, Boston, in the International Museum of Photography, Rochester, N.Y., bears a label stating that it was made between 4:40 and 5:30 PM on April 19, 1840. At such exposures moving objects could not be recorded, and portraiture was impractical. Even in blazing sunlight and with the face whitened by flour, a person had to sit immobile for several minutes.

Experiments were started in Europe and the United States to improve the optical, chemical, and practical aspects of the daguerreotype process to make it more feasible for portraiture, the most desired application. Using a camera with a mirror substituted for the lens, Alexander Wolcott opened in New York in March 1840, a "Daguerrean Parlor" for tiny portraits. This was the earliest known photography studio anywhere; the first studio in Europe was opened by Richard Beard in a glasshouse on the roof of the Royal Polytechnic Institution in London on March 23, 1841. Unlike the many daguerreotypists who were originally scientists or miniature painters, Beard had been a coal merchant and patent speculator. Having acquired the exclusive British license for the American mirror camera (he later also purchased the exclusive rights to Daguerre's invention in England, Wales, and the colonies), Beard employed the chemist John Frederick Goddard to try to improve and accelerate the exposure process. Among the techniques Goddard studied were two that Wolcott had tried: increasing the light sensitivity of the silver iodide with bromine vapours and filtering the blindingly bright daylight necessary for exposure through blue glass to ease the portrait sitter's eye strain. By December 1840 Goddard had succeeded well enough to produce tiny portraits ranging in size from one centimetre in diameter to 1.5 by 2.5 inches (four by six centimetres). By the time Beard opened his studio exposure times were said to vary between one and three minutes according to weather and time of day. Daguerreotype portraits were immensely popular, and the studio made considerable profits the first few years, but competition soon appeared and Beard lost his fortune in several lawsuits against infringers of his licenses.

The finest daguerreotypes in Britain were produced by Claudet, who opened a studio on the roof of the Royal Adelaide Gallery in June 1841. He was responsible for numerous improvements in photography, for the discovery that red light did not affect sensitive plates and could therefore be used safely in the darkroom, and for the practical introduction of stereoscopic daguerreotypes in 1851.

The most important advances in photographic lens and camera design came from József Petzval and Friedrich Voigtländer, both of Vienna. Petzval produced an achromatic portrait lens that was about 20 times faster than the simple meniscus lens the Parisian opticians Charles Chevalier and N.M.P. Lerebours had made for Daguerre's cameras. Voigtländer reduced Daguerre's clumsy wooden box to easily transportable proportions for the traveler. These valuable improvements were introduced by Voigtländer in January 1841. That same month another Viennese, Franz Kratochvila, freely published a chemical acceleration process in which the combined vapours of chlorine and bromine increased the sensitivity of the plate five times.

The improvements that had been made in lenses and sensitizing techniques reduced exposure times to approximately 20 to 40 seconds. Daguerreotyping became a flourishing industry, especially in the United States, which, it was generally conceded, led the world in the production of daguerreotypes. In the late 1840s every city had its

"daguerrean artist," and villages and towns were served by traveling photographers who had fitted up wagons as studios. In New York City alone there were 77 galleries in 1850. Of these, the most celebrated was that of Mathew B. Brady, who began in 1844 to form a "Gallery of Illustrious Americans," and to that end collected portraits of notables taken by his own and other cameramen. Twelve of the portraits were published by lithography in a folio volume. In Boston a studio operated by Albert Sands Southworth and Josiah Johnson Hawes that was advertised as "The Artists' Daguerreotype Rooms" produced the finest portraits ever made by the daguerreotype process. The partners avoided the stereotyped lighting and posing formulas of the average daguerreotypist and did not hesitate to portray their sitters unprettified and "as they were." Lemuel Shaw, a judge of the Supreme Court of Massachusetts, stands with crumpled coat and unruly locks of hair under a glare of sunshine; Lola Montez, adventuress, dancer, actress, lolls over the back of a chair, a cigarette between her gloved fingers. Cities and towns, as well as their inhabitants, were photographed by American daguerreotypists: the rapid growth of San Francisco was documented month by month, and the first history of the city, published in 1855, was illustrated by engravings made from daguerreotypes.

Development and use of the calotype process. The popularity of the daguerreotype surpassed that of the photogenic drawing, but Talbot continued work to improve his process. On Sept. 21–23, 1840, while experimenting with gallic acid, a chemical he was informed would increase the sensitivity of his prepared paper, Talbot discovered that the acid could be used to develop a latent image. This procedure revolutionized photography on paper as it had photography on metal in 1835. Whereas previously Talbot had needed a camera exposure of one hour to produce a 6.5- by 8.5-inch negative, he now found that one minute was sufficient. Developing the latent image had put photography on paper on a par with the daguerreotype. Talbot named his improved negative process the calotype, from the Greek meaning "beautiful picture," and protected his rights by patent.

The first and most aesthetically satisfying use made of this improved process was in the work of David Octavius Hill, a Scottish landscape painter, and his partner, Robert Adamson, an Edinburgh photographer. In 1843 Hill de-

cided to paint a group portrait of the ministers who in that year formed the Free Church of Scotland. There were more than 400 figures to be painted. Sir David Brewster, who knew of Talbot's process from the inventor himself, suggested to Hill that he make use of this new technique. Hill then enlisted the aid of Adamson, and together they made hundreds of photographs, not only of the members of the church meeting but also of people from all walks of life. Although their sitters were posed outdoors in glaring sunlight and had to endure exposures of upward of a minute, Hill and Adamson managed to retain spontaneity. Hill's vision was dominated by the painting style of the period in lighting and posing, particularly in the placement of the hands. Many of the calotypes are strikingly reminiscent of canvases by Sir Henry Raeburn and other contemporary artists. Indeed, William Etty, a Royal Academician, copied in oils the calotype Hill and Adamson made of him in 1844 and exhibited it as a self-portrait. In addition to their formal portraiture, the partners made a series of photographs of fishermen and their wives at Newhaven, in Edinburgh, and architectural studies.

The potential of the calotype for recording great monuments of architecture was shown by a number of Frenchmen, many of whom were trained as painters. In the 1850s they began to photograph historical buildings for the government. Working with cameras making photographs as large as 20 by 29 inches, Henri Le Secq, Charles Marville, and Charles Nègre produced remarkable calotypes of the cathedrals of Notre-Dame in Paris, Chartres, and Amiens, as well as other structures that were being restored after centuries of neglect. An establishment was set up in Lille, Fr., by Louis-Désiré Blanquart-Evrard for bulk printing these paper negatives. Among the products of this firm was a superb volume of photographs by the Parisian writer Maxime Du Camp taken during his travels with the writer Gustave Flaubert in Egypt, Palestine, and Syria, from 1849 to 1851.

Development and use of the collodion process. Photography was revolutionized in 1851 by the introduction of the collodion process for making glass negatives. This new technique, invented by the English sculptor Frederick Scott Archer, was 20 times faster than all previous methods and was, moreover, free from patent restrictions. The

Calotypes of architectural monuments

glass plate negatives recorded detail in a way that rivaled the daguerreotype, and from them paper prints could be made. The process had one serious drawback: the photographer had to sensitize his plate almost immediately before exposure and expose it and process it while the coating was moist. Collodion is a solution of nitrocellulose (guncotton) in alcohol and ether; when the solvents evaporate, a clear plasticlike film is formed. Since it is then impervious to water, the chemicals used for developing the exposed silver halides and removing the unexposed salts cannot penetrate to them. Despite the drawback that the photographer had to have a complete darkroom outfit with him always, the collodion process was almost at once universally adopted. It reigned supreme for more than 30 years and greatly increased the popularity of photography. Some of the most remarkable photographs of all time were produced by this wet-plate process.

At first the positive prints made from the glass plate negatives were produced by Talbot's salt paper method, but from the mid-1850s on they were made on albumen paper, a slow printing-out paper (*i.e.*, paper that produces a visible image on direct exposure, without chemical development) that had been coated with egg white before being sensitized. The egg white gave the paper a glossy surface that improved the picture. Albumen paper was introduced in 1850 by Blanquart-Evrard and remained in general use until World War I.

The new collodion process was also used to produce imitation daguerreotypes called positives on glass or ambrotypes. They were simply underexposed or bleached negatives that appeared positive with a dark coating or backing. In posing and lighting, these popular portraits were identical to daguerreotypes; they were of the same standard sizes, and they were enclosed in the same type of case. They did not approach the brilliancy of the daguerreotype, however. Tintypes, first known as ferrotypes or melainotypes, were cheap variations of the ambrotype. Instead of glass the collodion emulsion was coated on thin iron sheets enameled black. At first they were presented in cases, surrounded by narrow gilt frames, but by the 1860s this elaborate presentation had been abandoned, and the metal sheets were simply inserted in paper envelopes, each with a cutout window the size of the image. Easy to make, inexpensive to purchase, tintypes remained a kind of folk art through the 19th century. Poses were often informal, if not humorous.

Portraiture. A new style of portrait, introduced in Paris by André-Adolphe-Eugène Disdéri in 1854, was universally popular from 1859 onward. It came to be called the *carte de visite* because the size of the mounted photograph (four by 2½ inches) corresponded to that of a calling card. Disdéri used a four-lens camera to produce eight negatives on a single glass plate. Each picture could be separately posed, or several exposures could be made at once. The principal advantage of the system was its economy: to make eight portraits the photographer needed to sensitize only a single sheet of glass and make one print, which he then cut up into separate pictures. At first *cartes de visite* almost invariably showed the subjects standing. Backgrounds, which had usually been plain in the days of the daguerreotype, became ornate: furniture and such architectural fragments as papier-mâché columns and arches were introduced, and heavy-fringed velvet drapes were hung within range of the camera. With the advent of the cabinet-size (6½ by four inches) picture in 1866, the baroque tendencies of the photographer became yet more audacious, so that in 1871 a photographer wrote: "One good, plain background, disrobed of castles, piazzas, columns, curtains and what not, well worked, will suit every condition of life." It was at this period that retouching, the use of handwork on the negative, was introduced, as was the practice of painting over the photograph in oil colours.

In contrast to the excessive reliance on accessories and retouching shown by the popular portrait photographers of Europe and America, the work of two Frenchmen and one Englishwoman stands apart. In their portraiture they reached a level unsurpassed since the daguerreotypes of Southworth and Hawes and the calotypes of Hill and Adamson. These photographers were Gaspard-Félix Tour-

nachon, a Parisian writer, editor, and caricaturist who used the pseudonym of Nadar; Étienne Carjat, likewise a Parisian caricaturist; and Julia Margaret Cameron, wife of an eminent British jurist.

Nadar took up photography in 1853 as a means of making studies of the features of prominent Frenchmen for inclusion in a large caricature lithograph, the "Panthéon Nadar." He posed his sitters against plain backgrounds and bathed them with diffused daylight, which brought out every detail of face and dress. He knew most of them, and the powers of observation he had developed as a caricaturist led him to recognize their salient features, which he recorded directly, without the exaggeration that he put in his drawings. When Nadar's photographs were first exhibited, they won great praise in the *Gazette des Beaux Arts*, then the leading art magazine in France. Nadar was a colourful man who had a passion for balloons. He combined his interests by taking a series of aerial photographs, which inspired the French artist Honoré Daumier to produce a cartoon bearing the mocking title "Nadar Élevant la Photographie à la Hauteur de l'Art" ("Nadar Raising Photography to the Height of Art").

Carjat's portraits, more intense perhaps than Nadar's, have the dignity and distinction of those of his contemporary and rival.

Cameron took up photography as a pastime in 1864. Awkward as it was, she used the wet-plate process and began to take portraits of such celebrated Victorians of her acquaintance as Alfred Tennyson, George Frederick Watts, Thomas Carlyle, Charles Darwin, and Sir John F.W. Herschel. A number of her portraits were shown at the Paris International Exhibition of 1867. Cameron used a lens of the extreme focal length of 30 inches to obtain large close-ups. This lens required such long exposures that the subjects frequently moved. The lack of optical definition plus this accidental blurring was universally criticized, yet the very power of her work won her international praise. This can only be explained by the intensity of her vision. "When I have had these men before my camera," she wrote about her portraits of great men,

my whole soul has endeavoured to do its duty toward them in recording faithfully the greatness of the inner man as well as

the features of the outer man. The photograph thus obtained has almost been the embodiment of a prayer.

Besides these memorable portraits, Cameron produced a large number of allegorical studies, of children and young women in costume, acting out biblical scenes or themes based on the poetry of her hero, Tennyson. In making these pictures—which today seem weak and sentimental—she was much influenced by the Pre-Raphaelite painters and the photographic work of Oscar G. Rejlander and Henry Peach Robinson (see below), leaders in the production of photographs that emulated paintings.

Influence of painting. Consideration of photography as an aesthetic medium was given impetus by the formation of photographic societies, made up of both professionals and amateurs, who had been attracted to the camera by the popularity of the collodion process. In 1853 the Photographic Society, parent of the present Royal Photographic Society, was formed in London, and in the following year the Société Française de Photographie was founded in Paris.

At the first meeting of the Photographic Society the president, Sir Charles Eastlake (who was then also president of the Royal Academy), invited the miniature painter Sir William Newton to read a paper "Upon Photography in an Artistic View" (*Journal of the Photographic Society*, i, 1853). His argument was that photographs could be useful to the painter so long as they were taken "in accordance [as far as it is possible] with the acknowledged principles of Fine Art." One way by which the photographer could make his results more like works of art, Newton suggested, was to throw the subject slightly out of focus. He also recommended liberal retouching.

Combina-
tion
printing

An outcome of the urge to create photographs that would fit a priori concepts of what "art" should be was the practice of combining several negatives to make one print in order to achieve painterly compositions of subjects too complicated to be photographed in a straightforward manner. A famous example was by Oscar G. Rejlander, a Swede who had studied art in Rome and was practicing photography in England. He used 30 negatives to produce a 31- by 16-inch print titled "The Two Ways of Life," showing, in allegory as obvious as it was sentimental, that the way of the blessed led through good works and the way of the damned through vice. Rejlander, who described the technique in detail in photographic journals, stated that his purpose was to prove to artists the aesthetic possibilities of photography, which they had generally denied. The photograph was shown in the Manchester Art Treasures Exhibition of 1857 and was purchased by Queen Victoria for Prince Albert.

Rejlander's technique stimulated Henry Peach Robinson, a professional photographer who had been trained as an artist, to produce similar combination prints. He achieved fame with a five-negative print, "Fading Away," produced in 1858. The subject, a dying girl, was considered by critics as too painful a subject to be represented by photography. Perhaps the implied authenticity of the camera bothered them, for painters had long presented subjects of a far more painful nature.

Robinson became a most articulate member of the Photographic Society, and his teaching was even more influential than his photography. In 1869 appeared the first of many editions and translations of his book, *Pictorial Effect in Photography*. From an outmoded handbook on painting, Robinson borrowed compositional formulas the use of which, he claimed, would bring artistic success. The importance of balance was stressed, and the opposition of light against dark was made clear. The fault of the book lay not only in the assumption that rules set up for one art form could be applied to another but also in its intellectual and academic approach to art.

Robinson's work is weak and artificial by present standards of taste. Not only did he practice combination printing when it was not technically necessary, but he preferred to work in the studio, against painted backdrops and with props of natural objects, even foliage, mounted on casters. When he did photograph the real world, he took models with him, dressing them up to play the part of country girls.

So long as photographers maintained that the way to art was by the emulation of painting, critics were reluctant to admit the new medium to an independent aesthetic position. Portraits, when done as sensitively and as directly as those produced by Hill and Adamson, Nadar, and Cameron, won the praise of art critics. But sentimental genre scenes, posed and arranged for the camera, lacked the sharp objective truth that is a characteristic of photography. Other photographers, not concerned about producing art for exhibition, were making photographs of the world and man's activities with such extraordinary perception and understanding of the medium that often their work surpassed more consciously artistic works. These men took their cameras to battlefields and to far-away places, often at the risk of their lives.

Combat photography. In 1855 Roger Fenton sailed from London to the Crimea to photograph the war. He was sent to provide visual evidence countering the caustic written reports dispatched by William Russell, war correspondent for *The Times* of London, criticizing military mismanagement and the inadequate, unsanitary living

conditions of the soldiers. Fenton had to develop his wet plates in a horse-drawn van that had been converted into a darkroom. It was visible for miles in the bare landscape and a few times attracted enemy fire. Despite the difficulty, during his four-month stay Fenton produced 360 photographs, the first large-scale camera documentation of a war.

When the Civil War broke out in the United States, Mathew Brady, the New York daguerreotypist and portraitist, who had been among the first to adopt the wet-plate process, conceived the bold plan of making a photographic record of the hostilities. When President Lincoln told him the government could not finance such an undertaking, he invested his own savings in the project, expecting to recover his outlay by selling thousands of prints. Brady and his photographers—notably Alexander Gardner and Timothy H. O'Sullivan, who left his employ in the midst of hostilities—produced an amazing record of the battlefield. At his New York gallery, Brady showed pictures of the dead at Antietam. The *New York Times* reported on Oct. 20, 1862:

Mr. Brady has done something to bring home to us the terrible reality and earnestness of war. If he has not brought bodies and laid them on our dooryards and along the streets, he has done something very like it. . . . It seems somewhat singular

that the same sun that looked down on the faces of the slain blistering them, blotting out from the bodies all semblance to humanity, and hastening corruption, should have thus caught their features upon canvas, and given them perpetuity for ever. But it is so.

Long prized for their value as historical documents, the Civil War photographs are now valued for their aesthetic qualities as well. Unfortunately for Brady, immediately after the war they were seen as unnecessary reminders of hardship and conflict. Unable to sell the prints as he had planned, Brady died embittered in a charity hospital in New York City. Fenton's Crimean War photographs had similarly lost their audience as soon as the peace treaty was signed. Nevertheless, entrepreneurs hoping to sell prints or commemorative albums continued to finance the photographic documentation of the more important conflicts of the late 19th century. The Boer War and the Russo-Japanese War were also covered by photographers engaged by newspapers and by three American mass producers of stereographs.

Landscape photography. During the collision period scores of photographers journeyed to the far corners of the world, producing memorable travel views despite the trying conditions of the wet-plate process. Among the most successful was the Englishman Francis Frith. The

"Ruins of the Gallego Flour Mills, Richmond, Virginia" by Mathew B. Brady, 1865.

most active of several European photographers working in the Middle East in the late 1850s, he took hundreds of fine pictures of monuments along the Nile from Cairo to Abu Simbel, as well as in Syria and Palestine. Samuel Bourne, Felice Beato, John Thomson, and other British amateurs traveled to Asia, bringing back to England lively images of the nature, people, and customs of India, China, and Japan. Other British photographers concentrated on Europe: Charles Clifford recorded the landscape and architecture of Spain, Robert MacPherson that of Rome, and Thomas Annan of Glasgow and George Washington Wilson of Aberdeen the wildness, castles, and abbeys of Scotland. The Bisson brothers (Louis-Auguste and Auguste-Rosalie), Gustave Le Gray, and Edouard-Denis Baldus depicted the landscape and architecture of France. In the United States Carleton E. Watkins and the English-born Eadweard Muybridge both won recognition for their scenic views of Yosemite, the Columbia River, Alaska, and other wilderness regions of North America.

Photography on the American frontier

Landscape photography was usually intended for publication in books or as portfolios of prints to be sold to collectors, but in the United States photographers were often important members of government surveys and were also commissioned by railroad companies to make publicity pictures of track laying, bridge building, and spectacular scenery through which the new lines ran. Of the photographers of the American frontier, two stand out: Timothy H. O'Sullivan, of Civil War fame, and William Henry Jackson. O'Sullivan's photographs of the Southwest are of great beauty, particularly his views of Indian cliff dwellings in the Canyon de Chelly in Arizona, made in 1873. Jackson, self-trained as a painter in Vermont, crossed the plains as a wagon driver. In 1868 he opened a photographic gallery in Omaha, Neb. The Union Pacific Railroad was under construction, and he received an order to produce 10,000 stereographs. The excellence of his work led F.V. Hayden, a geologist, to hire him to photograph the Yellowstone as part of Hayden's government-financed expedition there in

George Eastman House Collection

"Canyon de Chelly, Arizona" by Timothy H. O'Sullivan, 1873.

1871. The photographs Jackson took were influential in the decision by Congress to create Yellowstone National Park. Later, in 1875, he recorded the immensity of the western landscape, using large glass plates.

Stereoscopic photography. Many of the landscape photographers also took stereographs. These double pictures, taken after 1856 with twin-lens cameras, produce a remarkable effect of three dimensions when viewed through a stereoscope. Stereography, first described in 1832 by the English physicist Charles Wheatstone, is uniquely photographic, since no artist could draw two scenes in exact perspective from viewpoints separated only 2½ inches—the normal distance between human eyes. Wheatstone's mirror stereoscope, however, was not practical for use with photographs, and the invention languished until the Scottish scientist Sir David Brewster designed a simplified viewing instrument, which was exhibited at the 1851 Great Exhibition in the Crystal Palace, London. Queen Victoria was entranced by the stereo daguerreotypes she saw there, and with the introduction of the collodion process, which simplified exposure and printing techniques, three-dimensional photography became a popular craze.

In 1854 the London Stereoscopic Company was formed. Their chief photographer was William England, whose lively street scenes of New York City in rainy weather and views of Niagara Falls taken in 1859 were the wonders of the day. The instantaneous street scenes, which showed pedestrians and vehicles stopped in their tracks, were made possible because the small size of the stereo-camera reduced exposure times to less than half a second. To minimize movement street views were usually taken from a first-floor window with the camera focused directly down the street. (Such views later inspired several Impressionists to paint similar street scenes.) Between 1860 and about 1920 a stereo viewer was as ubiquitous in British and American homes (where a simplified and cheap hand viewer was introduced by Oliver Wendell Holmes [the American physician was a great lover of photography]) as the television set is today. Millions of stereographs were circulated in the years before newspaper reproduction of photographs, and their impact was enormous.

Development of the dry plate. In the 1870s many attempts were made to find a dry substitute for wet collodion so that plates could be prepared well in advance and developed long after exposure. The suggestion casually made in 1871 by Richard Leach Maddox, an English physician, to suspend silver bromide in a gelatin emulsion led, in 1878, to the introduction of factory-produced dry plates coated with gelatin containing silver salts, an event that marked the beginning of the modern era of photography.

Gelatin plates were about 60 times more sensitive than collodion plates. The increased speed freed the camera from the tripod, and a great variety of small hand cameras that allowed photographers to take instantaneous snapshots became available at relatively low cost. Of these, the most popular was the Kodak camera, introduced by George Eastman in 1888. Its simplicity greatly speeded the growth of amateur photography. In place of glass plates, it contained a roll of negative material sufficient for taking 100 circular pictures, each roughly 2½ inches in diameter. After exposing the last negative, the entire camera was sent to one of the Eastman factories (Rochester, N.Y., or Harrow, Middlesex), where the roll was processed and printed. "You Press the Button, We Do the Rest" was Eastman's description of the Kodak system. At first Eastman's so-called "American film" was used in the camera. This film was paper based, and the gelatin layer containing the image was stripped away after development and fixing and transferred to a transparent support. In 1889 it was replaced by film on a transparent plastic base of nitrocellulose that had been developed by the Reverend Hannibal Goodwin of Newark, N.J., in 1887.

Photography of movement. A few years before the introduction of the dry plate, the world was amazed at the photographs of horses taken by Eadweard Muybridge in California. Using a series of 12 to 24 cameras ranged side by side opposite a reflecting screen, with their shutters released by the breaking of threads as the horse dashed by, Muybridge secured sets of sequence photographs of succes-

Invention of the Kodak camera

sive phases of the walk, the trot, and the gallop. When the pictures were published internationally in the popular and scientific press, they were so different from the traditional hand-drawn representation of a horse's steps that it was difficult to believe that they were accurate. To prove that his photographs were correct, Muybridge threw them upon a screen one after the other with a lantern-slide projector he had built for the purpose; the result was the world's first motion-picture presentation. This memorable event took place at the San Francisco Art Association in 1880.

Muybridge's early studies were taken with wet plates. With the new gelatin plates, he was able to improve his technique greatly, and in 1884–85, at the invitation of the University of Pennsylvania, he produced 781 sequence photographs of many kinds of animals as well as men and women engaged in a wide variety of activities.

Muybridge's photographic analysis of movement led the French physiologist Étienne-Jules Marey to develop chronophotography. Whereas Muybridge had employed a battery of cameras to record detailed, separate images of successive stages of movement, Marey used only one, recording an entire sequence of movement on a single plate. With Marey's method, the images of various phases of motion sometimes overlapped, but it was easier to see and understand the flow of movement. Marey was also able to record higher speeds at shorter intervals than Muybridge. Both his and Muybridge's work greatly contributed to the field of motion study and to the development of the motion picture.

Naturalistic photography. *Contributions of Emerson.* In the late 19th century the growing number of amateur photographers used the camera to capture daily occurrences

"Pond in Winter" by Peter Henry Emerson, 1888.

and important moments in their lives, but the members of the societies and clubs concerned with photography as an art became more and more divorced from matters of ordinary life. Subjects in the so-called art photographs were artificially composed in the studio in imitation of 17th-century Dutch paintings. Photographers strove to master complicated printing methods allowing manual interference. Photographing everyday life was considered mere record-making or documentation. Landscape pictures, the strength of British photographers in past decades, found little favour. When similar beliefs prevailed in French academic painting 35 years previously, the French realist painter Gustave Courbet was prompted to call for a "return to nature." So now Peter Henry Emerson, physician by profession and an ardent amateur photographer, attacked the artificiality of the photographs generally accepted as outstanding examples of the artistic use of the camera. Emerson's passionate plea for the return to natural subjects was indeed salutary, but of greater importance was his advice that photographers should respect the photographic process and limit their controls to those that were inherent.

Emerson's
photo-
graphs of
natural
subjects

In his book *Naturalistic Photography* (1889) Emerson further developed his theories (some of which he later disclaimed). Although his writings were influential, his photographs of the life of simple country folk presented a far more convincing argument for his beliefs. Emerson's photographs were far removed from the usual artificial genre studies and close to the graphic work of the French painter J.-F. Millet, which Emerson greatly admired. They were published in limited editions in handsome folio volumes and motivated other amateurs to seek inspiration in nature.

The photographs in Emerson's first and finest album, *Life and Landscape on the Norfolk Broads* (1886), were printed on the newly invented platinotype paper. In this printing paper, salts of iron and platinum replaced those of silver as the light-sensitive material. Platinotypes had a long and delicate tonal scale, and they did not fade, unlike the more common silver prints. Emerson helped to popularize the paper, which remained in use until about 1920, when the rising price of platinum made it impractical.

The Linked Ring and the Photo-Secession. The recognition of photography as an art rather than a mechanical process and its evaluation on its own terms rather than

according to the traditional rules governing painting were further advanced by the formation in London in 1892 of the Brotherhood of the Linked Ring. The group, which was founded by the prominent pictorial photographer H.P. Robinson, George Davison, a leader of the Art Nouveau movement, and others dissatisfied with the scientific bias of the London Photographic Society, held annual exhibitions, which they called salons. By 1901 it was their proud boast that "through the *Salon* the Linked Ring has clearly demonstrated that pictorial photography is able to stand alone and that it has a future entirely apart from that which is purely mechanical."

Similar groups formed in other countries. One of the most influential was the Photo-Secession, founded in the United States in 1902 by Alfred Stieglitz. Stieglitz, who had previously organized the Camera Club of New York City and served as editor of the club journal, *Camera Notes*, was a strong proponent of "straight" photography. He did not believe in retouching or manipulating in any way his negatives or prints. He had, as early as 1892-93, demonstrated the pictorial possibilities of the hand camera with his photographs of New York under all weather conditions.

A few of the Photo-Secession members, including Clarence H. White and Harry C. Rubinckam, favoured naturalistic photography like Stieglitz. Many, however, notably Edward Steichen and Alvin Langdon Coburn, were adherents of the impressionistic soft-focus school and of the newly introduced gum print process. This technique gave the photographer the utmost manual control. He coated paper with watercolour pigment of any desired tint mixed with gum arabic and potassium bichromate. On exposure to light beneath a negative, the pigment became insoluble according to the amount of light received. The print was "developed" simply by bathing it in water. If desired, areas could be eliminated by brushing them with hot water or by drawing on them.

Despite their stylistic differences, the members of the Photo-Secession were united in their disdain for the lack of standards and the general conduct of photographic exhibitions in the United States. They chose the name "secession" to dramatize their rebellion against the status quo, just as avant-garde German and Austrian painters had used the same word to make manifest their independence of officialdom. The record of the Photo-Secession

is contained in 50 issues of the much praised *Camera Work*, published by Stieglitz between 1903 and 1917; this quarterly publication contained superb reproductions of photographs but was of uneven quality, partly because of the members' stylistic differences. The photographs were occasionally overly sentimental, artificial, or banal, and indeed, far better work was being produced in New York City at this time by documentary photographers such as

"Blind Woman, New York" by Paul Strand, 1916; from *Camera Work*, 1917.

Jacob Riis and Lewis W. Hine, whose photographs were not then considered art.

In addition to *Camera Work*, the Photo-Secession had a gallery, which came to be known as 291 from the street number on Fifth Avenue, New York City, where it was located. There Stieglitz showed not only pictorial photographs but also, from 1906 on, avant-garde modern art, selected at first by Steichen in Paris. At 291 Americans saw, long before the Armory Show of 1913 made them popular, paintings and sculpture by Rodin, Marin, Toulouse-Lautrec, Cézanne, Van Gogh, Picasso, Brancusi, and Matisse. Stieglitz also organized there the first exhibitions in the world of drawings by children (1912) and of African art (1914).

Other important photographers of the period were Paul Strand and Coburn. The last two issues of *Camera Work* contained photographs by Strand only. They showed an entirely new approach. There were views looking down from unusual angles; there were bowls in quasi-abstract arrangements; there was a group of powerful open-air portraits taken in the streets of the lower East Side of New York City. These portraits had been taken with a 45° prism fitted over the lens, so that the subjects were unaware that they were being photographed. Coburn, one of the first of the Photo-Secessionists, made a series of photographs in 1912 looking down from tall buildings, which he exhibited as "New York from Its Pinnacles"; they were remarkable for the way in which emphasis was placed on form. He pushed this interest in abstraction to the total elimination of recognizable subject matter in his "Vortographs," some of which were published in *Photographs of the Year* in 1917.

POST-WORLD WAR I HISTORY

During the 1920s and '30s, a new, more realistic style of photography gained prominence, a reflection, perhaps, of post-World War I disillusionment. At the close of the war, Steichen, who had been in command of aerial photography for the American Expeditionary Forces, abandoned the broad, impressionistic style he had earlier practiced for sharply focused portraits of celebrities, taken for *Vanity Fair* and *Vogue* magazines. The painter Charles Sheeler used the camera to record the stark beauty of Pennsylvania barns and the forms of industrial structures.

Realistic
photog-
raphy in
the United
States

In California, Edward Weston, who had been working as a photographer for more than 15 years, turned in 1923 to a more direct and realistic use of the camera, with a certain emphasis upon abstract form that he never allowed to detract from the recognition of subject matter. "The camera should be used for a recording of life," he wrote in 1924, "for rendering the very substance and quintessence of the *thing itself*, whether it be polished steel or palpitating flesh." He formulated a working method based on the use of the classic view camera for eight- by 10-inch negatives, a high-quality lens, well stopped down to ensure great depth of field, and the complete avoidance of artificial lighting. He printed the negatives by contact on glossy bromide paper to secure maximum detail. Enlarging and retouching of any kind was inadmissible.

To Stieglitz this revaluation of photographic aesthetics was in fact a strengthening of the beliefs he had held since his student days. He produced some of his most powerful work in the 1920s—especially his photographs of cloud forms that he called "Equivalents" because they were equivalent to his thoughts and emotions. Ill health forced him to abandon the camera in 1936, but he continued to maintain an art gallery until his death in 1946.

Paul Strand, whose striking close-ups and semiabstract photographs Stieglitz had first exhibited, developed a style equally rigorous and self-disciplined during the same period. He produced powerful landscapes, direct portraits, and minute details of driftwood and plant life. In 1940 a portfolio of superb photographs Strand had taken in Mexico was issued. After Strand settled in France in 1950, he traveled extensively, producing similar publications on France, Italy, the Hebrides, Egypt, and Ghana, each providing insight into the life in small communities. Asked to define his sphere of interest, Strand once replied that he considered himself a photographer of people.

"Dunes, Oceano" by Edward Weston, 1936.

Edward Weston

Viewing the negatives of Strand led Ansel Adams in 1930 to make photography his career. He was then studying the piano and photographing for his own satisfaction. Long interested in nature—his first photographs were of the Sierra Nevada Range and Yosemite National Park—he refined and sharpened his technique. In 1932, with Willard Van Dyke, Edward and Brett Weston, Imogen Cunningham, and Sonya Noskowiak, Adams founded an informal society, Group f.64, so named for the smallest setting of the aperture of the lens that coupled maximum depth of field with maximum sharpness. Adams' great contribution was in what he called "the interpretation of the natural scene." His photographs "Mount Williamson—Clearing Storm"

(1944) and "Sierra Nevada from Lone Pine" (1944) are classics.

A major representative of the postwar realistic style, known as the *Neue Sachlichkeit* ("New Objectivity") in Germany, was Albert Renger-Patzsch, a professional photographer who spent most of his life in Essen. Beginning in 1922, he introduced a completely new approach to photography in Germany. He abhorred the vagueness and falsification of photography of the art nouveau period (1890–1914). A firm believer in straight photography, he was fascinated by the beauty of everyday things. Like Strand before him, Renger-Patzsch considered a purely objective photography to be the true, if unattainable, goal.

His photographs are characterized by strong design, factual documentation, and stark realism stressing materials. Like Weston he insisted that the final image should exist, in all its completeness, before the exposure was made and that the print should directly record this image in full detail.

Renger-Patzsch's work was first exhibited in 1925, and three years later his most famous book appeared, *Die Welt ist schön* ("The World Is Beautiful"). The very title set the work apart in a period when artists were more concerned with creating abstractions than interpreting the environment. Renger-Patzsch looked hard at the world. The art historian Heinrich Schwarz wrote in 1929: "If today the photographs of Renger-Patzsch create more pure pleasure than many paintings, it is not an accident, but evidence that the time has found in the photographer a more sensitive instrument for the expression of its artistic needs than in the painter." Renger-Patzsch's subsequent books were largely concerned with regional landscapes and architecture, but his last two publications, *Im Wald* (1958; "Trees") and *Gestein* (1966; "Stones"), have an abstract beauty inspired by their themes.

Neue Sachlichkeit gathered momentum when Karl Blossfeldt's breathtaking, detailed magnifications of plants, which he had taken around 1900 to assist him in modeling plants, were published in *Original Forms of Art* (1928), followed by the *Magic Garden of Nature* (1932). About that time, August Sander, sick of the sweet-looking, posed studio portraits by which he had made his living for nearly 30 years, vowed "From now on I only want the honest truth about our time and people." In *Portrait of an Epoch* (1929) Sander presented such an unflattering portrait of the German middle class that in 1934 the Nazis impounded all unsold copies. Sander's idea of photographing tradespeople in his studio in Cologne inspired the American fashion photographer Irving Penn to shoot a similar series 30 years later. In both cases the portraits are unconvincing because the workers are divorced from their usual surroundings. The finest portraits of the German intelligentsia of the 1920s were taken by Hugo Erfurth of Dresden. They are imbued with strong artistic conception and a sympathetic understanding of the sitter.

Influence of abstract art. In 1919 Christian Schad, a member of the Dada group of modern artists in Geneva, amused himself by arranging small, flat objects directly on photographic paper. Upon exposure to light, the paper darkened more or less or not at all, according to the opacity or transparency of the objects. These "schadographs," as they came to be called, were minor contributions to the Dada movement and would be forgotten except that they inspired the American Surrealist painter Man Ray and the Hungarian constructivist painter László Moholy-Nagy to produce similar, though larger, abstract photographs.

Man Ray had settled in Paris in 1921 and was supporting himself by taking portraits and fashion photographs. One day he accidentally set a glass funnel, a graduate, and a thermometer on a piece of photographic paper, thus producing "rayographs."

I turned on the light; before my eyes an image began to form, not quite a simple silhouette of the objects as in a straight photograph, but distorted and refracted by the glass more or less in contact with the paper.

"Photogram," photogram by László Moholy-Nagy, 1926.
George Eastman House Collection

About the same time, in Berlin, Moholy-Nagy (or perhaps his wife, Lucia, a trained photographer) began to use three-dimensional objects to make similar cameraless photographs, which he called "photograms." Although identical in technique, the work of each was quite different. Man Ray emphasized the distorted but recognizable object; Moholy-Nagy the play of light, no matter how abstract. The former brought to photography the vision of the Surrealists; the latter, that of the Constructivists.

As a teacher in the influential Bauhaus art school, Moholy-Nagy explored the potential of the unconventional use of the camera as a means of discovering form. He delighted in the worm's-eye and the bird's-eye view. He considered the negative an end as well as a means. Amazed at the power of the medium to make visible the invisible, he collected X rays, photomicrographs, and astronomical

and ultrahigh-speed photographs. When in 1925 he put together a book of these pictures titled *Painting, Photography, Film*, the eyes of the world were opened to the scope and breadth of photography as a tool for vision.

Photomontage. The art of combining photographs with watercolour paintings was a popular pastime in the 1870s. In the first decades of the 20th century the idea of freely combining mediums was revived when Cubist painters began to glue on their abstract canvases words clipped from newspapers, labels from bottles, and even actual objects. The extension of this collage technique (from the French *coller*, meaning "to glue") to photography was logical. The German artist John Heartfield, the greatest master of photomontage, claimed that the origin of the technique lay in postcards that he and his friend the German artist George Grosz sent to friends at the front during World War I. These were

a *mischmasch* of advertisements for hernia belts, student song books and dog food, labels from schnaps and wine bottles, and photographs from picture papers, cut up at will in such a way as to say, in pictures, what would have been banned by the censors if we had said it in words.

Heartfield's photomontages, which were published weekly, first in Berlin and later in Prague, between 1929 and 1938, have a savage quality. Violent contrasts of the scale and perspective of the image elements, the ruthless cropping of heads and bodies, the substitution of machine parts for vital organs, and other seeming illogical juxtapositions, were carefully calculated to have a shock effect. Heartfield's anti-Fascist montages were among the strongest protests made by any visual artist.

Excellent montages were also produced in the 1920s by the German artists Hannah Höch, Herbert Bayer, Otto Umbehr, and the Surrealist painter Max Ernst. Most of these combined photographs cut from newspapers with other ephemera to express a specific idea. The montages of the Constructivists are more architectural: space is created with the purely photographic self-portrait of the Russian artist El Lissitzky (1924) and a fantasy world is built by Moholy-Nagy in his "Leda and the Swan." The power of montage lies in the tensions set up by the juxtaposition of disparate visual elements.

Documentary photography. At this same period, the documentary photographs of Eugène Atget first became known to the public. Beginning around 1898, this French photographer produced approximately 10,000 photographs of Paris and its environs that were direct, straightforward, and poetic in their sympathetic rendering of the very fabric of the city. He photographed shop fronts, buildings, wheeled vehicles of all kinds, decorative details, and the

By courtesy of Mrs. Gertrud Heartfield

"Twenty Years Later," photomontage by John Heartfield, 1934.

Photo-
montage
technique

people who earned their living in the streets. Unknown to the photographic world, Atget worked alone, supporting himself by selling prints to architects, painters, and, above all, museums. The beauty of his photographs attracted the attention of Man Ray, who published a few of them in the periodical *La Revolution Surréaliste* in 1926. Upon Atget's death in 1927 his entire collection of prints and negatives was saved for posterity by the U.S. photographer Berenice Abbott (with the help of the New York art dealer Julien Levy); they are now in the collection of the Museum of Modern Art, New York City.

Although Atget was one of the most prominent photographers in the documentary field, he was by no means the first. The value of the photograph as a record of the world and man's conditions and achievements has been evident since the inception of the medium in 1839.

Early documentary photographs were used to relay information about important events (e.g., the Brady staff's record of the Civil War) as well as the scenery and people of distant or unexplored lands. They were also used to record the successive stages of significant or complex projects. The English artist Philip Henry Delamotte, for example, was hired to document in weekly photographs the progress of the construction of the Crystal Palace in London, from the laying of its foundation in 1852 to its opening by Queen Victoria two years later. Shortly afterward, by order of the French government, Édouard-Denis Baldus photographed to scale the sculpture, capitals, scrollwork, and other architectural details of the new wing of the Louvre Museum. Valuable work of a similar timely nature was undertaken by the English photographers Alfred and John Boal and Henry Dixon. Between 1875 and 1886 they worked for the Society for Photographing Old London, recording the historic buildings and relics that were gradually disappearing as a result of modernization.

The recognition of the power of photography to persuade as well as to inform came somewhat later. The classic sociological study *London Labour and the London Poor*, by Henry Mayhew (1851–62), was illustrated with drawings partly copied from daguerreotypes taken by Richard Beard; a sequel, patterned upon it, appeared in 1877—*Street Life in London*, by Adolphe Smith and John Thomson. The photographs, taken by Thomson, were moving, straightforward pictures of chimney sweeps, flower sellers, bargemen, and other tradesmen. They were reproduced by the woodburytype process, which gave exact, permanent facsimiles of the original prints. The intent of the publication was to show—as Charles Dickens had shown in his novels—the hardships and problems faced by the ever-growing working-class population of London. Each of the photographs was accompanied by a detailed explicative text by Smith. Oscar G. Rejlander photographed orphan children in the streets of London performing such humble tasks as cleaning boots and sweeping streets.

To Jacob A. Riis, a police reporter in New York City in the 1880s, the camera became the ally of his pen in the personal crusade he was waging to better the lot of the immigrants who then lived and worked in wretched conditions in tenements in Manhattan's Lower East Side. Himself an immigrant—he arrived in New York from Denmark in 1870—he knew at first hand the conditions he was seeking to eradicate. To supplement his written descriptions, he turned to photography. When the cameraman he employed proved unsatisfactory, he learned the process himself and was one of the first to use flash powder, a German invention recently introduced to the United States. His photographs, published in crude facsimile in newspapers and in his now-famous books, *How the Other Half Lives* (1890) and *Children of the Poor* (1892), were instrumental in stimulating legislative reform.

Beginning in 1905, Lewis W. Hine, a teacher at the Ethical Culture School in New York and a trained sociologist, began to make a pictorial record of immigrants passing through Ellis Island. He followed them in New York City, photographing them in their living quarters, at work, and in the streets. Later Hine traveled to textile mills, mines, and other places where young children were employed; largely through the evidence of his photographs, legislation was eventually passed against child-labour abuses.

In England Sir Benjamin Stone, a member of Parliament for Birmingham, was obsessed by the wish to document old English customs and pageants that he rightly feared would gradually disappear. He was the most active member of the National Photographic Record Association, which he had founded for this purpose in 1895, leaving to the city of Birmingham a collection of 22,000 photographs.

The body of photographs produced for the Farm Security Administration during the Great Depression in the United States has been preserved for future generations by the Library of Congress. The pictures cover the period from 1935 until the outbreak of World War II and were taken by a group of dedicated photographers, under the direction of Roy E. Stryker. Stryker, a professor of economics at Columbia University, was invited by the Secretary of Agriculture to form a historical section in the department to document the plight of farmers driven from their land in the dust bowl and who were migrating to the West. This at once took the form of a photographic project. The first photographer to be hired was Arthur Rothstein, a student of Stryker's. From California came Dorothea Lange, who had photographed migratory workers there. Her photographs are notable for their compassionate attitude toward people. In her "Migratory Pea Picker," a destitute young mother, surrounded by her children, peers at the camera with determination and courage. Walker Evans, with a direct uncompromising sense of environment and the beauty of everyday architecture, contributed a notable series. With the writer James Agee he documented the lives of sharecroppers in the book *Let Us Now Praise Famous Men* (1941). Others were documenting America at this time: Berenice Abbott produced a notable series of photographs of New York City, and Margaret Bourke-White with her husband, Erskine Caldwell, did a passionate survey of the South, which appeared in book form as *You Have Seen Their Faces* (1937).

Photojournalism. From the outset, photography has served the press. Within weeks after the French government's announcement of the process in 1839, magazines were publishing woodcuts or lithographs with the byline "from a daguerreotype." In fact, the two earliest illustrated weeklies—*The Illustrated London News*, which started in May 1842, and *L'Illustration*, based in Paris from its first issue in March 1843—owe their origin to the invention of photography. Early reproductions were generally crude, however, and carried little of the conviction of the original photograph. Regular use of photographs in magazines be-

gan with the perfection of the halftone process for facsimile reproduction in the 1890s. By 1915 newspapers had also turned to photography for reporting topical events, and the profession of newspaper illustrator gradually became obsolete. Although technical advances improved reproduction quality, the subjects and styles of early journalistic photography were generally unimaginative and dull.

Influence
of the
Ermanox
and Leica
cameras

It was not until the appearance of the Ermanox in 1924 and the Leica in 1925 that a new approach to pictorial journalism began to emerge. These two German-made miniature cameras, fitted with wide-aperture lenses, required extremely short exposure times for outdoor work and were even able to photograph indoor scenes by available light. This capability led to photographs whose informality of pose and sense of presence were remarkable. In 1928–29 two of the largest picture magazines in Europe, the *Münchener Illustrierte Presse* and the *Berliner Illustrierte Zeitung*, began to print the new style of photographs. Erich Salomon captured revealing candid portraits of politicians and other personalities by sneaking his camera into places and meetings officially closed to photographers. Felix H. Man was encouraged by Stefan Lorant, editor of the *Münchener Illustrierte*, to take sequences of photographs at interviews and cultural and social events. Lorant then laid out the photographs in imaginative picture essays.

The example of the German picture magazines was followed in other parts of Europe and in the United States. One was the short-lived *Vu*, established in Paris in 1928. An issue of *Vu* devoted entirely to the Spanish Civil War contained memorable photographs by Robert Capa. In 1936 both *Life* and *Look* were conceived in America, and a formula was evolved in which the picture editor, photographer, researcher, and writer constituted a team. The result was the creation of a definite photographic style.

Life's first
photog-
raphers

Life's first photographers were Margaret Bourke-White, already famous for her industrial photographs made largely for the magazine *Fortune*; Alfred Eisenstaedt, an experienced photo reporter for the Keystone Picture Agency in Germany; Peter Stackpole, whose photographs of the

Golden Gate Bridge in San Francisco attracted much attention; and Thomas D. McAvoy, a news photographer who had pioneered in photographing interior scenes by available light. The concept of *Life* from the start, according to its founder, Henry Luce, was to replace haphazard picture taking and editing with the "mind-guided camera." Photographers were briefed for their assignments and encouraged to take great quantities of photographs, in order that the editors might have a large selection. The visual organization of the picture story was carefully planned for maximum reader impact. The opening photograph of the picture essay established the situation, and like written narration there was a visual climax and a definite conclusion. Usually the photographs were chosen and arranged on the pages before the accompanying text was written. Unlike the illustrated article, the picture essay quite logically is based upon the photographs, and the text is devoted to information that cannot be expressed visually: names, dates, places.

Life and *Look* preferred to use pictures of great sharpness and depth. Thus, instead of unobtrusive miniature cameras, American photographers used large-format cameras requiring slow lenses, large plates, and additional flash light. At first, the photographers made great use of so-called synchroflash; *i.e.*, flash that was synchronized with the camera shutter. The next step was the multiple flash, which made possible more sophisticated and pleasing lighting effects. By duplicating the existing illumination with the flash lighting, photographers could await the moment when people were at their most natural and then make the exposure without the need for posing.

This way of photographing was soon challenged. Lorant, who had left the *Münchener Illustrierte Presse*, moved in 1934 from Germany to London. There, he established the magazines *Weekly Illustrated* (1934) and *Picture Post* (1938). Staff photographers on both magazines included old colleagues from Germany, such as Man and Kurt Hutton. They, as well as other contributors, were encouraged to develop the technique and pictorial style of available-light photographs so brilliantly begun in the 1920s. Their pictures had a remarkable naturalness that brought great reader appeal—so much so that *Life* began to publish sim-

Henri Cartier-Bresson—Magnum

ilar photographs and in 1945 hired a former *Picture Post* photographer, Leonard McCombe, with an extraordinary clause in his contract: he was forbidden to use flash.

Memorable groups of photographs have been taken for the picture magazines. Examples are Man's "A Day with Mussolini," first published in the *Münchener Illustrierte Presse* (1931), and then, with a brilliant new layout, in *Picture Post*; W. Eugene Smith's "Spanish Village" (1951) and "Nurse Midwife" (1951) in *Life*; and Eisenstaedt's informal, penetrating portraits of famous Britons, also in *Life*.

The photojournalist's ability to train himself to perceive the significant in the fraction of a second and to use the camera with such speed and precision that the instantaneous perception is preserved forever is a great creative gift. The gift is evident in the work of the Hungarian André Kertész as early as 1915 and in his later work in Paris during the 1920s. The Frenchman Henri Cartier-Bresson began around 1930 to develop the style that he later called the search for the "decisive moment." To him the camera was an "extension of the eye." With extraordinary precision he perceived a fully composed picture of the most fleeting scenes. Unlike many other photographers, he did not crop or recompose his pictures after they had been taken: every detail of a Cartier-Bresson photograph is present in the negative. He preferred the miniature 35-mm-film camera. When he found a picture possibility he stalked his prey unobtrusively, working with his camera to a visual climax.

Colour photography. Photography's transmutation of nature's colours into various shades of black and white had been considered a drawback of the process from its inception. Hence, at the request of a client, many portrait photographers collaborated with artists who hand-tinted daguerreotypes and calotypes or painted over albumen prints in oils. Some artists also copied the photograph onto canvas; others, such as Franz von Lenbach in Munich, had the image projected onto canvas that had been made light-sensitive, whereupon they painted freely over it. In Japan, where hand-coloured woodcuts had a great tradition and labour was cheap, some firms from the 1870s on sold photographs of scenic views and daily life that had been delicately hand-tinted. In the 1880s photochromes, colour prints made from hand-coloured photographs, became fashionable and remained popular until they were gradually replaced in the first decades of the 20th century by Autochrome plates.

The Autochrome process, the first practical colour photography process, was introduced in France in 1907 by

Auguste and Louis Lumière. It used a colour screen (a glass plate covered with grains of starch dyed to act as primary-colour filters and black dust that blocked all unfiltered light) coated with a thin film of panchromatic (i.e., sensitive to all colours) emulsion and resulted in a positive colour transparency. The Lumières' success was due in part to the introduction of panchromatic emulsion the previous year by a London firm of photographic plate manufacturers. All previous experimenters trying to solve the problem of colour photography had been seriously impeded by the comparative insensitivity of the earlier negative material to all colours except blue and violet.

Researchers continued to look for improvements and alternative colour processes, and in 1935 Leopold Godowsky, Jr., and Leopold Mannes, two American musicians working with the Kodak Research Laboratories, initiated the modern era of colour photography with their invention of Kodachrome film. With this reversal (slide) film, colour transparencies could be obtained that were suitable both for projection and for reproduction. A year later the Agfa Company of Germany developed the Agfacolor negative-positive process, but due to World War II the film did not become available until 1949. Meanwhile, Kodak had introduced in 1942 the Kodacolor negative-positive film that, 20 years later—after many improvements in quality and speed and a great reduction in price—became the most popular film used for amateur photography. Today about 80 percent of all photographs are shot in colour.

Later trends. Throughout its history, there have been two complementary yet distinct aesthetic approaches to photography. On the one hand, there has been the recognition of the basic qualities of photography and the desire to make use of them in a functional way. On the other hand, there have been those who believe that the most aesthetic use of photography is to relate it to other mediums. Since 1950 both these trends have been pursued with vigour, and to them has been added a third approach, the expressive, emotional use of photography pioneered by Stieglitz with his "equivalents" series.

In the United States, Minor White, through his long career, his writing, his teaching, and his founding and editing of the influential magazine *Aperture*, developed the Stieglitz approach to a highly sophisticated level. For him, the photograph must be transformed in such a manner that the viewer can read an inner message, which is not visible upon the surface, but which is carried by it. White's book *Mirrors, Messages, Manifestations* (1970) is a collection of superb photographs that present his spiritual biography.

To Aaron Siskind, who worked with wall scrawls, weathered wood and plaster, torn billboards, and what he called "the detritus of our world," the photograph must communicate more than the subject itself. The photographs of Harry Callahan express his highly developed sense of linear form, often by means of sharp contrasts of black and white and multiple images.

One of the finest photographers working after World War II was former *Life* photographer Andreas Feininger. His dramatic close-ups of architecture and nature reveal a thorough understanding of design, composition, and structure, which can perhaps be attributed to his early training as an architect.

Colour photography has become increasingly popular within the ranks of the amateur. Although many professionals have explored the artistic possibilities of colour, which can add intensity and realism to the picture and in-

crease interest in the subject, some prefer black-and-white to colour film for aesthetic reasons. Among professional colour photographers, Eliot F. Porter and Marie Cosindas (one of the first to work with Polaroid instant films) were the leaders in America: both preferred a somewhat realistic approach.

A considerable impediment to a more widespread use of colour in monographs and other publications studying the art of photography is the often prohibitive price of colour reproduction.

The urban social scene viewed objectively without sentiment or moralization—often called the "social landscape"—has been a subject of much interest to photographers in both the United States and Europe. The work of such photographers as Robert Frank, Bruce Davidson, and William Klein takes the form of penetrating sociological observations, somewhat reminiscent of the documentary

Robert Frank

photography of the 1930s. The approach differs in that, rather than presenting problems faced by a certain level of society, emphasis is placed on the effects of the urban environment upon people.

In England and Europe, trends closely parallel those in the United States. Bill Brandt, whose classic social reportage began with the book *The English at Home* (1936) and continued during World War II with trenchant photographs of life in the bomb shelters of London, changed his style during the 1950s. Using an extremely wide-angle lens he created startling abstract studies of nudes, some of which are reminiscent of Henry Moore sculptures. Cecil Beaton, fashion photographer for British *Vogue*, created pictures with exquisite taste. His moving photographs of London during the bombing of World War II and of other scenes of the war stress the human aspect rather than the military. The "social landscape" school is well represented in the work of Tony Ray-Jones and Raymond Moore. The strongest contribution probably lies in the field of photojournalism. George Rodger, one of the founders of the Magnum agency and a former *Life* photographer, and Bert Hardy, a former *Picture Post* photographer, provided a solid tradition for the work of Don McCullin, who—like Robert Capa before him—traveled from war to war, photographing with deep compassion the conflicts that appeared in his book *The Destruction Business* (1971).

The most imaginative photographs in Europe are mostly made for publication, rather than for exhibition or hanging in galleries and homes. Europeans, in general, do not consider the photographic print as an end in itself, but as a step toward reproduction in periodicals and books. Brassai (the pseudonym of Gyulas Halász) made his name in photography with the publication of *Paris de nuit* (1933), intimate and sympathetic photographs of night life in the more humble quarters of Paris. In the 1950s, like Aaron Siskind, he became fascinated with wall scrawls and graffiti. Robert Doisneau was a master of humour and satire, catching moments of absurdity in everyday life. Lucien Clergue turned to the natural scene and to the nude in surf. The tradition of cameraless abstraction was enriched by the Belgian Pierre Cordier with the introduction in 1958 of his "chimigrammes"—colour images made, not by light, but chemical action on photographic paper.

In Germany the greatest influence was the teaching of Otto Steinert at Saarbrücken and, since 1959, at the Folkwangschule in Essen. Almost single-handedly he brought back to Germany that spirit of experimentation and boldness of concept that had been suppressed during the Third Reich. An excellent photographer, Steinert was

the founder in 1951, together with the art historian J.A. Schmoll gennant Eisenweth, of a movement they named "Subjective Photography." He led the group "Fotoform," which first exhibited its work in 1950, to explore the creative potential of any possible expressive technique. Peter Keetman is one of the strongest representatives of Fotoform's dedication to creating innovative, expressive graphic designs and abstract patterns. Robert Häusser, a student of Steinert, was strongly influenced by Fotoform in his early work. Later he introduced mystifying ele-

ments into his landscapes, wilfully distorting reality until it bordered on abstract expressionism. Chargesheimer, like Robert Frank in the United States, laid great stress on the unpleasant side of his themes in hard, almost brutal photographs of German cities. Floris M. Neusüss, who teaches at the University of Kassel, in West Germany, is a great exponent of conceptual photography, which uses concepts as material and in which the preconceived idea is more important than the object. Erwin Fieger stands out with such books as *13 Photo-Essays* (1969), *Japan*, *Sunrise Island* (1971), and *Mexico* (1973) as one of the finest in the field of colour reportage. Horst Baumann specialized in illustration, particularly in colour.

The Austrian Ernst Haas was a master of colour photography, turning toward the abstract in his remarkable photographs of blurred action and bold compositions. A member of the Magnum group, a cooperative formed by Cartier-Bresson and others in 1947, Haas produced work that is international in scope.

Outstanding among Swiss photographers working after World War II was Werner Bischof, who, until his death in 1954, movingly photographed refugees in Europe, the famine in India, Japan, and the Incas of Peru. Superb colour work was produced by Emil Schulthess for his books *Africa* (1959), *The Amazon* (1962), *China* (1966), and others. Georg Gerster revealed in his aerial views, primarily taken in colour, a beauty of design that frequently comes close to modern art.

The Czechoslovakian Josef Sudek is best known abroad for his still lifes, Vilem Heckel for his photographs of industry and mountains, Karel Plicka for his views of Prague, and Josef Koudelka for his impressive work on Gypsies. In Sweden each member of the group of photographers known as TIO ("Ten") has produced outstanding work. Each works in a different field, but all are united by their modern style. The most gifted Russian photographer, Alexander M. Rodchenko, was too modern for Stalin's taste, and his work was banished until the dictator's death. During World War II Dimitri Baltermans produced fine reportage work on the front.

In Italy Franco Fontana, shooting in colour with tele-lenses, created amazing abstractions of landscapes, fields, and buildings; Mario de Biasi made a fine record of the uprising in Budapest in 1956; and Fulvio Roiter produced a series of travel books, the most sensitive and romantic

of which focused on his hometown, Venice. The chief concern of most photographers in Italy and elsewhere in Europe, however, is centred upon the recording of the social scene: Mario Giacomelli's series of photographs of nuns and village life is typical and outstanding.

In Japan the extraordinary documentary and landscape photographs by Hiroshi Hamaya parallel the straight photographic approach. Superb photographs were also produced by Takayuki Ogawa, the social realist, and by the imaginative Eikoh Hosoe.

Experimental approaches to photography

A lively interest in expanding the medium of photography beyond the straight approach was characteristic of much work in the late 20th century. The experimentation took many forms, including the revival of long-obsolete printing techniques such as the gum bichromate process and the platinotype. Perhaps the most startling change to come about after 1960 was an interchange of mediums between photographers and painters. Many photographers made liberal use of manual techniques, such as negative and print retouching and the addition of colour. Simultaneously, painters, who had long utilized photographs as tools for observation, boldly imitated the very quality of photographic vision and sometimes introduced unaltered photographs by collage techniques or silkscreen reproduction directly into their canvases.

Another late 20th-century trend was the photographer's increasing reliance on books for the presentation of his work. Several factors contributed to this practice, among them the demise of many of the major picture magazines, technical developments that provided better printing quality at lower costs, and the complete acceptance of photography as an art worthy of study and preservation.

(Be.N./H.E.R.G.)

The technology of photography

The most widely used photographic process is the black-and-white negative-positive system (Figure 1). In the camera the lens projects an image of the scene being photographed onto a film coated with light-sensitive silver salts, such as silver bromide. A shutter built into the lens admits light reflected from the scene for a given time to produce an invisible but developable image in the sensitized layer, thus exposing the film.

During development (in a darkroom) the silver salt crystals that have been struck by the light are converted into metallic silver, forming a visible deposit or density. The

more light that reaches a given area of the film, the more silver salt is rendered developable and the denser the silver deposit that is formed there. An image of various brightness levels thus yields a picture in which these brightnesses are tonally reversed—a negative. Bright subject details record as dark or dense areas in the developed film; dark parts of the subject record as areas of low density; *i.e.*, they have little silver. After development the film is treated with a fixing bath that dissolves away all undeveloped silver salt and so prevents subsequent darkening of such unexposed areas. Finally, a wash removes all soluble salts from the film emulsion, leaving a permanent negative silver image within the gelatin layer.

A positive picture is obtained by repeating this process. The usual procedure is enlargement: the negative is projected onto a sensitive paper carrying a silver halide emulsion similar to that used for the film. Exposure by the enlarger light source again yields a latent image of the negative. After a development and processing sequence the paper then bears a positive silver image. In contact printing the negative film and the paper are placed face to face in intimate contact and exposed by diffused light shining through the negative. The dense (black) portions of the negative image result in little exposure of the paper and, so, yield light image areas; thin portions of the negative let through more light and yield dark areas in the print, thus re-creating the light values of the original scene.

CAMERAS AND LENSES

Basic camera functions. In its simplest form, the camera is a light-tight container carrying a lens, a shutter, a diaphragm, a device for holding (and changing) the film in the correct image plane, and a viewfinder to allow the camera to be aimed at the desired scene.

The lens projects an inverted image of the scene in front of the camera onto the film in the image plane. The image is sharp only if the film is located at a specific distance behind the lens. This distance depends on the focal length of the lens (see below *Characteristics and parameters of lenses*) and the distance of the object in front of the lens. To photograph near and far subjects, all but the simplest cameras have a focusing adjustment that alters the distance between the lens and the film plane to make objects at the selected distance produce a sharp image on the film. In some cameras focusing adjustment is achieved by moving only the front element or internal elements of the lens, in effect modifying the focal length.

The shutter consists of a set of metallic leaves mounted in or behind the lens or a system of blinds positioned in front of the film. It can be made to open for a predetermined time to expose the film to the image formed by the lens. The time of this exposure is one of the two factors controlling the amount of light reaching the film. The other factor is the lens diaphragm, or aperture, an opening with an adjustable diameter. The combination of the diaphragm opening and exposure time is the photographic exposure. To obtain a film image that faithfully records all the tone gradation of the object, this exposure must be matched to the brightness (luminance) of the subject and to the sensitivity or speed of the film. Light meters built into most modern cameras measure the subject luminance and set the shutter or the lens diaphragm to yield a correctly exposed image.

Principal camera types. The simplest camera type, much used by casual amateurs, has most of the features listed in the previous section—lens, shutter, viewfinder, and film-holding system. The light-tight container traditionally had a box shape. Present-day equivalents are pocket cameras taking easy-load film cartridges or film disks. Typically, a fixed shutter setting gives about $1/50$ -second exposure; the lens is permanently set to record sharply all objects more than about five feet (1.5 metres) from the camera. Provision for a flash may be built in. Though simple to handle, such cameras are in daylight restricted to pictures of stationary or slow-moving subjects.

The 35-mm miniature camera. Perforated 35-millimetre (mm) film (originally standard motion-picture film) in cartridges holding 12 to 36 exposures with a nominal picture format of 24×36 mm is employed in miniature cameras.

Creation of a negative image

The two basic elements of exposure

Figure 1: Sequence of negative-positive process, from the photographing of the original scene to enlarged print (see text).

Smaller image formats down to 18×24 mm (half frame) may be used. The 35-mm camera has a lens with a range of apertures and a shutter with exposure times typically from one second to $\frac{1}{1,000}$ second or shorter, and it can focus on subject distances from infinity down to five feet or less. A winding lever or built-in motor advances the film from one frame to the next and at the same time tensions (cocks) the shutter for each exposure. At the end of the film load the film is rewound into the cartridge for removal from the camera in daylight.

A 35-mm camera usually has a direct-vision viewfinder, often combined with a rangefinder or autofocus system for accurate distance settings. Most current versions incorporate a light meter coupled with the exposure settings on the camera. Advanced models may have interchangeable lenses and an extended accessory system. Many 35-mm cameras are single-lens reflex types (see below).

The ultraminiature or subminiature. This camera takes narrow roll film (16-mm or 9.5-mm) in special cartridges or film disks. The picture size ranges from 8×10 mm to 13×17 mm. These formats are used for making millions of snapshotting pocket-size cameras; special versions may be as small as a matchbox for unobtrusive use.

The view, or technical, camera. For studio and commercial photography the view, or technical, camera takes single exposures on sheet films (formerly plates) usually between 4×5 inches and 8×10 inches. A front standard carries interchangeable lenses and shutters; a rear standard takes a ground-glass screen (for viewing and focusing) and sheet-film holders. The standards move independently on a rail or set of rails and are connected by bellows. Both standards can also be displaced laterally and vertically relative to each other's centre and swung or tilted about horizontal and vertical axes. These features provide versatility in image control (sharpness distribution, subject distance, and perspective), though not speed in use. The view camera is nearly always mounted on a tripod.

The medium-size hand camera. This type of camera takes sheet film (typical formats of from $2\frac{1}{2} \times 3\frac{1}{2}$ inches to 4×5 inches), roll film, or 70-mm film in interchangeable magazines; it has interchangeable lenses and may have a coupled rangefinder. Special types use wide-angle lenses and wide picture formats (e.g., $2\frac{1}{4} \times 4\frac{1}{2}$ to $2\frac{1}{4} \times 6\frac{3}{4}$ inches [6×12 to 6×17 centimetres]). The medium-size hand camera was popular with press photographers in the first half of the 20th century. Older versions had folding bellows and a lens standard on an extendable baseboard or strut system. Modern modular designs have a rigid body with interchangeable front and rear units.

The folding roll-film camera. The folding roll-film camera, now rare, resembles the 35-mm miniature camera in shutter and viewfinder equipment but has bellows and folds up to pocketable size when not in use. Generally it takes roll films holding eight to 16 exposures; typical picture sizes are $2\frac{1}{4} \times 2\frac{1}{4}$, $2\frac{1}{4} \times 3\frac{1}{4}$, or $1\frac{3}{4} \times 2\frac{1}{4}$ inches. Some 35-mm cameras were also produced with bellows.

The single-lens reflex. The ground-glass screen at the back of the studio, or view, camera slows down picture taking because the screen must be replaced by the film for an exposure. The single-lens reflex camera (Figure 2) has a screen, but the film remains constantly in position. A 45° mirror reflects the image-forming rays from the lens onto a screen in the camera top. The mirror moves out of the way during the exposure and back again afterward for viewing and focusing the next picture. The image on the screen therefore temporarily disappears from view during the exposure. Present-day single-lens reflexes are either 35-mm cameras or advanced roll-film models. Most 35-mm reflexes have optical prism systems for eye-level screen viewing, built-in light-meter and electronic exposure-control systems, interchangeable lenses, and numerous other refinements. Often the camera is part of an extensive accessory system. Advanced roll-film reflexes are even more modular, with interchangeable viewfinders, focusing screens, and lenses.

The twin-lens reflex. The twin-lens reflex is a comparatively bulky dual camera (Figure 3) with a fixed-mirror reflex housing and top screen mounted above a roll-film box camera. Its two lenses focus in unison so that the top

Figure 2: Single-lens reflex principle.

(Top) Before exposure, upright but laterally reversed image is visible on top screen. (Bottom) During exposure, with mirror up and shutter open, an upside down but laterally correct image is projected on the film.

screen shows the image sharpness and framing as recorded on the film in the lower section. The viewing image remains visible all the time, but the viewpoint difference (parallax) of the two lenses means that the framing on the top screen is not exactly identical with that on the film.

Shutter and diaphragm systems. Principal present-day shutters are the leaf shutter and the focal-plane shutter.

The leaf shutter. The leaf, or diaphragm, shutter consists of a series of blades or leaves fitted inside or just behind the lens. The shutter opens by swinging the leaves simultaneously outward to uncover the lens opening. The leaves stay open for a fixed time—the exposure time—and then close again. A combination of electromagnets or electromagnets and springs drives the mechanism, while an electronic circuit—often coupled with a light metering system—or an adjustable escapement in mechanical shutters controls the open time. This is typically between one second and $\frac{1}{500}$ second.

Focal-plane shutter. The focal-plane shutter consists of two light-tight fabric blinds or a combination of metal blinds moving in succession across the film immediately in front of the image plane. The first blind uncovers the film

Figure 3: Principles of the twin-lens reflex camera.

The fixed mirror deflects light rays coming through the viewing lens to a top screen, which shows the image upright but laterally reversed. Light from the object also goes through the taking lens, which is mounted on a common panel with the viewing lens, and is projected on the film.

Reflecting
the image
through
the lens

and the second blind covers it up again, the two blinds forming a traveling slit the width of which determines the exposure time: the narrower the slit, the shorter the time. The actual travel time is fairly constant for all exposure times. A mechanism or electromagnet and control circuit triggers the release of the second blind. Focal-plane shutters are usually adjustable for exposure times between one second (or longer) and $\frac{1}{1,000}$ to $\frac{1}{4,000}$ second.

Diaphragm and shutter settings. In the lens diaphragm a series of leaves increases or decreases the opening to control the light passing through the lens to the film. The diaphragm control ring carries a scale of so-called *f*-numbers, or stop numbers, in a series: such as 1.4, 2, 2.8, 4, 5.6, 8, 11, 16, 22, and 32. The squares of the *f*-numbers are inversely proportional to the amount of light admitted. In the above international standard series, each setting admits twice as much light as the next higher *f*-number, or stop (giving twice as much exposure).

Shutter settings on present-day cameras also follow a standard double-or-half sequence—e.g., 1, $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{15}$, $\frac{1}{30}$, $\frac{1}{60}$, $\frac{1}{125}$, $\frac{1}{250}$, $\frac{1}{500}$, $\frac{1}{1,000}$ second, and so forth. The shorter the exposure time, the “faster” the shutter speed.

Exposure values. An attempt to simplify the mathematics of *f*-number and shutter speed-control functions led to the formulation of exposure values (EV). These run in a simple whole-number series, each step (EV interval) doubling or halving the effective exposure. The lower the EV number, the greater the exposure. Thus, EV 10 gives twice as much exposure as EV 11 or half as much as EV 9. Each EV value covers a range of aperture/speed combinations of the same equivalent exposure; for instance, *f*/2.8 with $\frac{1}{250}$ second, *f*/4 with $\frac{1}{125}$ second, and *f*/5.6 with $\frac{1}{60}$ second. For a time some cameras carried an EV scale and coupled the aperture and speed settings; at a given EV setting in such cameras selecting various speeds automatically adjusted the aperture to compensate and vice versa. Exposure-value setting scales became obsolete with exposure automation, but the notation remains in use to indicate either exposure levels or—at specified film speeds—lighting levels requiring a given exposure.

Automatic-diaphragm systems. On a camera with a viewing screen (view camera or single-lens reflex) viewing and focusing are carried out with the lens diaphragm fully open, but the exposure is often made at a smaller aperture. Reflex cameras (and increasingly also view cameras) therefore incorporate a mechanism that automatically or semiautomatically stops down (reduces) the lens to the working aperture immediately before the exposure.

Methods of focusing and framing. The ground-glass (now mostly grained plastic) screen is the most direct way of viewing the image for framing and for sharpness control. The screen localizes the image plane for observation. The image is also visible without a screen, but then the eye can locate the image plane of maximum sharpness only with a precisely focused high-power magnifier. This aerial focusing method avoids interference of the ground-glass structure with sharpness assessment.

Focusing aids. The eye is not good at recognizing slight unsharpness, so focusing screens (especially in reflex cameras) often incorporate focusing aids such as a split-image wedge alone or with a microprism area, in the screen centre. The split-image wedge consists of a pair of prism wedges that split an out-of-focus image into two sharp halves laterally displaced relative to one another. When the lens is correctly focused the image becomes continuous across the wedge area—a point that the eye can assess more precisely. The microprism area contains several hundred or thousand minute wedges that give a blurred image very ragged outlines and a broken-up texture; these clear abruptly as the image becomes sharp.

The focusing screen is often overlaid by a pattern of fine concentric lens sections. Called a Fresnel screen, it redirects the light from the screen corners toward the observer's eye and makes the image evenly bright.

Cameras without a screen generally are equipped with a distance scale, the lens being set to the estimated object distance. More advanced cameras have an optical rangefinder as a distance-measuring aid; it consists of a viewfinder (see below) and a swinging mirror a few inches

to one side of the viewfinder axis. As the eye views an image of the object, the mirror superimposes a second image from a second viewpoint. On turning the mirror through the correct angle, which depends on the object distance, the two images are made to coincide. The mirror movement can be linked with a distance scale, or coupled with the lens focusing adjustment. When the lens is incorrectly focused, the rangefinder shows a double or split image. In place of a rotating mirror, the rangefinder may use swinging or rotating optical wedges (prisms).

Autofocus systems. Some cameras evaluate the coincidence (or lack thereof) between two rangefinder images by image analysis with a microchip system. This signals electronically when the lens is set to the correct distance and often carries out the distance setting by a servomotor built into the camera. Such focusing automation makes the camera even simpler to use. Alternative automatic ranging systems used in amateur cameras depend on triangulation with infrared rays or pulses sent out by a small light-emitting diode (LED), or on measurement of the time an ultrasonic signal takes to be reflected back from the subject (sonar).

While these devices measure distance automatically, single-lens reflex cameras may incorporate electronic image-analysis systems to measure sharpness. The signal output of such systems actuates red or green LEDs in the camera finder system to show whether the image is sharp or not. The same signal can control a servomotor in the lens for fully automatic focusing. These devices are limited at low lighting and contrast levels—where the human eye also finds sharpness assessment difficult.

Viewfinders. The sighting devices in cameras lacking screens are called viewfinders; they show how much of the scene will appear on the film. The simplest viewfinder is a wire frame above the camera front, with a second frame near the back to aid the eye in correct centring. Most present-day finders are built into the camera and are compact lens systems. Bright-frame finders show a white frame reflected into the view to outline the field recorded on the film. An alternative form is the reflecting viewfinder in which the photographer looks down into a field lens on top of the camera. The upper section of a twin-lens reflex camera is such a reflecting finder.

As the viewfinder axis in a camera other than a single-lens reflex does not usually coincide with the lens axis, the finder's and the lens's views do not exactly match. This parallax error is insignificant with distant subjects; with near ones it is responsible for the familiar fault of a portrait shot of a head that appears partly cut off in the picture even though it was fully visible in the finder. Camera viewfinders may have parallax-compensating devices.

The optical finder gives a direct upright and right-reading view of the subject with the camera held at eye level. The traditional reflex camera, held at waist level, showed a laterally reversed view. Modern reflexes have a pentaprism arrangement that permits upright, right-reading, eye-level viewing by redirecting the image from the horizontal screen on top of the camera.

Exposure-metering systems. Exposure meters, or light meters, measure the light in a scene to establish optimum camera settings for correct exposures. A light-sensitive cell generates or controls an electric current according to the amount of light reaching the cell. The current may energize a microammeter or circuit controlling LEDs to indicate exposure settings. In most modern cameras the current or signal acts on a microprocessor or other circuit that directly sets the shutter speed or lens aperture. The cell usually is a silicon or other photodiode generating a current that is then amplified. In older cadmium sulfide cells the light falling on the cell changed the latter's resistance to a current passing through it. Selenium cells, still used in some cameras, also generate a current but are larger and less sensitive.

Single-lens reflex cameras have one or more photocells fitted in the pentaprism housing to measure the brightness of the screen image. The exposure reading depends on the light coming through the lens (TTL metering) and so allows for the lens's angle of view, close-up exposure corrections, stray light, and other factors. Some TTL sys-

The series of *f*-numbers

Micro-prism grid of multiple wedges

Parallax problems with close-at-hand subjects

Through-the-lens (TTL) meter systems

tems divert the light from the lens to a photocell before it reaches the screen (e.g., by beam-splitting arrangements or the use of photocells behind a partly reflecting mirror), or they measure the light reflected from the film or from a specially structured first shutter blind at the beginning of, or during, the exposure. Such off-the-film (OTF) measurement is also used for electronic flash control (see below).

View cameras may use a photocell on a probe that can be moved to any point just in front of the focusing screen, thus measuring image brightness at selected points of the image plane. This takes place before the exposure, and the probe is then moved out of the way. Professional photographers also use hand-held separate exposure meters and transfer the readings manually to the camera.

Flash systems. Flash is a widely used artificial light source for photography, providing a reproducible light of high intensity and short duration. It can be synchronized with an instantaneous exposure. Being battery powered, small flash units are self-contained.

Electronic flash. The most common flash system depends on a high-voltage discharge through a gas-filled tube. A capacitor charged to several hundred volts (by a step-up circuit from low-voltage batteries or from the line voltage supply) provides the discharge energy. A low-voltage circuit generating a high-voltage pulse triggers the flash, which lasts typically $1/1,000$ second or less. Small electronic flash units may be built into or clipped onto the camera. Larger units are attached with brackets. Large professional units with floodlight and spotlight fittings are used in studio photography. Even small flashes often have adjustable reflectors, for example, to illuminate an indoor subject by the flash reflected from the ceiling or walls.

Automatic and dedicated flash. Electronic flash units often incorporate a fast-responding photodiode that cumulatively measures the light reflected from the subject and switches off the flash when that light has reached a preselected amount (computer flash). This flash-duration control thus adjusts the flash exposure automatically as long as the subject is within a certain distance range (typically from two to 20 feet). At lower power or near subject distances the duration of a computer flash may drop to $1/50,000$ second.

With certain camera-flash combinations OTF metering inside the camera can control the flash duration by suitable contacts made when the flash is attached to the camera. These "dedicated" flashes (so named because their control circuitry has to match that of specific cameras) may also signal in the camera finder when the flash is ready to operate and to set the camera automatically to its synchronizing shutter speed (see below).

Flashbulbs. An older type of flash is an oxygen-filled glass envelope containing a specific amount of aluminum or zirconium wire and means for igniting the wire in the bulb. The wire burns away with a brilliant flash lasting typically about $1/100$ to $1/50$ second. Each flashbulb can, however, yield only one flash. Current flashbulb systems use four to 10 tiny bulbs, each in its own reflector, arranged in cube or bar carriers that plug into cameras designed for them. The individual flashes are fired in turn by a battery and circuit in the camera through mechanically generated current pulses or other means. In view of the greater convenience of electronic flash, flashbulbs in their various forms are largely obsolescent.

Firing and synchronization. Flash units are usually fired with a switch in the camera shutter to synchronize the flash with the shutter opening. A contact in the camera's flash shoe (hot shoe) or a flash lead connects the unit with this shutter switch. The shutter contact usually closes the instant the shutter is opened. A focal plane shutter must fully uncover the film (generally at a shutter speed of $1/60$ second or slower) for flash synchronization. With flashbulbs the shutter must also stay open while the flash reaches its peak brightness—about $1/50$ second.

System cameras. From the development of the 35-mm miniature camera in the 1930s evolved the concept of the system camera that could be adapted to numerous jobs with a range of interchangeable components and specialized accessories. Today, most moderately advanced 35-mm miniatures take interchangeable lenses, close-up

and photomicrographic attachments, filters, flash units, and other accessories. The most elaborate camera systems also include such accessories as alternative finder systems; interchangeable reflex screens, film backs, and magazines; and remote-control and motor-drive systems. Modular professional roll-film and view cameras are built up from a selection of alternative camera bodies, film backs, bellows units, lenses, and shutters. This is the nearest approach to the universal camera, assembled as required to deal with practically every type of photography.

Characteristics and parameters of lenses. The lens forming an image in the camera is a converging lens, the simplest form of which is a single biconvex (lens-shaped) element. In theory such a lens makes a light beam of parallel rays converge to a point (the focus) behind the lens. The distance of this focus from the lens itself is the focal length, which depends on the curvature of the lens surfaces and the optical properties of the lens glass. An object at a very long distance (optically regarded as at "infinity") in front of the lens forms an inverted image in a plane (the focal plane) going through the focus. Light rays from nearer objects form an image in a plane behind the focal plane. The nearer the object, the farther behind the lens the corresponding image plane is located—which is why a lens has to be focused to get sharp images of objects at different distances.

Focal length and image scale. The image scale, or scale of reproduction, is the ratio of the image size to the object size; it is often quoted as a magnification. When the image is smaller than the object, the magnification of the object is less than 1.0. If the image is $1/20$ the size of the object, for example, the magnification may be expressed either as 0.05 or as 1:20. For an object at a given distance, the scale of the image depends on the focal length of the lens (Figure 4). A normal camera lens usually has a focal length approximately equal to the diagonal of the picture format covered. A lens of longer focal length gives a larger scale image but necessarily covers less of the scene in front of the camera. Conversely, a lens of shorter focal length yields an image on a smaller scale but—provided the angle of coverage is sufficient (see below)—takes in more of the scene. Many cameras, therefore, can be fitted with interchangeable lenses of different focal lengths to allow varying the image scale and field covered. The focal length of a lens in millimetres (sometimes in inches) is generally engraved on the lens mount.

Aperture. The aperture, or *f*-number, is the ratio of the focal length to the diameter of an incident light beam as it reaches the lens. For instance, if the focal length is 50 millimetres and the diameter of the incident light beam is 25 millimetres, the *f*-number is 2. This incident-beam diameter is often roughly the lens-diaphragm diameter, but it may be appreciably larger or smaller. The maximum

Figure 4: Effects of using lenses of different focal lengths.

Modular systems

aperture (f -number at the largest diaphragm opening) is also marked on the lens, usually in the form $f/2$, $f/2.8$, or $1:2$.

Angle of coverage. A lens must cover the area of a camera's film format to yield an image adequately sharp and with reasonably even brightness from the centre to the corners of the film. A normal lens should cover an angle of at least 60° . A wide-angle lens covers a greater angle—about 70° to 90° or more for an ultrawide-angle lens. A long-focus lens covers a smaller angle.

The angle of coverage depends on the lens design. Designations like "wide angle" or "narrow angle" are not necessarily synonymous with "short focus" and "long focus," as the latter terms refer to the focal length of the lens relative to the picture format.

Optical performance. A simple lens produces a very imperfect image, which is usually blurred away from the centre. The image may have colour fringes around object outlines, and straight lines may be distorted. Such defects, called aberrations, can be eliminated—and even then not completely—only by replacing the single lens element by a group of elements of appropriate shape and separation. Aberrations arising from some of the lens elements then counteract opposite aberrations produced by other elements. The larger the maximum aperture, the greater the angle of coverage, and the higher the degree of correction aimed at, the more complex camera lenses become. Lens design for relative freedom from aberrations involves advanced computer programming to calculate the geometric parameters of every lens element. Some aberrations can also be corrected by making one or more of the surfaces of a lens system aspheric; *i.e.*, with the variable curvature of a paraboloid or other surface rather than the constant curvature of a spherical one.

Lenses usually consist of optical glass. Transparent plastics also have come into use, especially as they can be molded into elements with aspheric surfaces. They are, however, more sensitive to mechanical damage.

Aberrations. There are a number of lens aberrations, each with its own characteristics. Chromatic aberration is present when the lens forms images by different-coloured light in different planes and at different scales. Colour-corrected lenses largely eliminate these faults. Spherical aberration is present when the outer parts of a lens do not bring light rays into the same focus as the central part. Images formed by the lens at large apertures are therefore unsharp but get sharper at smaller apertures. Curvature of field is present when the sharpest image is formed not on a flat plane but on a curved surface. Astigmatism occurs when the lens fails to focus image lines running in different directions in the same plane; in a picture of a rail fence, for instance, the vertical posts are sharp at a focus setting different from the horizontal rails. Another aberration, called coma, makes image points near the edges of the film appear as irregular, unsharp shapes. Distortion is present when straight lines running parallel with the picture edges appear to bow outward (barrel distortion) or inward (pincushion distortion).

Resolving power and contrast-transfer function. One way of testing lens performance is to observe the image it forms of patterns of increasingly closely spaced black lines separated by white spaces of line width. The closest spacing still recognizable in the image gives a resolving power value, expressed in line pairs (*i.e.*, black line plus white space) per millimetre. Photographs of such line patterns, or test targets, show the resolving power of the lens and film combination. For example, a resolution of 80–100 line pairs per millimetre on a fine-grain film represents very good performance for a normal miniature camera lens.

The visual sharpness of an image depends also on its contrast. Opticians, therefore, often plot the contrast with which the image is reproduced against the line spacing of that image. The resulting contrast-transfer curve, or function, gives a more reliable indication of the lens performance under practical picture-taking conditions.

Special lens types. Apart from general-purpose camera lenses of various focal lengths, there are lenses of special characteristics or design.

Telephoto lenses. Long-focus lenses are bulky, because they comprise not only the lens itself but also a mount

or tube to hold it at the appropriate focal distance from the film. Telephoto lenses are more compact; their combinations of lens groups make the back focus (the distance from the rear lens element to the film) as well as the length of the whole lens appreciably shorter than the focal length. Strictly, the term telephoto applies only to a lens of this optically reduced length; in practice long-focus lenses of all types tend to be called indiscriminately telephoto or "tele" lenses.

If a camera lens is interchangeable, an accessory teleconverter lens group can be positioned between the prime lens and the camera. This turns a normal lens into an even more compact telephoto system, which is less costly than a telephoto lens but which reduces the speed of the prime lens and usually impairs sharpness performance.

Wide-angle and retrofocus lenses. Short-focus, wide-angle lenses are usually mounted near the film. Single-lens reflex cameras need a certain minimum lens-to-film distance to accommodate the swinging mirror. Wide-angle (and sometimes normal-focus) lenses for such cameras therefore use retrofocus designs. In these the back focus is appreciably longer than the focal length. Both a telephoto and a retrofocus lens must be specially designed for its particular use to ensure optimum image performance.

Fish-eye lenses. For image angles greater than 110° , it becomes difficult to bring the lens close enough to the film to allow the rays between the lens and film to diverge sufficiently. The fish-eye lens overcomes this difficulty by making the rays diverge less behind the lens than they do in front. The resulting image shows appreciable distortion, with image details near the edges and corners progressively compressed. Fish-eye lenses usually cover angles between 140° and 210° and are used for unusual wide-angle effects where the distortion becomes a deliberate pictorial element. They also have certain scientific applications, for instance, to cover a horizon-to-horizon view of the sky in recording cloud formations.

Mirror lenses. Images can also be formed by light reflected from curved mirrors. This method, long used in astronomical telescopes, is applied to long-focus lens systems of short overall length by folding the light path back onto itself. A mirror lens or catadioptric system has no chromatic aberrations. Other aberrations are corrected by incorporating one or more appropriate lens elements. The arrangement of the system, with a central opening in the primary mirror, makes stopping down with a customary diaphragm difficult, and neutral-density filters are used to control light transmission.

Variable-focus lenses. In variable-focus lenses the focal length can be varied by movement of some of the elements or groups within the lens system. One lens can thus replace a range of interchangeable lenses.

The variable-focus, or zoom, lens was originally developed for motion-picture photography, in which adjustment of the focal length during a shot produced a zooming-in or zooming-out effect (hence the name). It is now widely used in single-lens reflex cameras where the reflex finder permits accurate continuous assessment of image coverage. In a true zoom lens the image changes in scale but not in sharpness during zooming; some varifocal lenses, however, need refocusing at different focal lengths. Due to correction requirements over a range of focal lengths, zoom lenses are complex systems containing from 12 to 20 elements. Zoom lenses for still cameras have focal-length ratios from 2:1 to 4:1 or more (*e.g.*, 35–135 mm for a 35-mm reflex).

Lens-changing systems. Miniature and roll-film cameras hold interchangeable lenses in screw or quick-change bayonet mounts. In a focal-plane shutter camera the usable range of focal lengths is practically unlimited. In cameras with leaf shutters, either the lens is mounted in front of the shutter or the lens is changed with the shutter. Some designs use convertible lenses with the rear components built into the camera together with the shutter; interchangeable front groups then provide different focal lengths in combination with the fixed rear group. View-camera lenses—usually with their own shutters—are mounted on lens boards that clip into and out of the front camera standard.

Afocal attachments provide the effect of alternative focal lengths with a fixed camera lens. They are magnifying or reducing telescopes without a focal length (hence afocal), yielding a virtual image that the camera lens projects onto the film. Their designated magnification factor indicates the effect on the image scale; e.g., a 1.5× tele attachment magnifies the image on the film 1½ times, while a 0.7× wide-angle attachment reduces the image scale to 0.7 times that of the prime camera lens.

Lens coating. When light passes from one optical medium to another (especially from air to glass and vice versa in a lens), about 4 to 8 percent of it is lost by reflection at the interface. This light loss builds up appreciably in complex multielement lenses. Some of the reflected light still reaches the film as ghost images or light spots or as general contrast-reducing scattered light.

To reduce such losses, the air-to-glass surfaces of modern lenses typically carry a microscopically thin coating of metallic fluorides. The coating eliminates most reflected rays. Complete elimination can occur only for light of one wavelength if the coating thickness and refractive index are exactly right. In practice a coated lens surface reflects about 0.5 percent of incident white light— $\frac{1}{10}$ of the light lost by an uncoated lens. Multiple coatings can reduce reflections over a wider wavelength range.

BLACK-AND-WHITE FILMS

The latent image. The sensitive surface of ordinary film is a layer of gelatin carrying minute suspended silver halide crystals or grains (the emulsion)—typically silver bromide with some silver iodide. Exposure to light in a camera produces an invisible change yielding a latent image, distinguishable from unexposed silver halide only by its ability to be reduced to metallic silver by certain developing agents.

Current theories postulate that silver halide crystals carry minute specks of metallic silver—so-called sensitivity specks—which amount in mass to about $\frac{1}{100,000,000}$ part of the silver halide crystal. A silver halide is a compound of silver with fluorine, chlorine, bromine, or iodine, but only the last three are light-sensitive. When light action releases electrons from the silver halide crystal, they migrate to the sensitivity specks. The resulting electric charge on the specks attracts silver ions from the neighbouring silver halide; and as the silver ions accumulate, they become metallic silver, causing the speck to grow. Halogen (e.g., bromine) atoms at the same time migrate to the surface of the silver halide crystal and are there absorbed by the gelatin of the emulsion. When the sensitivity speck is large enough, it provides a point of attack for the developer, which can then reduce the whole silver halide crystal to silver. Developers are selective organic reducing agents that attack only silver halide crystals that have sufficiently large sensitivity specks. The halide grains carrying a developable sensitivity speck make up the latent image.

Sensitometry and speed. The sensitivity or speed of a film determines how much light it needs to produce a given amount of silver on development. Sensitometry is the science of measuring this sensitivity, which is determined by giving the material a series of graduated exposures in an appropriate instrument (the sensitometer). After development under specified conditions, the density of the silver deposit produced by each exposure is measured and the densities are plotted on a graph against the logarithm of the exposure. The resulting characteristic curve, or $D/\log E$ curve (see below *Contrast*), shows how the film reacts to exposure changes. A specified point on the curve also serves as a criterion for calculating film speed by methods laid down in various national and international standards.

The internationally adopted scale is ISO speed, written, for example, 200/24°. The first half of this (200) is arithmetic with the value directly proportional to the sensitivity (and also identical with the still widely used ASA speed). The second half (24°) is logarithmic, increasing by 3° for every doubling of the speed (and matching the DIN speeds still used in parts of Europe). A film of 200/24° ISO is twice as fast (and for a given subject requires half as much exposure) as a film of 100/21° ISO, or half as fast as a film of 400/27° ISO.

All-around films for outdoor and some indoor photography have speeds between 80/20° and 200/24° ISO; fine-grain films for maximum image definition between 25/15° and 64/19° ISO; and high-speed and ultraspeed films for poor light from 400/27° ISO up.

Colour sensitivity. Initially, the silver halide emulsion is sensitive to ultraviolet radiation and to violet and blue light. Most films contain sensitizing dyes to extend their colour sensitivity through the whole visible spectrum. Such films, called panchromatic films, were introduced in 1904. They record subject colour values as gray tones largely corresponding to the visual brightness of the colours.

Non-colour-sensitized or blue-sensitive emulsions (without sensitizing dyes) are used for copying monochrome originals and similar applications needing no extended colour sensitivity. At one time orthochromatic films—sensitive to violet, blue, green, and yellow but not to red—were also used for general photography; now they are employed mainly for photographing of phosphor screens, such as cathode-ray tubes, and for other purposes requiring green but not red sensitivity.

Infrared films, developed in 1919, are sensitized to invisible infrared wavelengths. They are used in aerial photography to cut through atmospheric haze (which scatters blue light but not infrared rays) and for special purposes in scientific and forensic photography.

Filters. Filters can modify the way in which a film records colours as monochrome tone values. They are disks of coloured glass or gelatin with controlled transmission characteristics. Placed in front of the camera lens, they preferentially transmit light of their own colour and hold back light of other colours. A yellow or yellow-green filter is often used in landscape photography to prevent overexposure of the blue sky and to bring out detail in cloud formations. Orange and red filters make the sky still darker and cut through haze by absorbing scattered blue light.

Contrast filters differentiate between the gray values of objects of different colour but of similar brightness. For instance, a red flower and green foliage record in similar shades of mid-gray. A red filter holds back green light to darken the green foliage, making the flower lighter; a green filter absorbs red light, thus darkening the flower. Such deliberate tone distortion is widely used in photomicrography and other fields.

Other filter types used in photography include ultraviolet, infrared, and polarizing filters. Ultraviolet-absorbing filters screen out ultraviolet rays at high altitudes (e.g., in mountain photography). Because camera lenses are not normally corrected for such rays, the rays can reduce image sharpness, even though the lenses allow only a small amount of ultraviolet to be transmitted. Infrared filters are used with infrared film to hold back visible light. Polarizing filters polarize light and can absorb polarized light if suitably oriented. Light reflected at certain angles from shiny surfaces of nonmetallic media (glass, water, varnish) is polarized; a properly oriented polarizing filter subdues such reflections in a picture.

Because a filter screens out part of the light, its use calls for extra exposure, the amount of which is indicated by a filter factor—e.g., 2×, which means the exposure time must be multiplied by 2. For cameras with an exposure-value scale, a filter may specify an exposure value reduction (such as -1 or -1½; i.e., the indicated exposure value must be reduced by this amount). The factor of a given filter depends on the spectral sensitivity of the film, the colour quality of the lighting, the type of subject, the effect aimed at, and other exposure conditions.

Other film characteristics. Of practical interest to the photographer are the graininess, resolving power, and contrast of a film. Although they are characteristics of the film itself, they are influenced by the conditions of development (see below *Black-and-white processing and printing*).

Grain. The image derived from minute silver halide crystals is discontinuous in structure. This gives an appearance of graininess in big enlargements. The effect is most prominent with fast films, which have comparatively large silver halide crystals.

Resolving power and acutance. The fineness of detail

Use of
ortho-
chromatic
films

Filter
factors for
proper
exposure

Formation
of the
latent
image

that a film can resolve depends not only on its graininess but also on the light scatter or irradiation within the emulsion (which tends to spread image details) and on the contrast with which the film reproduces fine detail. These effects can be measured physically to give an acutance value, which is preferred to resolving power as a criterion of a film's sharpness performance. Fine-grain films with thin emulsions yield the highest acutance.

Contrast. High-contrast films reproduce tone differences in the subject as great density differences in the image; low-contrast films translate tone differences into small density differences. The characteristic curve of a film obtained by plotting the density against the logarithm of the exposure (mentioned earlier under *Sensitometry and speed*) can be used to express a film's contrast (see Figure 5). The slope of the straight-line section of the

Figure 5: Characteristic curves of low-contrast and high-contrast film (see text).

curve (sometimes called the gamma, actually the tangent of the angle α) indicates contrast: the steeper the slope, the higher the contrast rendering. General-purpose films yield medium contrast (gamma 0.7 to 1). High-contrast films (gamma 1.5 to 10) are used for copying line originals and other specialized purposes; low-contrast films for continuous-tone reproduction. Gamma is also used to indicate degree of development, since increased development generally results in a higher gamma.

Film structure and forms. Film consists of a number of layers and components: (1) A supercoat of gelatin, a few micrometres (one micrometre is 0.001 millimetre) thick, protects the emulsion from scratches and abrasion marks. (Pressure and rubbing can produce developable silver densities.) (2) The emulsion layer (silver halide suspended in gelatin) is usually nine to 12 micrometres (up to $\frac{1}{2},000$ inch) thick but may sometimes reach 25 micrometres. (3) A substrate or subbing layer promotes adhesion of the emulsion to the film base. (4) The film base, or support, is usually cellulose triacetate or a related polymer. The thickness may range from 0.08 to 0.2 millimetre (0.003 to 0.008 inch). Films for graphic arts and scientific purposes are often coated on a polyethylene terephthalate or other polyester support of high dimensional stability. Glass plates—once the most common support for negative materials—are now used only for applications requiring extreme emulsion flatness. (5) A backing layer on the rear of the film base counteracts curling. Usually it contains also a nearly opaque dye to suppress light reflection on the rear support surface. Such reflection (halation) reduces definition by causing halolike effects around very bright image points. Some film bases (especially in 35-mm films) are tinted gray to absorb light that has passed through the emulsion layer.

Sheet film. View and studio cameras generally take sheet film—single sheets (typical sizes range between $2\frac{1}{2} \times 3\frac{1}{2}$ and 8×10 inches) loaded in the darkroom into light-tight film holders for subsequent insertion in the camera.

Roll film. The term roll film is usually reserved for film wound up on a spool with an interleaving light-tight backing paper to protect the wound-up film. The spool is loaded into the camera in daylight, the backing paper leader threaded to a second spool, and the film wound from picture to picture once the camera is closed. This is the classical roll film of roll-film cameras. Common current film widths are 62 mm and 45 mm. The rear of the backing paper carries sets of consecutive numbers spaced at frame intervals for different image formats. In some roll-film cameras these numbers are visible through a viewing window in the camera and show how far the film must be wound to advance it from one picture to the next. Instant-loading cartridges also use paper-backed roll film.

Perforated film. Some film is perforated along its edges and rolled up on its own inside a light-tight cartridge, which can be loaded into the camera in daylight. Once the camera is closed, a transport sprocket engaging the edge perforations draws the film from the cartridge onto a spool and advances it from picture to picture. The most common film width is 35 mm (for 35-mm miniature cameras), and its cartridge typically holds enough film for up to 36 (sometimes 72) exposures. A 70-mm film for larger cameras and 16-mm strips for ultraminatures are packed and used in a similar way.

In March 1983 the Eastman Kodak Company announced the development of a new coding system for 35-mm film and cartridges. The DX film system employs optical, electrical, and mechanical encoding to transmit to appropriately equipped cameras such information as film type, film speed, and number of exposures. The system also supplies data that enable automatic photofinishing equipment to identify and sort film quickly, simplifying processing and printing. In the interest of uniformity, Kodak freely offered the DX system to all film and camera manufacturers, and within two years it was generally adopted.

Disk film. Some compact mass-market cameras take circular disks of film, 65 millimetres in diameter, in light-tight cartridges and coated on a 0.18-mm polyester base. In the camera the disk rotates as up to 15 exposures (frame size 8×10 millimetres) are recorded around the disk circumference. The disk lies flatter in the camera than rolled-up film and is suitable for more automated photofinishing; the high printing magnification required, however, limits the image quality.

PICTURE-TAKING TECHNIQUE

The main areas of practical camera handling in photography concern sharpness control, exposure, and lighting.

Sharpness control. The image on the film is sharpest when the lens is focused to the exact object distance. Usually, however, a scene includes objects at varying distances from the camera. Various factors affect the sharpness distribution in a picture of such a scene.

Depth of field. The sharpness in the image of objects in front of and behind the focused distance falls off gradually. Within a certain range of object distances this sharpness loss is still comparatively unnoticeable. This range is the depth of field and depends on: (1) the amount of sharpness loss regarded as acceptable; miniature negatives requiring big enlargement must be sharper than larger format negatives, which are enlarged less; (2) the lens aperture used: stopping down the lens (higher f -numbers) increases the depth of field; (3) the object distance: the depth of field is smaller for near objects than for more distant ones; and (4) the focal length of the lens: depth of field is reduced with longer focus lenses (and with larger picture formats requiring lenses of longer focal length), and the depth increases with shorter focus lenses. A depth of field indicator, often included on the focusing mounts of lenses, shows on the distance scale how far in front of and behind the focused distance objects will be in focus at different diaphragm openings.

Subject and camera movement. Movement of the subject while the camera shutter is open for the exposure leads to a blurred image. The exposure time must therefore be short enough to keep the blur within acceptable limits. The shutter speed required depends on the movement speed of the object, the scale of the image (movement blur becomes greater the nearer the subject or the longer the focal length of the lens used) and the movement direction; movement across the direction of view produces the most blurring.

Movement blur can be reduced, even with comparatively slow shutter speeds, by moving the camera (panning) to follow the subject during the exposure. This records the moving object comparatively sharply against a blurred background and emphasizes the impression of speed.

Camera shake through unsteady support during the exposure also creates image blur—over the whole picture in such cases. Hand-held shots generally demand shutter speeds of $\frac{1}{30}$ second or shorter. For longer times a firm camera support—such as a tripod—is essential.

Factors
influencing
depth of
field

Use of
anti-
halation
dye

Exposure technique. The correct exposure (aperture and shutter settings) can be derived from tables or calculators or by direct measurement of the subject luminance with a light meter.

Automatic meter control. Cameras with through-the-lens (TTL) exposure meters—and also hand-held meters pointed at the subject—measure the average reflected light intensity, yielding reliable exposures for subjects of average contrast and brightness distribution. Subjects of extreme contrast or very bright or dark dominant areas need overriding exposure corrections; automatic cameras often have provision for this. Such a TTL measurement is usually centre-weighted (predominantly based on the image centre). Some cameras (and meters) permit spot readings covering a small subject area only and give reliable exposures if this selected area is a medium subject tone.

The selection of an appropriate aperture and shutter speed among equivalent camera exposures depends on depth-of-field and subject-movement requirements. Some automatic cameras simplify this by selecting just one such combination at each exposure level (program automation).

Flash exposures. Most current electronic flash units incorporate a sensor cell that measures the light reflected from the subject and controls the flash duration (and hence the exposure) accordingly. In certain cameras in which photocells measure the light reflected from the film, the same cells can similarly control the flash duration of suitable dedicated flash units. Lacking these provisions, flash exposures may be determined by measurement or by guide-number calculation.

Special meters can measure flash light quantity on a scene during a test firing of flashes; these are used extensively with more elaborate studio setups.

Flash exposure calculations rely on the fact that the exposure depends only on the lens aperture. (The electronic flash is usually much shorter than the synchronizable shutter time.) The light intensity reaching the film is inversely proportional to the square of the diaphragm f -number. By basic illumination laws the light intensity on a scene is also inversely proportional to the square of the distance between the light source and subject. For a given flash source and film speed, the exposure is thus constant for a constant product of distance and f -number. Flash manufacturers quote this product as a guide number for various flash-film combinations. For rapid exposure calculation, dividing the guide number by the flash-to-subject distance gives the required f -number; dividing the guide number by the f -number gives the distance at which the flash must be arranged for correct exposure.

Some cameras use this principle for semiautomatic flash-exposure control: the aperture adjustment is coupled with the distance setting on the lens (or with an automatic rangefinding system) so that the lens aperture gets larger with increasing distance. This coupling is adjustable for different flash guide numbers.

Exposure latitude. The ideal negative exposure records the darkest subject shadows as a just visible density. More exposure yields a denser negative, which, however, can still give an acceptable print by appropriate print-exposure adjustment. This range of usable negative exposures, the exposure latitude, depends on the film and the subject. This latitude is greater the lower the subject contrast and the greater the film's exposure range (and, generally, the lower the film contrast). Because of exposure latitude, simple cameras with limited exposure adjustability can still yield acceptable pictures under differing light conditions.

Lighting technique. The kind of lighting on the scene governs the way in which the picture reproduces the subject. Orientation of the subject—as in taking a portrait—with respect to the light direction can often control the effect. Lighting from behind the camera gives flat effects, light from one side yields depth and modeling, while the principal light from behind the subject produces dramatic against-the-light effects of high contrast. Artificial light setups in the studio, with tungsten lamps or electronic flash, offer the greatest flexibility. Under such conditions the photographer can arrange two or more lamps for various lighting effects.

Directional lighting improves detail contrast and bril-

liance. Excessive subject contrast, however, makes accurate exposure settings difficult and may lead to loss of picture detail in the highlights or shadows. Fill-in lighting, by a flash or other light source on or near the camera, can illuminate heavy shadows facing the camera.

BLACK-AND-WHITE PROCESSING AND PRINTING

Negative development. Amateurs usually process films in developing tanks. In this type of development roll or miniature film is wound around a reel with a spiral groove, which keeps adjacent turns separated and allows access by the processing solutions. Once the tank is loaded (in the dark), processing takes place in normal light, the processing baths (developer, intermediate rinse, fixer) being poured into the tank at the appropriate intervals. Sheet films are similarly treated in small tanks or held in hangers and immersed sequentially in the different processing solutions. Large-scale commercial processing laboratories use machines that automatically feed the films through the solutions in proper sequence.

Developers and their characteristics. The developer consists typically of one or more developing agents, a preservative (such as sodium sulfite) to prevent oxidation by the air, an alkali (such as sodium carbonate) to activate the developer, and a restrainer or antifoggant to ensure that the developer acts only on exposed silver halide crystals. A developer's main characteristics are activity, development speed, and effect on film gradation, graininess, and sharpness. Developers may be prepared on the basis of published formulas or bought as ready-mixed powders or concentrates for dilution with water.

The developer is allowed to act for a specific time to build up the image to the required density and contrast. This time depends on the developer, the temperature, the degree of agitation, and the film—as indicated by recommendations from film and developer manufacturers.

Fixing. The fixing bath contains a chemical (sodium or ammonium thiosulfate) that converts the silver halide into soluble, complex silver salts that dissolve in the fixer. During this process the film loses its original silver halide milkiness overlaying the image and becomes clear. The fixer also contains a weak acid (to halt the development process) and a hardening agent to reduce gelatin swelling.

Washing and drying. Washing removes all residual soluble chemicals from the emulsion and must be thorough for image permanence. Films are hung up to dry after removal from the tank.

High-speed processing. Greatly reduced processing times are possible with high-activity developers at elevated temperatures and with fast-acting fixing agents, such as ammonium thiosulfate. Such processes can cut access time to the negative down to less than a minute. One-bath (monobath) processing in a solution containing both a fast-acting developing agent and fixing chemicals also reduces processing time. In special rapid-access processing equipment, films pass through chambers spraying the processing solutions onto the film surface or run in contact with monobath-soaked webs.

Printing. The simplest printing equipment is the contact printing frame in which the negative and printing paper are held together behind a glass plate during exposure to a suitable lamp. A printing box is essentially a printing frame with a built-in light source. Contact printing gives a positive of the same size as the negative.

Enlargers. Negatives usually are enlarged to prints of the desired final size. The enlarger is a projection system on a vertical column mounted on a horizontal baseboard. It has a lens, a film holder (negative carrier), and a lighting system (typically a lamp and condenser lens) for illuminating the negative. Raising or lowering the enlarger head on the column controls the image magnification; adjustment of the lens-to-negative distance focuses the image on the enlarging paper on the baseboard. In enlargers that focus automatically these two adjustments are linked mechanically to keep the image sharp all the time. Enlargers are made in various sizes to take different maximum negative formats.

Printing papers. Papers for enlarging and contact printing are produced in grades of differing exposure range—

Monobath processing with developer and fixer

Lens aperture as the key to flash exposure

Flexibility with studio lighting

Paper grades in order of contrast

i.e., ratios of shortest to longest exposure to produce the lightest tone and a full black, respectively. The various grades yield prints of a normal tone range from negatives of different contrasts: a soft paper grade for a high-contrast negative, a normal paper for a normal negative, a hard paper for soft negatives, and so on. Paper grades are also numbered—typically from 0 to 5—in ascending order of contrast. Variable-contrast papers use a mixture of two emulsions of a different contrast and colour sensitivity; the contribution of each is controlled by filters in the path of the exposing light.

Other characteristics of printing papers are the speed (slower for contact papers, faster for enlarging papers), image colour (blue-black to warm brown), surface texture (glossy, velvet, mat), and base thickness (single or double weight). Most printing materials use a resin-coated (plastic-laminated) paper base that absorbs no water during processing.

Printing exposures. Correct printing exposures are determined by trial and error or by test strips given a series of progressively increasing exposures. More sophisticated exposure control systems measure either the brightness of selected image portions projected on the enlarger base-board or the average light intensity reaching the paper during the exposure. Printing papers are exposed and processed in a darkroom lit by an olive-green or orange safelight. Printing papers are sensitive to violet, blue, and sometimes green light.

Print processing. The processing of prints consists of development, an intermediate rinse or stop bath, fixing, and washing. The developer and fixer are similar in principle to those used for negative films. In the normal method, dish or tray processing, prints are immersed successively in the solutions in dishes laid out side by side. Development is checked visually, the print remaining in the developer until the image has reached its full density. For drying, the prints may be clipped to a line, placed in a heated print dryer, or squeegeed onto a mirror-finished plate for a high-gloss surface.

Stabilization processing. Certain rapid-processing papers incorporate developing agents in their emulsions and are processed on a roller processor. This processor runs the paper through an activating bath for instant development and then through a stabilizing bath, followed by a pair of squeegeeing rollers from which the print emerges merely damp. This process takes about 10 to 15 seconds; the prints, however, do not keep quite as well as conventional prints, since unexposed silver salts are not removed from the emulsion but only converted into moderately light-stable compounds. Such prints can be made more permanent by subsequent fixing and washing.

Dry processing. Processing baths can be completely eliminated by incorporating in the emulsion of the paper development and stabilization chemicals that become active on heating. One method is to disperse the processing chemicals in the emulsion in microscopic capsules containing the solution and a blowing agent. On passing the exposed paper over a heated roller, the blowing agent bursts the capsules, and the liberated processing solutions act on the silver halide immediately around each capsule. The liquid solvent instantly evaporates, leaving a dry print. Encapsulation materials are used for such purposes as making proof prints of negatives and enlarging microfilm images. Certain non-silver processes in photocopying systems also offer dry processing.

COLOUR PHOTOGRAPHY

Colour reproduction. Present-day colour photographic processes are tricolour systems, reproducing different colours that occur in nature by suitable combinations of three primary-coloured stimuli. Each of these primary colours—blue-violet, green, and red—covers roughly one-third of the visible spectrum. Tricolour impressions can be produced by combining coloured lights (additive synthesis) or by passing white light through combinations of complementary filters, each of which holds back one of the primary colours (subtractive synthesis).

In additive synthesis a combination of red and blue-violet light (*e.g.*, light beams of the two colours directed

on the same spot of a white screen) gives a purplish pink (magenta); equal parts of red and green produce yellow, and equal parts of green and blue-violet produce bluish green (cyan). Superimposition of all three light beams on a screen yields white; combinations of varying proportions of two or three of the colours produce virtually all the other hues.

In subtractive synthesis yellow, magenta, and cyan filters or dye layers subtract varying proportions of the primary colours from white light. The yellow filter absorbs the blue component of white light and so controls the amount of blue present in a white-light beam that has passed through the filter. Similarly, the magenta filter controls the amount of green light left, and the cyan controls the amount of the red component. A cyan and a magenta filter superimposed in a white-light beam hold back both the red and the green component, making the emerging beam blue. Similarly, a cyan and a yellow filter together yield green, and a yellow and a magenta filter together yield red. Superimposing such filters or dye images of different densities in a white-light beam can therefore re-create any colour impression in the same way as superimposing light beams of the primary colours.

The difference between additive and subtractive synthesis is the approach: in additive synthesis colours are built up by combining different intensities of primary-coloured light, and in subtractive synthesis colours are achieved by removing different proportions of primary-coloured light from white light. Most modern colour films are based on subtractive synthesis. Either method of colour synthesis should be capable of reproducing every existing colour in nature. In practice, the reproduction is imperfect; no filter dyes meet the required ideal specifications. Nevertheless, for most purposes reproduction is adequate.

Colour films. *Reversal (slide) films.* To reproduce colour by subtractive three-colour synthesis (Figure 6), colour films first break down the colours of an image into their primary components by means of three separate sensitized layers, each of which responds exclusively to blue, green, or red light. The image in each layer is reversal-processed to yield a positive dye image in a colour complementary to the layer's spectral sensitivity. Thus, the blue-sensitive layer first yields a negative image of everything blue in the original scene (*e.g.*, the blue sky) and then a positive image of everything that is not blue. This positive image is coloured yellow. Similarly, the green-recording layer yields a magenta positive image of everything that is not green, and the red-recording layer a positive cyan image of everything that is not red. Blue sky, for instance, does not figure in the yellow positive image but does figure in the magenta positive image (not being green) and in the cyan positive image (not being red). The magenta and cyan dyes in the areas that were blue sky are superimposed, and white light passing through the resulting transparency loses its green and red, but not its blue, component; thus, the sky appears blue. Similarly, green subject components end up as positive yellow image density in the blue-recording and positive cyan density in the red-recording layer, combining to green in the transparency. Yellow records as a negative image in the green-recording and red-recording layers, hence leaving a positive yellow image only in the blue-recording layer. All other colours are formed by similar combinations of different densities of the dye images.

Negative (print) films. Negative colour materials work

Figure 6: Colour reproduction sequence with subtractive reversal film (see text).

Subtraction of primary colours by filters or dye layers

Disadvantage of prints finished by stabilization processing

in a similar way but yield a negative dye image by direct development. Blue subject tones record in the blue-sensitive film layer to produce a yellow negative image. Green colour components yield a magenta dye image in the green-responding layer, and red components yield a cyan dye image in the red-recording layer. With respect to the subject, the colour negative therefore reverses the tones in brightness as well as in colour. Printing the colour negative on a colour paper with three differentially responding layers reverses the process once more, reconstituting the original subject colours in a positive print.

Colour-film structure. Reversal colour film has these components: (1) A top layer of plain gelatin, which protects the underlying layers against abrasion and damage. (2) The first emulsion layer, which contains blue-sensitive silver halide plus a yellow-forming colour coupler. This is a colourless substance that reacts with the decomposition products of the developing agent to generate dye in all areas where a silver image is produced and in proportion to the density of that silver image. (3) A yellow filter layer, which holds back blue light from the subsequent emulsion layers. It disappears during the bleaching stage of processing. (4) The second emulsion layer, which contains blue- and green-sensitive silver halide plus a magenta-forming colour coupler. The blue sensitivity is suppressed by the yellow filter layer. (5) The next emulsion, which is blue-and-red sensitive (blue again being suppressed) and contains a cyan-forming colour coupler. (6) A substrate, which ensures optimum adhesion of the emulsion layers to the film base and may also contain light-absorbing silver to prevent the scattering of light by reflection from the support surface (halation). (7) The film base, or support, of clear cellulose acetate derivative (or sometimes polyester), typically about 0.005 inch thick. (8) The back of the support, which carries a light-absorbing layer (an alternative to the antihalation layer in the substrate); on roll film this also acts as an anticurl layer.

Variations
in reversal
colour
films

This scheme can vary. Often one or more of the selectively sensitized layers is duplicated. Some reversal colour films do not incorporate colour couplers in the emulsions but introduce them in the processing solutions. Processing such nonsubstantive colour films is more complex than processing substantive-coupler films containing couplers in the emulsions. Negative colour films are similar, but the couplers are often already coloured yellow or red or both. The unreacted couplers remain as positive images, which compensate for some deviations of the image dyes from the colour characteristics of ideal dyes. Such negatives have an apparently overall reddish or orange tint.

Some colour films come with different combinations of colour sensitivity and dye colour formed in the individual layers for deliberately falsified colour rendering (false-colour films) in special applications.

Colour-positive (print) materials have a paper or white, opaque film base instead of transparent film and have no antihalation layer. The emulsion sequence may be different from the above scheme; their spectral sensitivities may be keyed to the transmission characteristics of the negative dyes for better colour reproduction.

The dye images are reasonably lightfast but fade on prolonged exposure to ultraviolet-rich radiation. Colour transparencies and prints intended for continuous display may be protected by ultraviolet-absorbing coatings or filter layers.

Additive colour films. These are simpler in structure and consist, in addition to protective and other interlayers, of a film base, carrying a filter raster, and a black-and-white emulsion layer. The raster consists of sequences of very narrow red, green, and blue transparent filter lines (up to 1,800 lines per inch) through which the light from the lens passes before it reaches the emulsion layer. The emulsion layer is processed to a positive image. Red subject portions cause silver to be deposited behind non-red (*i.e.*, green and blue) filter elements, leaving the red filter lines transparent. Similarly, green subject details leave green filter lines transparent but block red and blue. Other colours affect areas behind two or even three filter lines—for example, yellow leaves red and green filter lines clear. In such areas the eye cannot resolve the separate

filter elements but gets an additive impression of yellow. Other colours form corresponding additive effects, including white, where all three filter elements are transparent. Because of the presence of the filter elements everywhere in the image, additive colour transparencies are much denser than subtractive ones; at high magnification the filter raster pattern may also become visible. Additive colour transparencies are used only in rapid-access diffusion-transfer systems (see below *Instant-picture photography*).

Colour balance. Colour film reacts to all hue and tone differences, including the prevailing light colour. A film recording approximately natural colours in daylight reproduces scenes photographed by tungsten light with a reddish overall tint—because this lighting is richer in red rays than is daylight. This spectral balance of different “white” light sources may be rated numerically by the colour temperature—a concept of theoretical physics that, with tungsten lighting, corresponds roughly to the absolute lamp-filament temperature. Such absolute temperatures are expressed in kelvins (K). The higher the colour temperature the richer the light is in bluish and the poorer it is in reddish rays and vice versa. Average daylight is rated at about 5,500 K, the light from an overcast sky from 6,500 K up; the colour temperature of tungsten lamps ranges between 2,600 and 3,400 K.

To ensure correct “white-light” colour reproduction with different types of lighting, the sensitivities of the three film layers must be matched to the colour temperature of the light. Colour slide (reversal) films are therefore made in different versions balanced for faithful rendering either with 5,500 to 6,000 K light sources (such as daylight or electronic flash) or with specified tungsten lighting (3,200 to 3,400 K).

Such accurate film balance matching is less vital with negative colour films since the colour rendering of the print can be modified during colour printing. “Universal” amateur negative colour films are usable with any light, from tungsten to daylight. For high quality, professional negative colour films are still preferentially balanced to either daylight or tungsten sources.

Strongly coloured filters are suitable only for special effects; they overlay the colour image with the filter colour. Pale correction filters can match a film to a light source other than that for which it is balanced—*e.g.*, pale blue, with a daylight-type film used in tungsten lighting, to raise in effect the colour temperature. Pale pink or amber filters similarly reduce the colour temperature for using artificial-light-balanced films in daylight. Colour-film manufacturers publish detailed recommendations of actual filters required for such conversion.

In outdoor photography, especially involving distant views, an ultraviolet-absorbing filter is often required, as ultraviolet radiation records in the blue-sensitive layer of the film, producing an overall blue cast in the transparency. A pale pink skylight filter for outdoor subjects lit only by skylight counteracts the cold, bluish colour rendering resulting from such illumination.

Colour-film processing. The processing sequence for colour materials is longer than for black-and-white films and requires more solutions. Development needs very precise timing and temperature control. Colour films can be processed in amateur developing tanks; professionals use sets of tanks in temperature-controlled water jackets with provision for standardized solution agitation.

Reversal colour-film processing. Most colour films use a standard processing sequence and chemistry (usually available in kits). For substantive films (incorporating couplers in the emulsion) the sequence comprises: (1) development to form a negative silver image in each emulsion layer; (2) a reversal bath that renders developable the remaining silver halide in each emulsion layer; (3) colour development to produce a positive silver image in the remaining silver halide plus a coincident dye image by reaction with the colour couplers; (4) bleaching and fixing to reconvert the negative and positive silver images into silver halide and to dissolve the latter out of the emulsion, leaving only the three dye images; (5) a final rinse and stabilizer to remove soluble chemicals and improve light-fastness of the dyes; and (6) drying. There are also intermediate rinse stages.

“Uni-
versal”
colour
films

Processing of colour films lacking couplers

The complete sequence without drying takes a little longer than 30 minutes.

Processing of nonsubstantive colour films, in which the couplers are in the colour developer, is more complex because each emulsion layer is reexposed by appropriately coloured light and colour-developed separately. This operation requires automated processing machinery.

Negative colour processing. Negative colour films are practically all of the substantive-coupler type. Most again follow a standard processing sequence consisting of colour development (forming a negative silver image in each emulsion layer together with a corresponding dye image), a rinse, and a bleaching and fixing stage to convert the silver image into silver halide and dissolve that (plus residual halide) out of the emulsion. A final rinse and drying conclude the process, which, excluding drying, takes about 12 minutes. Substantially the same procedure is followed for processing positive colour papers.

Colour printing. Colour print processing may be done in dishes or trays or in light-tight drums that are rotated manually or mechanically, processing solutions being poured in and out in succession. Professional colour laboratories use more elaborate versions of such rotating drum systems or roller or other automated machines that transport prints through the different solutions in turn.

Methods of obtaining colour control

Positive prints from colour negatives. Positive prints may be obtained from colour negatives by enlarging the colour negative onto a positive colour paper. Colour control consists of modifying the colour of the printing light by yellow, magenta, and cyan filters (typically by inserting high-density filters of these colours to varying degrees in the light path) to obtain a print of the correct or desired colour balance. The light is thoroughly mixed in a diffusing box before reaching the negative. An alternative method is to have three light sources behind the yellow, magenta, and cyan filters and to adjust their relative intensities or switch them on for different exposure times.

This subtractive, or white-light, printing method depends on subtracting or holding back colour components of white light. Commercial photofinishing printers often use an additive system in which prints are given successive exposures through high-density red, green, and blue filters. Each of these exposures forms the image in one of the emulsion layers of the paper; colour balance depends on the proportions of the individual exposures. In automatic colour printing systems the exposures are controlled by photocells that evaluate the red, green, and blue components of light transmitted by the negative.

Reversal colour printing. Colour transparencies can be printed on a reversal colour paper similar to a reversal film and processed in an analogous way. The same kind of colour control with filters is again possible, but the colour effect of the subtractive filters or of the additive filter exposures is reversed.

Dye-destruction processes. Dye-destruction processes differ from chromogenic colour materials (where colour images are produced during development) in starting off with emulsion layers containing the final dyes. During processing these are bleached in proportion to the silver image formed. Straightforward processing of a dye-destruction or dye-bleach material yields a positive image from a positive original and consists of: (1) development to form a silver image; (2) stop-fixing to arrest development and remove unexposed silver halide; (3) dye bleaching to bleach the dye in the areas containing a silver image; (4) silver bleaching to convert the silver image into silver halide; and (5) fixing to remove residual silver halide. Washing is done between all the processing stages.

Obtaining a positive image from a negative requires a more elaborate processing sequence, analogous to reversal processing in a chromogenic system. Dye-bleach materials use far more light-stable dyes than those produced by colour-coupling development. The positive-positive procedure also yields duplicate transparencies on dye-bleach materials with a transparent film base.

Diffusion-transfer colour prints. Materials derived from instant-picture diffusion-transfer processes (see below *Instant-picture photography*) have been adapted to colour print production. They are more expensive than tradi-

tional colour print materials but considerably easier to process. In their simplest form they require only a single highly alkaline activator bath followed by a water rinse, the whole sequence lasting about five to 10 minutes, with considerable processing latitude. Such materials exist for prints from either negatives or transparencies. The colour printing and filter control principles are the same as with the traditional processes described above.

Assembly colour prints. The original method of producing colour prints was based on separation negatives obtained by photographing the original scene on separate black-and-white plates or films through a blue, green, and red filter, respectively. This method analyzes the subject in terms of its tricolour components in the same way as the initial negative images in a three-layer colour film. Positive prints from the separation negatives, converted into colour images (e.g., by toning) and superimposed on top of each other, yield a subtractive tricolour print.

The main surviving assembly print process, dye transfer, uses a set of separation positives on a panchromatic matrix film made either from separation negatives of a colour transparency or by separation (three filtered exposures) from a colour negative. Appropriate processing converts the matrix film into a gelatin relief image whose depth is proportional to the positive silver density. Each matrix is soaked in a dye solution (yellow for the matrix derived from the blue-filter negative and so on), and the dyes from the matrices are transferred in succession to a single sheet of gelatin-coated paper. Elaborate care is required to ensure accurate superimposition (registration) of the dye images; the result is a positive colour print.

Prints by the dye transfer process

Transparency projection. Many amateur colour pictures are in the form of transparencies, particularly on 35-mm film. These are usually mounted in plastic or card frames or bound between glass for projection on a screen in a darkened room. The projector consists of a lens, a holder for the slide, and a lighting system (lamp, reflector, and condenser lenses to concentrate the light onto the slide). Modern slide projectors take the slides in magazines or trays holding 30 to 50 or more slides. An automatic slide transport feeds each slide from the tray into the light path of the projector and may be operated from a remote control unit or by pulses from a tape recorder, which can also record a commentary to the complete slide series. Some projectors feature remote-controlled or automatic focusing to keep each successive slide image sharp on the screen.

The standard miniature slide size is 2×2 inches for transparencies up to $1\frac{3}{8} \times 1\frac{3}{8}$ inches; the most usual transparency format in such slides is 24×36 millimetres. Projectors for larger slides (e.g., $2\frac{3}{4} \times 2\frac{3}{4}$ inches for transparencies up to $2\frac{1}{4} \times 2\frac{1}{4}$ inches) and ultraminiature projectors (e.g., 10×14 -millimetre transparencies in 3×3 -centimetre slide frames) are suitably scaled-up or scaled-down versions of the standard models.

The size of the projected image depends on the distance of the projector from the screen and the focal length of the projection lens. Projectors may also project from the back onto a translucent screen; such rear-projection setups are more compact, and the image is often bright enough for viewing in daylight. The rear-projection system is used in schools and for commercial displays. Elaborate slide shows are produced by linking two or more projectors aimed at the same or adjacent screen areas. With a suitably assembled slide set, the pictures can be made to change, overlap, and assemble, according to a predetermined program.

INSTANT-PICTURE PHOTOGRAPHY

History and evolution. Cameras with built-in processing facilities, to reduce the delay between exposure and the availability of the processed picture, were proposed from the 1850s onward. The ferrotype process later adapted for "while-you-wait" photography by itinerant street and beach photographers goes back almost as far. Because of the messiness of handling liquid chemicals in or just outside the camera, such systems remained largely impractical. In the 1940s Edwin H. Land, a U.S. scientist and inventor, designed a film configuration that included a sealed pod containing processing chemicals in a viscous jelly or paste form to permit virtually dry processing inside

The
Polaroid
process

the camera and yield a positive print within a minute or less of exposure. Land demonstrated (1947), and through his Polaroid Corporation marketed (1948), a camera and materials that realized this system. It used a positive sheet and negative emulsion, the latter being discarded after use. An instant-print colour film (Polacolor) was introduced in 1963 and an integral single-sheet colour film in 1972. After the mid-1970s other manufacturers offered similar instant-print processes. In 1977 Polaroid introduced an 8-mm colour movie film, and in 1982 it introduced still transparency films that permit rapid processing outside the camera.

Black-and-white diffusion transfer. The Polaroid process is based on negative paper carrying a silver halide emulsion and a nonsensitized, positive sheet containing development nuclei. After the exposure the two sheets are brought into intimate contact by being pulled between a pair of pressure rollers. These rupture a sealed pod (attached to the positive sheet) to spread processing chemicals—in the form of a viscous jelly—between the two sheets. This reagent develops a negative image and causes the silver salts from the unexposed areas to diffuse into the positive layer and deposit metallic silver on the development nuclei. After about 30 seconds to one minute the negative and positive sheets are peeled apart and the negative can be discarded. In special versions of the process the negative may be washed and treated to give a conventional negative for normal enlarging.

In the original Polaroid instant-picture process the material was a dual roll of negative and positive sheets. Later versions of this peel-apart process use film packs and sheet films. They require special cameras incorporating the pressure rollers that operate the spread of processing jelly while the peel-apart sandwich is fed out of the camera. Special camera backs with this mechanism allow the use of Polaroid materials in professional cameras taking interchangeable film holders or magazines. Peel-apart Polaroid systems include high-speed emulsions, high-contrast, process, transparency, and scientific materials.

Silver diffusion-transfer processes were invented in 1939 in Belgium and Germany and were used for a number of years in office copying systems until superseded by dry copying processes.

The Polacolor process. Polaroid colour film has a larger number of active layers, including a blue-sensitive silver halide emulsion backed by a layer consisting of a yellow dye-developer compound, a green-sensitive layer backed by a layer of magenta dye-developer, and a red-sensitive layer backed by a cyan dye-developer. The dye-developer in each case consists of dye molecules (not colour couplers) chemically linked to developing agent molecules.

After exposure and activation by the alkaline jelly, the dye-developer molecules in each layer migrate into the adjacent silver halide layer. Development of exposed silver halide to a negative image anchors the dye-developer molecule in position. Dye-developer molecules in unexposed image areas are not used up by development but migrate into the receiving layer of the positive material. There they are immobilized, remaining as dye images corresponding to a positive of each silver halide layer in the negative film. The dyes thus re-create a full-colour positive image. The process depends on the controlled diffusion of the dye-developer molecules, achieved by spacing layers and balanced exposure and development time. Developing takes about one minute. Polacolor films include an 8 × 10-inch material for regular studio and view cameras (with separate processing machinery) and giant formats of 20 × 24 inches or even larger for special cameras.

Single-sheet process. The Polaroid single-sheet, or integral, films contain all the negative and positive layers in a single preassembled film unit that is exposed through the transparent positive layer. The unit incorporates a viscous processing reagent that acts in principle similarly to the chemistry of the Polacolor process. It includes "opacifying" dyes and a highly opaque white pigment that together protect the negative layers against light during processing outside the camera. The pigment provides a background to the positive image after the dye-developer molecules from the negative layers have migrated into the receiving layer.

Other constituents of the system neutralize residual active chemicals after processing, for all chemistry remains within the single-sheet print. The print size is about $3\frac{1}{2} \times 4\frac{1}{4}$ inches, the effective image size about $3\frac{1}{8} \times 3\frac{1}{8}$ inches. The Eastman Kodak and Fuji Photo Film companies also have marketed single-sheet films and cameras that accept each other's films. These materials and cameras are not compatible with the Polaroid products.

Autoprocess materials. Because it requires cameras or camera backs with integral processing facilities, the instant-picture process is not suitable for conditions precluding immediate processing of the picture (e.g., in underwater or space photography), nor is it suitable for motion-picture or 35-mm cameras. Alternative procedures suggested to overcome this usually involve some form of semidry rapid-access processing. The Polaroid Autoprocess system uses 35-mm film in standard cartridges to fit any 35-mm camera. After exposure the film is driven through a table-top processor, which sandwiches the film with a stripping film carrying a thin layer of processing fluid. The latter processes the negative image, causes the formation of a positive image by a diffusion-transfer process, and then releases the negative layers, which are finally removed from the film (together with residual chemicals) by the stripping material. The transparencies remaining on the 35-mm film are immediately ready for viewing and projection. Black-and-white as well as colour systems (by an additive process) are available in this form.

Applications. Instant-picture processes have an advantage in applications that need quick access to a finished print. The initial field of the process was amateur snapshooting and instant portraits, from which evolved the taking of identification pictures for work and security passes. Such passes are made with special cameras that record a portrait together with personal details on a composite print that is then laminated to form a tamper-proof identity card. In studio photography instant prints provide a quick method of making exposure tests and checking the effect of lighting. Large- and giant-format Polacolor prints are used in studio portraiture; normal instant prints have numerous commercial applications. Instant pictures are also widely used in the laboratory to record experimental setups, for photomicrography and for infrared photography; for instant endoscopy and for clinical and forensic records; for rapid copying of normal colour transparencies; and for instant hard copy of oscilloscope, video, and computer graphic displays. Autoprocess transparencies are used for the rapid production of colour or black-and-white slides for lectures and publication and in various fields of scientific photography (including photomicrography) relying on the use of conventional 35-mm (usually single-lens reflex) cameras.

SPECIAL PHOTOSENSITIVE SYSTEMS

The high working speed (efficiency of converting light into permanent images) of silver halides makes them almost the only materials suitable for camera use. Numerous light-sensitive systems not using silver have been known since the beginning of photography. In view of silver's high price, a number of substitute systems have grown in importance, and new ones have appeared. Most of them are limited to office copying, microfilming, the graphic arts, and other applications in which flat copy is reproduced.

Electrophotography. Electrophotography covers a number of processes that rely on photoconductive substances whose electrical resistance decreases when light falls on them. A layer of such a substance with a grounded backing plate is given a uniform electrostatic charge in the dark. When a light image is projected onto the surface, the photoconductor allows the electrostatic charge to leak away in proportion to the exposure. This leaves an "image" charge that can be converted, in various ways, into a visible image.

In xerography the photoconductive layer is selenium, and the image is made visible by dusting the plate with an electrostatically charged powder (toner) having a charge that is the opposite of that of the electrostatic image. The powder adheres to the image portions only and is then transferred to a sheet of plain paper also under the in-

Principles
of
xerography

fluence of electrostatic fields. A final heat treatment fuses the powder into the paper for a permanent picture. The process usually makes a positive from a positive original. In office copying machines (the main application of xerography) the whole operating sequence is programmed and automated. A zinc oxide-coated paper may replace the selenium plate; if so, the pigment powder deposit is fused directly into the paper surface.

The process is used mainly for line images without intermediate tones between black and white. Modified procedures permit continuous-tone reproduction and—with coloured pigments—also colour printing.

In the electrophotographic process a transparent thermoplastic serves as the photoconductive layer. After the plastic is charged and exposed, the residual electrostatic charge forms stresses in the thermoplastic. Controlled heating deforms the surface in the image areas into a grain pattern, which is frozen into the plastic on cooling. The resulting image is light-scattering and is viewed by reflection or in special projection systems.

Colloid and photopolymer processes. A comparatively early non-silver process depended on organic colloid (gum or gelatin) treated with a bichromate. Exposure to light hardened the gelatin, rendering it insoluble, while unexposed portions could be washed away with warm water, leaving a relief image.

Photopolymer systems substitute a plastic precursor in place of the gelatin. The plastic precursor polymerizes to an insoluble plastic when exposed to light, and the unexposed soluble material is washed out by a suitable solvent. Photopolymer processes have been adapted for forming resists (protective coatings) for etching, as, for instance, in the manufacture of printed circuits. In indirect photopolymer systems a light-sensitive substance is mixed with a plastic precursor and on exposure decomposes into compounds that initiate polymerization of the plastic. The polymerizable layer may include a pigment for a final coloured image. Superimposing colour images derived from separation negatives can yield positives; systems of this type are used for quick colour proofing in photomechanical reproduction.

Diazonium processes. A diazo, or dyeline, process depends on the decomposition by light of organic diazonium salts. These salts can also couple with certain other compounds to form dyes. After exposure only the exposed (and decomposed) diazonium salt forms dye, producing a positive image from a positive original.

The materials are usually papers or transparent supports impregnated with the required chemicals. They are mainly sensitive to ultraviolet rays and can therefore be handled by normal tungsten lighting.

The light-decomposition of diazonium compounds also produces gaseous nitrogen. This phenomenon is utilized in vesicular processes that incorporate the diazonium compound in a thermoplastic layer. The nitrogen slowly diffuses out of this layer, but, if heat is applied immediately after exposure, the expanding nitrogen gas forms minute light-scattering bubbles visible as an image. The scattering power corresponds to the exposure. Further general exposure, after the plastic has cooled, decomposes the residual diazonium compound with gradual diffusion of the nitrogen out of the layer, destroying the latter's light sensitivity. This process and thermal dyeline systems are dry-processing instant-access systems and are used for making microfilm duplicates.

Photochromic systems. Certain dyelike substances can exist in a colourless and a coloured state. They are called photochromic compounds. The coloured state is formed by exposure to radiations of a certain wavelength. The compound reverts to its colourless state either in the dark or on treatment with radiation of a different wavelength. This reversibility is a primary characteristic of photochromism, and it is an instant-image system involving no processing.

Photochromic systems are used in microrecording (see below *Microfilming and microreproduction*). As the change of state takes place on a molecular level, the images are practically grain-free, and resolution is limited only by the resolving power of the optical system being used. Pho-

tochromic materials can be negative- or positive-working. With some photochromic compounds the dye image can be rendered permanent by optical or other treatment.

Glasses containing certain metal compounds also act as photochromic materials. Exposure to light breaks down the compounds into metal that forms a visible (and permanent) image in the glass. Another type of photochromic glass contains silver halide crystals dispersed in the glass melt. The action of light decomposes the silver halide, forming a visible silver deposit. The halogen cannot escape from the glass, so it recombines with the silver in the dark and the image fades. Such photochromic glasses are incorporated in automatic light-control devices; light transmission decreases as the intensity of the light reaching the glass rises. Such glass has found use in certain types of sunglasses.

Electronic photography. As television cameras and recorders became more compact, home video recording began to replace home movies in the amateur field in the late 1970s. Video recording of still images was incidental to this; it became widely involved in the storage of computer-generated or computer-processed images on magnetic tape or discs, for instance, in satellite photography, radiography, image scanning in picture transmission, and photomechanical reproduction.

A still video camera resembling traditional photographic apparatus (the Sony Mavica single-lens reflex) was first demonstrated in 1981. It uses a fast-rotating magnetic disc, two inches in diameter, recording on it up to 50 separate video images formed in a solid-state device in the camera. The images can be played back through a television receiver or monitor, or converted to paper in a printer that uses the video signals to control a printout device. Apart from being a potential rival to instant-picture photography, electronic records of this type are capable of direct transmission via telephone lines. Thus the process is of interest to press photographers, who can transmit pictures from their cameras directly to newspaper editorial offices without intermediate processing. The magnetic record also is able to directly control halftone engraving machines to engrave printing plates or cylinders.

SPECIAL TECHNIQUES AND APPLIED PHOTOGRAPHY

High-speed and stroboscopic photography. High-speed photography is generally concerned with exposure times shorter than about $\frac{1}{1,000}$ second (one millisecond) and often exposures shorter than $\frac{1}{1,000,000}$ second (one microsecond). This field partly overlaps that of high-speed cinematography—sequences of very short exposures. Exposure times can be reduced by high-speed shutter systems or by short-duration flash sources.

High-speed photography, together with high-speed cinematography, aids in the study of missiles, explosions, nuclear reactions, and other phenomena of military and scientific interest. In industry high-speed pictures show up movement phases of machinery, relays, and switches; dynamic fractures of materials or insulation breakdown; and, in natural science studies, flight movement of birds and insects.

High-speed shutters. The shortest exposure with mechanical shutters is about $\frac{1}{4,000}$ second. Special high-speed shutter systems are magneto-optical, electro-optical, or electronic. A magneto-optical shutter (Faraday shutter) consists of a glass cylinder placed inside a magnetic coil between two crossed polarizing filters; so long as the filters remain crossed, virtually no light can pass through. A brief current pulse through the coil generates a magnetic field that rotates the light's plane of polarization in the cylinder so that during the pulse some light passes through the second polarizing filter. The electro-optical shutter (Kerr cell) is made up of a liquid cell of nitrobenzene fitted with electrodes and again placed between two crossed polarizers. An electric pulse applied to the electrodes changes the polarization properties of the nitrobenzene so that this arrangement again transmits light. Minimum exposure time is around five nanoseconds (5×10^{-9} second). Image converter tubes electronically transmit and amplify an optical image focused on one end of a tube onto a phosphorescent screen at the other end. Electrons flow in the tube only in

Reversibility of the photochromic systems

Principle of the Kerr cell

the presence of an electric field, which can be controlled by short-time pulses down to a few nanoseconds.

High-speed light sources. The shortest electronic-flash duration is around one microsecond. Spark discharges in air between electrodes yield still shorter exposures; discharge voltage may go up to tens or hundreds of thousands of volts. Short-duration pulses applied to X-ray tubes produce X-ray flashes for high-speed radiography. The shortest exposures are between 20 and 50 nanoseconds. Special switching modes turn lasers into high-speed sources with durations down to a fraction of a nanosecond.

Synchronization. Generally the event photographed is made to trigger the exposure (the current pulse to operate the shutter or flash or spark source) to ensure correct synchronization. Examples are bullets interrupting a light beam to a photocell or self-luminous phenomena (explosions) triggering the system via a photocell circuit. The event and the exposure may be also triggered together by a signal from a common source.

Stroboscopic photography. Electronic-flash units designed to flash in rapid succession (up to several hundred times a second) can photograph a moving subject in front of a stationary camera with its shutter open to yield multiple images of successive movement phases. The technique has been used in pictorial and sports photography (e.g., recording the movement of dancers or golfers) and for analyzing movement cycles without a motion-picture camera. Stroboscopic flash can be synchronized with a selected movement phase of an object in rapid cyclic motion (e.g., a rotating machine component); the moving component illuminated in this way then appears stationary.

Aerial photography. Photographs from airborne or spaceborne vehicles either provide information on ground features for military and other purposes (reconnaissance) or record the dimensional disposition of such features (surveying).

Reconnaissance
photography for
capturing
detail

Reconnaissance photographs call for maximum sharpness and detail rendering. Infrared films are often used to bring out details not discernible visually. In nonmilitary applications such photographs may reveal ecological factors (tree diseases, crop variations) and traces of archaeological sites not visible from the ground. Such shots are generally taken with cameras using 5- or 9½-inch roll film in large magazines, built into the aircraft and operated electrically by the pilot or other crew member, or automatically at set intervals. Some systems incorporate a shutterless technique; the film runs continuously past a slit at a rate matched exactly to the image movement in the camera's focal plane as the aircraft flies over the ground (image motion compensation).

Aerial survey is a systematic procedure of photographing the ground for map production; exposures are made at intervals to partly overlap the view of successive pictures. The individual photographs are enlarged to the same degree and then assembled in a precise mosaic. Aerial photographs taken under precisely specified conditions can serve for accurate measurements of ground details by stereoscopic evaluation (see below *Stereoscopic and three-dimensional photography*).

Satellite and space photography. Satellites orbiting the Earth record changing meteorologic features (weather satellites) and broadcast the video images to ground stations where they may be recorded on magnetic tape or converted to hard-copy pictures by suitable printers. Video cameras in spacecraft sent to record surface details of other planets similarly scan electronically the view taken in by a lens and beam the scanning signals back to Earth, where they are recorded and reconverted to visible images. The signals are usually processed electronically to enhance image information and detail. Such enhancement often brings out more information than can be recorded by conventional photography. Similar techniques are used by military satellites monitoring ground features from high orbits above the Earth.

Underwater photography. Underwater photography requires either special watertight cameras or pressure-resistant housings for normal cameras. In both cases camera functions are controlled through pressure-tight glands. A flat glass or plastic window is usually in front of the

camera lens. The red and yellow absorption of the water more than a few feet below the surface turns colour photographs taken by daylight into virtually monochrome shots; hence artificial light is essential to show up the full colour range of fish and other underwater subjects. Light sources are battery-powered tungsten or tungsten-halogen lamps or electronic flash units (again in self-contained pressure-proof housings). For comfortable handling the weight of the housing with camera is adjusted to slight negative buoyancy. Complete camera and lighting outfits may be built into sledgelike or torpedo-like units with an electric or compressed-air motor for self-propulsion through the water.

Since the refractive index ratio of glass to water is lower than for glass to air, the light-bending power of a glass lens is less in water than in air. This factor reduces the lens's angle of view and makes objects appear at about three-fourths of their actual distance. This difference must be allowed for in focusing—possibly by a suitably calibrated distance scale or by fitting the housing with a compensating porthole, which acts as a diverging lens.

Underwater cameras with lenses designed for direct contact with the water eliminate the air space between the lens and the porthole. Such lenses can cover wider angles of view without distortion, but they do not give sharp images outside the water.

Underwater
cameras

Close-range and large-scale photography. Near photography to reveal fine texture and detail covers several ranges: (1) close-up photography at image scales between 0.1 and 1 (one-tenth to full natural size); (2) macrophotography between natural size and 10 to 20× magnification, using the camera lens on its own; (3) photomicrography at magnifications above about 20×, combining the camera with a microscope; and (4) electron micrography with an electron microscope at magnifications of 10,000 to 1,000,000×, which involves photography of the electron microscope's phosphor screen or placing a photographic emulsion inside the vacuum chamber of the electron microscope to record directly the image formed by the electron beams.

Close-up and macrophotography. Supplementary close-up lenses or extension tubes (placed between the lens and camera body) allow the camera to focus on near distances for large scales of reproduction. Special close-up rangefinders or distance gauges establish exactly the correct camera-to-subject distance and precise framing of the subject field. Special simple close-up cameras, as in fingerprint recording and certain fields of medical photography, are permanently set to a fixed near distance and have a distance gauge or similar device built in. Screen-focusing cameras (view and single-lens reflex) need no such aids, as the finder screen shows the precise focus and framing.

Extension tubes or extension bellows or both or "macro" lenses of extended focusing range are used for the macro range of distances. For optimum image quality macrophotographic lenses specially corrected for large image scales may be used or the camera lens reversed back to front.

Photomicrography. There are two principal methods of photographing through a microscope. In the first the camera, with its lens focused at infinity, is lined up in the optical axis of the microscope, which is also focused visually on infinity. In the other method the camera without lens is positioned behind the microscope eyepiece, which is focused to project the microscope image directly onto the film.

Special photomicrographic cameras generally employ the second method. Microscope adapters to provide a light-tight and rigid connection between the camera and microscope are available for both systems. Such microadapters may incorporate their own shutter and a beam splitter system for viewing and focusing of the microscope image through a focusing telescope. Photomicrographs are the essential adjunct to all microscopy to record biologic, bacteriologic, physical, and other observations in black-and-white or colour.

Stereoscopic and three-dimensional photography. Visual three-dimensional depth is perceived partly because of the fact that the human eyes see a scene from two viewpoints separated laterally by about 2½ inches. The two views show slightly different spatial relationships between

Basis of
depth
perception

near and distant objects (parallax); the visual process fuses these stereoscopic views into a three-dimensional impression. A similar impression is obtained by viewing a pair of stereoscopic photographs taken with two cameras or a twin camera with lenses $2\frac{1}{2}$ inches apart, so that the left eye sees only the picture taken by the left-hand lens and the right eye only that of the right-hand lens. Binocular viewers or stereo-selective projection systems permit such viewing.

Stereo photographs can also be combined in a single picture by splitting up the images into narrow vertical strips and interlacing them. On superimposing a carefully aligned lenticular grid on the composite picture, an observer directly sees all the strips belonging to the left-eye picture with the left eye and all the strips belonging to the right-eye picture with the right eye. Such parallax stereograms are seen in display advertising in shop windows. They also can be reproduced in print, overlaid by a lenticular pattern embossed in a plastic covering layer.

Photogrammetry makes use of stereo photography in measuring dimensions and shapes of ground objects in depth, as from successive exposure pairs made during an aerial survey flight. If all exposure parameters, including flying height, ground separation between exposures, and focal length of the aerial camera lens are known, the height of each ground feature can be measured. Photogrammetric plotting instruments do this and draw height contour curves of all features for aerial maps. Similar photogrammetric evaluation of stereo photographs of nearby subjects can also be made. For instance, it is possible to reconstruct accurately the scene of a highway accident. In industry a photogrammetric plot of an automobile model can be fed into a computer to program the machine tools that will shape the full-scale motor body components.

Infrared photography. Images formed by infrared and heat radiations can be recorded directly, on films sensitive to them, or indirectly, by photographing the image produced by some other system registering infrared radiation.

Silver halide emulsions can be sensitized to infrared rays with wavelengths up to around 1,200 nanometres (one nanometre is $\frac{1}{1,000,000}$ of a millimetre). The usual sensitivity range is 800 to 1,000 nanometres. Direct infrared-recording aerial photography shows up ground features of differential infrared reflection but similar light reflection (e.g., different types of foliage) and cuts through haze and mist. Special colour films with an infrared-sensitive layer and processed to colours different from the natural rendering (false-colour films) show up such differences still more clearly. In forensic photography infrared pictures reveal ink alterations in forgeries, differentiate stains, and help to identify specific textiles and other materials. In medicine infrared photographs show subcutaneous blood vessels, as the skin is transparent to infrared.

With suitable equipment it is possible to convert an infrared image into one visible on a fluorescent screen, where it can be photographed. In infrared scanner systems a moving mirror scans the object or scene and focuses the radiation onto an infrared-sensitive cell. The cell generates electric signals to modulate a light source, which, in turn, scans a photographic film or paper synchronously with the mirror. The resulting image records hotter and colder parts of the object as lighter and darker areas and can accurately establish actual temperatures of subject details. This system has been used to record temperature variations in the skin for the diagnosis of cancer.

Ultraviolet photography. Invisible shortwave ultraviolet radiations can be recorded directly or used in fluorescence photography. For direct ultraviolet recording the photographically useful wavelength range lies between 400 nanometres (visible violet) and about 200 nanometres and needs special optical systems transparent to ultraviolet rays (quartz, silica, or fluoride elements or combinations thereof). Light sources rich in ultraviolet such as mercury vapour lamps—with an ultraviolet-transmitting, but visually opaque, filter in front of the camera lens—ensure that the photograph records only the ultraviolet-reflecting characteristics of the subject.

Fluorescence photography records the glow or visible light given off by certain substances when they are irra-

diated by ultraviolet rays. The object is illuminated only by ultraviolet rays by screening out the visible light with a filter that transmits only ultraviolet radiation, and another filter that absorbs the ultraviolet rays is placed over the camera lens, permitting only the visible light (fluorescence) to be recorded on the film. Normal lenses and panchromatic or colour materials are used.

Ultraviolet photography can identify or separate pigments and fabrics and can detect forgeries of documents. Fluorescence photography can identify dyes, stains, specific chemical substances, and fluorescent components in microscope specimens. Ultraviolet microscopy offers increased resolution through the shorter wavelength radiations employed. Aerial and satellite photography by ultraviolet can show up ultraviolet-reflective ground features.

Radiography and other radiation recording techniques. Silver halide emulsions are sensitive to X rays, gamma rays, and charged particles emitted by radioactive substances. Some of these rays penetrate visually opaque materials to varying degrees to show up internal structures. Radiography covers techniques of recording the subsurface features of objects.

X-ray radiography. X rays (wavelengths between $\frac{1}{100}$ and $\frac{1}{100,000}$ that of visible light) are produced by high-voltage electron streams bombarding an electrode in a vacuum tube. For radiography the object to be recorded is placed between an X-ray tube and the film; the film registers the differential absorption of the X rays by the object's internal structure as a projection shadowgraph.

The most familiar application is in medicine for diagnosis and recording, including dental radiography. Industrial radiography permits nondestructive inspection of castings, welds, and engineering structures.

Gamma radiography. The technique of gamma-ray radiography is similar to that of X-ray radiography but relies on rays emitted by radioactive substances. Gamma rays have wavelengths from 100 to 1,000 times shorter than X rays and correspondingly greater penetrating power. Small gamma-ray sources are placed in areas inaccessible to X-ray tubes, such as inside pipelines. In all radiographic applications the exposure occurs under conditions of normal light, from which the radiographic film is protected by a light-tight (but radiation-transparent) wrapping.

Autoradiography. Autoradiography records the distribution of radioactive materials in botanical and histological specimens placed in contact with a photographic emulsion. This technique has been applied to the study of metabolism of plants and animals; it records the activity of organic compounds of radioactive isotopes introduced into the system of the plant or animal. In engineering studies autoradiography can be used to follow the transfer of radioactive substances from one surface to another in lubrication. The technique also has applications in machining and other metal-treatment processes.

Nuclear-track recording. Tracks of subatomic particles, such as protons, electrons, and mesons, produced by nuclear reactions, can be recorded by photographic means. The most common technique is to photograph the visible traces of such tracks in bubble or spark chambers with special camera and lens arrangements. Different arrangements can provide for coverage of large fields or the recording of tracks simultaneously from several directions for three-dimensional reconstruction.

Particle tracks can be recorded directly in thick (up to one millimetre) emulsion layers or in emulsion stacks (up to 20 inches) carried in high-altitude balloons and in spacecraft and satellites. Special processing procedures are required to deal with these emulsion thicknesses.

Astronomical photography. By the cumulative effect of light received over a long period, a photographic emulsion can record celestial objects too faint to be visible. Before radio telescopes (see MEASUREMENT AND OBSERVATION, PRINCIPLES, METHODS, AND INSTRUMENTS OF), photography was the only way of detecting many such objects.

Astronomical cameras are film- or plate-holding units built onto high-power telescopes, typically reflecting systems. The telescopes run on precision, clock-driven mounts to keep the optical axis stationary with respect to the sky area as the Earth rotates during an exposure time,

telescopes

which can run into several hours. For increased recording sensitivity, the telescope image may be intensified electronically.

Astronomical photographs taken through narrow-band colour filters—including infrared or ultraviolet transmitting filters—show selective emission characteristics of stars. In the case of the Sun and of planets, such photographs can reveal some surface details not observable by white light. Colour photographs reveal colours not directly visible because the intensity of starlight is too low to stimulate the eye's colour-vision mechanism.

Spectrography records the composition of light emitted by stars and other objects, the star image of the telescope being photographed through a diffraction grating, a device that disperses white light into constituent wavelengths. Elements present in the star or the gas mantle surrounding it can be identified from their characteristic spectral lines. Displacement of such lines from their known wavelength position can indicate the velocity with which the distant stellar systems recede from or approach the Earth.

Microfilming and microreproduction. Microfilming is the copying of documents, drawings, and other such matter at a reduced scale—typically 1:15 to 1:42—for compact storage. Complete microreproduction systems include methods of filing the film copies for easy retrieval and reenlargement. Various duplication methods allow microfilm records to be extensively distributed.

Documents, periodicals, and other printed matter are usually microfilmed on 16-mm film with an image size between 10×14 and 14×20 mm in a copying camera taking 100-foot lengths of film. Engineering drawings of high information content are microfilmed on 35-mm unperforated film with a standard image size of 32×45 mm. Films of up to 105 mm in width are also used. Automated microfilm cameras run continuously, documents being fed onto a moving band carried past the camera at a steady speed while the film runs past a slit at a matched rate.

Readers and reader printers are desk-top projectors that display the frames reenlarged to about natural size on a back projection screen. In a reader printer the image may also be projected on sensitized paper for full-size enlargements. Advanced readers have elaborate retrieval systems based on frame coding and run the microfilm rolls through at high speed until a specific searched image is reached.

Aperture cards or standard-size transparent jackets store microfilm images as single frames or groups of frames. Such unitized microfilms permit easier indexing and retrieval. Certain 35-mm microfilm cameras photograph the original document directly on film premounted in an aperture card and processed on the spot.

Widely used is the unitized microfiche system, which carries up to 98 frames, each about 9×12 mm, on a 4×6 -inch sheet of film. The microfiche camera repositions the film frame by frame after every exposure. Microfiche with a larger frame can also be produced by jacketing strips of 16-mm microfilm in multichannel plastic jackets 4×6 inches in size.

For greater space saving, microfilm images may be reduced beyond 1:100 on high-resolution photochromic image materials. Extreme fine-grain silver copies then hold 3,000 to 4,000 individual frames on a single 4×6 -inch film. This method, useful for complex catalogs and like purposes, offers easy retrieval of individual frames but requires a high-magnification reader.

THE PHOTOGRAPHY INDUSTRY

Present-day manufacture of cameras and other photographic equipment is concentrated in mass-production plants that make most of the components (camera bodies, lenses, shutters, and other parts) on largely automated machines; the components are then assembled by semiskilled or skilled labour. Smaller manufacturers of low- and medium-priced cameras obtain components for assembly from such specialist suppliers as shutter manufacturers and lens producers. High-quality precision cameras are produced on a smaller scale with automated fabrication of the engineering components but much more extensive manual assembly by highly skilled technicians. Components and functions of every camera are tested at every

production stage; less expensive cameras are usually batch-tested by a sampling procedure.

The raw material for lens manufacture covers a range of optical glasses of different optical characteristics. About 10 major worldwide glass producers supply the several dozen optical firms offering lenses of well-known brands. The glass is cast into blanks for specific lens elements and ground and polished to the required exact specifications, with the elements assembled in metal (sometimes plastic) mounts. Extensive production tests and optical performance checks safeguard quality standards.

Film base is produced either by coating a solution of the base material on large drums, where it solidifies (film casting), or by extrusion of plastics, such as polyester, in film extruders. For print materials, paper of suitable purity is coated with a barium sulfate emulsion in gelatin, to provide a smooth white surface, and then with the silver halide emulsion. Silver halide emulsions are made by mixing silver nitrate with a solution of alkali halide—typically potassium bromide and iodide—in gelatin. The silver halide then precipitates out as fine crystals. After cooling to a jelly, shredding, and washing, the emulsion is remelted and treated to increase speed and contrast. Colour sensitizers (and colour couplers for colour emulsions) and additives are introduced, and the gelatin emulsion is machine-coated on wide continuous webs of paper or film. Generally several coatings are applied—up to a dozen for certain colour films. Operations from emulsion mixing onward are carried on in total darkness. After cooling and drying, the material is batch-tested for consistent characteristics and then is cut and packed.

Photofinishing laboratories process most amateur and some professional photographers' films and prints. In the 1980s, virtually all of the total business of the laboratories in the United States was in colour processing.

Photofinishing laboratories use machines that carry the films in spliced-together lengths or on racks through successive tanks of the processing solutions. Prints are usually made to standard formats on automatic enlargers, taking both the negatives and the paper in continuous rolls. The paper rolls of 250 or 500 feet are processed in continuous-strip processors, which deliver prints dry and ready for automatic cutting. Many printers have automatic exposure measurement based on overall negative density, with automatically controlled colour correction for colour negatives. High-capacity colour printers of this type can produce 2,000 to 3,000 prints per hour. Coding systems identify individual films and corresponding prints by customer or order number for final re-sorting. More exacting processing services grade colour negatives before printing by light transmission measurements through different colour filters; the resulting exposure data may be punched as edge codes in the film itself or programmed on perforated paper tape. When the tape is run through the printer together with the film, the perforations directly control the colour exposures and corrections. Advanced automatic printing systems may involve electronically controlled image enhancement.

Enlargements to special sizes and colour printing for professional photographers require individual enlarging by skilled personnel on conventional enlargers with advanced automation features of focusing, exposure measurement, and colour control. Other processing services include duplication of transparencies, various types of photocopying (partly on coin-operated copiers in public places), microfilming, and microfilm processing. (L.A.Ma./Ed.)

The evolution of photographic techniques is traced in H. FOX TALBOT (WILLIAM HENRY FOX TALBOT), *The Pencil of Nature* (1844-46, reprinted 1969), the inventor's account, illustrated with 24 actual calotypes; GEORGES POTONNÉE, *The History of the Discovery of Photography* (1936, reissued 1973; originally published in French, 1925), a detailed account of the early days of photography; JOSEF MARIA EDER, *History of Photography* (1945, reprinted 1978; originally published in German, 4th rev. ed., 2 vol., 1932), a pioneer Austrian work that deals primarily with the scientific and technological development of photography; BEAUMONT NEWHALL (ed.), *On Photography: A Sourcebook of Photo History in Facsimile* (1956), an anthology of the inventors' own accounts of various processes; D.B. THOMAS, *The First Negatives: An Account of the Discovery and Early Use of the Negative-Positive Photographic Process* (1964); JOSEPH S. FRIEDMAN, *The History of Color Photography*, 2nd ed. (1968); HELMUT GERNSHEIM, *The History of Photography from the Camera Obscura to the Beginning of the Modern Era*, 2nd ed. (1969), the first part of which was revised as *The Origins of Photography* (1982); and GAIL BUCKLAND, *Fox Talbot and the Invention of Photography* (1980).

Camera history and technology is outlined in LESLIE D. STROEBEL, *View Camera Technique*, 5th ed. (1986), on the use of studio and field cameras in industrial, commercial, and other applications; MICHEL AUER, *The Illustrated History of the Camera from 1839 to the Present*, trans. from French and adapted by D.B. TUBBS (1975); BRIAN COE, *Cameras: From Daguerreotypes to Instant Pictures* (1978); and EATON S. LOTHROP, JR., *A Century of Cameras from the Collection of the International Museum of Photography at George Eastman House*, rev. and expanded ed. (1982).

Lenses and optical principles are described in C.B. NEBLETTE and ALLEN E. MURRAY, *Photographic Lenses*, rev. ed. (1973); ARTHUR COX, *Photographic Optics*, 15th rev. ed. (1974), classic manual of lens principles and use; and SIDNEY F. RAY, *The Photographic Lens* (1979), an introduction.

Film and the techniques of taking pictures are examined in WALTER NURNBERG, *Lighting for Photography: Means and Methods*, 16th rev. ed. (1968, reissued 1971); and MICHAEL LANGFORD, *Basic Photography*, 5th ed. (1986), and *Advanced Photography: A Grammar of Techniques*, 4th ed. (1980), manuals of practical technique for professional photographers.

Film processing and printing are the subject of D.H.O. JOHN and G.T.J. FIELD, *A Textbook of Photographic Chemistry* (1963), basics of chemical reactions in black-and-white processing; C.I. JACOBSON and R.E. JACOBSON, *Developing: The Negative-Technique*, 18th ed. (1972), manual of all aspects of negative technique; C.I. JACOBSON and L.A. MANNHEIM, *Enlarging*, 22nd ed. (1975), manual of positive technique in black and white and colour; L.F.A. MASON, *Photographic Processing Chemistry*, 2nd ed. (1975), detailed treatment of processing mechanisms and reactions; GRANT HAIST, *Modern Photographic Processing*, 2 vol. (1979), chemistry and technology of black-and-white and colour processing; and JAN ARNOW, *Handbook of Alternative Photographic Processes* (1982).

Colour photography is treated in LOUIS WALTON SIPLEY, *A Half Century of Color* (1951); RALPH M. EVANS, W.T. HANSON, JR., and W. LYLE BREWER, *Principles of Color Photography* (1953), principles of colour rendering, response, and reproduction; D.A. SPENCER, *Colour Photography in Practice*, rev. ed. by L.A. MANNHEIM and VISCOUNT HANWORTH (1966, reissued 1975), containing both theory and practical techniques; R.W.G. HUNT, *The Reproduction of Colour*, 3rd ed. (1975), a standard handbook on colour photography, television, and printing, with moderately advanced mathematical treatment; and GERT KOSHOFFER, *Farbfotografie*, 3 vol. (1981), a complete historical review, including a lexicon of equipment and materials.

Special photographic techniques and applications are the focus of HAROLD E. EDGERTON and JAMES R. KILLIAN, JR., *Flash! Seeing the Unseen by Ultra High-Speed Photography*, 2nd ed. (1954), and *Moments of Vision: The Stroboscopic Revolution in Photography* (1979, reprinted 1984); J. BERGNER, E. GELBKE, and W. MEHLISS, *Practical Photomicrography* (1966; originally published in German, 1961), a comprehensive manual; R.F. SAXE, *High-Speed Photography* (1966), a condensed but comprehensive survey; JOHN BRACKETT HERSEY (ed.), *Deep-Sea Photography* (1967); C.R. ARNOLD, P.J. ROLLS, and J.C.J. STEWART, *Applied Photography* (1971), on scientific applications; H. LOU GIBSON, *Photography by Infrared*, 3rd ed. (1978); and GJON MILLI, *Gjon Mili: Photographs and Recollections* (1980), on stroboscopic photography. (H.E.R.G./L.A.Ma.)

Photosynthesis

Photosynthesis, which means putting together with light, is the process by which green plants and certain other organisms transform light energy into chemical energy. During photosynthesis in green plants, light energy is captured and used to convert water, carbon dioxide, and minerals into oxygen and energy-rich organic compounds.

It would be impossible to overestimate the importance of photosynthesis in the maintenance of life on Earth. If photosynthesis ceased, there would soon be little food or other organic matter on Earth. Most organisms would disappear, and in time the Earth's atmosphere would become nearly devoid of gaseous oxygen. The only organisms able to exist under such conditions would be the chemosynthetic bacteria, which can utilize the chemical energy of certain inorganic compounds and thus are not dependent on the conversion of light energy.

Photosynthesis also is responsible for the "fossil fuels" (*i.e.*, coal, oil, and gas) that power industrial society. In past ages, green plants and small organisms that fed on plants increased faster than they were consumed, and their remains were deposited in the Earth's crust by sedimentation and other geological processes. There, protected from oxidation, these organic remains were slowly converted to fossil fuels. These fuels not only provide much of the energy used in factories, homes, and transportation, but

they also serve as the raw material for plastics and other synthetic products. Unfortunately, modern civilization is using up in a few centuries the excess of photosynthetic production accumulated over millions of years.

Requirements for food, materials, and energy in a world where human population is rapidly growing have created a need to increase both the amount of photosynthesis and the efficiency of converting photosynthetic output into products useful to people. One response to these needs—the so-called "Green Revolution"—has achieved enormous improvements in agricultural yield through the use of chemical fertilizers, pest and plant disease control, plant breeding, and mechanized tilling, harvesting, and crop processing. This effort has limited severe famines to a few areas of the world despite rapid population growth, but it has not eliminated widespread malnutrition.

A second agricultural revolution, based on plant genetic engineering, may lead to increases in plant productivity and thereby partially alleviate malnutrition. Since the 1970s, molecular biologists have possessed the means to manipulate a plant's genetic material (DNA) to achieve improvements in disease and drought resistance, product yield and quality, frost hardiness, and other desirable properties. In the future, such genetic engineering may result in improvements in the process of photosynthesis.

This article is divided into the following sections:

The process of photosynthesis: the light reactions	803		

GENERAL CHARACTERISTICS

Development of the idea. The study of photosynthesis began in 1771, with observations made by the English chemist Joseph Priestley. Priestley had burned a candle in a closed container until the air within the container could no longer support combustion. He then placed a sprig of mint plant in the container and discovered that after several days the mint had produced some substance (later recognized as oxygen) that enabled the confined air to again support combustion. In 1779 the Dutch physician Jan Ingenhousz expanded upon Priestley's work, showing that the plant must be exposed to light if the combustible substance (*i.e.*, oxygen) was to be restored; he also demonstrated that this process required the presence of the green tissues of the plant.

In 1782 it was demonstrated that the combustion-supporting gas (oxygen) was formed at the expense of another gas, or "fixed air," which had been identified the year before as carbon dioxide. Gas-exchange experiments in 1804 showed that the gain in weight of a plant grown in a carefully weighed pot was the sum of carbon, which came entirely from absorbed carbon dioxide, and water taken up by plant roots. Almost half a century passed before the concept of chemical energy developed sufficiently to permit the discovery (in 1845) that light energy from

the sun is stored as chemical energy in products formed during photosynthesis.

Overall reaction of photosynthesis. In chemical terms, photosynthesis is a light-energized oxidation-reduction process. (Oxidation refers to the removal of electrons from a molecule; reduction refers to the gain of electrons by a molecule.) In plant photosynthesis, the energy of light is used to drive the oxidation of water (H₂O), producing oxygen gas (O₂), hydrogen ions (H⁺), and electrons. Most of the removed electrons and hydrogen ions ultimately are transferred to carbon dioxide (CO₂), which is reduced to organic products. Other electrons and hydrogen ions are used to reduce nitrate and sulfate to amino and sulfhydryl groups in amino acids, which are the building blocks of proteins. In most green cells, carbohydrates—especially starch and the sugar sucrose—are the major direct organic products of photosynthesis. The overall reaction in which carbohydrates—represented by the general formula (CH₂O)—are formed during plant photosynthesis can be indicated by the following equation:

This equation is merely a summary statement, for the process of photosynthesis actually involves numerous complex reactions. These reactions occur in two stages:

the "light" stage, consisting of photochemical (*i.e.*, light-dependent) reactions; and the "dark" stage, comprising chemical reactions controlled by enzymes (organic catalysts). During the first stage, the energy of light is absorbed and used to drive a series of electron transfers, resulting in the synthesis of the energy-rich compound adenosine triphosphate (ATP) and the electron donor reduced nicotinamide dinucleotide phosphate (NADPH). During the dark stage, the ATP and NADPH formed in the light reactions are used to reduce carbon dioxide to organic carbon compounds. This assimilation of inorganic carbon into organic compounds is called carbon fixation.

During the 20th century, comparisons between photosynthetic processes in green plants and in certain photosynthetic sulfur bacteria provided important information about the photosynthetic mechanism. Sulfur bacteria use hydrogen sulfide (H_2S) as a source of hydrogen atoms and produce sulfur instead of oxygen during photosynthesis. The overall reaction is

In the 1930s Dutch biologist Cornelis van Niel recognized that the utilization of carbon dioxide to form organic compounds was similar in the two types of photosynthetic organisms. Suggesting that differences existed in the light-dependent stage and in the nature of the compounds used as a source of hydrogen atoms, he proposed that hydrogen was transferred from hydrogen sulfide (in bacteria) or water (in green plants) to an unknown acceptor (called A), which was reduced to H_2A . During the dark reactions, which are similar in both bacteria and green plants, the reduced acceptor (H_2A) reacted with carbon dioxide (CO_2) to form carbohydrate (CH_2O) and to oxidize the unknown acceptor to A. This putative reaction can be represented as:

Van Niel's proposal was important because the popular (but incorrect) theory had been that oxygen was removed from carbon dioxide (rather than hydrogen from water) and that carbon then combined with water to form carbohydrate (rather than the hydrogen from water combining with CO_2 to form CH_2O).

By 1940 chemists were using heavy isotopes to follow the reactions of photosynthesis. Water marked with an isotope of oxygen (^{18}O) was used in early experiments. Plants that photosynthesized in the presence of water containing H_2^{18}O produced oxygen gas containing ^{18}O ; those that photosynthesized in the presence of normal water produced normal oxygen gas. These results provided strong support for van Niel's theory that the oxygen gas produced during photosynthesis is derived from water.

Basic products of photosynthesis. As has been stated, carbohydrates are the most important direct organic product of photosynthesis in the majority of green plants. The formation of a simple carbohydrate, glucose, is indicated by a chemical equation,

Little free glucose is produced in plants; instead, glucose units are linked together to form starch or are joined with fructose, another sugar, to form sucrose (see BIOCHEMICAL COMPONENTS OF ORGANISMS: *Carbohydrates*).

Not only carbohydrates, as was once thought, but also amino acids, proteins, lipids (or fats), pigments, and other organic components of green tissues are synthesized during photosynthesis. Minerals supply the elements (*e.g.*, nitrogen, N; phosphorus, P; sulfur, S) required to form these compounds. Chemical bonds are broken between oxygen (O) and carbon (C), hydrogen (H), nitrogen, and sulfur, and new bonds are formed in products that include gaseous oxygen (O_2) and organic compounds. More energy is required to break the bonds between oxygen and other elements (*e.g.*, in water, nitrate, and sulfate) than is released when new bonds form in the products. This

difference in bond energy accounts for a large part of the light energy stored as chemical energy in the organic products formed during photosynthesis. Additional energy is stored in making complex molecules from simple ones.

Evolution of the process. Although life and the quality of the atmosphere today depend on photosynthesis, it is likely that green plants evolved long after the first living cells. When the Earth was young, electrical storms and solar radiation probably provided the energy for the synthesis of complex molecules from abundant simpler ones, such as water, ammonia, and methane. The first living cells probably evolved from these complex molecules (see LIFE). For example, the accidental joining together (condensation) of the amino acid glycine and the fatty acid acetate may have formed complex organic molecules known as porphyrins; these molecules, in turn, may have evolved further into coloured molecules called pigments; *e.g.*, chlorophylls of green plants, bacteriochlorophyll of photosynthetic bacteria, hemin (the red pigment of blood), and cytochromes, a group of pigment molecules essential in both photosynthesis and cellular respiration.

Primitive coloured cells then had to evolve mechanisms for using the light energy absorbed by their pigments. At first, the energy may have been used immediately to initiate reactions useful to the cell. As the process for utilization of light energy continued to evolve, however, a larger part of the absorbed light energy probably was stored as chemical energy, to be used to maintain life. Green plants, with their ability to use light energy to convert carbon dioxide and water to carbohydrates and oxygen, are the culmination of this evolutionary process.

The first oxygenic (oxygen-producing) cells probably were the cyanophytes, or "blue-green algae," which appeared about 2,000,000,000 to 3,000,000,000 years ago. These microscopic organisms are believed to have greatly increased the oxygen content of the atmosphere, making possible the development of aerobic (oxygen-using) organisms. Cyanophytes are prokaryotic cells; that is, they contain no distinct, membrane-enclosed subcellular particles (organelles), such as nuclei and chloroplasts. Green plants, by contrast, are composed of eukaryotic cells, in which the photosynthetic apparatus is contained within membrane-bound chloroplasts. There is a theory that the first photosynthetic eukaryotes were red algae that may have developed when nonphotosynthetic eukaryotic cells engulfed cyanophytes. Within the host cells, these cyanophytes are thought to have evolved into chloroplasts. Alternatively, the ancestors of chloroplasts in green plants may have been another oxygenic prokaryote like *Prochloron*, an organism that has been found only growing symbiotically inside ascidians.

There are a number of photosynthetic bacteria that are not oxygenic (*e.g.*, the sulfur bacteria previously discussed). The evolutionary pathway that led to these bacteria diverged from the one that resulted in oxygenic organisms. In addition to the absence of oxygen production, nonoxygenic photosynthesis differs from oxygenic photosynthesis in two other ways: light of longer wavelengths is absorbed and used by pigments called bacteriochlorophylls, and reduced compounds other than water (such as hydrogen sulfide or organic molecules) provide the electrons needed for the reduction of carbon dioxide.

Bacterial
photo-
synthesis

FACTORS THAT INFLUENCE

THE RATE OF PHOTOSYNTHESIS

The rate of photosynthesis is defined in terms of the rate of oxygen production either per unit mass (or area) of green plant tissues or per unit weight of total chlorophyll. The amount of light, the carbon dioxide supply, the temperature, the water supply, and the availability of minerals are the most important environmental factors that directly affect the rate of photosynthesis in land plants. The rate of photosynthesis also is determined by the plant species and its physiological state—*e.g.*, its health, its maturity, and whether or not it is in flower.

Light intensity and temperature. As has been mentioned, the complex mechanism of photosynthesis includes a photochemical, or light-dependent, stage and an enzymatic, or dark, stage that involves chemical reactions.

Origin of
oxygen gas
in photo-
synthesis

These stages can be distinguished by studying the rates of photosynthesis at various degrees of light saturation (*i.e.*, intensity) and at different temperatures. Over a range of moderate temperatures and at low to medium light intensities (relative to the normal range of the plant species), the rate of photosynthesis increases as the intensity increases and is independent of temperature. As the light intensity increases to higher levels, however, the rate becomes increasingly dependent on temperature and less dependent on intensity; light "saturation" is achieved at a specific light intensity, and the rate then is dependent only on temperature if all other factors are constant. In the light-dependent range before saturation, therefore, the rate of photosynthesis is determined by the rates of photochemical steps. At high light intensities, some of the chemical reactions of the dark stage become rate-limiting. At light saturation, rate increases with temperature until a point is reached beyond which no further rate increase can occur. In many land plants, moreover, a process called photorespiration occurs at high light intensities and temperatures. Photorespiration competes with photosynthesis and limits further increases in the rate of photosynthesis, especially if the supply of water is limited (see below *Photorespiration*).

Carbon dioxide. Included among the rate-limiting steps of the dark stage of photosynthesis are the chemical reactions by which organic compounds are formed using carbon dioxide as a carbon source. The rates of these reactions can be increased somewhat by increasing the carbon dioxide concentration. During the past century, the level of carbon dioxide in the atmosphere has been rising due to the extensive combustion of fossil fuels. The atmospheric level of carbon dioxide climbed from about 0.028 percent in 1860 to 0.0315 percent by 1958 (when improved measurements began), and to 0.034 percent by 1981. This increase in carbon dioxide directly increases plant photosynthesis, but the size of the increase depends on the species and physiological condition of the plant. Furthermore, if increasing levels of atmospheric carbon dioxide result in climatic changes, including increased global temperatures as some meteorologists predict, these changes will affect photosynthesis rates.

Water. For land plants, water availability can function as a limiting factor in photosynthesis and plant growth. Besides the requirement for water in the photosynthetic reaction itself, water is transpired from the leaves; that is, water evaporates from the leaves to the atmosphere via the stomates. These stomates are small openings through the leaf epidermis, or outer skin; they permit the entry of carbon dioxide but also allow the exit of water vapour. The stomates open and close according to the physiological needs of the leaf. In hot and arid climates the stomates may close to conserve water, but this closure limits the entry of carbon dioxide and hence the rate of photosynthesis, while the wasteful process of photorespiration may increase. If the level of carbon dioxide in the atmosphere increases, more carbon dioxide could enter through a smaller opening of the stomates, so that more photosynthesis could occur with a given supply of water.

Minerals. Several minerals are required for healthy plant growth and for maximum rates of photosynthesis. Nitrate or ammonia, sulfate, phosphate, iron, magnesium, and potassium are required in substantial amounts for the synthesis of amino acids, proteins, coenzymes, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), chlorophyll and other pigments, and other essential plant constituents. Smaller amounts of such elements as manganese, copper, and chlorine are required in photosynthesis. Some other trace elements are needed for various nonphotosynthetic functions in plants.

Internal factors. Each plant species adapts to a range of environmental factors. Within this normal range of conditions, complex regulatory mechanisms in the plant's cells adjust the activities of enzymes (*i.e.*, organic catalysts). These adjustments maintain a balance in the overall photosynthetic process and control it in accordance with the needs of the whole plant. With a given plant species, for example, doubling the carbon dioxide level might cause a temporary increase of nearly twofold in the rate of photosynthesis; a few hours later, however, the rate might fall to

the original level because photosynthesis had made more sucrose than the rest of the plant could use. By contrast, another plant species provided with such carbon dioxide enrichment might be able to use more sucrose and would continue to photosynthesize and to grow faster throughout most of its life cycle.

ENERGY EFFICIENCY OF PHOTOSYNTHESIS

The energy efficiency of photosynthesis is the ratio of the energy stored to the energy of light absorbed. The chemical energy stored is the difference between that contained in gaseous oxygen and organic compound products and the energy of water, carbon dioxide, and other reactants. The amount of energy stored can only be estimated because many products are formed, and these vary with the plant species and environmental conditions. If the equation for glucose formation given earlier is used to approximate the actual storage process, the production of one mole (*i.e.*, 6.02×10^{23} molecules; abbreviated *N*) of oxygen and one-sixth mole of glucose results in the storage of about 117 kilocalories (kcal) of chemical energy. This amount must then be compared to the energy of light absorbed to produce one mole of oxygen in order to calculate the efficiency of photosynthesis.

Light can be described as a wave of particles known as photons; these are units of energy, or light quanta. The quantity *N* photons is called an einstein. The energy of light varies inversely with the length of the photon waves; that is, the shorter the wavelength, the greater the energy content. The energy (*e*) of a photon is given by the equation $e = hc/\lambda$, where *c* is the velocity of light, *h* is Planck's constant, and λ is the light wavelength. The energy (*E*) of an einstein is $E = Ne = Nhc/\lambda = 28,600/\lambda$, when *E* is in kilocalories and λ is given in nanometres (nm; 1 nm = 10^{-9} metres). An einstein of red light with a wavelength of 680 nm has an energy of about 42 kcal. Blue light has a shorter wavelength and therefore more energy than red light. Regardless of whether the light is blue or red, however, the same number of einsteins are required for photosynthesis per mole of oxygen formed. The part of the solar spectrum used by plants has an estimated mean wavelength of 570 nanometres; therefore, the energy of light used during photosynthesis is approximately 28,600/570, or 50 kilocalories per einstein.

In order to compute the amount of light energy involved in photosynthesis, one other value is needed: the number of einsteins absorbed per mole of oxygen evolved. This is called the quantum requirement. The minimum quantum requirement for photosynthesis under optimal conditions is about nine. Thus the energy used is 9×50 , or 450 kilocalories per mole of oxygen evolved. Therefore, the estimated maximum energy efficiency of photosynthesis is the energy stored per mole of oxygen evolved—117 kilocalories—divided by 450; that is, 117/450, or 26 percent.

The actual percentage of solar energy stored by plants is much less than the maximum energy efficiency of photosynthesis. An agricultural crop in which the biomass (total dry weight) stores as much as 1 percent of total solar energy received on an annual area-wide basis is exceptional, although a few cases of higher yields (perhaps as much as 3.5 percent in sugarcane) are reported. There are several reasons for this difference between the predicted maximum efficiency of photosynthesis and the actual energy stored in biomass. First, more than half of the incident sunlight is composed of wavelengths too long to be absorbed, while some of the remainder is reflected or lost to the leaves. Consequently, plants can at best absorb only about 34 percent of the incident sunlight. Second, plants must carry out a variety of physiological processes in such nonphotosynthetic tissues as roots and stems; these processes, as well as cellular respiration in all parts of the plant, use up stored energy. Third, rates of photosynthesis in bright sunlight sometimes exceed the needs of the plants, resulting in the formation of excess sugars and starch. When this happens, the regulatory mechanisms of the plant slow down the process of photosynthesis, allowing more absorbed sunlight to go unused. Fourth, in many plants, energy is wasted by the process of photorespiration. Finally, the growing season may last only a few

Energy of
light

Quantum
require-
ment

months of the year; sunlight received during other seasons is not used. Furthermore, it should be noted that if only agricultural products (e.g., seeds, fruits, and tubers, rather than total biomass) are considered as the end product of the energy conversion process of photosynthesis, the efficiency falls even further.

CHLOROPLASTS, THE PHOTOSYNTHETIC UNITS OF GREEN PLANTS

The process of plant photosynthesis takes place entirely within the chloroplasts. Detailed studies of the role of these organelles date from the work of the British biochemist Robert Hill. About 1940 Hill discovered that green particles obtained from broken cells could produce oxygen from water in the presence of light and a chemical compound, such as ferric oxalate, able to serve as an electron acceptor. This process is known as the Hill reaction. During the 1950s Daniel Arnon and other American biochemists prepared plant cell fragments in which not only the Hill reaction but also the synthesis of the energy-storage compound ATP occurred. In addition, the coenzyme NADP was used as the final acceptor of electrons, replacing the nonphysiological electron acceptors used by Hill. His procedures were refined further so that individual small pieces of isolated chloroplast membranes, or lamellae, could perform the Hill reaction. These small pieces of lamellae were then fragmented into pieces so small that they performed only the light reactions of the photosynthetic process. It is now possible also to isolate the entire chloroplast so that it can carry out the complete process of photosynthesis, from light absorption, oxygen formation, and the reduction of carbon dioxide to the formation of glucose and other products.

Structural features. The intricate structural organization of the photosynthetic apparatus is essential for the efficient performance of the complex process of photosynthesis. The chloroplast is enclosed in a double outer membrane, and its size approximates a spheroid about 2,500 nanometres thick and 5,000 nanometres long. Some single-celled algae have one chloroplast that occupies more than half the cell volume. Leaf cells of higher plants contain many chloroplasts, each approximately the size of the one in some algal cells.

When thin sections of a chloroplast are examined under the electron microscope (Figure 1), several features are apparent. Chief among these are the intricate internal membranes (i.e., the lamellae) and the stroma, a colourless matrix in which the lamellae are embedded. Also visible are starch granules, which appear as dense bodies.

The stroma is basically a solution of enzymes and small molecules. The dark reactions occur in the stroma, the

soluble enzymes of which catalyze the conversion of carbon dioxide and minerals to carbohydrates and other organic compounds. The capacity for carbon fixation and reduction is lost if the outer membrane of the chloroplast is broken, allowing the stroma enzymes to leak out.

A single lamella, which contains all the photosynthetic pigments, is approximately 10–15 nanometres thick. The lamellae exist in more-or-less flat sheets, a few of which extend through much of the length of the chloroplast. Examination of cross sections of lamellae under the electron microscope shows that their edges are joined to form closed hollow disks that are called thylakoids ("saclike"). The chloroplasts of most higher plants have regions, called grana, in which the thylakoids are very tightly stacked. When viewed by electron microscopy at an oblique angle, the grana appear as stacks of disks. When viewed in cross section (Figure 1), it is apparent that some thylakoids extend from one grana through the stroma into other grana. The thin aqueous spaces inside the thylakoids are believed to be connected with each other via these stroma thylakoids. These thylakoid spaces are isolated from the stroma spaces by the relatively impermeable lamellae.

The light reactions occur exclusively in the thylakoids. The complex structural organization of lamellae is required for proper thylakoid function; intact thylakoids apparently are necessary for the formation of ATP. Thylakoids that have been broken down to smaller units can no longer form ATP, even when the conversion of light into chemical energy occurs during electron transport in these units. Such lamellar fragments can carry out the Hill reaction, with the transfer of electrons from water to NADP^+ .

Chemical composition of lamellae. *Lipids.* Lamellae consist of about equal amounts of lipids and proteins. About one-fourth of the lipid portion of the lamellae consists of pigments and coenzymes; the remainder consists of various lipids, including polar compounds such as phospholipids and galactolipids. These polar lipid molecules have "head" groups that attract water (i.e., are hydrophilic) and fatty acid "tails" that are oil soluble and repel water (i.e., are hydrophobic). When polar lipids are placed in an aqueous environment, they can line up with the fatty acid tails side by side. A second layer of phospholipids forms tail-to-tail with the first, establishing a lipid bilayer in which the hydrophilic heads are in contact with the aqueous solution on each side of the bilayer. Sandwiched between the heads are the hydrophobic tails, creating a hydrophobic environment from which water is excluded. This lipid bilayer is an essential feature of all biological membranes (see CELLS: *The plasma membrane*). The hydrophobic parts of proteins and lipid-soluble cofactors and pigments are dissolved or embedded in the lipid bilayer. Lamellar membranes can function as electrical insulating material and permit a charge, or potential difference, to develop across the membrane. Such a charge can be a source of chemical or electrical energy.

Approximately one-fifth of the lamellar lipids are chlorophyll molecules; one type, chlorophyll *a*, is more abundant than the second type, chlorophyll *b*. The chlorophyll molecules are specifically bound to small protein molecules. Most of these chlorophyll-proteins are "light-harvesting" pigments. These absorb light and pass its energy on to special chlorophyll *a* molecules that are directly involved in the conversion of light energy to chemical energy. When one of these special chlorophyll *a* molecules is excited by light energy (as described later), it gives up an electron. There are two types of these special chlorophyll *a* molecules: one, called P_{680} , has an absorption spectrum that peaks at 684 nanometres; the other, called P_{700} , shows an absorption peak at 700 nanometres.

Although chlorophylls are the main light-absorbing molecules in green plants, other pigments such as carotenes and carotenoids (which are responsible for the yellow-orange colour of carrots) also can absorb light and may supplement chlorophyll as the light-absorbing molecules in some plant cells. The light energy absorbed by these pigments must be passed to chlorophyll before conversion to chemical energy can occur.

Proteins. Many of the lamellar proteins are components of the chlorophyll-protein complexes described above.

Electron
carrier
molecules

Other proteins include enzymes and protein-containing coenzymes. Enzymes are required as organic catalysts for specific reactions within the lamellae. Protein coenzymes, also called cofactors, include important electron carrier molecules called cytochromes, which are iron-containing pigments with the pigment portions attached to protein molecules. During electron transfer, an electron is accepted by an iron atom in the pigment portion of a cytochrome molecule, which thus is reduced; then the electron is transferred to the iron atom in the next cytochrome carrier in the electron transfer chain, thus oxidizing the first cytochrome and reducing the next one in the chain.

In addition to the metal atoms found in the pigment portions of cytochrome molecules, metal atoms also are found in other protein molecules of the lamellae. In proteins with a total molecular weight of 900,000 (based on the weight of hydrogen as one), there are two atoms of manganese, 10 atoms of iron, and six atoms of copper. These metal atoms are required for the catalytic activity of some of the enzymes important in photosynthesis. The manganese atoms are involved in water-splitting and oxygen formation. Both copper- and iron-containing proteins function in electron transport between water and the final electron-acceptor molecule of the light stage of photosynthesis, an iron-containing protein called ferredoxin. Ferredoxin is a soluble component in the chloroplasts. In its reduced form, it gives electrons directly to the systems that reduce nitrate and sulfate and via NADPH to the system that reduces carbon dioxide. A copper-containing protein called plastocyanin (PC) carries electrons at one point in the electron transport chain. PC molecules are water soluble and can move through the inner space of the thylakoids, carrying electrons from one place to another.

Quinones. Small molecules called plastoquinones are found in substantial numbers in the lamellae. Like the cytochromes, quinones have important roles in carrying electrons between the components of the light reactions. Since they are lipid soluble, they can diffuse through the membrane. They can carry one or two electrons and, in their reduced form (with added electrons), they carry hydrogen atoms that can be released as hydrogen ions when the added electrons are passed on, for example, to a cytochrome.

THE PROCESS OF PHOTOSYNTHESIS: THE LIGHT REACTIONS

Light absorption and energy transfer. The light energy absorbed by a chlorophyll molecule excites some electrons within the structure of the molecule to higher energy levels, or excited states. Light of shorter wavelength (such as blue) has more energy than light of longer wavelength (such as red), so that absorption of blue light creates an excited state of higher energy. A molecule raised to this higher energy state quickly gives up the "extra" energy as heat and falls to its lowest excited state. This lowest excited state is similar to that of a molecule that has just absorbed the longest wavelength light capable of exciting it. In the case of chlorophyll *a*, this lowest excited state corresponds to that of a molecule that has absorbed red light of about 680 nanometres.

The return of a chlorophyll *a* molecule from its lowest excited state to its original low-energy state (ground state) requires the release of the extra energy of the excited state. This can occur in one of several ways. In photosynthesis, most of this energy is conserved as chemical energy by the transfer of an electron from a special chlorophyll *a* molecule (P_{680} or P_{700}) to an electron acceptor. When this electron transfer is blocked by inhibitors, such as the herbicide dichlorophenylmethylurea (DCMU), or by low temperature, the energy can be released as red light. Such re-emission of light is called fluorescence. The examination of fluorescence from photosynthetic material in which electron transfer has been blocked has proved to be a useful tool for scientists studying the light reactions.

The pathway of electrons. The general features of a widely accepted mechanism for photoelectron transfer, in which two light reactions occur during the transfer of electrons from water to carbon dioxide, were proposed by Robert Hill and Derek Bendall, in 1960. A modified

scheme for this mechanism is shown in Figure 2. In this figure the vertical scale represents the relative potential (in volts) of various cofactors of the electron-transfer chain to be oxidized or reduced. Molecules that in their oxidized form have the strongest affinity for electrons (*i.e.*, are strong oxidizing agents) are near the bottom of the scale. Molecules that in their oxidized form are difficult to reduce are near the top of the scale; once they have accepted electrons, these molecules are strong reducing agents.

Figure 2: Flow of electrons during the light reaction stage of photosynthesis. Arrows pointing upward represent light reactions that increase the chemical potential; arrows slanting downward represent flow of electrons via carriers in the membrane (see text).

The actual photochemical steps are indicated by the two vertical arrows, which signify that the special pigments P_{680} and P_{700} receive light energy from the light-harvesting chlorophyll-protein molecules and are raised in energy from their ground state to excited states, symbolized as P_{680}^* and P_{700}^* . In their excited state, these pigments are extremely strong reducing agents that quickly transfer electrons to the first acceptor. These first acceptors also are strong reducing agents and rapidly pass electrons to more stable carriers. In light reaction I the first acceptor may be pheophytin (Ph; a molecule similar to chlorophyll), which also has a strong reducing potential and quickly transfers electrons to the next acceptor. Q_A and Q_B are special quinones, similar to plastoquinone. They receive electrons from pheophytin and pass them to the intermediate electron carriers, which include the plastoquinone (PQ) pool and the cytochromes b and f (Cyt_b and Cyt_f) associated in a complex with an iron-sulfur protein (Fe-S).

In light reaction I the identity of the first electron acceptor, X, is not known. It passes electrons on to iron-sulfur proteins (Fe-S-protein) in the lamellar membrane, after which the electrons flow to ferredoxin (Fd), a small, water-soluble iron-sulfur protein. When $NADP^+$ and a suitable enzyme are present, two ferredoxin molecules, carrying one electron each, transfer two electrons to $NADP^+$, which picks up a proton (*i.e.*, a hydrogen ion) and becomes NADPH.

Each time a P_{680} or P_{700} molecule gives up an electron, it returns to its ground (unexcited) state, but with a positive charge due to the loss of the electron. These positively charged ions are extremely strong oxidizing agents that remove an electron from a suitable donor. The P_{680}^+ of light reaction II is capable of taking electrons from water in the presence of appropriate catalysts. There is good evidence that two or more manganese atoms complexed with protein are involved in this catalysis, taking four electrons from two water molecules (with release of four hydrogen ions). The manganese-protein complex gives up these electrons one at a time via an unidentified carrier Z to P_{680}^+ , reducing it to P_{680} . When manganese is selectively removed by chemical treatment, the thylakoids lose the capacity to oxidize water, but all other parts of the electron pathway remain intact.

In light reaction I, P_{700}^+ recovers electrons from plastocyanin (PC), which in turn receives them from intermediate carriers, including the plastoquinone pool and cytochrome b and cytochrome f molecules. The pool of intermediate carriers may receive electrons from water via light reaction II and Q_A and Q_B . Transfer of electrons from water to ferredoxin via the two light reactions and interme-

Electron
transfer
chains

of P_{680}^+
and P_{700}^+

diate carriers is called noncyclic electron flow. Alternately, electrons may be transferred only by light reaction I, in which case they are recycled from ferredoxin back to the intermediate carriers (dashed line, Figure 2). This process is called cyclic electron flow.

Evidence of two light reactions. Many lines of evidence support the concept of electron flow via two light reactions. An early study by the U.S. biochemist Robert Emerson employed the algae *Chlorella*, which was illuminated with red light alone, with blue light alone, and with red and blue light at the same time. Oxygen evolution was measured in each case. It was substantial with blue light alone but not with red light alone. With both red and blue light together, the amount of oxygen evolved far exceeded the sum of that seen with blue and red light alone. These experimental data pointed to the existence of two types of light reactions that, when operating in tandem, would yield the highest rate of oxygen evolution. It is now known that light reaction I can use light of a slightly longer wavelength than red ($\lambda = 680$ nanometres), while light reaction II requires light with a wavelength of 680 nanometres or shorter.

Since those early studies, the two light reactions have been separated in many ways, including separation of the membrane particles in which each reaction occurs. As discussed previously, lamellae can be disrupted mechanically into fragments that absorb light energy and break the bonds of water molecules (*i.e.*, oxidize water) to produce oxygen, hydrogen ions, and electrons. These electrons can be transferred to ferredoxin, the final electron acceptor of the light stage. No transfer of electrons from water to ferredoxin occurs if the herbicide DCMU is present. The subsequent addition of certain reduced dyes (*i.e.*, electron donors) restores the light reduction of NADP^+ but without oxygen production, suggesting that light reaction I but not light reaction II is functioning. It is now known that DCMU blocks the transfer of electrons from Q_A to the PQ pool (see Figure 2).

When treated with certain detergents, lamellae can be broken down into smaller particles capable of carrying out single light reactions. One type of particle can absorb light energy, oxidize water, and produce oxygen (light reaction II), but a special dye molecule must be supplied to accept the electrons. In the presence of electron donors, such as a reduced dye, a second type of lamellar particle can absorb light and transfer electrons from the electron donor to ferredoxin (light reaction I).

Photosystems I and II. The structural and photochemical properties of the minimum particles capable of performing light reactions I and II have received much study. Treatment of lamellar fragments with neutral detergents releases these particles, designated photosystem I and photosystem II, respectively. Subsequent harsher treatment (with charged detergents) and separation of the individual polypeptides with electrophoretic techniques has helped identify the components of the photosystems. Each photosystem consists of a light-harvesting complex and a core complex. Each core complex contains a reaction centre with the pigment (either P_{700} or P_{680}) that can be photochemically oxidized, together with electron acceptors and electron donors. In addition, the core complex has some 40 to 60 chlorophyll molecules bound to proteins. In addition to the light absorbed by the chlorophyll molecules in the core complex, the reaction centres receive a major part of their excitation from the pigments of the light-harvesting complex.

Quantum requirements. The quantum requirements of the individual light reactions of photosynthesis are defined as the number of light photons absorbed for the transfer of one electron. The quantum requirement for each light reaction has been found to be approximately one photon. The total number of quanta required, therefore, to transfer the four electrons that result in the formation of one molecule of oxygen via the two light reactions should be four times two, or eight. It appears, however, that additional light is absorbed and used to form ATP by a cyclic photophosphorylation pathway (see next section). The actual quantum requirement, therefore, probably is nine to 10.

THE PROCESS OF PHOTOSYNTHESIS:

THE CONVERSION OF LIGHT ENERGY TO ATP

The electron transfers of the light reactions provide the energy for the synthesis of two compounds vital to the dark reactions: NADPH and ATP. The previous section explained how noncyclic electron flow results in the reduction of NADP^+ to NADPH. In this section, the synthesis of the energy-rich compound ATP is described.

ATP is formed by the addition of a phosphate group to a molecule of adenosine diphosphate (ADP); or to state it in chemical terms, by the phosphorylation of ADP. This reaction requires a substantial input of energy, much of which is captured in the bond that links the added phosphate group to ADP. Because light energy powers this reaction in the chloroplasts, the production of ATP during photosynthesis is referred to as photophosphorylation.

Unlike the production of NADPH, the photophosphorylation of ADP occurs in conjunction with both cyclic and noncyclic electron flow (see Figure 2). In fact researchers speculate that the sole purpose of cyclic electron flow may be for photophosphorylation, since this process involves no net transfer of electrons to reducing agents. The relative amounts of cyclic and noncyclic flow may be adjusted in accordance with changing physiological needs for ATP and reduced ferredoxin and NADPH in chloroplasts. In contrast to electron transfer in light reactions I and II, which can occur in membrane fragments, intact thylakoids are required for efficient photophosphorylation. This requirement stems from the special nature of the mechanism linking photophosphorylation to electron flow in the lamellae.

The theory relating the formation of ATP to electron flow in the membranes of both chloroplasts and mitochondria (the organelles responsible for ATP formation during cellular respiration) was first proposed by the English biochemist Peter Mitchell. This chemiosmotic theory has been somewhat modified to fit later experimental facts, and there is still debate over many of the details. The general features, however, are widely accepted. A central feature is the formation of a hydrogen ion (proton) concentration gradient and an electrical charge across intact lamellae. The potential energy stored by the proton gradient and electrical charge is then used to drive the energetically unfavourable conversion of ADP and inorganic phosphate (P_i) to ATP and water.

The manganese-protein complex associated with light reaction II is exposed to the interior of the thylakoid. Consequently, the oxidation of water during light reaction II leads to release of hydrogen ions (protons) into the inner thylakoid space. Furthermore, it is likely that photoreaction II entails the transfer of electrons across the lamella toward its outer face, so that when plastoquinone molecules are reduced they can receive protons from the outside of the thylakoid. When these reduced plastoquinone molecules are oxidized, giving up electrons to the cytochrome-iron-sulfur complex, protons are released inside the thylakoid. Because the lamella is impermeable to them, the release of protons inside the thylakoid by oxidation of both water and plastoquinone leads to a higher concentration of protons inside the thylakoid than outside it. In other words, a proton gradient is established across the lamella. The movement of electrons (negatively charged particles) outward across the lamella during both light reactions results in the establishment of an electrical charge across the lamella. (Some scientists believe, however, that the proton gradient and electrical charge required for ATP formation need not be between inner and outer thylakoid space but only within the membrane.)

An enzyme complex located partly in and on the lamellae catalyzes the reaction in which ATP is formed from ADP and inorganic phosphate. The reverse of this reaction is catalyzed by an enzyme called ATP-ase, hence the enzyme complex is sometimes called an ATP-ase complex. It is also called the coupling factor. It consists of hydrophilic polypeptides (F_1), which project from the outer surface of the lamellae, and hydrophobic polypeptides (F_0), which are embedded inside the lamellae. Researchers hypothesize that F_0 forms a channel that permits protons to flow through the lamellar membrane to F_1 . The enzymes in F_1

The chemiosmotic theory of ATP formation

Lamellar fragments

then catalyze ATP formation, using both the proton supply and the lamellar transmembrane charge.

In summary, the use of light energy for ATP formation occurs indirectly: a proton gradient and electrical charge—built up in or across the lamellae as a consequence of electron flow in the light reactions—provide the energy to drive the synthesis of ATP from ADP and P_i .

THE PROCESS OF PHOTOSYNTHESIS: CARBON FIXATION AND REDUCTION

The assimilation of carbon into organic compounds is the result of a complex series of enzymatically regulated chemical reactions—the dark reactions. This term is something of a misnomer, for these reactions can take place in either light or darkness. Furthermore, some of the enzymes involved in the so-called dark reactions become inactive in prolonged darkness.

Elucidation of the carbon pathway. Radioactive isotopes of carbon (^{14}C) and phosphorus (^{32}P) have been valuable in identifying the intermediate compounds formed during carbon assimilation. A photosynthesizing plant does not strongly discriminate between the natural carbon isotopes and ^{14}C . During photosynthesis in the presence of $^{14}\text{CO}_2$, the compounds formed become labelled with the radioisotope. During very short exposures, only the first intermediates in the carbon-fixing pathway become labelled. Early investigations showed that some radioactive products were formed even when the light was turned off and the $^{14}\text{CO}_2$ was added just afterward in the dark, confirming the nature of the carbon fixation as a “dark” reaction.

The U.S. biochemist Melvin Calvin, a Nobel Prize recipient for his work on the carbon reduction cycle, allowed green plants to photosynthesize in the presence of radioactive carbon dioxide for a few seconds under various experimental conditions. Products that became labelled with radioactive carbon during Calvin's experiments included a three-carbon compound called 3-phosphoglycerate (abbreviated PGA, see Figure 3), sugar phosphates, amino acids, sucrose, and carboxylic acids. When photosynthesis was stopped after two seconds, the principal radioactive product was PGA, which therefore was identified as the first compound formed during carbon dioxide fixation in green plants.

Further studies with ^{14}C as well as with inorganic phosphate labelled with ^{32}P led to the mapping of the carbon fixation and reduction pathway called the reductive pentose phosphate cycle (RPP cycle). An additional pathway for carbon transport in certain plants was later discovered in other laboratories (see below *Carbon fixation via C_4 acids*). All the steps in these pathways can be carried out in the laboratory by isolated enzymes in the dark. Several steps require the ATP or NADPH generated by the light reactions. In addition, some of the enzymes are fully active only when conditions simulate those in green cells

exposed to light. In vivo, these enzymes are active during photosynthesis but not in the dark.

The reductive pentose phosphate cycle. *Overall reaction.* The RPP cycle, in which carbon is fixed, reduced, and utilized, involves the formation of intermediate sugar phosphates in a cyclic sequence (Figure 3). One complete RPP cycle incorporates three molecules of carbon dioxide and produces one molecule of the three-carbon compound glyceraldehyde-3-phosphate (Gal3P). This three-carbon sugar phosphate usually is either exported from the chloroplasts or is converted to starch (dashed lines).

Figure 3 summarizes the main steps that take place during one complete turn of the RPP cycle. ATP and NADPH formed during the light reactions are utilized for key steps in this pathway and provide the energy and reducing equivalents (*i.e.*, electrons) to drive the sequence in the direction shown. For each molecule of carbon dioxide that is fixed, two molecules of NADPH and three molecules of ATP from the light reactions are required. The overall reaction can be represented as follows:

The cycle is composed of four stages: (1) carboxylation, (2) reduction, (3) isomerization/condensation/dismutation, and (4) phosphorylation.

Carboxylation. The initial incorporation of carbon dioxide, which is catalyzed by the enzyme ribulose 1,5-bisphosphate carboxylase, proceeds by the addition of carbon dioxide to the five-carbon compound ribulose 1,5-bisphosphate (RuBP) and the splitting of the resulting unstable six-carbon compound into two molecules of PGA, a three-carbon compound. As indicated in Figure 3, this reaction occurs three times during each complete turn of the cycle; thus, six molecules of PGA are produced.

Reduction. The six molecules of PGA are first phosphorylated with ATP by the enzyme PGA-kinase, yielding six molecules of 1,3-diphosphoglycerate (DPGA). These then are reduced with NADPH and the enzyme glyceraldehyde-3-phosphate dehydrogenase to give six molecules of Gal3P. These reactions are the reverse of two steps of the process glycolysis in cellular respiration (see METABOLISM).

Isomerization/condensation/dismutation. For each complete RPP cycle, one of the Gal3P molecules, with its three carbon atoms, is the net product and may be transferred out of the chloroplast or converted to starch inside the chloroplast (dashed lines, Figure 3). For the cycle to regenerate, the other five Gal3P molecules (with a total of 15 carbon atoms) must be converted back to three molecules of five-carbon RuBP. The conversion of Gal3P to RuBP begins with a complex series of enzymatically regulated reactions (not shown in Figure 3) that lead to the synthesis of the five-carbon compound ribulose-5-phosphate (Ru5P). The occurrence of this complex series, which entails isomerization, condensation, and dismutation reactions, is indicated by the broken arrow in Figure 3.

Phosphorylation. The three molecules of Ru5P are converted to the carboxylation substrate, RuBP, by the enzyme phosphoribulokinase, using ATP. This reaction, shown below, completes the cycle.

Regulation of the cycle. Photosynthesis cannot occur at night, but the respiratory process of glycolysis—which uses some of the same reactions as the RPP cycle, except in the reverse—does take place. Thus, some steps in the RPP cycle would be wasteful if allowed to occur in the dark because they would counteract the reactions of glycolysis. For this reason, some enzymes of the RPP cycle are “turned off” (*i.e.*, become inactive) in the dark.

Even in the presence of light, changes in physiological conditions frequently necessitate adjustments in the relative rates of reactions of the RPP cycle, so that enzymes for some reactions change in their catalytic activity. These alterations in enzyme activity typically are brought about by changes in levels of such chloroplast components as reduced ferredoxin, acids, and soluble components (*e.g.*, P_i and magnesium ions).

Products of carbon reduction. The most important use of Gal3P is its export from the chloroplasts to the cyto-

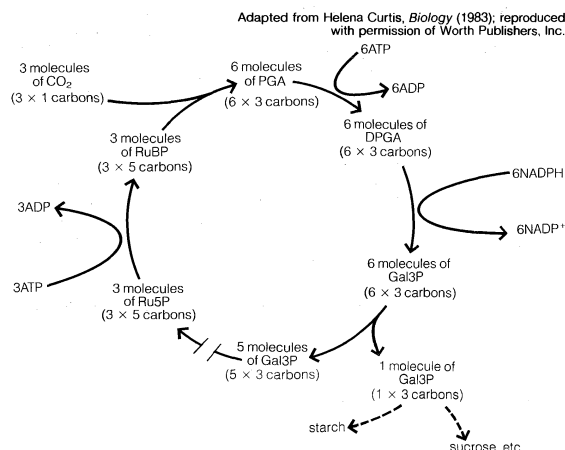

Figure 3: Pathway of carbon dioxide fixation and reduction in photosynthesis, the reductive pentose phosphate cycle. The diagram represents one complete turn of the cycle, with the net production of one molecule of Gal3P. The nine molecules of ATP and six molecules of NADPH come from the light reactions (see text).

plasm of green cells, where it is used for biosynthesis of products needed by the plant. In land plants, a principal product is sucrose, which is translocated from the green cells of the leaves to other parts of the plant. Other key products include the carbon skeletons of certain primary amino acids, such as alanine, glutamate, and aspartate. To complete the synthesis of these compounds, amino groups are added to the appropriate carbon skeletons made from Gal3P. Sulfur amino acids such as cysteine are formed by adding sulfhydryl groups and amino groups. Other biosynthesis pathways lead from Gal3P to lipids, pigments, and most of the constituents of green cells.

Synthesis
of starch

Starch synthesis and accumulation in the chloroplasts occurs particularly when photosynthetic carbon fixation exceeds the needs of the plant. Under such circumstances, sugar phosphates accumulate in the cytoplasm, binding cytoplasmic P_i . The export of Gal3P from the chloroplasts is tied to a one-for-one exchange of P_i for Gal3P, so less cytoplasmic P_i results in decreased export of Gal3P and decreased P_i in the chloroplast. These changes trigger alterations in the activities of regulated enzymes, leading to increased starch synthesis. This starch can be broken down at night and used as a source of reduced carbon and energy for the physiological needs of the plant. Too much starch in the chloroplasts leads to diminished rates of photosynthesis, however. Thus, under the ideal photosynthetic conditions of a bright, warm day, many plants have slower rates of photosynthesis in the afternoon.

Photorespiration. Under conditions of high light intensity, hot weather, and water limitation, the productivity of the RPP cycle is limited in many plants by the occurrence of photorespiration. This process converts sugar phosphates back to carbon dioxide; it is initiated by the oxygenation of RuBP (*i.e.*, the combination of gaseous oxygen [O_2] with RuBP). This oxygenation reaction yields only one molecule of PGA and one molecule of a two-carbon acid, phosphoglycolate, which is subsequently converted in part to carbon dioxide. The reaction of oxygen with RuBP is in direct competition with the carboxylation reaction ($CO_2 + RuBP$) that initiates the RPP cycle and is, in fact, catalyzed by the same protein, ribulose 1,5-bisphosphate carboxylase. The relative concentrations of oxygen and carbon dioxide within the chloroplasts determine whether oxygenation or carboxylation is favoured. The concentration of oxygen inside the chloroplasts may be higher than atmospheric (20 percent) due to photosynthetic oxygen evolution, whereas the internal carbon dioxide concentration may be lower than atmospheric (0.035 percent) due to photosynthetic uptake. Any increase in the internal carbon dioxide pressure tends to help the carboxylation reaction compete more effectively with oxygenation.

Carbon fixation via C_4 acids. Certain plants—including the important crops sugarcane and corn (maize), as well as other diverse species believed to have evolved in the drier tropical areas—have developed a special mechanism of carbon fixation that largely prevents photorespiration. The leaves of these plants have special anatomy and biochemistry. In particular, photosynthetic functions are divided between mesophyll and bundle sheath leaf cells. The carbon fixation pathway begins in the mesophyll cells, where carbon dioxide is added to the three-carbon acid phosphoenolpyruvate (PEPA) by an enzyme called phosphoenolpyruvate carboxylase. The product of this reaction is the four-carbon acid oxaloacetate, which is reduced to malate, another four-carbon acid, in one form of C_4 pathway. Malate then is translocated to bundle sheath cells, which are located near the vascular system of the leaf. There, malate enters the chloroplasts and is oxidized and decarboxylated (*i.e.*, loses CO_2) by malic enzyme. This

yields carbon dioxide, which is fed into the RPP cycle of the bundle sheath cells, and pyruvate, a three-carbon acid that is translocated back to the mesophyll cells. In the mesophyll chloroplasts, the enzyme pyruvate orthophosphate dikinase (PPDK) uses ATP and P_i to convert pyruvate back to PEPA, completing the C_4 cycle. There are several variations of this pathway in different species. For example, the amino acids aspartate and alanine can substitute for malate and pyruvate in some species.

The C_4 pathway acts as a shuttle for carrying carbon dioxide into the chloroplasts of the bundle sheath cells, where it is used in carbohydrate synthesis. The resulting higher level of internal carbon dioxide in these chloroplasts serves to increase the ratio of carboxylation to oxygenation, thus minimizing photorespiration. Although the plant must expend extra energy to drive this shuttle, the energy loss is more than compensated by the near elimination of photorespiration under conditions where it would otherwise occur. Sugarcane and certain other plants that employ this pathway have the highest annual yields of biomass of all species.

Advantage
of the C_4
pathway

THE MOLECULAR BIOLOGY OF PHOTOSYNTHESIS

Oxygenic photosynthesis occurs in both prokaryotic cells (cyanophytes) and eukaryotic cells (algae and higher plants). In eukaryotic cells, which contain chloroplasts and a nucleus, the genetic information needed for the reproduction of the photosynthetic apparatus is contained partly in the chloroplast chromosome and partly in chromosomes of the nucleus. For example, the carboxylation enzyme ribulose 1,5-bisphosphate carboxylase is a large protein molecule comprising a complex of eight large polypeptide subunits and eight small polypeptide subunits. The gene for the large subunits is located in the chloroplast chromosome, while the gene for the small subunits is in the nucleus. Transcription of the DNA of the nuclear gene yields messenger RNA (mRNA) that encodes the information for the synthesis of the small polypeptides. During this synthesis, which occurs on the cytoplasmic ribosomes, some extra amino acid residues are added to form a recognition leader on the end of the polypeptide chain. This leader is recognized by special receptor sites on the outer chloroplast membrane; these receptor sites then allow the polypeptide to penetrate the membrane and enter the chloroplast. The leader is removed and the small subunits combine with the large subunits, which have been synthesized on chloroplast ribosomes according to mRNA transcribed from the chloroplast DNA. The expression of nuclear genes that code for proteins needed in the chloroplasts appears to be under control of events in the chloroplasts in some cases; for example, the synthesis of some nuclear-encoded chloroplast enzymes may occur only when light is absorbed by chloroplasts.

Principles of Physical Science

Physical science, like all the natural sciences, is concerned with describing and relating to one another those experiences of the surrounding world that are shared by different observers and whose description can be agreed upon. One of its principal fields, physics, deals with the most general properties of matter, such as the behaviour of bodies under the influence of forces, and with the origins of those forces. In the discussion of this question, the mass and shape of a body are the only properties that play a significant role, its composition often being irrelevant. Physics, however, does not focus solely on the gross mechanical behaviour of bodies, but shares with chemistry the goal of understanding how the arrangement of individual atoms into molecules and larger assemblies confers particular properties. Moreover, the atom itself may be analyzed into its more basic constituents and their interactions.

The present opinion, rather generally held by physicists, is that these fundamental particles and forces, treated quantitatively by the methods of quantum mechanics, can reveal in detail the behaviour of all material objects. This is not to say that everything can be deduced mathematically from a small number of fundamental principles, since the complexity of real things defeats the power of mathematics or of the largest computers. Nevertheless, whenever it has been found possible to calculate the relationship between an observed property of a body and its deeper

structure, no evidence has ever emerged to suggest that the more complex objects, even living organisms, require that special new principles be invoked, at least so long as only matter, and not mind, is in question. The physical scientist thus has two very different roles to play: on the one hand, he has to reveal the most basic constituents and the laws that govern them; and, on the other, he must discover techniques for elucidating the peculiar features that arise from complexity of structure without having recourse each time to the fundamentals.

This modern view of a unified science, embracing fundamental particles, everyday phenomena, and the vastness of the Cosmos, is a synthesis of originally independent disciplines, many of which grew out of useful arts. The extraction and refining of metals, the occult manipulations of alchemists, and the astrological interests of priests and politicians all played a part in initiating systematic studies that expanded in scope until their mutual relationships became clear, giving rise to what is customarily recognized as modern physical science.

For a survey of the major fields of physical science and their development, see the articles PHYSICAL SCIENCES, THE; and EARTH SCIENCES, THE. For coverage of various related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 111–133, 10/31, and 10/32, and the *Index*.

The development of quantitative science

Modern physical science is characteristically concerned with numbers—the measurement of quantities and the discovery of the exact relationship between different measurements. Yet this activity would be no more than the compiling of a catalog of facts unless an underlying recognition of uniformities and correlations enabled the investigator to choose what to measure out of an infinite range of choices available. Proverbs purporting to predict weather are relics of science prehistory and constitute evidence of a general belief that the weather is, to a certain degree, subject to rules of behaviour. Modern scientific weather forecasting attempts to refine these rules and relate them to more fundamental physical laws so that measurements of temperature, pressure, and wind velocity at a large number of stations can be assembled into a detailed model of the atmosphere whose subsequent evolution can be predicted—not by any means perfectly but almost always more reliably than was previously possible.

Between proverbial weather lore and scientific meteorol-

ogy lies a wealth of observations that have been classified and roughly systematized into the natural history of the subject—for example, prevailing winds at certain seasons, more or less predictable warm spells such as Indian summer, and correlation between Himalayan snowfall and intensity of monsoon. In every branch of science this preliminary search for regularities is an almost essential background to serious quantitative work, and in what follows it will be taken for granted as having been carried out.

Compared to the caprices of weather, the movements of the stars and planets exhibit almost perfect regularity, and so the study of the heavens became quantitative at a very early date, as evidenced by the oldest records from China and Babylon. Objective recording and analysis of these motions, when stripped of the astrological interpretations that may have motivated them, represent the beginning of scientific astronomy. The heliocentric planetary model (c. 1510) of the Polish astronomer Nicolaus Copernicus, which replaced the Ptolemaic geocentric model, and the precise description of the elliptical orbits of the planets (1609) by the German astronomer Johannes Kepler, based

Initial
achieve-
ments of
modern
quantita-
tive science

on the inspired interpretation of centuries of patient observation that had culminated in the work of Tycho Brahe of Denmark, may be regarded fairly as the first great achievements of modern quantitative science.

A distinction may be drawn between an observational science like astronomy, where the phenomena studied lie entirely outside the control of the observer, and an experimental science such as mechanics or optics, where the investigator sets up the arrangement to his own taste. In the hands of Isaac Newton not only was the study of colours put on a rigorous basis but a firm link also was forged between the experimental science of mechanics and observational astronomy by virtue of his law of universal gravitation and his explanation of Kepler's laws of planetary motion. Before proceeding as far as this, however, attention must be paid to the mechanical studies of Galileo Galilei, the most important of the founding fathers of modern physics, insofar as the central procedure of his work involved the application of mathematical deduction to the results of measurement.

It is nowadays taken for granted by scientists that every measurement is subject to error so that repetitions of apparently the same experiment give different results. In the intellectual climate of Galileo's time, however, when logical syllogisms that admitted no gray area between right and wrong were the accepted means of deducing conclusions, his novel procedures were far from compelling. In judging his work one must remember that the conventions now accepted in reporting scientific results were adopted long after Galileo's time. Thus if, as is said, he stated as a fact that two objects dropped from the leaning tower of Pisa reached the ground together with not so much as a hand's breadth between them, it need not be inferred that he performed the experiment himself or that, if he did, the result was quite so perfect. Some such experiment had indeed been performed a little earlier (1586) by the Flemish mathematician Simon Stevin, but Galileo idealized the result. A light ball and a heavy ball do not reach the ground together, nor is the difference between them always the same, for it is impossible to reproduce the ideal of dropping them exactly at the same instant. Nevertheless, Galileo was satisfied that it came closer to the truth to say that they fell together than that there was a significant difference between their rates. This idealization of imperfect experiments remains an essential scientific process, though nowadays it is considered proper to present (or at least have available for scrutiny) the primary observations, so that others may judge independently whether they are prepared to accept the author's conclusion as to what would have been observed in an ideally conducted experiment.

The principles may be illustrated by repeating, with the advantage of modern instruments, an experiment such as Galileo himself performed—namely, that of measuring the time taken by a ball to roll different distances down a gently inclined channel. The following account is of a real experiment designed to show in a very simple example how the process of idealization proceeds, and how the preliminary conclusions may then be subjected to more searching test.

Lines equally spaced at six centimetres (2.4 inches) were scribed on a brass channel, and the ball was held at rest beside the highest line by means of a card. An electronic timer was started at the instant the card was removed, and the timer was stopped as the ball passed one of the other lines. Seven repetitions of each timing showed that the measurements typically spread over a range of $\frac{1}{20}$ of a second, presumably because of human limitations. In such a case, where a measurement is subject to random error, the average of many repetitions gives an improved estimate of what the result would be if the source of random error were eliminated; the factor by which the estimate is improved is roughly the square root of the number of measurements. Moreover, the theory of errors attributable to the German mathematician Carl Friedrich Gauss allows one to make a quantitative estimate of the reliability of the result, as expressed in the table by the conventional symbol \pm . This does not mean that the first result in column 2 is guaranteed to lie between 0.671

The Galileo Experiment		
distance, x (in centimetres)	time, t (in seconds)	$(t + 0.09)/\sqrt{x}$
6	0.678 ± 0.007	0.314
12	0.997 ± 0.006	0.314
18	1.240 ± 0.007	0.313
24	1.444 ± 0.011	0.313
30	1.627 ± 0.010	0.313

and 0.685 but that, if this determination of the average of seven measurements were to be repeated many times, about two-thirds of the determinations would lie within these limits.

The representation of measurements by a graph, as in Figure 1, was not available to Galileo but was developed shortly after his time as a consequence of the work of the French mathematician-philosopher René Descartes. The points appear to lie close to a parabola, and the curve that is drawn is defined by the equation $x = 12t^2$. The fit is not quite perfect, and it is worth trying to find a better formula. Since the operations of starting the timer when the card is removed to allow the ball to roll and stopping it as the ball passes a mark are different, there is a possibility that, in addition to random timing errors, a systematic error appears in each measured value of t ; that is to say, each measurement t is perhaps to be interpreted as $t + t_0$, where t_0 is an as-yet-unknown constant timing error. If this is so, one might look to see whether the measured times were related to distance not by $x = at^2$, where a is a constant, but by $x = a(t + t_0)^2$. This may also be tested graphically by first rewriting the equation as $\sqrt{x} = \sqrt{a}(t + t_0)$, which states that when the values of \sqrt{x} are plotted against measured values of t they should lie on a straight line. Figure 2 verifies this prediction rather closely; the line does not pass through the origin but rather cuts the horizontal axis at -0.09 second. From this, one deduces that $t_0 = 0.09$ second and that $(t + 0.09)x$ should be the same for all the pairs of measurements given in the table. The third column shows that this is certainly the case. Indeed, the constancy is better than might have been expected in view of the estimated errors. This must be regarded as a statistical accident; it does not imply any greater assurance in the correctness of the formula than if the figures in the last column had ranged, as they might very well have done, between 0.311 and 0.315. One would be surprised if a repetition of the whole experiment again yielded so nearly constant a result.

A possible conclusion, then, is that for some reason—probably observational bias—the measured times underestimate by 0.09 second the real time t it takes a ball, starting from rest, to travel a distance x . If so, under ideal conditions x would be strictly proportional to t^2 . Further experiments, in which the channel is set at different but still gentle slopes, suggest that the general rule takes the form $x = at^2$, with a proportional to the slope. This tentative idealization of the experimental measurements may

need to be modified, or even discarded, in the light of further experiments. Now that it has been cast into mathematical form, however, it can be analyzed mathematically to reveal what consequences it implies. Also, this will suggest ways of testing it more searchingly.

From a graph such as Figure 1, which shows how x depends on t , one may deduce the instantaneous speed of the ball at any instant. This is the slope of the tangent drawn to the curve at the chosen value of t ; at $t = 0.6$ second, for example, the tangent as drawn describes how x would be related to t for a ball moving at a constant speed of about 14 centimetres per second. The lower slope before this instant and the higher slope afterward indicate that the ball is steadily accelerating. One could draw tangents at various values of t and come to the conclusion that the instantaneous speed was roughly proportional to the time that had elapsed since the ball began to roll. This procedure, with its inevitable inaccuracies, is rendered unnecessary by applying elementary calculus to the supposed formula. The instantaneous speed v is the derivative of x with respect to t ; if

$$x = at^2, \quad v = \frac{dx}{dt} = 2at.$$

The implication that the velocity is strictly proportional to elapsed time is that a graph of v against t would be a straight line through the origin. On any graph of these quantities, whether straight or not, the slope of the tangent at any point shows how velocity is changing with time at that instant; this is the instantaneous acceleration f . For a straight-line graph of v against t , the slope and therefore the acceleration are the same at all times. Expressed mathematically, $f = dv/dt = d^2x/dt^2$; in the present case, f takes the constant value $2a$.

The preliminary conclusion, then, is that a ball rolling down a straight slope experiences constant acceleration and that the magnitude of the acceleration is proportional to the slope. It is now possible to test the validity of

Figure 3: A ball rolling in a curved channel (see text).

the conclusion by finding what it predicts for a different experimental arrangement. If possible, an experiment is set up that allows more accurate measurements than those leading to the preliminary inference. Such a test is provided by a ball rolling in a curved channel so that its centre traces out a circular arc of radius r , as in Figure 3. Provided the arc is shallow, the slope at a distance x from its lowest point is very close to x/r , so that acceleration of the ball toward the lowest point is proportional to x/r . Introducing c to represent the constant of proportionality, this is written as a differential equation

$$\frac{d^2x}{dt^2} = -\frac{cx}{r}.$$

Here it is stated that, on a graph showing how x varies with t , the curvature d^2x/dt^2 is proportional to x and has the opposite sign, as illustrated in Figure 4. As the graph crosses the axis, x and therefore the curvature are zero, and the line is locally straight. This graph represents the oscillations of the ball between extremes of $\pm A$ after it has been released from $x = A$ at $t = 0$. The solution of the differential equation of which the diagram is the graphic representation is

$$x = A \cos(\omega t),$$

where ω , called the angular frequency, is written for $\sqrt{c/r}$. The ball takes time $T = 2\pi/\omega = 2\pi\sqrt{r/c}$ to return to its original position of rest, after which the oscillation is repeated indefinitely or until friction brings the ball to rest.

According to this analysis, the period, T , is independent of the amplitude of the oscillation, and this rather unexpected prediction is one that may be stringently tested. Instead of letting the ball roll on a curved channel, the same path is more easily and exactly realized by making it the bob of a simple pendulum. To test that the period is independent of amplitude two pendulums may be made as nearly identical as possible, so that they keep in step when swinging with the same amplitude. They are then swung with different amplitudes. It requires considerable care to detect any difference in period unless one amplitude is large, when the period is slightly longer. An observation that very nearly agrees with prediction, but not quite, does not necessarily show the initial supposition to be mistaken. In this case, the differential equation that predicted exact constancy of period was itself an approximation. When it is reformulated with the true expression for the slope replacing x/r , the solution (which involves quite heavy mathematics) shows a variation of period with amplitude that has been rigorously verified. Far from being discredited, the tentative assumption has emerged with enhanced support.

Galileo's law of acceleration, the physical basis of the expression $2\pi\sqrt{c/r}$ for the period, is further strengthened by finding that T varies inversely as the square root of r —i.e., the length of the pendulum.

In addition, such measurements allow the value of the constant c to be determined with a high degree of precision, and it is found to coincide with the acceleration g of a freely falling body. In fact, the formula for the period of small oscillations of a simple pendulum of length r , $T = 2\pi\sqrt{r/g}$, is at the heart of some of the most precise methods for measuring g . This would not have happened unless the scientific community had accepted Galileo's description of the ideal behaviour and did not expect to be shaken in its belief by small deviations, so long as they could be understood as reflecting inevitable random discrepancies between the ideal and its experimental realization. The development of quantum mechanics in the first quarter of the 20th century was stimulated by the reluctant acceptance that this description systematically failed when applied to objects of atomic size. In this case, it was not a question, as with the variations of period, of translating the physical ideas into mathematics more precisely; the whole physical basis needed radical revision. Yet, the earlier ideas were not thrown out—they had been found to work well in far too many applications to be discarded. What emerged was a clearer understanding of the circumstances in which their absolute validity could safely be assumed.

Figure 4: Oscillation of a simple pendulum (see text).

The experiments just described in detail as examples of scientific method were successful in that they agreed with expectation. They would have been just as successful if, in spite of being well conducted, they had disagreed because they would have revealed an error in the primary assumptions. The philosopher Karl Popper's widely accepted criterion for a scientific theory is that it must not simply pass such experimental tests as may be applied but that it must be formulated in such a way that falsification is in principle possible. For all its value as a test of scientific pretensions, however, it must not be supposed that the experimenter normally proceeds with Popper's criterion in mind. Normally he hopes to convince himself that his initial conception is correct. If a succession of tests agrees with (or fails to falsify) a hypothesis, it is regarded as reasonable to treat the hypothesis as true, at all events until it is discredited by a subsequent test. The scientist is not concerned with providing a guarantee of his conclusion, since, however many tests support it, there remains the possibility that the next one will not. His concern is to convince himself and his critical colleagues that a hypothesis has passed enough tests to make it worth accepting until a better one presents itself.

The Newtonian paradigm

Up to this point the investigation has been concerned exclusively with kinetics—that is to say, providing an accurate mathematical description of motion, in this case of a ball on an inclined plane, with no implied explanation of the physical processes responsible. Newton's general dynamic theory, as expounded in his *Philosophiæ Naturalis Principia Mathematica* of 1687, laid down in the form of his laws of motion, together with other axioms and postulates, the rules to follow in analyzing the motion of bodies interacting among themselves. This theory of classical mechanics is described in detail in the article MECHANICS, but some general comments may be offered here. For the present purpose, it seems sufficient to consider only bodies moving along a straight line and acted upon by forces parallel to the motion. Newton's laws are, in fact, considerably more general than this and encompass motion in curves as a result of forces deflecting a body from its initial direction.

Newton's first law may more properly be ascribed to Galileo. It states that a body continues at rest or in uniform motion along a straight line unless it is acted upon by a force, and it enables one to recognize when a force is acting. A tennis ball struck by a racket experiences a sudden change in its motion attributable to a force exerted by the racket. The player feels the shock of the impact. According to Newton's third law (action and reaction are equal and opposite), the force that the ball exerts on the racket is equal and opposite to that which the racket exerts on the ball. Moreover, a second balanced action and reaction acts between player and racket.

Newton's second law quantifies the concept of force, as well as that of inertia. A body acted upon by a steady force suffers constant acceleration. Thus a freely falling body or a ball rolling down a plane has constant acceleration, as has been seen, and this is to be interpreted in Newton's terms as evidence that the force of gravity, which causes

the acceleration, is not changed by the body's motion. The same force (e.g., applied by a string which includes a spring balance to check that the force is the same in different experiments) applied to different bodies causes different accelerations; and it is found that, if a chosen strength of force causes twice the acceleration in body *A* as it does in body *B*, then a different force also causes twice as much acceleration in *A* as in *B*. The ratio of accelerations is independent of the force, and is therefore a property of the bodies alone. They are said to have inertia (or inertial mass) in inverse proportion to the accelerations. This experimental fact, which is the essence of Newton's second law, enables one to assign a number to every body that is a measure of its mass. Thus a certain body may be chosen as a standard of mass and assigned the number 1. Another body is said to have mass *m* if the body shows only a fraction $1/m$ of the acceleration of this standard when the two are subjected to the same force. By proceeding in this way, every body may be assigned a mass. It is because experiment allows this definition to be made that a given force causes every body to show acceleration *f* such that mf is the same for all bodies. This means that the product mf is determined only by the force and not by the particular body on which it acts, and mf is defined to be the numerical measure of the force. In this way a consistent set of measures of force and mass is arrived at, having the property that $F = mf$. In this equation *F*, *m*, and *f* are to be interpreted as numbers measuring the strength of the force, the magnitude of the mass, and the rate of acceleration; and the product of the numbers *m* and *f* is always equal to the number *F*. The product *mv*, called *motus* (motion) by Newton, is now termed momentum. Newton's second law states that the rate of change of momentum equals the strength of the applied force.

In order to assign a numerical measure *m* to the mass of a body, a standard of mass must be chosen and assigned the value $m = 1$. Similarly, to measure displacement a unit of length is needed, and for velocity and acceleration a unit of time also must be defined. Given these, the numerical measure of a force follows from mf without need to define a unit of force. Thus in the *Système Internationale d'Unités* (SI), in which the units are the standard kilogram, the standard metre, and the standard second, a force of magnitude unity is one that, applied to a mass of one kilogram, causes its velocity to increase steadily by one metre per second during every second the force is acting.

The idealized observation of Galileo that all bodies in free-fall accelerate equally implies that the gravitational force causing acceleration bears a constant relation to the inertial mass. According to Newton's postulated law of gravitation, two bodies of mass m_1 and m_2 , separated by a distance *r*, exert equal attractive forces on each other (the equal action and reaction of the third law of motion) of magnitude proportional to $m_1 m_2 / r^2$. The constant of proportionality, *G*, in the gravitational law, $F = Gm_1 m_2 / r^2$, is thus to be regarded as a universal constant, applying to all bodies, whatever their constitution. The constancy of gravitational acceleration, *g*, at a given point on the Earth is a particular case of this general law.

In the same way that the timing of a pendulum provided a more rigorous test of Galileo's kinematical theory than could be achieved by direct testing with balls rolling down planes, so with Newton's laws the most searching tests are indirect and based on mathematically derived consequences. Kepler's laws of planetary motion are just such an example, and in the two centuries after Newton's *Principia* the laws were applied to elaborate and arduous computations of the motion of all planets, not simply as isolated bodies attracted by the Sun but as a system in which every one perturbs the motion of the others by mutual gravitational interactions. (The work of the French mathematician and astronomer Pierre-Simon, Marquis de Laplace, was especially noteworthy.) Calculations of this kind have made it possible to predict the occurrence of eclipses many years ahead. Indeed, the history of past eclipses may be written with extraordinary precision so that, for instance, Thucydides' account of the lunar eclipse

law of
gravitation

that fatally delayed the Athenian expedition against Syracuse in 413 BC matches the calculations perfectly (see ECLIPSE, OCCULTATION, AND TRANSIT). Similarly, unexplained small departures from theoretical expectation of the motion of Uranus led John Couch Adams of England and Urbain-Jean-Joseph Le Verrier of France to predict in 1845 that a new planet (Neptune) would be seen at a particular point in the heavens. The discovery of Pluto in 1930 was achieved in much the same way.

There is no obvious reason why the inertial mass m that governs the response of a body to an applied force should also determine the gravitational force between two bodies, as described above. Consequently, the period of a pendulum is independent of its material and governed only by its length and the local value of g ; this has been verified with an accuracy of a few parts per million. Still more sensitive tests, as originally devised by the Hungarian physicist Roland, Baron von Eötvös (1890), and repeated several times since, have demonstrated clearly that the accelerations of different bodies in a given gravitational environment are identical within a few parts in 10^{12} . An astronaut in free orbit can remain poised motionless in the centre of the cabin of his spacecraft, surrounded by differently constituted objects, all equally motionless (except for their extremely weak mutual attractions) because all of them are identically affected by the gravitational field in which they are moving. He is unaware of the gravitational force, just as those on the Earth are unaware of the Sun's attraction, moving as they do with the Earth in free orbit around the Sun. Albert Einstein made this experimental finding a central feature of his general theory of relativity (see RELATIVITY).

Newton believed that everything moved in relation to a fixed but undetectable spatial frame so that it could be said to have an absolute velocity. Time also flowed at the same steady pace everywhere. Even if there were no matter in the universe, the frame of the universe would still exist, and time would still flow even though there was no one to observe its passage. In Newton's view, when matter is present it is unaffected by its motion through space. If the length of a moving metre stick were compared with the length of one at rest, they would be found to be the same. Clocks keep universal time whether they are moving or not; therefore, two identical clocks, initially synchronized, would still be synchronized after one had been carried into space and brought back. The laws of motion take such a form that they are not changed by uniform motion. They were devised to describe accurately the response of bodies to forces whether in the heavens or on the Earth, and they lose no validity as a result of the Earth's motion at 30 kilometres per second in its orbit around the Sun. This motion, in fact, would not be discernible by an observer in a closed box. The supposed invariance of the laws of motion, in addition to standards of measurement, to uniform translation was called "Galilean invariance" by Einstein.

Galilean
invariance

The impossibility of discerning absolute velocity led in Newton's time to critical doubts concerning the necessity of postulating an absolute frame of space and universal time, and the doubts of the philosophers George Berkeley and Gottfried Wilhelm Leibniz, among others, were still more forcibly presented in the severe analysis of the foundations of classical mechanics by the Austrian physicist Ernst Mach in 1883. James Clerk Maxwell's theory of electromagnetic phenomena (1865), including his description of light as electromagnetic waves, brought the problem to a state of crisis. It became clear that if light waves were propagated in the hypothetical ether that filled all space and provided an embodiment of Newton's absolute frame (see below), it would not be logically consistent to accept both Maxwell's theory and the ideas expressed in Galilean invariance, for the speed of light as it passed an observer would reveal how rapidly he was traveling through the ether.

Ingenious attempts by the physicists George FitzGerald of Ireland and Hendrik A. Lorentz of The Netherlands to devise a compromise to salvage the notion of ether were eventually superseded by Einstein's special theory of relativity (see RELATIVITY). Einstein proposed in 1905 that all

laws of physics, not solely those of mechanics, must take the same form for observers moving uniformly relative to one another, however rapidly. In particular, if two observers, using identical metre sticks and clocks, set out to measure the speed of a light signal as it passes them, both would obtain the same value no matter what their relative velocity might be; in a Newtonian world, of course, the measured values would differ by the relative velocity of the two observers. This is but one example of the counterintuitive character of relativistic physics, but the deduced consequences of Einstein's postulate have been so frequently and so accurately verified by experiment that it has been incorporated as a fundamental axiom in physical theory.

With the abandonment of the ether hypothesis, there has been a reversion to a philosophical standpoint reluctantly espoused by Newton. To him and to his contemporaries the idea that two bodies could exert gravitational forces on each other across immense distances of empty space was abhorrent. However, attempts to develop Descartes's notion of a space-filling fluid ether as a transmitting medium for forces invariably failed to account for the inverse square law. Newton himself adopted a pragmatic approach, deducing the consequences of his laws and showing how well they agreed with observation; he was by no means satisfied that a mechanical explanation was impossible, but he confessed in the celebrated remark, "Hypotheses non fingo" (Latin: "I frame no hypotheses"), that he had no solution to offer.

A similar reversion to the safety of mathematical description is represented by the rejection, during the early 1900s, of the explanatory ether models of the 19th century and their replacement by model-free analysis in terms of relativity theory. This certainly does not imply giving up the use of models as imaginative aids in extending theories, predicting new effects, or devising interesting experiments; if nothing better is available, however, a mathematical formulation that yields verifiably correct results is to be preferred over an intuitively acceptable model that does not.

Interplay of experiment and theory

The foregoing discussion should have made clear that progress in physics, as in the other sciences, arises from a close interplay of experiment and theory. In a well-established field like classical mechanics, it may appear that experiment is almost unnecessary and all that is needed is the mathematical or computational skill to discover the solutions of the equations of motion. This view, however, overlooks the role of observation or experiment in setting up the problem in the first place. To discover the conditions under which a bicycle is stable in an upright position or can be made to turn a corner, it is first necessary to invent and observe a bicycle. The equations of motion are so general and serve as the basis for describing so extended a range of phenomena that the mathematician must usually look at the behaviour of real objects in order to select those that are both interesting and soluble. His analysis may indeed suggest the existence of interesting related effects that can be examined in the laboratory; thus, the invention or discovery of new things may be initiated by the experimenter or the theoretician. To employ terms such as this has led, especially in the 20th century, to a common assumption that experimentation and theorizing are distinct activities, rarely performed by the same person. It is true that almost all active physicists pursue their vocation primarily in one mode or the other. Nevertheless, the innovative experimenter can hardly make progress without an informed appreciation of the theoretical structure, even if he is not technically competent to find the solution of particular mathematical problems. By the same token, the innovative theorist must be deeply imbued with the way real objects behave, even if he is not technically competent to put together the apparatus to examine the problem. The fundamental unity of physical science should be borne in mind during the following outline of characteristic examples of experimental and theoretical physics.

CHARACTERISTIC EXPERIMENTAL PROCEDURES

Unexpected observation. The discovery of X rays (1895) by Wilhelm Conrad Röntgen of Germany was certainly serendipitous. It began with his noticing that when an electric current was passed through a discharge tube a nearby fluorescent screen lit up, even though the tube was completely wrapped in black paper.

Ernest Marsden, a student engaged on a project, reported to his professor, Ernest Rutherford (then at the University of Manchester in England), that alpha particles from a radioactive source were occasionally deflected more than 90° when they hit a thin metal foil. Astonished at this observation, Rutherford deliberated on the experimental data to formulate his nuclear model of the atom (1911).

Heike Kamerlingh Onnes of The Netherlands, the first to liquefy helium, cooled a thread of mercury to within 4 K of absolute zero (4 K equals -269°C) to test his belief that electrical resistance would tend to vanish at zero. This was what the first experiment seemed to verify, but a more careful repetition showed that instead of falling gradually, as he expected, all trace of resistance disappeared abruptly just above 4 K. This phenomenon of superconductivity, which Kamerlingh Onnes discovered in 1911, defied the orthodox explanation until 1957.

The not-so-unexpected chance. From 1807 the Danish physicist and chemist Hans Christian Ørsted came to believe that electrical phenomena could influence magnets, but it was not until 1819 that he turned his investigations to the effects produced by an electric current. On the basis of his tentative models he tried on several occasions to see if a current in a wire caused a magnet needle to turn when it was placed transverse to the wire, but without success. Only when it occurred to him, without forethought, to arrange the needle parallel on the wire did the long-sought effect appear.

A second example of this type of experimental situation involves the discovery of electromagnetic induction by the English physicist and chemist Michael Faraday. Aware that an electrically charged body induces a charge in a nearby body, Faraday sought to determine whether a steady current in a coil of wire would induce such a current in another short-circuited coil close to it. He found no effect except in instances where the current in the first coil was switched on or off, at which time a momentary current appeared in the other. He was in effect led to the concept of electromagnetic induction by changing magnetic fields.

Qualitative tests to distinguish alternative theories. At the time that Augustin-Jean Fresnel presented his wave theory of light to the French Academy (1815), the leading physicists were adherents of Newton's corpuscular theory. It was pointed out by Siméon-Denis Poisson, as a fatal objection, that Fresnel's theory predicted a bright spot at the very centre of the shadow cast by a circular obstacle. When this was in fact observed by François Arago, Fresnel's theory was immediately accepted.

Another qualitative difference between the wave and corpuscular theories concerned the speed of light in a transparent medium. To explain the bending of light rays toward the normal to the surface when light entered the medium, the corpuscular theory demanded that light go faster while the wave theory required that it go slower. Jean-Bernard-Léon Foucault showed that the latter was correct (1850).

The three categories of experiments or observations discussed above are those that do not demand high-precision measurement. The following, however, are categories in which measurement at varying degrees of precision is involved.

Direct comparison of theory and experiment. This is one of the commonest experimental situations. Typically, a theoretical model makes certain specific predictions, perhaps novel in character, perhaps novel only in differing from the predictions of competing theories. There is no fixed standard by which the precision of measurement may be judged adequate. As is usual in science, the essential question is whether the conclusion carries conviction, and this is conditioned by the strength of opinion regarding alternative conclusions.

Where strong prejudice obtains, opponents of a heterodox

conclusion may delay acceptance indefinitely by insisting on a degree of scrupulosity in experimental procedure that they would unhesitatingly dispense with in other circumstances. For example, few experiments in paranormal phenomena, such as clairvoyance, which have given positive results under apparently stringent conditions, have made converts among scientists. In the strictly physical domain, the search for ether drift provides an interesting study. At the height of acceptance of the hypothesis that light waves are carried by a pervasive ether, the question of whether the motion of the Earth through space dragged the ether with it was tested (1887) by A.A. Michelson and Edward W. Morley of the United States by looking for variations in the velocity of light as it traveled in different directions in the laboratory. Their conclusion was that there was a small variation, considerably less than the Earth's velocity in its orbit around the Sun, and that the ether was therefore substantially entrained in the Earth's motion. According to Einstein's relativity theory (1905), no variation should have been observed, but during the next 20 years another American investigator, Dayton C. Miller, repeated the experiment many times in different situations and concluded that, at least on a mountaintop, there was a real "ether wind" of about 10 kilometres per second. Although Miller's final presentation was a model of clear exposition, with evidence scrupulously displayed and discussed, it has been set aside and virtually forgotten. This is partly because other experiments failed to show the effect; however, their conditions were not strictly comparable, since few, if any, were conducted on mountaintops. More significantly, other tests of relativity theory supported it in so many different ways as to lead to the consensus that one discrepant set of observations cannot be allowed to weigh against the theory.

At the opposite extreme may be cited the 1919 expedition of the English scientist-mathematician Arthur Stanley Eddington to measure the very small deflection of the light from a star as it passed close to the Sun—a measurement that requires a total eclipse. The theories involved here were Einstein's general theory of relativity and the Newtonian particle theory of light, which predicted only half the relativistic effect. The conclusion of this exceedingly difficult measurement—that Einstein's theory was followed within the experimental limits of error, which amounted to ± 30 percent—was the signal for worldwide feting of Einstein. If his theory had not appealed aesthetically to those able to appreciate it and if there had been any passionate adherents to the Newtonian view, the scope for error could well have been made the excuse for a long drawn-out struggle, especially since several repetitions at subsequent eclipses did little to improve the accuracy. In this case, then, the desire to believe was easily satisfied. It is gratifying to note that recent advances in radio astronomy have allowed much greater accuracy to be achieved, and Einstein's prediction is now verified within about 1 percent.

During the decade after his expedition, Eddington developed an extremely abstruse fundamental theory that led him to assert that the quantity $hc/2\pi e^2$ (h is Planck's constant, c the velocity of light, and e the charge on the electron) must take the value 137 exactly. At the time, uncertainties in the values of h and e allowed its measured value to be given as 137.29 ± 0.11 ; in accordance with the theory of errors, this implies that there was estimated to be about a 1 percent chance that a perfectly precise measurement would give 137. In the light of Eddington's great authority there were many prepared to accede to his belief. Since then the measured value of this quantity has come much closer to Eddington's prediction and is given as 137.03604 ± 0.00011 . The discrepancy, though small, is 330 times the estimated error, compared with 2.6 times for the earlier measurement, and therefore a much more weighty indication against Eddington's theory. As the intervening years have cast no light on the virtual impenetrability of his argument, there is now hardly a physicist who takes it seriously.

Compilation of data. Technical design, whether of laboratory instruments or for industry and commerce, depends on knowledge of the properties of materials (density,

Subjectivity

strength, electrical conductivity, etc.), some of which can only be found by very elaborate experiments (*e.g.*, those dealing with the masses and excited states of atomic nuclei). One of the important functions of standards laboratories is to improve and extend the vast body of factual information, but much also arises incidentally rather than as the prime objective of an investigation or may be accumulated in the hope of discovering regularities or to test the theory of a phenomenon against a variety of occurrences.

When chemical compounds are heated in a flame, the resulting colour can be used to diagnose the presence of sodium (orange), copper (green-blue), and many other elements. This procedure has long been used. Spectroscopic examination shows that every element has its characteristic set of spectral lines, and the discovery by the Swiss mathematician Johann Jakob Balmer of a simple arithmetic formula relating the wavelengths of lines in the hydrogen spectrum (1885) proved to be the start of intense activity in precise wavelength measurements of all known elements and the search for general principles. With the Danish physicist Niels Bohr's quantum theory of the hydrogen atom (1913) began an understanding of the basis of Balmer's formula; thenceforward spectroscopic evidence underpinned successive developments toward what is now a successful theory of atomic structure.

Tests of fundamental concepts. Coulomb's law states that the force between two electric charges varies as the inverse square of their separation. Direct tests, such as those performed with a special torsion balance by the French physicist Charles-Augustin de Coulomb, for whom the law is named, can be at best approximate. A very sensitive indirect test, devised by the English scientist and clergyman Joseph Priestley (following an observation by Benjamin Franklin) but first realized by the English physicist and chemist Henry Cavendish (1771), relies on the mathematical demonstration that no electrical changes occurring outside a closed metal shell—as, for example, by connecting it to a high voltage source—produce any effect inside if the inverse square law holds. Since modern amplifiers can detect minute voltage changes, this test can be made very sensitive. It is typical of the class of null measurements in which only the theoretically expected behaviour leads to no response and any hypothetical departure from theory gives rise to a response of calculated magnitude. It has been shown in this way that if the force between charges, r apart, is proportional not to $1/r^2$ but to $1/r^{2+x}$, then x is less than 2×10^{-9} .

According to the relativistic theory of the hydrogen atom proposed by the English physicist P.A.M. Dirac (1928), there should be two different excited states exactly coinciding in energy. Measurements of spectral lines resulting from transitions in which these states were involved hinted at minute discrepancies, however. Some years later (*c.* 1950) Willis E. Lamb, Jr., and Robert C. Retherford of the United States, employing the novel microwave techniques that wartime radar contributed to peacetime research, were able not only to detect the energy difference between the two levels directly but to measure it rather precisely as well. The difference in energy, compared to the energy above the ground state, amounts to only four parts in 10,000,000, but this was one of the crucial pieces of evidence that led to the development of quantum electrodynamics, a central feature of the modern theory of fundamental particles (see SUBATOMIC PARTICLES: *Quantum electrodynamics*).

CHARACTERISTIC THEORETICAL PROCEDURES

Only at rare intervals in the development of a subject, and then only with the involvement of a few, are theoretical physicists engaged in introducing radically new concepts. The normal practice is to apply established principles to new problems so as to extend the range of phenomena that can be understood in some detail in terms of accepted fundamental ideas. Even when, as with the quantum mechanics of Werner Heisenberg (formulated in terms of matrices; 1925) and of Erwin Schrödinger (developed on the basis of wave functions; 1926), a major revolution is initiated, most of the accompanying theoretical activity

involves investigating the consequences of the new hypothesis as if it were fully established in order to discover critical tests against experimental facts. There is little to be gained by attempting to classify the process of revolutionary thought because every case history throws up a different pattern. What follows is a description of typical procedures as normally used in theoretical physics. As in the preceding section, it will be taken for granted that the essential preliminary of coming to grips with the nature of the problem in general descriptive terms has been accomplished, so that the stage is set for systematic, usually mathematical, analysis.

Direct solution of fundamental equations. Insofar as the Sun and planets, with their attendant satellites, can be treated as concentrated masses moving under their mutual gravitational influences, they form a system that has not so overwhelmingly many separate units as to rule out step-by-step calculation of the motion of each. Modern high-speed computers are admirably adapted to this task and are used in this way to plan space missions and to decide on fine adjustments during flight. Most physical systems of interest, however, are either composed of too many units or are governed not by the rules of classical mechanics but rather by quantum mechanics, which is much less suited for direct computation.

Dissection. The mechanical behaviour of a body is analyzed in terms of Newton's laws of motion by imagining it dissected into a number of parts, each of which is directly amenable to the application of the laws or has been separately analyzed by further dissection so that the rules governing its overall behaviour are known. A very simple illustration of the method is given by the arrangement in Figure 5A, where two masses are joined by a light string passing over a pulley. The heavier mass, m_1 , falls with constant acceleration, but what is the magnitude of the acceleration? If the string were cut, each mass would experience the force, m_1g or m_2g , due to its gravitational attraction and would fall with acceleration g . The fact that the string prevents this is taken into account by assuming that it is in tension and also acts on each mass. When the string is cut just above m_2 , the state of accelerated motion just before the cut can be restored by applying equal and opposite forces (in accordance with Newton's third law) to the cut ends, as in Figure 5B; the string above the cut pulls the string below upward with a force T , while the string below pulls that above downward to the same extent. As yet, the value of T is not known. Now if the string is light, the tension T is sensibly the same everywhere along it, as may be seen by imagining a second cut, higher up,

Figure 5: Dissection of a complex system into elementary parts (see text).

Direct
and
indirect
testing

Applica-
tion of
established
principles
to new
problems

to leave a length of string acted upon by T at the bottom and possibly a different force T' at the second cut. The total force $T - T'$ on the string must be very small if the cut piece is not to accelerate violently, and, if the mass of the string is neglected altogether, T and T' must be equal. This does not apply to the tension on the two sides of the pulley, for some resultant force will be needed to give it the correct accelerative motion as the masses move. This is a case for separate examination, by further dissection, of the forces needed to cause rotational acceleration. To simplify the problem one can assume the pulley to be so light that the difference in tension on the two sides is negligible. Then the problem has been reduced to two elementary parts—on the right the upward force on m_2 is $T - m_2g$, so that its acceleration upward is $T/m_2 - g$; and on the left the downward force on m_1 is $m_1g - T$, so that its acceleration downward is $g - T/m_1$. If the string cannot be extended, these two accelerations must be identical, from which it follows that $T = 2m_1m_2g/(m_1 + m_2)$ and the acceleration of each mass is $g(m_1 - m_2)/(m_1 + m_2)$. Thus if one mass is twice the other ($m_1 = 2m_2$), its acceleration downward is $g/3$.

A liquid may be imagined divided into small volume elements, each of which moves in response to gravity and the forces imposed by its neighbours (pressure and viscous drag). The forces are constrained by the requirement that the elements remain in contact, even though their shapes and relative positions may change with the flow. From such considerations are derived the differential equations that describe fluid motion (see MECHANICS: *Fluid mechanics*).

The dissection of a system into many simple units in order to describe the behaviour of a complex structure in terms of the laws governing the elementary components is sometimes referred to, often with a pejorative implication, as reductionism. Insofar as it may encourage concentration on those properties of the structure that can be explained as the sum of elementary processes to the detriment of properties that arise only from the operation of the complete structure, the criticism must be considered seriously. The physical scientist is, however, well aware of the existence of the problem (see below *Simplicity and complexity*). If he is usually unrepentant about his reductionist stance, it is because this analytical procedure is the only systematic procedure he knows, and it is one that has yielded virtually the whole harvest of scientific inquiry. What is set up as a contrast to reductionism by its critics is commonly called the holistic approach, whose title confers a semblance of high-mindedness while hiding the poverty of tangible results it has produced.

Simplified models. The process of dissection was early taken to its limit in the kinetic theory of gases, which in its modern form essentially started with the suggestion of the Swiss mathematician Daniel Bernoulli (in 1738) that the pressure exerted by a gas on the walls of its container is the sum of innumerable collisions by individual molecules, all moving independently of each other. Boyle's law—that the pressure exerted by a given gas is proportional to its density if the temperature is kept constant as the gas is compressed or expanded—follows immediately from Bernoulli's assumption that the mean speed of the molecules is determined by temperature alone. Departures from Boyle's law require for their explanation the assumption of forces between the molecules. It is very difficult to calculate the magnitude of these forces from first principles, but reasonable guesses about their form led Maxwell (1860) and later workers to explain in some detail the variation with temperature of thermal conductivity and viscosity, while the Dutch physicist Johannes Diederik van der Waals (1873) gave the first theoretical account of the condensation to liquid and the critical temperature above which condensation does not occur.

The first quantum mechanical treatment of electrical conduction in metals was provided in 1928 by the German physicist Arnold Sommerfeld, who used a greatly simplified model in which electrons were assumed to roam freely (much like non-interacting molecules of a gas) within the metal as if it were a hollow container. The most remarkable simplification, justified at the time by its success

rather than by any physical argument, was that the electrical force between electrons could be neglected. Since then, justification—without which the theory would have been impossibly complicated—has been provided in the sense that means have been devised to take account of the interactions whose effect is indeed considerably weaker than might have been supposed. In addition, the influence of the lattice of atoms on electronic motion has been worked out for many different metals. This development involved experimenters and theoreticians working in harness; the results of specially revealing experiments served to check the validity of approximations without which the calculations would have required excessive computing time.

These examples serve to show how real problems almost always demand the invention of models in which, it is hoped, the most important features are correctly incorporated while less-essential features are initially ignored and allowed for later if experiment shows their influence not to be negligible. In almost all branches of mathematical physics there are systematic procedures—namely, perturbation techniques—for adjusting approximately correct models so that they represent the real situation more closely.

Recasting of basic theory. Newton's laws of motion and of gravitation and Coulomb's law for the forces between charged particles lead to the idea of energy as a quantity that is conserved in a wide range of phenomena (see below *Conservation laws and extremal principles*). It is frequently more convenient to use conservation of energy and other quantities than to start an analysis from the primitive laws. Other procedures are based on showing that, of all conceivable outcomes, the one followed is that for which a particular quantity takes a maximum or a minimum value—e.g., entropy change in thermodynamic processes, action in mechanical processes, and optical path length for light rays.

GENERAL OBSERVATIONS

The foregoing accounts of characteristic experimental and theoretical procedures are necessarily far from exhaustive. In particular, they say too little about the technical background to the work of the physical scientist. The mathematical techniques used by the modern theoretical physicist are frequently borrowed from the pure mathematics of past eras. The work of Augustin-Louis Cauchy on functions of a complex variable, of Arthur Cayley and James Joseph Sylvester on matrix algebra, and of Bernhard Riemann on non-Euclidean geometry, to name but a few, were investigations undertaken with little or no thought for practical applications.

The experimental physicist, for his part, has benefited greatly from technological progress and from instrumental developments that were undertaken in full knowledge of their potential research application but were nevertheless the product of single-minded devotion to the perfecting of an instrument as a worthy thing-in-itself. The developments during World War II provide the first outstanding example of technology harnessed on a national scale to meet a national need. Postwar advances in nuclear physics and in electronic circuitry, applied to almost all branches of research, were founded on the incidental results of this unprecedented scientific enterprise. The semiconductor industry sprang from the successes of microwave radar and, in its turn, through the transistor, made possible the development of reliable computers with power undreamed of by the wartime pioneers of electronic computing. From all these, the research scientist has acquired the means to explore otherwise inaccessible problems. Of course, not all of the important tools of modern-day science were the by-products of wartime research. The electron microscope is a good case in point. Moreover, this instrument may be regarded as a typical example of the sophisticated equipment to be found in all physical laboratories, of a complexity that the research-oriented user frequently does not understand in detail, and whose design depended on skills he rarely possesses.

It should not be thought that the physicist does not give a just return for the tools he borrows. Engineering and technology are deeply indebted to pure science, while

Recourse to perturbation techniques

Reductionism

Impact of advances in technology and instrumentation

much modern pure mathematics can be traced back to investigations originally undertaken to elucidate a scientific problem.

Concepts fundamental to the attitudes and methods of physical science

FIELDS

Newton's law of gravitation and Coulomb's electrostatic law both give the force between two particles as inversely proportional to the square of their separation and directed along the line joining them. The force acting on one particle is a vector. It can be represented by a line with arrowhead; the length of the line is made proportional to the strength of the force, and the direction of the arrow shows the direction of the force. If a number of particles are acting simultaneously on the one considered, the resultant force is found by vector addition; the vectors representing each separate force are joined head to tail, and the resultant is given by the line joining the first tail to the last head.

In what follows the electrostatic force will be taken as typical, and Coulomb's law is expressed in the form $F = q_1 q_2 r / 4\pi\epsilon_0 r^3$. The boldface characters F and r are vectors, F being the force which a point charge q_1 exerts on another point charge q_2 . The combination r/r^3 is a vector in the direction of r , the line joining q_1 to q_2 , with magnitude $1/r^2$ as required by the inverse square law. When r is rendered in lightface, it means simply the magnitude of the vector r , without direction. The combination $4\pi\epsilon_0$ is a constant whose value is irrelevant to the present discussion. The combination $q_1 r / 4\pi\epsilon_0 r^3$ is called the electric field strength due to q_1 at a distance r from q_1 , and is designated by E ; it is clearly a vector parallel to r . At every point in space E takes a different value, determined by r , and the complete specification of $E(r)$ —that is, the magnitude and direction of E at every point r —defines the electric field. If there are a number of different fixed charges, each produces its own electric field of inverse square character, and the resultant E at any point is the vector sum of the separate contributions. Thus the magnitude and direction of E may change in a complicated fashion from point to point. Any particle carrying charge q that is put in a place where the field is E experiences a force qE (provided the other charges are not displaced when it is inserted; if they are $E(r)$ must be recalculated for the actual positions of the charges).

A vector field, varying from point to point, is not always easily represented by a diagram, and it is often helpful for this purpose, as well as in mathematical analysis, to introduce the potential ϕ , from which E may be deduced. To appreciate its significance, the concept of vector gradient must be explained.

Gradient. The contours on a standard map are lines along which the height of the ground above sea level is constant. They usually take a complicated form, but if one imagines contours drawn at very close intervals of height and a small portion of the map to be greatly enlarged, the contours of this local region will become very nearly straight, like the two drawn in Figure 6 for heights h and $h + \delta h$.

Walking along any of these contours, one remains on the level. The slope of the ground is steepest along PQ , and, if the distance from P to Q is δl , the gradient is $\delta h / \delta l$ or dh/dl in the limit when δh and δl are allowed to go to zero. The vector gradient is a vector of this magnitude drawn parallel to PQ and is written as $\text{grad } h$, or ∇h . Walking along any other line PR at an angle θ to PQ , the slope is less in the ratio PQ/PR , or $\cos \theta$. The slope along PR is $(\text{grad } h) \cos \theta$ and is the component of the vector $\text{grad } h$ along a line at an angle θ to the vector itself. This is an example of the general rule for finding components of vectors. In particular, the components parallel to the x and y directions have magnitude $\partial h / \partial x$ and $\partial h / \partial y$ (the partial derivatives, represented by the symbol ∂ , mean, for instance, that $\partial h / \partial x$ is the rate at which h changes with distance in the x direction, if one moves so as to keep y constant; and $\partial h / \partial y$ is the rate of change in the y direction, x being constant). This result is expressed by

$$\text{grad } h = \left[\frac{\partial h}{\partial x}, \frac{\partial h}{\partial y} \right],$$

the quantities in brackets being the components of the vector along the coordinate axes. Vector quantities that vary in three dimensions can similarly be represented by three Cartesian components, along x , y , and z axes; e.g., $V = (V_x, V_y, V_z)$.

Figure 6: Definition of a vector gradient (see text).

Line integral. Imagine a line, not necessarily straight, drawn between two points A and B and marked off in innumerable small elements like δl in Figure 7, which is to be thought of as a vector. If a vector field takes a value V at this point, the quantity $V \delta l \cdot \cos \theta$ is called the scalar product of the two vectors V and δl and is written as $V \cdot \delta l$. The sum of all similar contributions from the different δl gives, in the limit when the elements are made infinitesimally small, the line integral $\int_A^B V \cdot dl$ along the line chosen.

Reverting to the contour map, it will be seen that $\int_A^B (\text{grad } h) \cdot dl$ is just the vertical height of B above A and that the value of the line integral is the same for all choices of line joining the two points. When a scalar quantity ϕ , having magnitude but not direction, is uniquely defined at every point in space, as h is on a two-dimensional map, the vector $\text{grad } \phi$ is then said to be irrotational, and $\phi(r)$ is the potential function from which a vector field $\text{grad } \phi$ can be derived. Not all vector fields can be derived from a potential function, but the Coulomb and gravitational fields are of this form.

Figure 7: Definition of line integral (see text).

Potential. A potential function $\phi(r)$ defined by $\phi = A/r$, where A is a constant, takes a constant value on every sphere centred at the origin. The set of nesting spheres is the analogue in three dimensions of the contours of height on a map, and $\text{grad } \phi$ at a point r is a vector pointing normal to the sphere that passes through r ; it therefore lies along the radius through r , and has magnitude $-A/r^2$. That is to say, $\text{grad } \phi = -Ar/r^3$ and describes a field of inverse square form. If A is set equal to $q_1/4\pi\epsilon_0$, the electrostatic field due to a charge q_1 at the origin is $E = -\text{grad } \phi$.

When the field is produced by a number of point charges, each contributes to the potential $\phi(r)$ in proportion to the size of the charge and inversely as the distance from the charge to the point r . To find the field strength E at r , the potential contributions can be added as numbers and contours of the resultant ϕ plotted; from these E

Vector
notation

Figure 8: Equipotentials (continuous lines) and field lines (broken lines) around two electric charges of magnitude +3 and -1 (see text).

follows by calculating $-\text{grad } \phi$. By the use of the potential, the necessity of vector addition of individual field contributions is avoided. An example of equipotentials is shown in Figure 8. Each is determined by the equation $3/r_1 - 1/r_2 = \text{constant}$, with a different constant value for each, as shown. For any two charges of opposite sign, the equipotential surface, $\phi = 0$, is a sphere, as no other is.

Conservative forces. The inverse square laws of gravitation and electrostatics are examples of central forces where the force exerted by one particle on another is along the line joining them and is also independent of direction. Whatever the variation of force with distance, a central force can always be represented by a potential; forces for which a potential can be found are called conservative. The work done by the force $F(r)$ on a particle as it moves

along a line from A to B is the line integral $\int_A^B F \cdot dl$, or $-\int_A^B \text{grad } \phi \cdot dl$ if F is derived from a potential ϕ , and this integral is just the difference between ϕ at A and B .

The ionized hydrogen molecule consists of two protons bound together by a single electron, which spends a large fraction of its time in the region between the protons. Considering the force acting on one of the protons, one sees that it is attracted by the electron, when it is in the middle, more strongly than it is repelled by the other proton. This argument is not precise enough to prove that the resultant force is attractive, but an exact quantum mechanical calculation shows that it is if the protons are not too close together. At close approach proton repulsion dominates, but as one moves the protons apart the attractive force rises to a peak and then soon falls to a low value. The distance, 1.06×10^{-10} metre, at which the force changes sign, corresponds to the potential ϕ taking its lowest value and is the equilibrium separation of the protons in the ion. This is an example of a central force field that is far from inverse square in character.

A similar attractive force arising from a particle shared between others is found in the strong nuclear force that holds the atomic nucleus together. The simplest example is the deuteron, the nucleus of heavy hydrogen, which consists either of a proton and a neutron or of two neutrons bound by a positive pion (a meson that has a mass 273 times that of an electron when in the free state). There is no repulsive force between the neutrons analogous to the Coulomb repulsion between the protons in the hydrogen ion, and the variation of the attractive force with distance follows the law $F = (g^2/r^2)e^{-r/r_0}$, in which g is a constant analogous to charge in electrostatics and r_0 is a distance of 1.4×10^{-15} metre, which is something like the separation of individual protons and neutrons in a nucleus. At separations closer than r_0 , the law of force approximates to an inverse square attraction, but the exponential term kills the attractive force when r is only a few times r_0 (e.g.,

when r is $5r_0$, the exponential reduces the force 150 times).

Since strong nuclear forces at distances less than r_0 share an inverse square law with gravitational and Coulomb forces, a direct comparison of their strengths is possible. The gravitational force between two protons at a given distance is only about 5×10^{-39} times as strong as the Coulomb force at the same separation, which itself is 1,400 times weaker than the strong nuclear force. The nuclear force is therefore able to hold together a nucleus consisting of protons and neutrons in spite of the Coulomb repulsion of the protons. On the scale of nuclei and atoms, gravitational forces are quite negligible; they only make themselves felt when extremely large numbers of electrically neutral atoms are involved, as on a terrestrial or a cosmological scale.

Field lines. The vector field, $V = -\text{grad } \phi$, associated with a potential ϕ is always directed normal to the equipotential surfaces, and the variations in space of its direction can be represented by continuous lines drawn accordingly, like those in Figure 8. The arrows show the direction of the force that would act on a positive charge; they thus point away from the charge +3 in its vicinity and toward the charge -1. If the field is of inverse square character (gravitational, electrostatic), the field lines may be drawn to represent both direction and strength of field. Thus from an isolated charge q a large number of radial lines may be drawn, filling the solid angle evenly. Since the field strength falls away as $1/r^2$ and the area of a sphere centred on the charge increases as r^2 , the number of lines crossing unit area on each sphere varies as $1/r^2$, in the same way as the field strength. In this case, the density of lines crossing an element of area normal to the lines represents the field strength at that point. The result may be generalized to apply to any distribution of point charges. The field lines are drawn so as to be continuous everywhere except at the charges themselves, which act as sources of lines. From every positive charge q , lines emerge (i.e., with outward-pointing arrows) in number proportional to q , while a similarly proportionate number enter negative charge $-q$. The density of lines then gives a measure of the field strength at any point. This elegant construction holds only for inverse square forces.

Gauss's theorem. At any point in space one may define an element of area dS by drawing a small, flat, closed loop. The area contained within the loop gives the magnitude of the vector area dS , and the arrow representing its direction is drawn normal to the loop. Then, if the electric field in the region of the elementary area is E , the flux through the element is defined as the product of the magnitude dS and the component of E normal to the element—i.e., the scalar product $E \cdot dS$. A charge q at the centre of a sphere of radius r generates a field $E = qr/4\pi\epsilon_0 r^3$ on the surface of the sphere whose area is $4\pi r^2$, and the total flux through the surface is $\int_S E \cdot dS = q/\epsilon_0$. This is independent of r , and the German mathematician Karl Friedrich Gauss showed that it does not depend on q being at the centre nor even on the surrounding surface being spherical. The total flux of E through a closed surface is equal to $1/\epsilon_0$ times the total charge contained within it, irrespective of how that charge is arranged. It is readily seen that this result is consistent with the statement in the preceding paragraph—if every charge q within the surface is the source of q/ϵ_0 field lines, and these lines are continuous except at the charges, the total number leaving through the surface is Q/ϵ_0 , where Q is the total charge. Charges outside the surface contribute nothing, since their lines enter and leave again.

Gauss's theorem takes the same form in gravitational theory, the flux of gravitational field lines through a closed surface being determined by the total mass within. This enables a proof to be given immediately of a problem that caused Newton considerable trouble. He was able to show, by direct summation over all the elements, that a uniform sphere of matter attracts bodies outside as if the whole mass of the sphere were concentrated at its centre. Now it is obvious by symmetry that the field has the same magnitude everywhere on the surface of the sphere, and this symmetry is unaltered by collapsing the mass to a point at the centre. According to Gauss's theorem, the

Gauss's theorem in gravitational theory

Strong nuclear force

total flux is unchanged, and the magnitude of the field must therefore be the same. This is an example of the power of a field theory over the earlier point of view by which each interaction between particles was dealt with individually and the result summed.

Images. A second example illustrating the value of field theories arises when the distribution of charges is not initially known, as when a charge q is brought close to a piece of metal or other electrical conductor and experiences a force. When an electric field is applied to a conductor, charge moves in it; so long as the field is maintained and charge can enter or leave, this movement of charge continues and is perceived as a steady electric current. An isolated piece of conductor, however, cannot carry a steady current indefinitely because there is nowhere for the charge to come from or go to. When q is brought close to the metal, its electric field causes a shift of charge in the metal to a new configuration in which its field exactly cancels the field due to q everywhere on and inside the conductor. The force experienced by q is its interaction with the canceling field. It is clearly a serious problem to calculate E everywhere for an arbitrary distribution of charge, and then to adjust the distribution to make it vanish on the conductor. When, however, it is recognized that after the system has settled down, the surface of the conductor must have the same value of ϕ everywhere, so that $E = -\text{grad } \phi$ vanishes on the surface, a number of specific solutions can easily be found.

In Figure 8, for instance, the equipotential surface $\phi = 0$ is a sphere. If a sphere of uncharged metal is built to coincide with this equipotential, it will not disturb the field in any way. Moreover, once it is constructed, the charge -1 inside may be moved around without altering the field pattern outside, which therefore describes what the field lines look like when a charge $+3$ is moved to the appropriate distance away from a conducting sphere carrying charge -1 . More usefully, if the conducting sphere is momentarily connected to the Earth (which acts as a large body capable of supplying charge to the sphere without suffering a change in its own potential), the required charge -1 flows to set up this field pattern. This result can be generalized as follows: if a positive charge q is placed at a distance r from the centre of a conducting sphere of radius a connected to the Earth, the resulting field outside the sphere is the same as if, instead of the sphere, a negative charge $q' = -(a/r)q$ had been placed at a distance $r' = r(1 - a^2/r^2)$ from q on a line joining it to the centre of the sphere. And q is consequently attracted toward the sphere with a force $qq'/4\pi\epsilon_0 r'^2$, or $q^2 ar/4\pi\epsilon_0(r^2 - a^2)^2$. The fictitious charge $-q'$ behaves somewhat, but not exactly, like the image of q in a spherical mirror, and hence this way of constructing solutions, of which there are many examples, is called the method of images.

Divergence and Laplace's equation. When charges are not isolated points but form a continuous distribution with a local charge density ρ being the ratio of the charge δq in a small cell to the volume δv of the cell, then the flux of E over the surface of the cell is $\rho\delta v/\epsilon_0$, by Gauss's theorem, and is proportional to δv . The ratio of the flux to δv is called the divergence of E and is written $\text{div } E$. It is related to the charge density by the equation $\text{div } E = \rho/\epsilon_0$. If E is expressed by its Cartesian components (e_x, e_y, e_z),

$$\text{div } E = \frac{\partial e_x}{\partial x} + \frac{\partial e_y}{\partial y} + \frac{\partial e_z}{\partial z}.$$

And since $E_x = -\partial\phi/\partial x$, etc.,

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} = -\frac{\rho}{\epsilon_0}.$$

The expression on the left side is usually written as $\nabla^2\phi$ and is called the Laplacian of ϕ . It has the property, as is obvious from its relationship to ρ , of being unchanged if the Cartesian axes of x, y , and z are turned bodily into any new orientation.

If any region of space is free of charges, $\rho = 0$ and $\nabla^2\phi = 0$ in this region. The latter is Laplace's equation, for which many methods of solution are available, providing a powerful means of finding electrostatic (or gravitational) field patterns.

Non-conservative fields. The magnetic field B is an example of a vector field that cannot in general be described as the gradient of a scalar potential. There are no isolated poles to provide, as electric charges do, sources for the field lines. Instead, the field is generated by currents and forms vortex patterns around any current-carrying conductor. Figure 9 shows the field lines for a single straight wire. If one forms the line integral $\int B \cdot dl$ around the closed path formed by any one of these field lines, each increment $B \cdot dl$ has the same sign and, obviously, the integral cannot vanish as it does for an electrostatic field. The value it takes is proportional to the total current enclosed by the path. Thus every path that encloses the conductor yields the same value for $\int B \cdot dl$; i.e., $\mu_0 I$, where I is the current and μ_0 is a constant for any particular choice of units in which B, l , and I are to be measured.

If no current is enclosed by the path, the line integral vanishes and a potential ϕ_B may be defined. Indeed, in the example shown in Figure 9, a potential may be defined even for paths that enclose the conductor, but it is many-valued because it increases by a standard increment $\mu_0 I$ every time the path encircles the current. A contour map of height would represent a spiral staircase (or, better, a spiral ramp) by a similar many-valued contour. The conductor carrying I is in this case the axis of the ramp. Like E in a charge-free region, where $\text{div } E = 0$, so also $\text{div } B = 0$; and where ϕ_B may be defined, it obeys Laplace's equation, $\nabla^2\phi_B = 0$.

Figure 9: Magnetic field lines around a straight current-carrying wire (see text).

Within a conductor carrying a current or any region in which current is distributed rather than closely confined to a thin wire, no potential ϕ_B can be defined. For now the change in ϕ_B after traversing a closed path is no longer zero or an integral multiple of a constant $\mu_0 I$ but is rather μ_0 times the current enclosed in the path and therefore depends on the path chosen. To relate the magnetic field to the current, a new function is needed, the curl, whose name suggests the connection with circulating field lines.

The curl of a vector, say, $\text{curl } B$, is itself a vector quantity. To find the component of $\text{curl } B$ along any chosen direction, draw a small closed path of area A lying in the plane normal to that direction, and evaluate the line integral $\int B \cdot dl$ around the path. As the path is shrunk in size, the integral diminishes with the area, and the limit of $A^{-1} \int B \cdot dl$ is the component of $\text{curl } B$ in the chosen direction. The direction in which the vector $\text{curl } B$ points is the direction in which $A^{-1} \int B \cdot dl$ is largest.

To apply this to the magnetic field in a conductor carrying current, the current density J is defined as a vector pointing along the direction of current flow, and the magnitude of J is such that JA is the total current flowing across a small area A normal to J . Now the line integral of B around the edge of this area is $A \text{ curl } B$ if A is very

Magnetic fields

small, and this must equal μ_0 times the contained current. It follows that

$$\text{curl } \mathbf{B} = \mu_0 \mathbf{J}.$$

Expressed in Cartesian coordinates,

$$\frac{\partial B_y}{\partial z} - \frac{\partial B_z}{\partial y} = \mu_0 J_x,$$

with similar expressions for J_y and J_z . These are the differential equations relating the magnetic field to the currents that generate it.

A magnetic field also may be generated by a changing electric field, and an electric field by a changing magnetic field. The description of these physical processes by differential equations relating $\text{curl } \mathbf{B}$ to $\partial \mathbf{E} / \partial t$, and $\text{curl } \mathbf{E}$ to $\partial \mathbf{B} / \partial t$ is the heart of Maxwell's electromagnetic theory and illustrates the power of the mathematical methods characteristic of field theories. Further examples will be found in the mathematical description of fluid motion, in which the local velocity $\mathbf{v}(\mathbf{r})$ of fluid particles constitutes a field to which the notions of divergence and curl are naturally applicable.

Examples of differential equations for fields. *Continuity.* An incompressible fluid flows so that the net flux of fluid into or out of a given volume within the fluid is zero. Since the divergence of a vector describes the net flux out of an infinitesimal element, divided by the volume of the element, the velocity vector \mathbf{v} in an incompressible fluid must obey the equation $\text{div } \mathbf{v} = 0$. If the fluid is compressible, however, and its density $\rho(\mathbf{r})$ varies with position because of pressure or temperature variations, the net outward flux of mass from some small element is determined by $\text{div}(\rho \mathbf{v})$, and this must be related to the rate at which the density of the fluid within is changing:

$$\text{div}(\rho \mathbf{v}) = - \frac{\partial \rho}{\partial t}.$$

Diffusion. A dissolved molecule or a small particle suspended in a fluid is constantly struck at random by molecules of the fluid in its neighbourhood, as a result of which it wanders erratically. This is called Brownian motion in the case of suspended particles. It is usually safe to assume that each one in a cloud of similar particles is moved by collisions from the fluid and not by interaction between the particles themselves. When a dense cloud gradually spreads out, much like a drop of ink in a beaker of water, this diffusive motion is the consequence of random, independent wandering by each particle. Two equations can be written to describe the average behaviour. The first is a continuity equation: if there are $n(\mathbf{r})$ particles per unit volume around the point \mathbf{r} , and the flux of particles across an element of area is described by a vector \mathbf{F} , meaning the number of particles crossing unit area normal to \mathbf{F} in unit time,

$$\text{div } \mathbf{F} = - \frac{\partial n}{\partial t}$$

describes the conservation of particles. Secondly, Fick's law states that the random wandering causes an average drift of particles from regions where they are denser to regions where they are rarer, and that the mean drift rate is proportional to the gradient of density and in the opposite sense to the gradient:

$$\mathbf{F} = - D \text{grad } n,$$

where D is a constant—the diffusion constant.

These two equations can be combined into one differential equation for the changes that n will undergo,

$$D \nabla^2 n = \frac{\partial n}{\partial t},$$

which defines uniquely how any initial distribution of particles will develop with time. Thus the spreading of a small drop of ink is rather closely described by the particular solution,

$$n = \left(\frac{C}{t^{3/2}} \right) \exp \left(\frac{-r^2}{4Dt} \right),$$

in which C is a constant determined by the total number

of particles in the ink drop. When t is very small at the start of the process, all the particles are clustered near the origin of r , but, as t increases, the radius of the cluster increases in proportion to the square root of the time, while the density at the centre drops as the three-halves power to keep the total number constant. The distribution of particles with distance from the centre at three different times is shown in Figure 10. From this diagram one may calculate what fraction, after any chosen interval, has moved farther than some chosen distance from the origin. Moreover, since each particle wanders independently of the rest, it also gives the probability that a single particle will migrate farther than this in the same time. Thus a problem relating to the behaviour of a single particle, for which only an average answer can usefully be given, has been converted into a field equation and solved rigorously. This is a widely used technique in physics.

Figure 10: Diffusive spread of a cloud of particles initially concentrated at a point. The value given for each curve represents the time elapsed since n , the particles per unit volume around point r , began to disperse (see text).

Further examples of field equations. The equations describing the propagation of waves (electromagnetic, acoustic, deep water waves, and ripples) are discussed in relevant articles, as is the Schrödinger equation for probability waves that governs particle behaviour in quantum mechanics (see below *Fundamental constituents of matter*). The field equations that embody the special theory of relativity are more elaborate with space and time coordinates no longer independent of each other, though the geometry involved is still Euclidean. In the general theory of relativity, the geometry of this four-dimensional space-time is non-Euclidean (see RELATIVITY).

CONSERVATION LAWS AND EXTREMAL PRINCIPLES

It is a consequence of Newton's laws of motion that the total momentum remains constant in a system completely isolated from external influences. The only forces acting on any part of the system are those exerted by other parts; if these are taken in pairs, according to the third law, A exerts on B a force equal and opposite to that of B on A . Since, according to the second law, the momentum of each changes at a rate equal to the force acting on it, the momentum change of A is exactly equal and opposite to that of B when only mutual forces between these two are considered. Because the effects of separate forces are additive, it follows that for the system as a whole no momentum change occurs. The centre of mass of the whole system obeys the first law in remaining at rest or moving at a constant velocity, so long as no external influences are brought to bear. This is the oldest of the conservation laws and is invoked frequently in solving dynamic problems.

The total angular momentum (also called moment of momentum) of an isolated system about a fixed point is conserved as well. The angular momentum of a particle of mass m moving with velocity \mathbf{v} at the instant when it is at a distance \mathbf{r} from the fixed point is $m\mathbf{r} \wedge \mathbf{v}$. The quantity written as $\mathbf{r} \wedge \mathbf{v}$ is a vector (the vector product of \mathbf{r} and \mathbf{v}) having components with respect to Cartesian axes

$$\mathbf{r} \wedge \mathbf{v} = (y v_z - z v_y, z v_x - x v_z, x v_y - y v_x).$$

The meaning is more easily appreciated if all the particles

Conservation of angular momentum

Phenomenon of Brownian motion

lie and move in a plane. The angular momentum of any one particle is the product of its momentum mv and the distance of nearest approach of the particle to the fixed point if it were to continue in a straight line. The vector is drawn normal to the plane. Conservation of total angular momentum does not follow immediately from Newton's laws but demands the additional assumption that any pair of forces, action and reaction, are not only equal and opposite but act along the same line. This is always true for central forces, but it holds also for the frictional force developed along sliding surfaces. If angular momentum were not conserved, one might find an isolated body developing a spontaneous rotation with respect to the distant stars or, if rotating like the Earth, changing its rotational speed without any external cause. Such small changes as the Earth experiences are explicable in terms of disturbances from without—*e.g.*, tidal forces exerted by the Moon. The law of conservation of angular momentum is not called into question.

Nevertheless, there are noncentral forces in nature, as, for example, when a charged particle moves past a bar magnet. If the line of motion and the axis of the magnet lie in a plane, the magnet exerts a force on the particle perpendicular to the plane while the magnetic field of the moving particle exerts an equal and opposite force on the magnet. At the same time, it exerts a couple tending to twist the magnet out of the plane. Angular momentum is not conserved unless one imagines that the balance of angular momentum is distributed in the space around the magnet and charge and changes as the particle moves past. The required result is neatly expressed by postulating the possible existence of magnetic poles that would generate a magnetic field analogous to the electric field of a charge (a bar magnet behaves roughly like two such poles of opposite sign, one near each end). Then there is associated with each pair, consisting of a charge q and a pole P , angular momentum $\mu_0 Pq/4\pi$, as if the electric and magnetic fields together acted like a gyroscope spinning about the line joining P and q . With this contribution included in the sum, angular momentum is always conserved.

Conser-
vation of
energy

The device of associating mechanical properties with the fields, which up to this point had appeared merely as convenient mathematical constructions, has even greater implications when conservation of energy is considered. This conservation law, which is regarded as basic to physics, seems at first sight, from an atomic point of view, to be almost trivial. If two particles interact by central forces, for which a potential function ϕ may be defined such that $\text{grad } \phi$ gives the magnitude of the force experienced by each, it follows from Newton's laws of motion that the sum of ϕ and of their separate kinetic energies, defined as $1/2mv^2$, remains constant. This sum is defined to be the total energy of the two particles and, by its definition, is automatically conserved. The argument may be extended to any number of particles interacting by means of central forces; a potential energy function may always be found, depending only on the relative positions of the particles, which may be added to the sum of the kinetic energies (depending only on the velocities) to give a total energy that is conserved.

The concept of potential energy, thus introduced as a formal device, acquires a more concrete appearance when it is expressed in terms of electric and magnetic field strengths for particles interacting by virtue of their charges. The quantities $1/2\epsilon_0 E^2$ and $B^2/2\mu_0$ may be interpreted as the contributions per unit volume of the electric and magnetic fields to the potential energy, and, when these are integrated over all space and added to the kinetic energy, the total energy thus expressed is a conserved quantity. These expressions were discovered during the heyday of ether theories, according to which all space is permeated by a medium capable of transmitting forces between particles (see above). The electric and magnetic fields were interpreted as descriptions of the state of strain of the ether, so that the location of stored energy throughout space was no more remarkable than it would be in a compressed spring. With the abandonment of the ether theories following the rise of relativity theory, this visualizable model ceased to have validity.

The idea of energy as a real constituent of matter has, however, become too deeply rooted to be abandoned lightly, and most physicists find it useful to continue treating electric and magnetic fields as more than mathematical constructions. Far from being empty, free space is viewed as a storehouse for energy, with E and B providing not only an inventory but expressions for its movements as represented by the momentum carried in the fields. Wherever E and B are both present, and not parallel, there is a flux of energy, amounting to $E \wedge B/\mu_0$, crossing unit area and moving in a direction normal to the plane defined by E and B . This energy in motion confers momentum on the field, $E \wedge B/\mu_0 c$, per unit volume as if there were mass associated with the field energy. Indeed, the English physicist J.J. Thomson showed in 1881 that the energy stored in the fields around a moving charged particle varies as the square of the velocity as if there were extra mass carried with the electric field around the particle. Herein lie the seeds of the general mass-energy relationship developed by Einstein in his special theory of relativity; $E = mc^2$ expresses the association of mass with every form of energy. Neither of two separate conservation laws, that of energy and that of mass (the latter particularly the outcome of countless experiments involving chemical change), is in this view perfectly true, but together they constitute a single conservation law, which may be expressed in two equivalent ways—conservation of mass, if to the total energy E is ascribed mass E/c^2 , or conservation of energy, if to each mass m is ascribed energy mc^2 . The delicate measurements by Eötvös and later workers (see above) show that the gravitational forces acting on a body do not distinguish different types of mass, whether intrinsic to the fundamental particles or resulting from their kinetic and potential energies. For all its apparently artificial origins, then, this conservation law enshrines a very deep truth about the material universe, one that has not yet been fully explored.

Conser-
vation
of mass-
energy

An equally fundamental law, for which no exception is known, is that the total electrical charge in an isolated system is conserved. In the production of a negatively charged electron by an energetic gamma ray, for example, a positively charged positron is produced simultaneously. An isolated electron cannot disappear, though an electron and a positron, whose total charge is zero and whose mass is $2m_e$ (twice the mass of an electron), may simultaneously be annihilated. The energy equivalent of the destroyed mass appears as gamma ray energy $2m_e c^2$.

For macroscopic systems—*i.e.*, those composed of objects massive enough for their atomic structure to be discounted in the analysis of their behaviour—the conservation law for energy assumes a different aspect. In the collision of two perfectly elastic objects, to which billiard balls are a good approximation, momentum and energy are both conserved. Given the paths and velocities before collision, those after collision can be calculated from the conservation laws alone. In reality, however, although momentum is always conserved, the kinetic energy of the separating balls is less than what they had on approach. Soft objects, indeed, may adhere on collision, losing most of their kinetic energy. The lost energy takes the form of heat, raising the temperature (if only imperceptibly) of the colliding objects. From the atomic viewpoint the total energy of a body may be divided into two portions: on the one hand, the external energy consisting of the potential energy associated with its position and the kinetic energy of motion of its centre of mass and its spin; and, on the other, the internal energy due to the arrangement and motion of its constituent atoms. In an inelastic collision the sum of internal and external energies is conserved, but some of the external energy of bodily motion is irretrievably transformed into internal random motions. The conservation of energy is expressed in the macroscopic language of the first law of thermodynamics—namely, energy is conserved provided that heat is taken into account. The irreversible nature of the transfer from external energy of organized motion to random internal energy is a manifestation of the second law of thermodynamics.

The irreversible degradation of external energy into random internal energy also explains the tendency of all

Manifestations of the extremal principle

systems to come to rest if left to themselves. If there is a configuration in which the potential energy is less than for any slightly different configuration, the system may find stable equilibrium here because there is no way in which it can lose more external energy, either potential or kinetic. This is an example of an extremal principle—that a state of stable equilibrium is one in which the potential energy is a minimum with respect to any small changes in configuration. It may be regarded as a special case of one of the most fundamental of physical laws, the principle of increase of entropy, which is a statement of the second law of thermodynamics in the form of an extremal principle—the equilibrium state of an isolated physical system is that in which the entropy takes the maximum possible value. This matter is discussed further below and, in particular, in the article THERMODYNAMICS.

The earliest extremal principle to survive in modern physics was formulated by the French mathematician Pierre de Fermat in about 1660. As originally stated, the path taken by a ray of light between two fixed points in an arrangement of mirrors, lenses, and so forth, is that which takes the least time. The laws of reflection and refraction may be deduced from this principle if it is assumed as Fermat did, correctly, that in a medium of refractive index μ light travels more slowly than in free space by a factor μ . Strictly, the time taken along a true ray path is either less or greater than for any neighbouring path. If all paths in the neighbourhood take the same time, the two chosen points are such that light leaving one is focused on the other. The perfect example is exhibited by an elliptical mirror, such as the one in Figure 11; all paths from F_1 to the ellipse and thence to F_2 have the same length. In conventional optical terms, the ellipse has the property that every choice of paths obeys the law of reflection, and every ray from F_1 converges after reflection onto F_2 . Also shown in the figure are two reflecting surfaces tangential to the ellipse that do not have the correct curvature to focus light from F_1 onto F_2 . A ray is reflected from F_1 to F_2 only at the point of contact. For the flat reflector the path taken is the shortest of all in the vicinity, while for the reflector that is more strongly curved than the ellipse it is the longest. Fermat's principle and its application to focusing by mirrors and lenses finds a natural explanation in the wave theory of light (see LIGHT).

Figure 11: An elliptic mirror focusing all rays of light from F_1 onto F_2 (see text).

in nature that have been found, if not actively misleading, too imprecise to retain a place in modern science.

Fermat's and Hamilton's principles are but two examples out of many whereby a procedure is established for finding the correct solution to a problem by discovering under what conditions a certain function takes an extremal value. The advantages of such an approach are that it brings into play the powerful mathematical techniques of the calculus of variations and, perhaps even more important, that in dealing with very complex situations it may allow a systematic approach by computational means to a solution that may not be exact but is near enough the right answer to be useful.

Fermat's principle, stated as a theorem concerning light rays but later restated in terms of the wave theory, found an almost exact parallel in the development of wave mechanics. The association of a wave with a particle by the physicists Louis-Victor de Broglie and Erwin Schrödinger was made in such a way that the principle of least action followed by an analogous argument.

FUNDAMENTAL CONSTITUENTS OF MATTER

Development of the atomic theory. The idea that matter is composed of atoms goes back to the Greek philosophers, notably Democritus, and has never since been entirely lost sight of, though there have been periods when alternative views were more generally preferred. Newton's contemporaries, Robert Hooke and Robert Boyle, in particular, were atomists, but their interpretation of the sensation of heat as random motion of atoms was overshadowed for more than a century by the conception of heat as a subtle fluid dubbed caloric. It is a tribute to the strength of caloric theory that it enabled the French scientist Sadi Carnot to arrive at his great discoveries in thermodynamics. In the end, however, the numerical rules for the chemical combination of different simple substances, together with the experiments on the conversion of work into heat by Benjamin Thompson (Count Rumford) and James Prescott Joule, led to the downfall of the theory of caloric. Nevertheless, the rise of ether theories to explain the transmission of light and electromagnetic forces through apparently empty space postponed for many decades the general reacceptance of the concept of atoms. The discovery in 1858 by the German scientist and philosopher Hermann von Helmholtz of the permanence of vortex motions in perfectly inviscid fluids encouraged the invention—throughout the latter half of the 19th century and especially in Great Britain—of models in which vortices in a structureless ether played the part otherwise assigned to atoms. In recent years the recognition that certain localized disturbances in a fluid, the so-called solitary waves, might persist for a very long time has led to attempts, so far unsuccessful, to use them as models of fundamental particles.

These attempts to describe the basic constituents of matter in the familiar language of fluid mechanics were at least atomic theories in contrast to the anti-atomistic movement at the end of the 19th century in Germany under the influence of Ernst Mach and Wilhelm Ostwald. For all their scientific eminence, their argument was philosophical rather than scientific, springing as it did from the conviction that the highest aim of science is to describe the relationship between different sensory perceptions without the introduction of unobservable concepts. Nonetheless, an inspection of the success of their contemporaries using atomic models shows why this movement failed. It suffices to mention the systematic construction of a kinetic theory of matter in which the physicists Ludwig Boltzmann of Austria and J. Willard Gibbs of the United States were the two leading figures. To this may be added Hendrik Lorentz's electron theory, which explained in satisfying detail many of the electrical properties of matter; and, as a crushing argument for atomism, the discovery and explanation of X-ray diffraction by Max von Laue of Germany and his collaborators, a discovery that was quickly developed, following the lead of the British physicist William Henry Bragg and his son Lawrence, into a systematic technique for mapping the precise atomic structure of crystals.

While the concept of atoms was thus being made in-

Principle of least action A similar extremal principle in mechanics, the principle of least action, was proposed by the French mathematician and astronomer Pierre-Louis Moreau de Maupertuis but rigorously stated only much later, especially by the Irish mathematician and scientist William Rowan Hamilton in 1835. Though very general, it is well enough illustrated by a simple example, the path taken by a particle between two points A and B in a region where the potential $\phi(r)$ is everywhere defined. Once the total energy E of the particle has been fixed, its kinetic energy T at any point P is the difference between E and the potential energy ϕ at P . If any path between A and B is assumed to be followed, the velocity at each point may be calculated from T , and hence the time t between the moment of departure from A and passage through P . The action for this path is found by evaluating the integral $\int_A^B (T - \phi) dt$, and the actual path taken by the particle is that for which the action is minimal. It may be remarked that both Fermat and Maupertuis were guided by Aristotelian notions of economy

dispensable, the ancient belief that they were probably structureless and certainly indestructible came under devastating attack. J.J. Thomson's discovery of the electron in 1897 soon led to the realization that the mass of an atom largely resides in a positively charged part, electrically neutralized by a cloud of much lighter electrons. A few years later Ernest Rutherford and Frederick Soddy showed how the emission of alpha and beta particles from radioactive elements causes them to be transformed into elements of different chemical properties. By 1913, with Rutherford as the leading figure, the foundations of the modern theory of atomic structure were laid. It was determined that a small, massive nucleus carries all the positive charge whose magnitude, expressed as a multiple of the fundamental charge of the proton, is the atomic number. An equal number of electrons carrying a negative charge numerically equal to that of the proton form a cloud whose diameter is several thousand times that of the nucleus around which they swarm. The atomic number determines the chemical properties of the atom, and in alpha decay a helium nucleus, whose atomic number is 2, is emitted from the radioactive nucleus, leaving one whose atomic number is reduced by 2. In beta decay the nucleus in effect gains one positive charge by emitting a negative electron and thus has its atomic number increased by unity.

The nucleus, itself a composite body, was soon being described in various ways, none completely wrong but none uniquely right. Pivotal was James Chadwick's discovery in 1932 of the neutron, a nuclear particle with very nearly the same mass as the proton but no electric charge. After this discovery, investigators came to view the nucleus as consisting of protons and neutrons, bound together by a force of limited range, which at close quarters was strong enough to overcome the electrical repulsion between the protons. A free neutron survives for only a few minutes before disintegrating into a readily observed proton and electron, along with an elusive neutrino, which has no charge and zero, or at most extremely small, mass. The disintegration of a neutron also may occur inside the nucleus, with the expulsion of the electron and neutrino; this is the beta-decay process. It is common enough among the heavy radioactive nuclei but does not occur with all nuclei because the energy released would be insufficient for the reorganization of the resulting nucleus. Certain nuclei have a higher-than-ideal ratio of protons to neutrons and may adjust the proportion by the reverse process, a proton being converted into a neutron with the expulsion of a positron and an antineutrino. For example, a magnesium nucleus containing 12 protons and 11 neutrons spontaneously changes to a stable sodium nucleus with 11 protons and 12 neutrons. The positron resembles the electron in all respects except for being positively rather than negatively charged. It was the first antiparticle to be discovered. Its existence had been predicted, however, by Dirac after he had formulated the quantum mechanical equations describing the behaviour of an electron (see below). This was one of the most spectacular achievements of a spectacular albeit brief epoch, during which the basic conceptions of physics were revolutionized.

Rise of quantum mechanics. The idea of the quantum was introduced by the German physicist Max Planck in 1900 in response to the problems posed by the spectrum of radiation from a hot body, but the development of quantum theory soon became closely tied to the difficulty of explaining by classical mechanics the stability of Rutherford's nuclear atom. Bohr led the way in 1913 with his model of the hydrogen atom, but it was not until 1925 that the arbitrary postulates of his quantum theory found consistent expression in the new quantum mechanics that was formulated in apparently different but in fact equivalent ways by Heisenberg, Schrödinger, and Dirac (see MECHANICS: *Quantum mechanics*). In Bohr's model the motion of the electron around the proton was analyzed as if it were a classical problem, mathematically the same as that of a planet around the Sun, but it was additionally postulated that, of all the orbits available to the classical particle, only a discrete set was to be allowed, and Bohr devised rules for determining which orbits they were. In Schrödinger's wave mechanics the problem is also written

down in the first place as if it were a classical problem, but, instead of proceeding to a solution of the orbital motion, the equation is transformed by an explicitly laid down procedure from an equation of particle motion to an equation of wave motion. The newly introduced mathematical function Ψ , the amplitude of Schrödinger's hypothetical wave, is used to calculate not how the electron moves but rather what the probability is of finding the electron in any specific place if it is looked for there.

Schrödinger's prescription reproduced in the solutions of the wave equation the postulates of Bohr but went much further. Bohr's theory had come to grief when even two electrons, as in the helium atom, had to be considered together, but the new quantum mechanics encountered no problems in formulating the equations for two or any number of electrons moving around a nucleus. Solving the equations was another matter; yet, numerical procedures were applied with devoted patience to a few of the simpler cases and demonstrated beyond cavil that the only obstacle to solution was calculational and not an error of physical principle. Modern computers have vastly extended the range of application of quantum mechanics not only to heavier atoms but also to molecules and assemblies of atoms in solids, and always with such success as to inspire full confidence in the prescription.

From time to time many physicists feel uneasy that it is necessary first to write down the problem to be solved as though it were a classical problem and then to subject it to an artificial transformation into a problem in quantum mechanics. It must be realized, however, that the world of experience and observation is not the world of electrons and nuclei. When a bright spot on a television screen is interpreted as the arrival of a stream of electrons, it is still only the bright spot that is perceived and not the electrons. The world of experience is described by the physicist in terms of visible objects, occupying definite positions at definite instants of time—in a word, the world of classical mechanics. When the atom is pictured as a nucleus surrounded by electrons, this picture is a necessary concession to human limitations; there is no sense in which one can say that, if only a good enough microscope were available, this picture would be revealed as genuine reality. It is not that such a microscope has not been made; it is actually impossible to make one that will reveal this detail. The process of transformation from a classical description to an equation of quantum mechanics, and from the solution of this equation to the probability that a specified experiment will yield a specified observation, is not to be thought of as a temporary expedient pending the development of a better theory. It is better to accept this process as a technique for predicting the observations that are likely to follow from an earlier set of observations. Whether electrons and nuclei have an objective existence in reality is a metaphysical question to which no definite answer can be given. There is, however, no doubt that to postulate their existence is, in the present state of physics, an inescapable necessity if a consistent theory is to be constructed to describe economically and exactly the enormous variety of observations on the behaviour of matter. The habitual use of the language of particles by physicists induces and reflects the conviction that, even if the particles elude direct observation, they are as real as any everyday object.

Following the initial triumphs of quantum mechanics, Dirac in 1928 extended the theory so that it would be compatible with the special theory of relativity. Among the new and experimentally verified results arising from this work was the seemingly meaningless possibility that an electron of mass m might exist with any negative energy between $-mc^2$ and $-\infty$. Between $-mc^2$ and $+mc^2$, which is in relativistic theory the energy of an electron at rest, no state is possible. It became clear that other predictions of the theory would not agree with experiment if the negative-energy states were brushed aside as an artifact of the theory without physical significance. Eventually Dirac was led to propose that all the states of negative energy, infinite in number, are already occupied with electrons and that these, filling all space evenly, are imperceptible. If, however, one of the negative-energy electrons is

Electron-
positron
pairs

given more than $2mc^2$ of energy, it can be raised into a positive-energy state, and the hole it leaves behind will be perceived as an electron-like particle, though carrying a positive charge. Thus this act of excitation leads to the simultaneous appearance of a pair of particles—an ordinary negative electron and a positively charged but otherwise identical positron. This process was observed in cloud-chamber photographs by Carl David Anderson of the United States in 1932. The reverse process was recognized at the same time; it can be visualized either as an electron and a positron mutually annihilating one another, with all their energy (two lots of rest energy, each mc^2 , plus their kinetic energy) being converted into gamma rays (electromagnetic quanta), or as an electron losing all this energy as it drops into the vacant negative-energy state that simulates a positive charge. When an exceptionally energetic cosmic-ray particle enters the Earth's atmosphere, it initiates a chain of such processes in which gamma rays generate electron-positron pairs; these in turn emit gamma rays which, though of lower energy, are still capable of creating more pairs, so that what reaches the Earth's surface is a shower of many millions of electrons and positrons.

Not unnaturally, the suggestion that space was filled to infinite density with unobservable particles was not easily accepted in spite of the obvious successes of the theory. It would have seemed even more outrageous had not other developments already forced theoretical physicists to contemplate abandoning the idea of empty space. Quantum mechanics carries the implication that no oscillatory system can lose all its energy; there must always remain at least a "zero-point energy" amounting to $h\nu/2$ for an oscillator with natural frequency ν (h is Planck's constant). This also seemed to be required for the electromagnetic oscillations constituting radio waves, light, X rays, and gamma rays. Since there is no known limit to the frequency ν , their total zero-point energy density is also infinite; like the negative-energy electron states, it is uniformly distributed throughout space, both inside and outside matter, and presumed to produce no observable effects.

Developments in particle physics. It was at about this moment, say 1930, in the history of the physics of fundamental particles that serious attempts to visualize the processes in terms of everyday notions were abandoned in favour of mathematical formalisms. Instead of seeking modified procedures from which the awkward, unobservable infinities had been banished, the thrust was toward devising prescriptions for calculating what observable processes could occur and how frequently and how quickly they would occur. An empty cavity which would be described by a classical physicist as capable of maintaining electromagnetic waves of various frequencies, ν , and arbitrary amplitude now remains empty (zero-point oscillation being set aside as irrelevant) except insofar as photons, of energy $h\nu$, are excited within it. Certain mathematical operators have the power to convert the description of the assembly of photons into the description of a new assembly, the same as the first except for the addition or removal of one. These are called creation or annihilation operators, and it need not be emphasized that the operations are performed on paper and in no way describe a laboratory operation having the same ultimate effect. They serve, however, to express such physical phenomena as the emission of a photon from an atom when it makes a transition to a state of lower energy. The development of these techniques, especially after their supplementation with the procedure of renormalization (which systematically removes from consideration various infinite energies that naive physical models throw up with embarrassing abundance), has resulted in a rigorously defined procedure that has had dramatic successes in predicting numerical results in close agreement with experiment. It is sufficient to cite the example of the magnetic moment of the electron. According to Dirac's relativistic theory, the electron should possess a magnetic moment whose strength he predicted to be exactly one Bohr magneton ($eh/4\pi m$, or 9.27×10^{-24} joule per tesla). In practice, this has been found to be not quite right, as, for instance, in the experiment of Lamb and Retherford mentioned earlier; more recent determi-

nations give 1.0011596522 Bohr magnetons. Calculations by means of the theory of quantum electrodynamics give 1.0011596525 in impressive agreement.

This account represents the state of the theory in about 1950, when it was still primarily concerned with problems related to the stable fundamental particles, the electron and the proton, and their interaction with electromagnetic fields. Meanwhile, studies of cosmic radiation at high altitudes—those conducted on mountains or involving the use of balloon-borne photographic plates—had revealed the existence of the pi-meson (pion), a particle 273 times as massive as the electron, which disintegrates into the mu-meson (muon), 207 times as massive as the electron, and a neutrino. Each muon in turn disintegrates into an electron and two neutrinos. The pion has been identified with the hypothetical particle postulated in 1935 by the Japanese physicist Yukawa Hideki as the particle that serves to bind protons and neutrons in the nucleus. Many more unstable particles have been discovered in recent years. Some of them, just as in the case of the pion and the muon, are lighter than the proton, but many are more massive. An account of such particles is given in the article SUBATOMIC PARTICLES.

The term particle is firmly embedded in the language of physics, yet a precise definition has become harder as more is learned. When examining the tracks in a cloud-chamber or bubble-chamber photograph, one can hardly suspend disbelief in their having been caused by the passage of a small charged object. However, the combination of particle-like and wavelike properties in quantum mechanics is unlike anything in ordinary experience, and, as soon as one attempts to describe in terms of quantum mechanics the behaviour of a group of identical particles (e.g., the electrons in an atom), the problem of visualizing them in concrete terms becomes still more intractable. And this is before one has even tried to include in the picture the unstable particles or to describe the properties of a stable particle like the proton in relation to quarks. These hypothetical entities, worthy of the name particle to the theoretical physicist, are apparently not to be detected in isolation, nor does the mathematics of their behaviour encourage any picture of the proton as a molecule-like composite body constructed of quarks. Similarly, the theory of the muon is not the theory of an object composed, as the word is normally used, of an electron and two neutrinos. The theory does, however, incorporate such features of particle-like behaviour as will account for the observation of the track of a muon coming to an end and that of an electron starting from the end point. At the heart of all fundamental theories is the concept of countability. If a certain number of particles is known to be present inside a certain space, that number will be found there later, unless some have escaped (in which case they could have been detected and counted) or turned into other particles (in which case the change in composition is precisely defined). It is this property, above all, that allows the idea of particles to be preserved.

Undoubtedly, however, the term is being strained when it is applied to photons that can disappear with nothing to show but thermal energy or be generated without limit by a hot body so long as there is energy available. They are a convenience for discussing the properties of a quantized electromagnetic field, so much so that the condensed-matter physicist refers to the analogous quantized elastic vibrations of a solid as phonons without persuading himself that a solid really consists of an empty box with particle-like phonons running about inside. If, however, one is encouraged by this example to abandon belief in photons as physical particles, it is far from clear why the fundamental particles should be treated as significantly more real, and, if a question mark hangs over the existence of electrons and protons, where does one stand with atoms or molecules? The physics of fundamental particles does indeed pose basic metaphysical questions to which neither philosophy nor physics has answers. Nevertheless, the physicist has confidence that his constructs and the mathematical processes for manipulating them represent a technique for correlating the outcomes of observation and experiment with such precision and over so wide a

and anni-
hilation
operators

range of phenomena that he can afford to postpone deeper inquiry into the ultimate reality of the material world.

SIMPLICITY AND COMPLEXITY

The search for fundamental particles and the mathematical formalism with which to describe their motions and interactions has in common with the search for the laws governing gravitational, electromagnetic, and other fields of force the aim of finding the most economical basis from which, in principle, theories of all other material processes may be derived. Some of these processes are simple—a single particle moving in a given field of force, for example—if the term refers to the nature of the system studied and not to the mathematical equipment that may sometimes be brought to bear. A complex process, on the other hand, is typically one in which many interacting particles are involved and for which it is hardly ever possible to proceed to a complete mathematical solution. A computer may be able to follow in detail the movement of thousands of atoms interacting in a specified way, but a wholly successful study along these lines does no more than display on a large scale and at an assimilable speed what nature achieves on its own. Much can be learned from these studies, but, if one is primarily concerned with discovering what will happen in given circumstances, it is frequently quicker and cheaper to do the experiment than to model it on a computer. In any case, computer modeling of quantum mechanical, as distinct from Newtonian, behaviour becomes extremely complicated as soon as more than a few particles are involved.

The art of analyzing complex systems is that of finding the means to extract from theory no more information than one needs. It is normally of no value to discover the speed of a given molecule in a gas at a given moment; it is, however, very valuable to know what fraction of the molecules possess a given speed. The correct answer to this question was found by Maxwell, whose argument was ingenious and plausible. More rigorously, Boltzmann showed that it is possible to proceed from the conservation laws governing molecular encounters to general statements, such as the distribution of velocities, which are largely independent of how the molecules interact. In thus laying the foundations of statistical mechanics, Boltzmann provided an object lesson in how to avoid recourse to the fundamental laws, replacing them with a new set of rules appropriate to highly complex systems. This point is discussed further in *Entropy and disorder* below.

Analyzing complex systems by means of simplified models

The example of statistical mechanics is but one of many that together build up a hierarchical structure of simplified models whose function is to make practicable the analysis of systems at various levels of complexity. Ideally, the logical relationship between each successive pair of levels should be established so that the analyst may have confidence that the methods he applies to his special problem are buttressed by the enormous corpus of fact and theory that comprises physical knowledge at all levels. It is not in the nature of the subject for every connection to be proved with mathematical rigour, but, where this is lacking, experiment will frequently indicate what trust may be placed in the intuitive steps of the argument.

For instance, it is out of the question to solve completely the quantum mechanical problem of finding the stationary states in which an atomic nucleus containing perhaps 50 protons or neutrons can exist. Nevertheless, the energy of these states can be measured and models devised in which details of particle position are replaced by averages, such that when the simplified model is treated by the methods of quantum mechanics the measured energy levels emerge from the calculations. Success is attained when the rules for setting up the model are found to give the right result for every nucleus. Similar models had been devised earlier by the English physicist Douglas R. Hartree to describe the cloud of electrons around the nucleus. The increase in computing power made it feasible to add extra details to the model so that it agreed even better with the measured properties of atoms. It is worth noting that when the extranuclear electrons are under consideration it is frequently unnecessary to refer to details of the nucleus, which might just as well be a point charge; even if this is too simplistic,

a small number of extra facts usually suffices. In the same way, when the atoms combine chemically and molecules in a gas or a condensed state interact, most of the details of electronic structure within the atom are irrelevant or can be included in the calculation by introducing a few extra parameters; these are often treated as empirical properties. Thus the degree to which an atom is distorted by an electric field is often a significant factor in its behaviour, and the investigator dealing with the properties of assemblies of atoms may prefer to use the measured value rather than the atomic theorist's calculation of what it should be. However, he knows that enough of these calculations have been successfully carried out for his use of measured values in any specific case to be a time-saver rather than a denial of the validity of his model.

These examples from atomic physics can be multiplied at all levels so that a connected hierarchy exists, ranging from fundamental particles and fields, through atoms and molecules, to gases, liquids, and solids that were studied in detail and reduced to quantitative order well before the rise of atomic theory. Beyond this level lie the realms of the Earth sciences, the planetary systems, the interior of stars, galaxies, and the Cosmos as a whole. And with the interior of stars and the hypothetical early universe, the entire range of models must be brought to bear if one is to understand how the chemical elements were built up or to determine what sort of motions are possible in the unimaginably dense, condensed state of neutron stars.

The following sections make no attempt to explore all aspects and interconnections of complex material systems, but they highlight a few ideas which pervade the field and which indicate the existence of principles that find little place in the fundamental laws yet are the outcome of their operation.

SYMMETRY

The normal behaviour of a gas on cooling is to condense into a liquid and then into a solid, though the liquid phase may be left out if the gas starts at a low enough pressure. The solid phase of a pure substance is usually crystalline, having the atoms or molecules arranged in a regular pattern so that a suitable small sample may define the whole. The unit cell is the smallest block out of which the pattern can be formed by stacking replicas. The checkerboard in Figure 12 illustrates the idea; here the unit cell has been chosen out of many possibilities to contain one white square and one black, dissected into quarters. For crystals, of course, the unit cell is three-dimensional. A very wide variety of arrangements is exhibited by different substances, and it is the great triumph of X-ray crystallography to have provided the means for

Concept of the unit cell

Figure 12: The unit cell as the smallest representative sample of the whole. In the case of this checkerboard, the unit cell consists of one white square, and one shaded square dissected into quarters.

determining experimentally what arrangement is involved in each case.

One may ask whether mathematical techniques exist for deducing the correct result independently of experiment, and the answer is almost always no. An individual sulfur atom, for example, has no features that reflect its preference, in the company of others, for forming rings of eight. This characteristic can only be discovered theoretically by calculating the total energy of different-sized rings and of other patterns and determining after much computation that the ring of eight has the lowest energy of all. Even then the investigator has no assurance that there is no other arrangement which confers still lower energy. In one of the forms taken by solid sulfur, the unit cell contains 128 atoms in a complex of rings. It would be an inspired guess to hit on this fact without the aid of X rays or the expertise of chemists, and mathematics provides no systematic procedure as an alternative to guessing or relying on experiment.

Nevertheless, it may be possible in simpler cases to show that calculations of the energy are in accord with the observed crystal forms. Thus, when silicon is strongly compressed, it passes through a succession of different crystal modifications for each of which the variation with pressure of the energy can be calculated. The pressure at which a given change of crystal form takes place is that at which the energy takes the same value for both modifications involved. As this pressure is reached, one gives way to the other for the possession of the lower energy. The fact that the calculation correctly describes not only the order in which the different forms occur but also the pressures at which the changeovers take place indicates that the physical theory is in good shape; only the power is lacking in the mathematics to predict behaviour from first principles.

The changes in symmetry that occur at the critical points where one modification changes to another are complex examples of a widespread phenomenon for which simple analogues exist. A perfectly straight metal strip, firmly fixed to a base so that it stands perfectly upright, remains straight as an increasing load is placed on its upper end until a critical load is reached. Any further load causes the strip to heel over and assume a bent form, and it only takes a minute disturbance to determine whether it will bend to the left or to the right. The fact that either outcome is equally likely reflects the left-right symmetry of the arrangement, but once the choice is made the symmetry is broken. The subsequent response to changing load and the small vibrations executed when the strip is struck lightly are characteristic of the new unsymmetrical shape. If one wishes to calculate the behaviour, it is essential to avoid assuming that an arrangement will always remain symmetrical simply because it was initially so. In general, as with the condensation of sulfur atoms or with the crystalline transitions in silicon, the symmetry implicit in the formulation of the theory will be maintained only in the totality of possible solutions, not necessarily in the particular solution that appears in practice. In the case of the condensation of a crystal from individual atoms, the spherical symmetry of each atom tells one no more than that the crystal may be formed equally well with its axis pointing in any direction; and such information provides no help in finding the crystal structure. In general, there is no substitute for experiment. Even with relatively simple systems such as engineering structures, it is all too easy to overlook the possibility of symmetry breaking leading to calamitous failure.

It should not be assumed that the critical behaviour of a loaded strip depends on its being perfectly straight. If the strip is not, it is likely to prefer one direction of bending to the other. As the load is increased, so will the intrinsic bend be exaggerated, and there will be no critical point at which a sudden change occurs. By tilting the base, however, it is possible to compensate for the initial imperfection and to find once more a position where left and right are equally favoured. Then the critical behaviour is restored, and at a certain load the necessity of choice is present as with a perfect strip. The study of this and numerous more complex examples is the province of the

so-called catastrophe theory. A catastrophe, in the special sense used here, is a situation in which a continuously varying input to a system gives rise to a discontinuous change in the response at a critical point. The discontinuities may take many forms, and their character may be sensitive in different ways to small changes in the parameters of the system. Catastrophe theory is the term used to describe the systematic classification, by means of topological mathematics, of these discontinuities. Wide-ranging though the theory may be, it cannot at present include in its scope most of the symmetry-breaking transitions undergone by crystals.

ENTROPY AND DISORDER

As is explained in detail in the article THERMODYNAMICS, the laws of thermodynamics make possible the characterization of a given sample of matter—after it has settled down to equilibrium with all parts at the same temperature—by ascribing numerical measures to a small number of properties (pressure, volume, energy, and so forth). One of these is entropy. As the temperature of the body is raised by adding heat, its entropy as well as its energy is increased. On the other hand, when a volume of gas enclosed in an insulated cylinder is compressed by pushing on the piston, the energy in the gas increases while the entropy stays the same or, usually, increases a little. In atomic terms, the total energy is the sum of all the kinetic and potential energies of the atoms, and the entropy, it is commonly asserted, is a measure of the disorderly state of the constituent atoms. The heating of a crystalline solid until it melts and then vaporizes is a progress from a well-ordered, low-entropy state to a disordered, high-entropy state. The principal deduction from the second law of thermodynamics (or, as some prefer, the actual statement of the law) is that, when an isolated system makes a transition from one state to another, its entropy can never decrease. If a beaker of water with a lump of sodium on a shelf above it is sealed in a thermally insulated container and the sodium is then shaken off the shelf, the system, after a period of great agitation, subsides to a new state in which the beaker contains hot sodium hydroxide solution. The entropy of the resulting state is higher than the initial state, as can be demonstrated quantitatively by suitable measurements.

The idea that a system cannot spontaneously become better ordered but can readily become more disordered, even if left to itself, appeals to one's experience of domestic economy and confers plausibility on the law of increase of entropy. As far as it goes, there is much truth in this naive view of things, but it cannot be pursued beyond this point without a much more precise definition of disorder. Thermodynamic entropy is a numerical measure that can be assigned to a given body by experiment; unless disorder can be defined with equal precision, the relation between the two remains too vague to serve as a basis for deduction. A precise definition is to be found by considering the number, labeled W , of different arrangements that can be taken up by a given collection of atoms, subject to their total energy being fixed. In quantum mechanics, W is the number of different quantum states that are available to the atoms with this total energy (strictly, in a very narrow range of energies). It is so vast for objects of everyday size as to be beyond visualization; for the helium atoms contained in one cubic centimetre of gas at atmospheric pressure and at 0° C the number of different quantum states can be written as 1 followed by 170 million million zeroes (written out, the zeroes would fill nearly one trillion sets of the *Encyclopædia Britannica*).

The science of statistical mechanics, as founded by the aforementioned Ludwig Boltzmann and J. Willard Gibbs, relates the behaviour of a multitude of atoms to the thermal properties of the material they constitute. Boltzmann and Gibbs, along with Max Planck, established that the entropy, S , as derived through the second law of thermodynamics, is related to W by the formula $S = k \ln W$, where k is the Boltzmann constant (1.380662×10^{-23} joule per kelvin) and $\ln W$ is the natural (Napierian) logarithm of W . By means of this and related formulas it is possible in principle, starting with the quantum mechanics of the

Catastrophe theory

Symmetry breaking

Thermodynamic entropy

constituent atoms, to calculate the measurable thermal properties of the material. Unfortunately, there are rather few systems for which the quantum mechanical problems succumb to mathematical analysis, but among these are gases and many solids, enough to validate the theoretical procedures linking laboratory observations to atomic constitution.

When a gas is thermally isolated and slowly compressed, the individual quantum states change their character and become mixed together, but the total number W does not alter. In this change, called adiabatic, entropy remains constant. On the other hand, if a vessel is divided by a partition, one side of which is filled with gas while the other side is evacuated, piercing the partition to allow the gas to spread throughout the vessel greatly increases the number of states available so that W and the entropy rise. The act of piercing requires little effort and may even happen spontaneously through corrosion. To reverse the process, waiting for the gas to accumulate accidentally on one side and then stopping the leak, would mean waiting for a time compared to which the age of the universe would be imperceptibly short. The chance of finding an observable decrease in entropy for an isolated system can be ruled out.

This does not mean that a part of a system may not decrease in entropy at the expense of at least as great an increase in the rest of the system. Such processes are indeed commonplace but only when the system as a whole is not in thermal equilibrium. Whenever the atmosphere becomes supersaturated with water and condenses into a cloud, the entropy per molecule of water in the droplets is less than it was prior to condensation. The remaining atmosphere is slightly warmed and has a higher entropy. The spontaneous appearance of order is especially obvious when the water vapour condenses into snow crystals. A domestic refrigerator lowers the entropy of its contents while increasing that of its surroundings. Most important of all, the state of nonequilibrium of the Earth irradiated by the much hotter Sun provides an environment in which the cells of plants and animals may build order—*i.e.*, lower their local entropy at the expense of their environment. The Sun provides a motive power that is analogous (though much more complex in detailed operation) to the electric cable connected to the refrigerator. There is no evidence pointing to any ability on the part of living matter to run counter to the principle of increasing (overall) disorder as formulated in the second law of thermodynamics.

Irreversible
tendency
toward
disorder

The irreversible tendency toward disorder provides a sense of direction for time which is absent from space. One may traverse a path between two points in space without feeling that the reverse journey is forbidden by physical laws. The same is not true for time travel, and yet the equations of motion, whether in Newtonian or quantum mechanics, have no such built-in irreversibility. A motion picture of a large number of particles interacting with one another looks equally plausible whether run forward or backward. To illustrate and resolve this paradox it is convenient to return to the example of a gas enclosed in a vessel divided by a pierced partition. This time, however, only 100 atoms are involved (not 3×10^{19} as in one cubic centimetre of helium), and the hole is made so small that atoms pass through only rarely and no more than one at a time. This model is easily simulated on a computer, and Figure 13 shows a typical sequence during which there are 500 transfers of atoms across the partition. The number on one side starts at the mean of 50 and fluctuates randomly while not deviating greatly from the mean. Where the fluctuations are larger than usual, as indicated by the arrows, there is no systematic tendency for their growth to the peak to differ in form from the decay from it. This is in accord with the reversibility of the motions when examined in detail.

If one were to follow the fluctuations for a very long time and single out those rare occasions when a particular number occurred that was considerably greater than 50, say 75, one would find that the next number is more likely to be 74 than 76. Such would be the case because, if there are 75 atoms on one side of the partition, there

Figure 13: Fluctuations in the number of particles, out of 100, on one side of a perforated partition dividing a box into equal halves (see text).

will be only 25 on the other, and it is three times more likely that one atom will leave the 75 than that one will be gained from the 25. Also, since the detailed motions are reversible, it is three times more likely that the 75 was preceded by a 74 rather than by a 76. In other words, if one finds the system in a state that is far from the mean, it is highly probable that the system has just managed to get there and is on the point of falling back. If the system has momentarily fluctuated into a state of lower entropy, the entropy will be found to increase again immediately.

It might be thought that this argument has already conceded the possibility of entropy decreasing. It has indeed, but only for a system on the minute scale of 100 atoms. The same computation carried out for 3×10^{19} atoms would show that one would have to wait interminably (*i.e.*, enormously longer than the age of the universe) for the number on one side to fluctuate even by as little as one part per million. A physical system as big as the Earth, let alone the entire Galaxy—if set up in thermodynamic equilibrium and given unending time in which to evolve—might eventually have suffered such a huge fluctuation that the condition known today could have come about spontaneously. In that case man would find himself, as he does, in a universe of increasing entropy as the fluctuation recedes. Boltzmann, it seems, was prepared to take this argument seriously on the grounds that sentient creatures could only appear as the aftermath of a large enough fluctuation. What happened during the inconceivably prolonged waiting period is irrelevant. Modern cosmology shows, however, that the universe is ordered on a scale enormously greater than is needed for living creatures to evolve, and Boltzmann's hypothesis is correspondingly rendered improbable in the highest degree. Whatever started the universe in a state from which it could evolve with an increase of entropy, it was not a simple fluctuation from equilibrium. The sensation of time's arrow is thus referred back to the creation of the universe, an act that lies beyond the scrutiny of the physical scientist.

It is possible, however, that in the course of time the universe will suffer "heat death," having attained a condition of maximum entropy, after which tiny fluctuations are all that will happen. If so, these will be reversible, like the graph of Figure 13, and will give no indication of a direction of time. Yet, because this undifferentiated cosmic soup will be devoid of structures necessary for consciousness, the sense of time will in any case have vanished long since.

CHAOS

Many systems can be described in terms of a small number of parameters and behave in a highly predictable manner. Were this not the case, the laws of physics might never have been elucidated. If one maintains the swing of a pendulum by tapping it at regular intervals, say once per swing, it will eventually settle down to a regular oscillation. Now let it be jolted out of its regularity; in due course it will revert to its previous oscillation as if nothing had disturbed it. Systems that respond in this well-behaved manner have been studied extensively and have frequently

been taken to define the norm, from which departures are somewhat unusual. It is with such departures that this section is concerned.

An example not unlike the periodically struck pendulum is provided by a ball bouncing repeatedly in a vertical line on a base plate that is caused to vibrate up and down to counteract dissipation and maintain the bounce. With a small but sufficient amplitude of base motion the ball synchronizes with the plate, returning regularly once per cycle of vibration. With larger amplitudes the ball bounces higher but still manages to remain synchronized until eventually this becomes impossible. Two alternatives may then occur: (1) the ball may switch to a new synchronized mode in which it bounces so much higher that it returns only every two, three, or more cycles, or (2) it may become unsynchronized and return at irregular, apparently random, intervals. Yet, the behaviour is not random in the way that raindrops strike a small area of surface at irregular intervals. The arrival of a raindrop allows one to make no prediction of when the next will arrive; the best one can hope for is a statement that there is half a chance that the next will arrive before the lapse of a certain time. By contrast, the bouncing ball is described by a rather simple set of differential equations that can be solved to predict without fail when the next bounce will occur and how fast the ball will be moving on impact, given the time of the last bounce and the speed of that impact. In other words, the system is precisely determinate, yet to the casual observer it is devoid of regularity. Systems that are determinate but irregular in this sense are called chaotic; like so many other scientific terms, this is a technical expression that bears no necessary relation to the word's common usage.

Determinate yet irregular systems

The coexistence of irregularity with strict determinism can be illustrated by an arithmetic example, one that lay behind some of the more fruitful early work in the study of chaos, particularly by the physicist Mitchell J. Feigenbaum following an inspiring exposition by Robert M. May. Suppose one constructs a sequence of numbers starting with an arbitrarily chosen x_0 (between 0 and 1) and writes the next in the sequence, x_1 , as $Ax_0(1 - x_0)$; proceeding in the same way to $x_2 = Ax_1(1 - x_1)$, one can continue indefinitely, and the sequence is completely determined by the initial value x_0 and the value chosen for A . Thus, starting from $x_0 = 0.9$ with $A = 2$, the sequence rapidly settles to a constant value: 0.09, 0.18, 0.2952, 0.4161, 0.4859, 0.4996, 0.5000, 0.5000, and so forth.

When A lies between 2 and 3, it also settles to a constant but takes longer to do so. It is when A is increased above 3 that the sequence shows more unexpected features. At first, until A reaches 3.42, the final pattern is an alternation of two numbers, but with further small increments of A it changes to a cycle of 4, followed by 8, 16, and so forth at ever-closer intervals of A . By the time A reaches 3.57, the length of the cycle has grown beyond bounds—it shows no periodicity however long one continues the sequence. This is the most elementary example of chaos, but it is easy to construct other formulas for generating number sequences that can be studied rapidly with the aid of the smallest programmable computer. By such “experimental arithmetic” Feigenbaum found that the transition from regular convergence through cycles of 2, 4, 8, and so forth to chaotic sequences followed strikingly similar courses for all, and he gave an explanation that involved great subtlety of argument and was almost rigorous enough for pure mathematicians.

The chaotic sequence shares with the chaotic bouncing of the ball in the earlier example the property of limited predictability, as distinct from the strong predictability of the periodically driven pendulum and of the regular sequence found when A is less than 3. Just as the pendulum, having been disturbed, eventually settles back to its original routine, so the regular sequence, for a given choice of A , settles to the same final number whatever initial value x_0 may be chosen. By contrast, when A is large enough to generate chaos, the smallest change in x_0 leads eventually to a completely different sequence, and the smallest disturbance to the bouncing ball switches it to a different but equally chaotic pattern. This is illustrated for the number

sequence in Figure 14, where two sequences are plotted (successive points being joined by straight lines) for $A = 3.7$ and x_0 chosen to be 0.9 and 0.9000009, a difference of one part per million. For the first 35 terms the sequences differ by too little to appear on the graph, but a record of the numbers themselves shows them diverging steadily until by the 40th term the sequences are unrelated. Although the sequence is completely determined by the first term, one cannot predict its behaviour for any considerable number of terms without extremely precise knowledge of the first term. The initial divergence of the two sequences is roughly exponential, each pair of terms being different by an amount greater than that of the preceding pair by a roughly constant factor. Put another way, to predict the sequence in this particular case out to n terms, one must know the value of x_0 to better than $n/8$ places of decimals. If this were the record of a chaotic physical system (e.g., the bouncing ball), the initial state would be determined by measurement with an accuracy of perhaps 1 percent (i.e., two decimal places), and prediction would be valueless beyond 16 terms. Different systems, of course, have different measures of their “horizon of predictability,” but all chaotic systems share the property that every extra place of decimals in one’s knowledge of the starting point only pushes the horizon a small extra distance away. In practical terms, the horizon of predictability is an impassable barrier. Even if it is possible to determine the initial conditions with extremely high precision, every physical system is susceptible to random disturbances from outside that grow exponentially in a chaotic situation until they have swamped any initial prediction. It is highly probable that atmospheric movements, governed by well-defined equations, are in a state of chaos. If so, there can be little hope of extending indefinitely the range of weather forecasting except in the most general terms. There are clearly certain features of climate, such as annual cycles of temperature and rainfall, which are exempt from the ravages of chaos. Other large-scale processes may still allow long-range prediction, but the more detail one asks for in a forecast, the sooner will it lose its validity.

Horizon of predictability

Figure 14: Sensitivity of a chaotic number sequence to initial value, illustrating the horizon of predictability (see text).

Linear systems for which the response to a force is strictly proportional to the magnitude of the force do not show chaotic behaviour. The pendulum, if not too far from the vertical, is a linear system, as are electrical circuits containing resistors that obey Ohm's law or capacitors and inductors for which voltage and current also are proportional. The analysis of linear systems is a well-established technique that plays an important part in the education of a physicist. It is relatively easy to teach, since the range of behaviour exhibited is small and can be encapsulated in a few general rules. Nonlinear systems, on the other hand, are bewilderingly versatile in their modes of behaviour and are, moreover, very commonly unamenable to elegant mathematical analysis. Until large computers became readily available, the natural history of nonlinear systems was little explored and the extraordinary prevalence of chaos unappreciated. To a considerable degree physicists have been persuaded, in their innocence, that predictability is a characteristic of a well-established theoretical structure; given the equations defining a system, it is only a matter of computation to determine how it will behave. However, once it becomes clear how many systems are sufficiently nonlinear to be considered for chaos,

Prevalence of chaos in nonlinear systems

it has to be recognized that prediction may be limited to short stretches set by the horizon of predictability. Full comprehension is not to be achieved by establishing firm fundamentals, important though they are, but must frequently remain a tentative process, a step at a time, with frequent recourse to experiment and observation in the event that prediction and reality have diverged too far.

BIBLIOGRAPHY. ERIC M. ROGERS, *Physics for the Inquiring Mind: The Methods, Nature, and Philosophy of Physical Science* (1960), is especially good on the origins of astronomy and mechanics, with minimal mathematics. Of the many general student texts, the *Berkeley Physics Course*, 5 vol. (1965–71), covering mechanics, electricity and magnetism, waves, quantum physics, and statistical physics; and DAVID HALLIDAY and ROBERT RESNICK, *Fundamentals of Physics*, 3rd ed. (1988), are recommended. *The Feynman Lectures on Physics*, 3 vol. (1963–65), by RICHARD P. FEYNMAN, ROBERT B. LEIGHTON, and MATTHEW SANDS, instructs students and teachers in the whole range of physical concepts, with characteristically revealing insights. See also JEFFERSON HANE WEAVER (ed.), *The World of Physics: A Small Library of the Literature of Physics from Antiquity to the Present*, 3 vol. (1987), an anthology covering the history of the major concepts of physics.

Expositions of more limited scope, reflecting on general principles for the benefit of nonspecialists, include H. BONDI, *Assumption and Myth in Physical Theory* (1967); RICHARD P. FEYNMAN, *The Character of Physical Law* (1965); and J.M. ZIMAN, *Public Knowledge: An Essay Concerning the Social Dimension of Science* (1968). At a more advanced level, M.S. LONGAIR, *Theoretical Concepts in Physics* (1984); and PETER GALISON, *How Experiments End* (1987), illustrate typical research procedures by means of case studies. ERNST MACH, *The Science of Me-*

chanics, 6th ed. (1974; originally published in German, 9th ed., 1933), is both a detailed history and a classic critique of fundamental assumptions. E.T. WHITTAKER, *A History of the Theories of Aether and Electricity*, vol. 1, *The Classical Theories*, rev. and enlarged ed. (1951, reprinted 1973), is equally detailed but less philosophically oriented.

Special topics in more recent physics are treated by ALBERT EINSTEIN, *Relativity: The Special & the General Theory* (1920; originally published in German, 1917), and many later editions; WOLFGANG RINDLER, *Essential Relativity: Special, General, and Cosmological*, rev. 2nd ed. (1979); STEVEN WEINBERG, *The Discovery of Subatomic Particles* (1983), and *The First Three Minutes: A Modern View of the Origin of the Universe*, updated ed. (1988); NATHAN SPIELBERG and BRYON D. ANDERSON, *Seven Ideas that Shook the Universe* (1985); P.C.W. DAVIES, *The Forces of Nature*, 2nd ed. (1986); A. ZEE, *Fearful Symmetry: The Search for Beauty in Modern Physics* (1986); and TONY HEY and PATRICK WALTERS, *The Quantum Universe* (1987).

The principles of catastrophe theory are presented, without mathematical detail, in V.I. ARNOLD, *Catastrophe Theory*, 2nd rev. and expanded ed. (1986; originally published in Russian, 2nd ed. enlarged, 1983), which is notably scornful of speculative applications. A full treatment is provided in TIM POSTON and IAN STEWART, *Catastrophe Theory and Its Applications* (1978).

Introductions to chaotic processes are found in A.B. PIPPARD, *Response and Stability: An Introduction to the Physical Theory* (1985); and JAMES GLEICK, *Chaos: Making a New Science* (1987). More systematic is J.M.T. THOMPSON and H.B. STEWART, *Nonlinear Dynamics and Chaos: Geometrical Methods for Engineers and Scientists* (1986). Anthologies of influential early papers are BAI-LIN HAO (comp.), *Chaos* (1984); and PREDRAG CVITANOVIĆ (comp.), *Universality in Chaos* (1984).

The Physical Sciences

The physical sciences are the ongoing refined and systematic efforts to understand the inorganic world and the results of those efforts. They are generally divided into four broad areas: physics, chemistry, astronomy, and the Earth sciences. The historical development of the first three is surveyed in this article; due attention is also given to their scope, principal concerns, and methods. A complementary treatment of the Earth sciences is provided in a separate article.

Physics, in its modern sense, was founded in the mid-19th century as a synthesis of several older sciences—namely, those of mechanics, optics, acoustics, electricity, magnetism, heat, and the physical properties of matter. The synthesis was based in large part on the recognition that the different forces of nature are related and are, in fact, interconvertible because they are forms of energy.

The boundary between physics and chemistry is somewhat arbitrary. As it has developed in the 20th century, physics is concerned with the structure and behaviour of individual atoms and their components, while chemistry deals with the properties and reactions of molecules. These latter depend on energy, especially heat, as well as on atoms; hence, there is a strong link between physics and chemistry. Chemists tend to be more interested in the specific properties of different elements and compounds,

whereas physicists are concerned with general properties shared by all matter.

Astronomy is the science of the entire universe beyond the Earth; it includes the Earth's gross physical properties, such as its mass and rotation, insofar as they interact with other bodies in the solar system. Until the 18th century, astronomers were concerned primarily with the Sun, Moon, planets, and comets. During the last two centuries, however, the study of stars, galaxies, nebulae, and the interstellar medium has become increasingly important. Celestial mechanics, the science of the motion of planets and other solid objects within the solar system, was the first testing ground for Newton's laws of motion and thereby helped to establish the fundamental principles of classical (that is, pre-20th-century) physics. Astrophysics, the study of the physical properties of celestial bodies, arose during the 19th century and is closely connected with the determination of the chemical composition of those bodies. In the 20th century physics and astronomy have become more intimately linked through cosmological theories, especially those based on the theory of relativity.

For coverage of topics related to physics, chemistry, and astronomy in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 111–133, 10/31, and 10/32.

History of the physical sciences

HERITAGE OF ANTIQUITY AND THE MIDDLE AGES

The physical sciences ultimately derive from the rationalistic materialism that emerged in classical Greece, itself an outgrowth of magical and mythical views of the world. The Greek philosophers of the 6th and 5th centuries BC abandoned the animism of the poets and explained the world in terms of ordinarily observable natural processes. These early philosophers posed the broad questions that still underlie science: How did the world order emerge

from chaos? What is the origin of multitude and variety in the world? How can motion and change be accounted for? What is the underlying relation between form and matter? Greek philosophy answered these questions in terms that provided the framework for science for approximately 2,000 years.

Ancient Middle Eastern and Greek astronomy. Western astronomy had its origins in Egypt and Mesopotamia. Egyptian astronomy, which was neither a very well-developed nor an influential study, was largely concerned with time reckoning. Its main lasting contribution was the civil

Egyptian and Mesopotamian origins

calendar of 365 days, consisting of 12 months of 30 days each and five additional festival days at the end of each year. This calendar played an important role in the history of astronomy, allowing astronomers to calculate the number of days between any two sets of observations.

Babylonian astronomy, dating back to about 1800 BC, constitutes one of the earliest systematic, scientific treatments of the physical world. In contrast to the Egyptians, the Babylonians were interested in the accurate prediction of astronomical phenomena, especially the first appearance of the new Moon. Using the zodiac as a reference, by the 4th century BC, they developed a complex system of arithmetic progressions and methods of approximation by which they were able to predict first appearances. At no point in the Babylonian astronomical literature is there the least evidence of the use of geometric models. The mass of observations they collected and their mathematical methods were important contributions to the later flowering of astronomy among the Greeks.

The Pythagoreans (5th century BC) were responsible for one of the first Greek astronomical theories. Believing that the order of the cosmos is fundamentally mathematical, they held that it is possible to discover the harmonies of the universe by contemplating the regular motions of the heavens. Postulating a central fire about which all the heavenly bodies including the Earth and Sun revolve, they constructed the first physical model of the solar system. Subsequent Greek astronomy derived its character from a comment ascribed to Plato, in the 4th century BC, who is reported to have instructed the astronomers to "save the phenomena" in terms of uniform circular motion. That is to say, he urged them to develop predictively accurate theories using only combinations of uniform circular motion. As a result, Greek astronomers never regarded their geometric models as true or as being physical descriptions of the machinery of the heavens. They regarded them simply as tools for predicting planetary positions.

Eudoxus of Cnidus (4th century BC) was the first of the Greek astronomers to rise to Plato's challenge. He developed a theory of homocentric spheres, a model that represented the universe by sets of nesting concentric spheres the motions of which combined to produce the planetary and other celestial motions. Using only uniform circular motions, Eudoxus was able to "save" the rather complex planetary motions with some success. His theory required four homocentric spheres for each planet and three each for the Sun and Moon. The system was modified by Callippus, a student of Eudoxus, who added spheres to improve the theory, especially for Mercury and Venus. Aristotle, in formulating his cosmology, adopted Eudoxus' homocentric spheres as the actual machinery of the heavens. The Aristotelian cosmos was like an onion consisting of a series of some 55 spheres nested about the Earth, which was fixed at the centre. In order to unify the system, Aristotle added spheres in order to "unroll" the motions of a given planet so that they would not be transmitted to the next inner planet.

The theory of homocentric spheres failed to account for two sets of observations: (1) brightness changes suggesting that planets are not always the same distance from the Earth, and (2) bounded elongations (*i.e.*, Venus is never observed to be more than about 48° and Mercury never more than about 24° from the Sun). Heracleides of Pontus (4th century BC) attempted to solve these problems by having Venus and Mercury revolve about the Sun, rather than the Earth, and having the Sun and other planets revolve in turn about the Earth, which he placed at the centre. In addition, to account for the daily motions of the heavens, he held that the Earth rotates on its axis. Heracleides' theory had little impact in antiquity except perhaps on Aristarchus of Samos (3rd century BC), who apparently put forth a heliocentric hypothesis similar to the one Copernicus was to propound in the 16th century.

Hipparchus (fl. 130 BC) made extensive contributions to both theoretical and observational astronomy. Basing his theories on an impressive mass of observations, he was able to work out theories of the Sun and Moon that were more successful than those of any of his predecessors. His primary conceptual tool was the eccentric circle, a circle

in which the Earth is at some point eccentric to the geometric centre. He used this device to account for various irregularities and inequalities observed in the motions of the Sun and Moon. He also proved that the eccentric circle is mathematically equivalent to a geometric figure called an epicycle-deferent system, a proof probably first made by Apollonius of Perga a century earlier.

Among Hipparchus' observations, one of the most significant was that of the precession of the equinoxes—*i.e.*, a gradual apparent increase in longitude between any fixed star and the equinoctial point (either of two points on the celestial sphere where the celestial equator crosses the ecliptic). Thus the north celestial pole, the point on the celestial sphere defined as the apparent centre of rotation of the stars, moves relative to the stars in its vicinity. In the heliocentric theory, this effect is ascribed to a change in the Earth's rotational axis, which traces out a conical path around the axis of the orbital plane.

Claudius Ptolemy (fl. AD 140) applied the theory of epicycles to compile a systematic account of Greek astronomy. He elaborated theories for each of the planets, as well as for the Sun and Moon. His theory generally fitted the data available to him with a good degree of accuracy, and his book, the *Almagest*, became the vehicle by which Greek astronomy was transmitted to astronomers of the Middle Ages and Renaissance. It essentially molded astronomy for the next millennium and a half.

Greek physics. Several kinds of physical theories emerged in ancient Greece, including both generalized hypotheses about the ultimate structure of nature and more specific theories that considered the problem of motion from both metaphysical and mathematical points of view. Attempting to reconcile the antithesis between the underlying unity and apparent multitude and diversity of nature, the Greek atomists Leucippus (mid-5th century BC), Democritus (late 5th century BC), and Epicurus (late 4th and early 3rd century BC) asserted that nature consists of immutable atoms moving in empty space. According to this theory, the various motions and configurations of atoms and clusters of atoms are the causes of all the phenomena of nature.

In contrast to the particulate universe of the atomists, the Stoics (principally Zeno, of Citium, bridging 4th and 3rd centuries BC, Chrysippus [3rd century BC], and Poseidonius of Apamea [fl. c. 100 BC]) insisted on the continuity of nature, conceiving of both space and matter as continuous and as infused with an active, airlike spirit—*pneuma*—which serves to unify the frame of nature. The inspiration for the Stoic emphasis on pneumatic processes probably arose from earlier experiences with the "spring" (*i.e.*, compressibility and pressure) of the air. Neither the atomic theory nor Stoic physics survived the criticism of Aristotle and his theory.

In his physics, Aristotle was primarily concerned with the philosophical question of the nature of motion as one variety of change. He assumed that a constant motion requires a constant cause; that is to say, as long as a body remains in motion, a force must be acting on that body. He considered the motion of a body through a resisting medium as proportional to the force producing the motion and inversely proportional to the resistance of the medium. Aristotle used this relationship to argue against the possibility of the existence of a void, for in a void resistance is zero, and the relationship loses meaning. He considered the cosmos to be divided into two qualitatively different realms, governed by two different kinds of laws. In the terrestrial realm, within the sphere of the Moon, rectilinear up-and-down motion is characteristic. Heavy bodies, by their nature, seek the centre and tend to move downward in a natural motion. It is unnatural for a heavy body to move up, and such unnatural or violent motion requires an external cause. Light bodies, in direct contrast, move naturally upward. In the celestial realm, uniform circular motion is natural, thus producing the motions of the heavenly bodies.

Archimedes (3rd century BC) fundamentally applied mathematics to the solution of physical problems and brilliantly employed physical assumptions and insights leading to mathematical demonstrations, particularly in problems

of statics and hydrostatics. He was thus able to derive the law of the lever rigorously and to deal with problems of the equilibrium of floating bodies.

Islamic and medieval science. Greek science reached a zenith with the work of Ptolemy in the 2nd century AD. The lack of interest in theoretical questions in the Roman world reduced science in the Latin West to the level of predigested handbooks and encyclopaedias that had been distilled many times. Social pressures, political persecution, and the anti-intellectual bias of some of the early Church Fathers drove the few remaining Greek scientists and philosophers to the East. There they ultimately found a welcome when the rise of Islam in the 7th century stimulated interest in scientific and philosophical subjects. Most of the important Greek scientific texts were preserved in Arabic translations. Although the Muslims did not alter the foundations of Greek science, they made several important contributions within its general framework. When interest in Greek learning revived in western Europe during the 12th and 13th centuries, scholars turned to Islamic Spain for the scientific texts. A spate of translations resulted in the revival of Greek science in the West and coincided with the rise of the universities. Working within a predominantly Greek framework, scientists of the late Middle Ages reached high levels of sophistication and prepared the ground for the scientific revolution of the 16th and 17th centuries.

Mechanics was one of the most highly developed sciences pursued in the Middle Ages. Operating within a fundamentally Aristotelian framework, medieval physicists criticized and attempted to improve many aspects of Aristotle's physics.

The problem of projectile motion was a crucial one for Aristotelian mechanics, and the analysis of this problem represents one of the most impressive medieval contributions to physics. Because of the assumption that continuation of motion requires the continued action of a motive force, the continued motion of a projectile after losing contact with the projector required explanation. Aristotle himself had proposed explanations of the continuation of projectile motion in terms of the action of the medium. The ad hoc character of these explanations rendered them unsatisfactory to most of the medieval commentators, who nevertheless retained the fundamental assumption that continued motion requires a continuing cause.

The most fruitful alternative to Aristotle's attempts to explain projectile motion resulted from the concept of impressed force. According to this view, there is an incorporeal motive force that is imparted to the projectile, causing it to continue moving. Such views were espoused by John Philoponus of Alexandria (fl. 6th century), Avicenna, the Persian philosopher (d. 1037), and the Arab Abū al Barakāt al-Baghdādī (d. 1164). In the 14th century the French philosopher Jean Buridan developed a new version of the impressed-force theory, calling the quality impressed on the projectile "impetus." Impetus, a permanent quality for Buridan, is measurable by the initial velocity of the projectile and by the quantity of matter contained in it. Buridan employed this concept to suggest an explanation of the everlasting motions of the heavens.

During the 1300s certain Oxford scholars pondered the philosophical problem of how to describe the change that occurs when qualities increase or decrease in intensity and came to consider the kinematic aspects of motion. Dealing with these problems in a purely hypothetical manner without any attempt to describe actual motions in nature or to test their formulas experimentally, they were able to derive the result that in a uniformly accelerated motion, distance increases as the square of the time.

Although medieval science was deeply influenced by Aristotle's philosophy, adherence to his point of view was by no means dogmatic. During the 13th century, theologians at the University of Paris were disturbed by certain statements in Aristotle that seemed to imply limitations of God's powers as well as other statements, such as the eternity of the world, which stood in apparent contradiction to scripture. In 1277 Pope John XXI condemned 219 propositions, many from Aristotle and St. Thomas Aquinas, which had clearly theological consequences. Many of

these condemned propositions had scientific implications as well. For example, one of these propositions states, "That the first cause (*i.e.*, God) could not make several worlds." Although it is unlikely that anyone in the Middle Ages actually asserted the existence of many worlds, the condemnation led to the discussion of that possibility, as well as other important problems such as the possibility that the Earth moved.

THE SCIENTIFIC REVOLUTION

During the 15th, 16th, and 17th centuries, scientific thought underwent a revolution. A new view of nature emerged, replacing the Greek view that had dominated science for almost 2,000 years. Science became an autonomous discipline, distinct from both philosophy and technology, and it came to be regarded as having utilitarian goals. By the end of this period, it may not be too much to say that science had replaced Christianity as the focal point of European civilization. Out of the ferment of the Renaissance and Reformation there arose a new view of science, bringing about the following transformations: the reeducation of common sense in favour of abstract reasoning; the substitution of a quantitative for a qualitative view of nature; the view of nature as a machine rather than as an organism; the development of an experimental method that sought definite answers to certain limited questions couched in the framework of specific theories; the acceptance of new criteria for explanation, stressing the "how" rather than the "why" that had characterized the Aristotelian search for final causes.

Astronomy. The scientific revolution began in astronomy. Although there had been earlier discussions of the possibility of the Earth's motion, the Polish astronomer Nicolaus Copernicus was the first to propound a comprehensive heliocentric theory, equal in scope and predictive capability to Ptolemy's geocentric system. Motivated by the desire to satisfy Plato's dictum, Copernicus was led to overthrow traditional astronomy because of its alleged violation of the principle of uniform circular motion and its lack of unity and harmony as a system of the world. Relying on virtually the same data as Ptolemy had possessed, Copernicus turned the world inside out, putting the Sun at the centre and setting the Earth into motion around it. Copernicus' theory, published in 1543, possessed a qualitative simplicity that Ptolemaic astronomy appeared to lack. To achieve comparable levels of quantitative precision, however, the new system became just as complex as the old. Perhaps the most revolutionary aspect of Copernican astronomy lay in Copernicus' attitude toward the reality of his theory. In contrast to Platonic instrumentalism, Copernicus asserted that to be satisfactory astronomy must describe the real, physical system of the world.

The reception of Copernican astronomy amounted to victory by infiltration. By the time large-scale opposition to the theory had developed in the church and elsewhere, most of the best professional astronomers had found some aspect or other of the new system indispensable. Copernicus' book *De revolutionibus orbium coelestium, libri VI* (1543; *On the Revolutions of the Celestial Spheres*) became a standard reference for advanced problems in astronomical research, particularly for its mathematical techniques. Thus, it was widely read by mathematical astronomers, in spite of its central cosmological hypothesis, which was widely ignored. In 1551 the German astronomer Erasmus Reinhold published the *Tabulae prutenicae* ("Prutenic Tables"), computed by Copernican methods. The tables were more accurate and more up-to-date than their 13th-century predecessor and became indispensable to both astronomers and astrologers.

During the 16th century the Danish astronomer Tycho Brahe, rejecting both the Ptolemaic and Copernican systems, was responsible for major changes in observation, unwittingly providing the data that ultimately decided the argument in favour of the new astronomy. Using larger, stabler, and better calibrated instruments, he observed regularly over extended periods, thereby obtaining a continuity of observations that were accurate for planets to within about one minute of arc—several times better than any previous observation. Several of Tycho's observations

view

contradicted Aristotle's system: a nova that appeared in 1572 exhibited no parallax (meaning that it lay at a very great distance) and was thus not of the sublunary sphere and therefore contrary to the Aristotelian assertion of the immutability of the heavens; similarly, a succession of comets appeared to be moving freely through a region that was supposed to be filled with solid, crystalline spheres. Tycho devised his own world system—a modification of Heraclides'—to avoid various undesirable implications of the Ptolemaic and Copernican systems.

At the beginning of the 17th century, the German astronomer Johannes Kepler placed the Copernican hypothesis on firm astronomical footing. Converted to the new astronomy as a student and deeply motivated by a neo-Pythagorean desire for finding the mathematical principles of order and harmony according to which God had constructed the world, Kepler spent his life looking for simple mathematical relationships that described planetary motions. His painstaking search for the real order of the universe forced him finally to abandon the Platonic ideal of uniform circular motion in his search for a physical basis for the motions of the heavens.

Kepler's laws

In 1609 Kepler announced two new planetary laws derived from Tycho's data: (1) the planets travel around the Sun in elliptical orbits, one focus of the ellipse being occupied by the Sun; and (2) a planet moves in its orbit in such a manner that a line drawn from the planet to the Sun always sweeps out equal areas in equal times. With these two laws, Kepler abandoned uniform circular motion of the planets on their spheres, thus raising the fundamental physical question of what holds the planets in their orbits. He attempted to provide a physical basis for the planetary motions by means of a force analogous to the magnetic force, the qualitative properties of which had been recently described in England by William Gilbert in his influential treatise, *De Magnete, Magneticisque Corporibus et de Magno Magnete Tellure* (1600; *William Gilbert of Colchester . . . on the Great Magnet of the Earth*). The impending marriage of astronomy and physics had been announced. In 1618 Kepler stated his third law, which was one of many laws concerned with the harmonies of the planetary motions: (3) the square of the period in which a planet orbits the Sun is proportional to the cube of its mean distance from the Sun.

Galileo's observation

A powerful blow was dealt to traditional cosmology by Galileo Galilei, who early in the 17th century used the telescope, a recent invention of Dutch lens grinders, to look toward the heavens. In 1610 Galileo announced observations that contradicted many traditional cosmological assumptions. He observed that the Moon is not a smooth, polished surface, as Aristotle had claimed, but that it is jagged and mountainous. Earthshine on the Moon revealed that the Earth, like the other planets, shines by reflected light. Like the Earth, Jupiter was observed to have satellites; hence, the Earth had been demoted from its unique position. The phases of Venus proved that that planet orbits the Sun, not the Earth.

Physics. *Mechanics.* The battle for Copernicanism was fought in the realm of mechanics as well as astronomy. The Ptolemaic-Aristotelian system stood or fell as a monolith, and it rested on the idea of Earth's fixity at the centre of the cosmos. Removing the Earth from the centre destroyed the doctrine of natural motion and place, and circular motion of the Earth was incompatible with Aristotelian physics.

Galileo's contributions to the science of mechanics were related directly to his defense of Copernicanism. Although in his youth he adhered to the traditional impetus physics, his desire to mathematize in the manner of Archimedes led him to abandon the traditional approach and develop the foundations for a new physics that was both highly mathematizable and directly related to the problems facing the new cosmology. Interested in finding the natural acceleration of falling bodies, he was able to derive the law of free fall (the distance, s , varies as the square of the time, t^2). Combining this result with his rudimentary form of the principle of inertia, he was able to derive the parabolic path of projectile motion. Furthermore, his principle of inertia enabled him to meet the traditional

physical objections to the Earth's motion: since a body in motion tends to remain in motion, projectiles and other objects on the terrestrial surface will tend to share the motions of the Earth, which will thus be imperceptible to someone standing on the Earth.

The 17th-century contributions to mechanics of the French philosopher René Descartes, like his contributions to the scientific endeavour as a whole, were more concerned with problems in the foundations of science than with the solution of specific technical problems. He was principally concerned with the conceptions of matter and motion as part of his general program for science—namely, to explain all the phenomena of nature in terms of matter and motion. This program, known as the mechanical philosophy, came to be the dominant theme of 17th-century science.

The rise of mechanical philosophy

Descartes rejected the idea that one piece of matter could act on another through empty space; instead, forces must be propagated by a material substance, the "ether," that fills all space. Although matter tends to move in a straight line in accordance with the principle of inertia, it cannot occupy space already filled by other matter, so the only kind of motion that can actually occur is a vortex in which each particle in a ring moves simultaneously.

According to Descartes, all natural phenomena depend on the collisions of small particles, and so it is of great importance to discover the quantitative laws of impact. This was done by Descartes's disciple, the Dutch physicist Christiaan Huygens, who formulated the laws of conservation of momentum and of kinetic energy (the latter being valid only for elastic collisions).

The work of Sir Isaac Newton represents the culmination of the scientific revolution at the end of the 17th century. His monumental *Philosophiæ Naturalis Principia Mathematica* (1687; *Mathematical Principles of Natural Philosophy*) solved the major problems posed by the scientific revolution in mechanics and in cosmology. It provided a physical basis for Kepler's laws, unified celestial and terrestrial physics under one set of laws, and established the problems and methods that dominated much of astronomy and physics for well over a century. By means of the concept of force, Newton was able to synthesize two important components of the scientific revolution, the mechanical philosophy and the mathematization of nature.

The impact of Newton

Newton was able to derive all these striking results from his three laws of motion:

1. Every body continues in its state of rest or of motion in a straight line unless it is compelled to change that state by force impressed on it;
2. The change of motion is proportional to the motive force impressed and is made in the direction of the straight line in which that force is impressed;
3. To every action there is always opposed an equal reaction: or, the mutual actions of two bodies upon each other are always equal.

The second law was put into its modern form $F = ma$ (where a is acceleration) by the Swiss mathematician Leonhard Euler in 1750. In this form, it is clear that the rate of change of velocity is directly proportional to the force acting on a body and inversely proportional to its mass.

In order to apply his laws to astronomy, Newton had to extend the mechanical philosophy beyond the limits set by Descartes. He postulated a gravitational force acting between any two objects in the universe, even though he was unable to explain how this force could be propagated.

The universality of gravitation

By means of his laws of motion and a gravitational force proportional to the inverse square of the distance between the centres of two bodies, Newton could deduce Kepler's laws of planetary motion. Galileo's law of free fall is also consistent with Newton's laws. The same force that causes objects to fall near the surface of the Earth also holds the Moon and planets in their orbits.

Newton's physics led to the conclusion that the shape of the Earth is not precisely spherical but should bulge at the Equator. The confirmation of this prediction by French expeditions in the mid-18th century helped persuade most European scientists to change from Cartesian to Newtonian physics. Newton also used the nonspherical shape of the Earth to explain the precession of the equinoxes,

using the differential action of the Moon and Sun on the equatorial bulge to show how the axis of rotation would change its direction.

Optics. The science of optics in the 17th century expressed the fundamental outlook of the scientific revolution by combining an experimental approach with a quantitative analysis of phenomena. Optics had its origins in Greece, especially in the works of Euclid (c. 300 BC), who stated many of the results in geometric optics that the Greeks had discovered, including the law of reflection: the angle of incidence is equal to the angle of reflection. In the 13th century, such men as Roger Bacon, Robert Grosseteste, and John Pecham, relying on the work of the Arab Alhazen (d. 1039), considered numerous optical problems, including the optics of the rainbow. It was Kepler, taking his lead from the writings of these 13th-century opticians, who set the tone for the science in the 17th century. Kepler introduced the point by point analysis of optical problems, tracing rays from each point on the object to a point on the image. Just as the mechanical philosophy was breaking the world into atomic parts, so Kepler approached optics by breaking organic reality into what he considered to be ultimately real units. He developed a geometric theory of lenses, providing the first mathematical account of Galileo's telescope.

Descartes sought to incorporate the phenomena of light into mechanical philosophy by demonstrating that they can be explained entirely in terms of matter and motion. Using mechanical analogies, he was able to derive mathematically many of the known properties of light, including the law of reflection and the newly discovered law of refraction.

Newton's
theory of
colours

Many of the most important contributions to optics in the 17th century were the work of Newton, especially the theory of colours. Traditional theory considered colours to be the result of the modification of white light. Descartes, for example, thought that colours were the result of the spin of the particles that constitute light. Newton upset the traditional theory of colours by demonstrating in an impressive set of experiments that white light is a mixture out of which separate beams of coloured light can be separated. He associated different degrees of refrangibility with rays of different colours, and in this manner he was able to explain the way prisms produce spectra of colours from white light.

His experimental method was characterized by a quantitative approach, since he always sought measurable variables and a clear distinction between experimental findings and mechanical explanations of those findings. His second important contribution to optics dealt with the interference phenomena that came to be called "Newton's rings." Although the colours of thin films (e.g., oil on water) had been previously observed, no one had attempted to quantify the phenomena in any way. Newton observed quantitative relations between the thickness of the film and the diameters of the rings of colour, a regularity he attempted to explain by his theory of fits of easy transmission and fits of easy reflection. Notwithstanding the fact that he generally conceived of light as being particulate, Newton's theory of fits involves periodicity and vibrations of ether, the hypothetical fluid substance permeating all space (see above).

Huygens was the second great optical thinker of the 17th century. Although he was critical of many of the details of Descartes's system, he wrote in the Cartesian tradition, seeking purely mechanical explanations of phenomena. Huygens regarded light as something of a pulse phenomenon, but he explicitly denied the periodicity of light pulses. He developed the concept of wave front, by means of which he was able to derive the laws of reflection and refraction from his pulse theory and to explain the recently discovered phenomenon of double refraction.

Chemistry. Chemistry had manifold origins, coming from such diverse sources as philosophy, alchemy, metallurgy, and medicine. It emerged as a separate science only with the rise of mechanical philosophy in the 17th century. Aristotle had regarded the four elements earth, water, air, and fire as the ultimate constituents of all things. Transmutable each into the other, all four elements were

believed to exist in every substance. Originating in Egypt and the Middle East, alchemy had a double aspect: on the one hand it was a practical endeavour aimed to make gold from baser substances, while on the other it was a cosmological theory based on the correspondence between man and the universe at large. Alchemy contributed to chemistry a long tradition of experience with a wide variety of substances. Paracelsus, a 16th-century Swiss natural philosopher, was a seminal figure in the history of chemistry, putting together in an almost impenetrable combination the Aristotelian theory of matter, alchemical correspondences, mystical forms of knowledge, and chemical therapy in medicine. His influence was widely felt in succeeding generations.

During the first half of the 17th century, there were few established doctrines that chemists generally accepted as a framework. As a result, there was little cumulative growth of chemical knowledge. Chemists tended to build detailed systems, "chemical philosophies," attempting to explain the entire universe in chemical terms. Most chemists accepted the traditional four elements (air, earth, water, fire), or the Paracelsian principles (salt, sulfur, mercury), or both, as the bearers of real qualities in substances; they also exhibited a marked tendency toward the occult.

The interaction between chemistry and mechanical philosophy altered this situation by providing chemists with a shared language. The mechanical philosophy had been successfully employed in other areas; it seemed consistent with an experimental empiricism and seemed to provide a way to render chemistry respectable by translating it into the terms of the new science. Perhaps the best example of the influence of the mechanical philosophy is the work of Robert Boyle. The thrust of his work was to understand the chemical properties of matter, to provide experimental evidence for the mechanical philosophy, and to demonstrate that all chemical properties can be explained in mechanical terms. He was an excellent laboratory chemist and developed a number of important techniques, especially colour-identification tests.

chemistry

SCIENCE FROM THE ENLIGHTENMENT TO THE 20TH CENTURY

Seminal contributions to science are those that change the tenor of the questions asked by succeeding generations. The works of Newton formed just such a contribution. The mathematical rigour of the *Principia* and the experimental approach of the *Opticks* became models for scientists of the 18th and 19th centuries. Celestial mechanics developed in the wake of his *Principia*, extending its scope and refining its mathematical methods. The more qualitative, experimental, and hypothetical approach of Newton's *Opticks* influenced the sciences of optics, electricity and magnetism, and chemistry.

Celestial mechanics and astronomy. Eighteenth-century theoretical astronomy in large measure derived both its point of view and its problems from the *Principia*. In this work Newton had provided a physics for the Copernican worldview by, among other things, demonstrating the implications of his gravitational theory for a two-body system consisting of the Sun and a planet. While Newton himself had grave reservations as to the wider scope of his theory, the 18th century witnessed various attempts to extend it to the solution of problems involving three gravitating bodies.

Early in the 18th century the English astronomer Edmond Halley, having noted striking similarities in the comets that had been observed in 1531, 1607, and 1682, argued that they were the periodic appearances every 75 years or so of but a single comet that he predicted would return in 1758. Months before its expected return, the French mathematician Alexis Clairaut employed rather tedious and brute-force mathematics to calculate the effects of the gravitational attraction of Jupiter and Saturn on the otherwise elliptical orbit of Comet Halley. Clairaut was finally able to predict in the fall of 1758 that Comet Halley would reach perihelion in April of 1759, with a leeway of one month. Its actual return, in March, was an early confirmation of the scope and power of the Newtonian theory.

Three-body
problem

It was, however, the three-body problem of either two planets and the Sun or the Sun–Earth–Moon system that provided the most persisting and profound test of Newton’s theory. This problem, involving more regular members of the solar system (*i.e.*, those describing nearly circular orbits having the same sense of revolution and in nearly the same plane), permitted certain simplifying assumptions and thereby invited more general and elegant mathematical approaches than the comet problem. An illustrious group of 18th-century continental mathematicians (including Clairaut; the Bernoulli family and Leonhard Euler of Switzerland; and Jean Le Rond d’Alembert, Joseph-Louis, comte de Lagrange, and Pierre-Simon, marquis de Laplace, of France) attacked these astronomical problems, as well as related ones in Newtonian mechanics, by developing and applying the calculus of variations as it had been formulated by Leibniz. It is a lovely irony that this continental exploitation of Leibniz’ mathematics—which was itself closely akin to Newton’s version of calculus, which he called fluxions—was fundamental for the deepening establishment of the Newtonian theory to which Leibniz had objected because it reintroduced, according to Leibniz, occult forces into physics.

In order to attack the lunar theory, which also commanded attention as the most likely astronomical approach to the navigational problem of determining longitude at sea, Clairaut was forced to adopt methods of approximation, having derived general equations that neither he nor anyone else could integrate. Even so, Clairaut was unable to calculate from gravitational theory a value for the progression of the lunar apogee greater than 50 percent of the observed value; therefore, he supposed in 1747 (with Euler) that Newton’s inverse-square law was but the first term of a series and, hence, an approximation not valid for distances as small as that between the Earth and Moon. This attempted refinement of Newtonian theory proved to be fruitless, however, and two years later Clairaut was able to obtain, by more detailed and elaborate calculations, the observed value from the simple inverse-square relation.

Certain of the three-body problems, most notably that of the secular acceleration of the Moon, defied early attempts at solution but finally yielded to the increasing power of the calculus of variations in the service of Newtonian theory. Thus it was that Laplace—in his five-volume *Traité de mécanique céleste* (1798–1827; *Celestial Mechanics*)—was able to comprehend the whole solar system as a dynamically stable, Newtonian gravitational system. The secular acceleration of the Moon reappeared as a theoretical problem in the middle of the 19th century, persisting into the 20th century and ultimately requiring that the effects of the tides be recognized in its solution.

Discovery
of Uranus,
Neptune,
and Pluto

Newtonian theory was also employed in much more dramatic discoveries that captivated the imagination of a broad and varied audience. Within 40 years of the discovery of Uranus in 1781 by the German-born British astronomer William Herschel, it was recognized that the planet’s motion was somewhat anomalous. In the next 20 years the gravitational attraction of an unobserved planet was suspected to be the cause of Uranus’ persisting deviations. In 1845 Urbain-Jean-Joseph Le Verrier of France and John Couch Adams of England independently calculated the position of this unseen body; the visual discovery (at the Berlin Observatory in 1846) of Neptune in just the position predicted constituted an immediately engaging and widely understood confirmation of Newtonian theory. In 1915 the American astronomer Percival Lowell published his prediction of yet another outer planet to account for further perturbations of Uranus not caused by Neptune. Pluto was finally discovered by sophisticated photographic techniques in 1930 and observed visually in 1950.

In the second half of the 19th century, the innermost region of the solar system also received attention. In 1859 Le Verrier calculated the specifications of an intra-mercurial planet to account for a residual advance in the perihelion of Mercury’s orbit (38 seconds of arc per century), an effect that was not gravitationally explicable in terms of known bodies. While a number of sightings of this predicted planet were reported between 1859 and 1878—

the first of these resulting in Le Verrier’s naming the new planet Vulcan—they were not confirmed by observations made either during subsequent solar eclipses or at the times of predicted transits of Vulcan across the Sun.

The theoretical comprehension of Mercury’s residual motion involved the first successful departure from Newtonian gravitational theory. This came in the form of Einstein’s formulation of the principle of the general of relativity, one consequence of which was a correction term for a body in motion. The correction involves the square of the ratio of the body’s velocity to the enormous velocity of light and hence, among the planets, is appreciable only for the fastest: Mercury. Einstein’s theory accounted for the residual effect, which by 1915 was calculated to be 43 seconds. This achievement, combined with the 1919 observation of the bending of a ray of light passing near a massive body (another consequence of general relativity theory), constitutes the main experimental verification of that theory.

Mercury’s
motion
and the
theory of
relativity

Astronomy of the 18th, 19th, and early 20th centuries was not quite so completely Newtonian, however. Herschel’s discovery of Uranus, for example, was not directly motivated by gravitational considerations. Nine years earlier, a German astronomer, Johann D. Titius, had announced a purely numerical sequence, subsequently refined by another German astronomer, Johann E. Bode, that related the mean radii of the planetary orbits—a relation entirely outside gravitational theory. The sequence, called Bode’s law (or the Bode–Titius law), is given by $0 + 4 = 4$, $3 + 4 = 7$, $3 \times 2 + 4 = 10$, $3 \times 4 + 4 = 16$, and so on, yielding additional values of 28, 52, and 100. If the measured radius of the Earth’s orbit is defined as being 10, then to a very good approximation that of Mercury is 4, Venus is 7, Mars is 15 plus, Jupiter is 52, and Saturn is 95 plus. The fit where it can be made is good and continues since the next number in the sequence is 196 and the measured radius for Uranus’ orbit is 191, but no planet had been observed to correspond to the Bode–Titius law value of 28. Powerful computational methods finally verified the existence of the asteroid Ceres and confirmed the law. The Bode–Titius law subsequently provided simplifying assumptions for the calculations of the predicted positions, which led to the observations of Neptune and Pluto, while the novel properties of the asteroids (nearly 500 of which had been discovered by the end of the century) stimulated star charts of the zodiacal regions, provided the means for improved measurements of solar-system distances, and forced astronomers, by their very number and variety, to face the question of the allocation of resources.

Regularities in the structure of the solar system, such as the Bode–Titius law, and the fact that all planets move in the same direction around the Sun suggested that the system might originally have been formed by a simple mechanistic process. Laplace proposed that this process was driven by the cooling of the hot, extended, rotating atmosphere of the primitive Sun. As the atmosphere contracted, it would have to rotate faster (to conserve angular momentum), and when centrifugal force exceeded gravity at the outside, a ring of material would be detached, later to condense into a planet. The process would be repeated several times and might also produce satellites. After Herschel suggested that the nebulas he observed in the sky were condensing to stars, the Laplace theory became known as the “nebular hypothesis.” It was the favoured theory of the origin of the solar system throughout the 19th century. During this period the associated idea that the Earth was originally a hot fluid ball that slowly cooled down while forming a solid outer crust dominated geologic speculation.

The
nebular
hypothesis

Attempts to detect the motion of the Earth caused investigators of the 18th and 19th centuries observational problems that were directly motivated by the Copernican theory. In 1728 the English astronomer James Bradley attributed annual changes that he observed in stellar positions to a slight tilting of the telescope with respect to the true direction of the star’s light, a tilting that compensated for the Earth’s motion. This effect, which depends also on the ratio of the Earth’s velocity to the velocity of light, is the so-called aberration of light.

In 1838 the long-sought “stellar parallax” effect—the apparent motion of nearby stars due to the Earth’s annual motion around the Sun—was discovered by the German astronomer Friedrich Wilhelm Bessel. While antiscientific as a verification of the Copernican hypothesis, the measurement of parallax provided for the first time a direct quantitative estimate of the distances of a few stars.

While attention has been focused on the more positional aspects of astronomy, mention should be made of two other broad areas of investigation that in their 19th-century form derived largely from the work of William Herschel. These areas, dealing with more structural features of the heavens and with the physical character of the stars, developed in large measure with advancements in physics.

Optics. Since they provided the principal basis for subsequent investigations, Newton’s optical views were subject to close consideration until well into the 19th century. From his researches into the phenomena of colour, Newton became convinced that dispersion necessarily accompanies refraction and that chromatic aberration (colour distortion) could therefore be eliminated by employing reflectors, rather than refractors, as telescopes. By the mid-18th century Euler and others had theoretical arguments against Newton, and Euler offered the human eye as an example of an achromatic lens system. Although he was virtually alone in this, Euler also rejected Newton’s essentially corpuscular theory of the nature of light by explaining optical phenomena in terms of vibrations in a fluid ether. The dominance of Newton’s theory throughout the 18th century was due partly to its successful direct application by Newton and his followers and partly to the comprehensiveness of Newton’s thought. For example, Bradley’s observations found an immediate and natural explanation in terms of the corpuscular theory that also was supported by the accelerating success of Newton’s gravitational theory involving discrete particles of matter.

At the turn of the century, Thomas Young, an English physician studying the power of accommodation of the eye (*i.e.*, its focusing power), was led gradually to extensive investigations and discoveries in optics, including the effect of interference. By means of a wave theory of light, Young was able to explain both this effect, which in its most dramatic manifestation results in two rays of light canceling each other to produce darkness, and also the various colour phenomena observed by Newton. The wave theory of light was developed from 1815 onward in a series of brilliant mathematical and experimental memoirs of the physicist Augustin-Jean Fresnel but was countered by adherents of the corpuscular theory, most notably by a group of other French scientists, Pierre-Simon Laplace, Siméon-Denis Poisson, Étienne Malus, and Jean-Baptiste Biot, and most strikingly in connection with Malus’ discovery (1808) of the polarization of light by reflection. Following Young’s suggestion in 1817, Fresnel was able to render polarization effects comprehensible by means of a wave theory that considered light to be a transverse rather than a longitudinal wave, as the analogy with sound had suggested.

The propagation of a transverse wave, the velocity of which through various media and under a variety of conditions was measured terrestrially with increasing accuracy from mid-century onward, seemed to require an ether having the properties of a highly elastic solid (*e.g.*, such as steel), which, however, offered no resistance to the planetary motions. These bizarre properties stimulated a number of mechanical models of the ether, most notably those of the English physicist William Thomson, Lord Kelvin. In order to encompass the aberration of light by means of his wave theory, Fresnel had assumed that the motionless ether freely permeated the opaque Earth and thus remained unaffected by its motions. Furthermore, he derived as a theoretical consequence (verified experimentally in mid-century by Armand-Hippolyte-Louis Fizeau) that the ether was partially, and only partially, dragged along by a moving transparent substance depending on the index of refraction of the substance. However, all subsequent investigators (most notably the American scientists A.A. Michelson and Edward W. Morley, in 1887) failed in their attempts to measure the required ether

drift. It was just to escape this difficulty of a necessary but undetected ether drift that George Francis FitzGerald of England and the Dutch theorist Hendrik Antoon Lorentz independently, at the close of the century, postulated the contraction of moving bodies in the direction of their motion through the ether. The Lorentz-FitzGerald contraction involves the square of the ratio of the velocity of the body to the velocity of light and ensures theoretically the experimental undetectability of the ether drift. It was the seeming necessity of arbitrary postulations of this kind that was eliminated by Einstein’s formulation of relativity theory.

Electricity and magnetism. Until the end of the 18th century, investigations in electricity and magnetism exhibited more of the hypothetical and spontaneous character of Newton’s *Opticks* than the axiomatic and somewhat forbidding tone of his *Principia*. Early in the century, in England Stephen Gray and in France Charles François de Cisternay DuFay studied the direct and induced electrification of various substances by the two kinds of electricity (then called vitreous and resinous and now known as positive and negative), as well as the capability of these substances to conduct the “effluvium” of electricity. By about mid-century, the use of Leyden jars (to collect charges) and the development of large static electricity machines brought the experimental science into the drawing room, while the theoretical aspects were being cast in various forms of the single-fluid theory (by the American Benjamin Franklin and the German-born physicist F.M.U.T.H. Aepinus, among others) and the two-fluid theory.

By the end of the 18th century, in England, Joseph Priestley had noted that no electric effect was exhibited inside an electrified hollow metal container and had brilliantly inferred from this similarity that the inverse-square law (of gravity) must hold for electricity as well. In a series of painstaking memoirs, the French physicist Charles-Augustin de Coulomb, using a torsion balance that Henry Cavendish had used in England to measure the gravitational force, demonstrated the inverse-square relation for electrical and magnetic attractions and repulsions. Coulomb went on to apply this law to calculate the surface distribution of the electrical fluid in such a fundamental manner as to provide the basis for the 19th-century extensions by Poisson and Lord Kelvin.

The discovery of galvanic electricity and the development of voltaic electricity opened whole new areas of investigation for the 19th century by providing convenient sources of sustained electrical current. The Danish physicist Hans Christian Ørsted’s discovery, in 1820, of the magnetic effect accompanying an electric current led almost immediately to quantitative laws of electromagnetism and electrodynamics. By 1827, André-Marie Ampère had published a series of mathematical and experimental memoirs on his electrodynamic theory that not only rendered electromagnetism comprehensible but also ordinary magnetism, identifying both as the result of electrical currents. Ampère solidly established his electrodynamics by basing it on inverse-square forces (which, however, are directed at right angles to, rather than in, the line connecting the two interacting elements) and by demonstrating that the effects do not violate Newton’s third law of motion, notwithstanding their transverse direction.

Michael Faraday’s discovery in 1831 of electromagnetic induction (the inverse of the effect discovered by Ørsted), his experimental determination of the identity of the various forms of electricity (1833), his discovery of the rotation of the plane of polarization of light by magnetism (1845), in addition to certain findings of other investigators—*e.g.*, the discovery by James Prescott Joule in 1843 (and others) of the mechanical equivalent of heat (the conservation of energy)—all served to emphasize the essential unity of the forces of nature. Within electricity and magnetism attempts at theoretical unification were conceived in terms of either gravitational-type forces acting at a distance, as with Ampère, or, with Faraday, in terms of lines of force and the ambient medium in which they were thought to travel. The German physicists Wilhelm Eduard Weber and Rudolph Kohlrausch, in order to determine the

effects

coefficients in his theory of the former kind, measured the ratio of the electromagnetic and electrostatic units of electrical charge to be equal to the velocity of light.

The Scottish physicist James Clerk Maxwell developed his profound mathematical electromagnetic theory from 1855 onward. He drew his conceptions from Faraday and thus relied fundamentally on the ether required by optical theory, while using ingenious mechanical models. One consequence of Maxwell's mature theory was that an electromagnetic wave must be propagated through the ether with a velocity equal to the ratio of the electromagnetic to electrostatic units. Combined with the earlier results of Weber and Kohlrausch, this result implied that light is an electromagnetic phenomenon. Moreover, it suggested that electromagnetic waves of wavelengths other than the narrow band corresponding to visible light should exist in nature or could be artificially generated.

Maxwell's theory received direct verification in 1886, when Heinrich Hertz of Germany detected the predicted electromagnetic waves. Their use in long-distance communication—"radio"—followed within two decades, and gradually physicists became acquainted with the entire electromagnetic spectrum.

Chemistry. Eighteenth-century chemistry was derived from and remained involved with questions of mechanics, light, and heat as well as with iatrochemistry and notions of medical therapy and the interaction between substances and the formation of new substances. Chemistry took many of its problems and much of its viewpoint from the *Opticks* and especially the "Queries" with which that work ends. Newton's suggestion of a hierarchy of clusters of unalterable particles formed by virtue of the specific attractions of its component particles led directly to comparative studies of interactions and thus to the tables of affinities of the physician Herman Boerhaave and others early in the century. This work culminated at the end of the century in the Swede Torbern Bergman's table that gave quantitative values of the affinity of substances both for reactions when "dry" and when in solution and that considered double as well as simple affinities.

Seventeenth-century investigations of "airs" or gases, combustion and calcination, and the nature and role of fire were incorporated by the chemists Johann Joachim Becher and Georg Ernst Stahl of Sweden into a theory of phlogiston. According to this theory, which was most influential after the middle of the 18th century, the fiery principle, phlogiston, was released into the air in the processes of combustion, calcination, and respiration. The theory explained that air was simply the receptacle for phlogiston, and any combustible or calcinable substance contained phlogiston as a principle or element and thus could not itself be elemental. Iron, in rusting, was considered to lose its compound nature and to assume its elemental state as the calx of iron by yielding its phlogiston into the ambient air.

Investigations that isolated and identified various gases in the second half of the 18th century, most notably the English chemist Joseph Black's quantitative manipulations of "fixed air" (carbon dioxide) and Joseph Priestley's discovery of "dephlogisticated air" (oxygen), were instrumental for the French chemist Antoine Lavoisier's formulation of his own oxygen theory of combustion and rejection of the phlogiston theory (*i.e.*, he explained combustion not as the result of the liberation of phlogiston, but rather as the result of the combination of the burning substance with oxygen). This transformation coupled with the reform in nomenclature at the end of the century (due to Lavoisier and others)—a reform that reflected the new conceptions of chemical elements, compounds, and processes—constituted the revolution in chemistry.

Very early in the 19th century, another study of gases, this time in the form of a persisting Newtonian approach to certain meteorological problems by the British chemist John Dalton, led to the enunciation of a chemical atomic theory. From this theory, which was demonstrated to agree with the law of definite proportions and from which the law of multiple proportions was derived, Dalton was able to calculate definite atomic weights by assuming the simplest possible ratio for the numbers of combining atoms.

For example, knowing from experiment that the ratio of the combining weights of hydrogen to oxygen in the formation of water is 1 to 8 and by assuming that one atom of hydrogen combined with one atom of oxygen, Dalton affirmed that the atomic weight of oxygen was eight, based on hydrogen as one. At the same time, however, in France, Joseph-Louis Gay-Lussac, from his volumetric investigations of combining gases, determined that two volumes of hydrogen combined with one of oxygen to produce water. While this suggested H₂O rather than Dalton's HO as the formula for water, with the result that the atomic weight of oxygen becomes 16, it did involve certain inconsistencies with Dalton's theory.

As early as 1811 the Italian physicist Amedeo Avogadro was able to reconcile Dalton's atomic theory with Gay-Lussac's volumetric law by postulating that Dalton's atoms were indeed compound atoms, or polyatomic. For a number of reasons, one of which involved the recent successes of electrochemistry, Avogadro's hypothesis was not accepted until it was reintroduced by the Italian chemist Stanislao Cannizzaro half a century later. From the turn of the century, the English scientist Humphry Davy and many others had employed the strong electric currents of voltaic piles for the analysis of compound substances and the discovery of new elements. From these results, it appeared obvious that chemical forces were essentially electrical in nature and that two hydrogen atoms, for example, having the same electrical charge, would repel each other and could not join to form the polyatomic molecule required by Avogadro's hypothesis. Until the development of a quantum-mechanical theory of the chemical bond, beginning in the 1920s, bonding was described by empirical "valence" rules but could not be satisfactorily explained in terms of purely electrical forces.

Between the presentation of Avogadro's hypothesis in 1811 and its general acceptance soon after 1860, several experimental techniques and theoretical laws were used by various investigators to yield different but self-consistent schemes of chemical formulas and atomic weights. After its acceptance, these schemes became unified. Within a few years of the development of another powerful technique, spectrum analysis, by the German physicists Gustav Kirchhoff and Robert Bunsen in 1859, the number of chemical elements whose atomic weights and other properties were known had approximately doubled since the time of Avogadro's announcement. By relying fundamentally but not slavishly upon the determined atomic weight values and by using his chemical insight and intuition, the Russian chemist Dmitry Ivanovich Mendeleev provided a classification scheme that ordered much of this burgeoning information and was a culmination of earlier attempts to represent the periodic repetition of certain chemical and physical properties of the elements.

The significance of the atomic weights themselves remained unclear. In 1815 William Prout, an English chemist, had proposed that they might all be integer multiples of the weight of the hydrogen atom, implying that the other elements are simply compounds of hydrogen. More accurate determinations, however, showed that the atomic weights are significantly different from integers. They are not, of course, the actual weights of individual atoms, but by 1870 it was possible to estimate those weights (or rather masses) in grams by the kinetic theory of gases and other methods. Thus one could at least say that the atomic weight of an element is proportional to the mass of an atom of that element. (M.J.O./J.B.Sp./S.G.B.)

DEVELOPMENTS AND TRENDS OF THE 20TH CENTURY

Astronomy. Some of the most spectacular advances in modern astronomy have come from research on the large-scale structure and development of the universe. This research goes back to William Herschel's observations of nebulae at the end of the 18th century. Some astronomers considered them to be "island universes"—huge stellar systems outside of and comparable to the Milky Way Galaxy, to which the solar system belongs. Others, following Herschel's own speculations, thought of them simply as gaseous clouds—relatively small patches of diffuse matter within the Milky Way Galaxy, which might be in the

Avogadro's hypothesis

The nature of light

Theory of phlogiston

Lavoisier's revolution

process of developing into stars and planetary systems, as described in Laplace's nebular hypothesis.

In 1912 Vesto Melvin Slipher began at the Lowell Observatory in Arizona an extensive program to measure the velocities of nebulae, using the Doppler shift of their spectral lines. (Doppler shift is the observed change in wavelength of the radiation from a source that results from the relative motion of the latter along the line of sight.) By 1925 he had studied about 40 nebulae, most of which were found to be moving away from the Earth according to the red shift (displacement toward longer wavelengths) of their spectra.

Although the nebulae were apparently so far away that their distances could not be measured directly by the stellar parallax method, an indirect approach was developed on the basis of a discovery made in 1908 by Henrietta Swan Leavitt at the Harvard College Observatory. Leavitt studied the magnitudes (apparent brightnesses) of a large number of variable stars, including the type known as Cepheid variables. Some of them were close enough to have measurable parallaxes so that their distances and thus their intrinsic brightnesses could be determined. She found a correlation between brightness and period of variation. Assuming that the same correlation holds for all stars of this kind, their observed magnitudes and periods could be used to estimate their distances.

In 1923 the American astronomer Edwin P. Hubble identified a Cepheid variable in the so-called Andromeda Nebula. Using Leavitt's period-brightness correlation, Hubble estimated its distance to be approximately 900,000 light-years. Since this was much greater than the size of the Milky Way system, it appeared that the Andromeda Nebula must be another galaxy (island universe) outside of our own.

In 1929 Hubble combined Slipher's measurements of the velocities of nebulae with further estimates of their distances and found that on the average such objects are moving away from the Earth with a velocity proportional to their distance. Hubble's velocity-distance relation suggested that the universe of galactic nebulae is expanding, starting from an initial state about 2,000,000,000 years ago in which all matter was contained in a fairly small volume. Revisions of the distance scale in the 1950s and later increased the "Hubble age" of the universe to more than 10,000,000,000 years.

Calculations by Aleksandr A. Friedmann in the Soviet Union, Willem de Sitter in The Netherlands, and Georges Lemaître in Belgium, based on Einstein's general theory of relativity, showed that the expanding universe could be explained in terms of the evolution of space itself. According to Einstein's theory, space is described by the non-Euclidean geometry proposed in 1854 by the German mathematician G.F. Bernhard Riemann. Its departure from Euclidean space is measured by a "curvature" that depends on the density of matter. The universe may be finite, though unbounded, like the surface of a sphere. Thus the expansion of the universe refers not merely to the motion of extragalactic stellar systems within space but also to the expansion of the space itself.

The beginning of the expanding universe was linked to the formation of the chemical elements in a theory developed in the 1940s by the physicist George Gamow, a former student of Friedmann who had emigrated to the United States. Gamow proposed that the universe began in a state of extremely high temperature and density and exploded outward—the so-called big bang. Matter was originally in the form of neutrons, which quickly decayed into protons and electrons; these then combined to form hydrogen and heavier elements.

Gamow's students Ralph Alpher and Robert Herman estimated in 1948 that the radiation left over from the big bang should by now have cooled down to a temperature just a few degrees above absolute zero (0 K, or -459° F). In 1965 the predicted cosmic background radiation was discovered by Arno A. Penzias and Robert W. Wilson of the Bell Telephone Laboratories as part of an effort to build sensitive microwave-receiving stations for satellite communication. Their finding provided unexpected evidence for the idea that the universe was in a state of very

high temperature and density sometime between 10,000-, 000,000 and 20,000,000,000 years ago.

Evolution of stars and formation of chemical elements. Just as the development of cosmology relied heavily on ideas from physics, especially Einstein's general theory of relativity, so did theories of stellar structure and evolution depend on discoveries in atomic physics. These theories also offered a fundamental basis for chemistry by showing how the elements could have been synthesized in stars.

The idea that stars are formed by the condensation of gaseous clouds was part of the 19th-century nebular hypothesis (see above). The gravitational energy released by this condensation could be transformed into heat, but calculations by Hermann von Helmholtz and Lord Kelvin indicated that this process would provide energy to keep the Sun shining for only about 20,000,000 years. Evidence from radiometric dating, starting with the work of the British physicist Ernest Rutherford in 1905, showed that the Earth is probably several billion years old. Astrophysicists were perplexed: what source of energy has kept the Sun shining for such a long time?

In 1925 Cecilia Payne, a graduate student from Britain at Harvard College Observatory, analyzed the spectra of stars using statistical atomic theories that related them to temperature, density, and composition. She found that hydrogen and helium are the most abundant elements in stars, though this conclusion was not generally accepted until it was confirmed four years later by the noted American astronomer Henry Norris Russell. By this time Prout's hypothesis that all the elements are compounds of hydrogen had been revived by physicists in a somewhat more elaborate form. The deviation of atomic weights from exact integer values (expressed as multiples of hydrogen) could be explained partly by the fact that some elements are mixtures of isotopes with different atomic weights and partly by Einstein's relation between mass and energy (taking account of the binding energy of the forces that hold together the atomic nucleus). The German physicist Werner Heisenberg proposed in 1932 that, whereas the hydrogen nucleus consists of just one proton, all heavier nuclei contain protons and neutrons. Since a proton can be changed into a neutron by fusing it with an electron, this meant that all the elements could be built up from protons and electrons—i.e., from hydrogen atoms.

In 1938 the German-born physicist Hans Bethe proposed the first satisfactory theory of stellar energy generation based on the fusion of protons to form helium and heavier elements. He showed that once elements as heavy as carbon had been formed, a cycle of nuclear reactions could produce even heavier elements. Fusion of hydrogen into heavier elements would also provide enough energy to account for the Sun's energy generation over a period of billions of years. Although Bethe's theory, as extended by Fred Hoyle, Edwin E. Salpeter, and William A. Fowler, is the best one available, there is still some doubt about its accuracy because the neutrinos supposedly produced by the fusion reactions have not been observed in the amounts predicted.

According to the theory of stellar evolution developed by the Indian-born American astrophysicist Subrahmanyan Chandrasekhar and others, a star will become unstable after it has converted most of its hydrogen to helium and may go through stages of rapid expansion and contraction. If the star is much more massive than the Sun, it will explode violently, giving rise to a supernova. The explosion will synthesize heavier elements and spread them throughout the surrounding interstellar medium, where they provide the raw material for the formation of new stars and eventually of planets and living organisms.

After a supernova explosion, the remaining core of the star may collapse further under its own gravitational attraction to form a dense star composed mainly of neutrons. This so-called neutron star, predicted theoretically in the 1930s by the astronomers Walter Baade and Fritz Zwicky, is apparently the same as the pulsar (a source of rapid, very regular pulses of radio waves), discovered in 1967 by Jocelyn Bell of the British radio astronomy group under Antony Hewish at Cambridge University.

More massive stars may undergo a further stage of evolu-

tion beyond the neutron star: they may collapse to a black hole, in which the gravitational force is so strong that even light cannot escape. The black hole as a singularity in an idealized space-time universe was predicted from the general relativity theory by the German astronomer Karl Schwarzschild in 1916. Its role in stellar evolution was later described by the American physicists J. Robert Oppenheimer and John Wheeler. During the 1980s, possible black holes were thought to have been located in X-ray sources and at the centre of certain galaxies (see below *Study of the stars*).

Solar-system astronomy. This area of investigation, which lay relatively dormant through the first half of the 20th century, was revived in the 1960s under the stimulus of the Soviet and American space programs. Missions to the Moon and planets yielded a wealth of complex information which has yet to be completely assimilated by scientists. A single example of the resulting change in ideas about the history of the solar system will have to suffice here. Before the first manned lunar landing in 1969, there were three competing hypotheses about the origin of the Moon: (1) formation in its present orbit simultaneously with the Earth, as described in the nebular hypothesis; (2) formation elsewhere and subsequent capture by the Earth; and (3) ejection from the Earth by fission (popularly known theory that the Moon emanated from what is now the Pacific Ocean Basin). Following the analysis of lunar samples and theoretical criticism of these hypotheses, lunar scientists came to the conclusion that none of them was satisfactory. Photographs of the surface of Mercury taken by the U.S. Mariner 10 spacecraft in 1974, however, showed that it is heavily cratered like the Moon's surface. This finding, together with theoretical calculations by V.S. Safronov of the Soviet Union and George W. Wetherill of the United States on the formation of planets by accumulation (accretion or aggregation) of smaller solid bodies, suggested that the Earth was also probably subject to heavy bombardment soon after its formation. In line with this, a theory proposed by the American astronomers William K. Hartmann and A.G.W. Cameron has become the most popular. According to their theory, the Earth was struck by a Mars-sized object, and the force of the impact vaporized the outer parts of both bodies. The vapour thus produced remained in orbit around the Earth and eventually condensed to form the Moon. Like the hypothesis proposed by Luis Alvarez that attributes the extinction of the dinosaurs to an asteroid impact, the Hartmann-Cameron theory seemed so bizarre that it could not have been taken seriously until compelling evidence became available.

The Hartmann-Cameron theory

Physics. During the years 1896–1932 the foundations of physics changed so radically that many observers describe this period as a scientific revolution comparable in depth, if not in scope, to the one that took place during the 16th and 17th centuries. The 20th-century revolution changed many of the ideas about space, time, mass, energy, atoms, light, force, determinism, and causality that had apparently been firmly established by Newtonian physics during the 18th and 19th centuries. Moreover, according to some interpretations, the new theories demolished the basic metaphysical assumption of earlier science that the entire physical world has a real existence and objective properties independent of human observation.

The 20th-century scientific revolution

Closer examination of 19th-century physics shows that Newtonian ideas were already being undermined in many areas and that the program of mechanical explanation was openly challenged by several influential physicists toward the end of the century. Yet, there was no agreement as to what the foundations of a new physics might be. Modern textbook writers and popularizers often try to identify specific paradoxes or puzzling experimental results—e.g., the failure to detect the Earth's absolute motion in the Michelson-Morley experiment—as anomalies that led physicists to propose new fundamental theories such as relativity. Historians of science have shown, however, that most of these anomalies did not directly cause the introduction of the theories that later resolved them. As with Copernicus' introduction of heliocentric astronomy, the motivation seems to have been a desire to satisfy aesthetic principles

of theory structure rooted in earlier views of the world rather than a need to account for the latest experiment or calculation.

Radioactivity and the transmutation of elements. The discovery of radioactivity by the French physicist Henri Becquerel in 1896 is generally taken to mark the beginning of 20th-century physics. The successful isolation of radium and other intensely radioactive substances by Marie and Pierre Curie focused the attention of scientists and the public on this remarkable phenomenon and promoted a wide range of experiments.

Ernest Rutherford soon took the lead in studying the nature of radioactivity. He found that there are two distinct kinds of radiation emitted in radioactivity called alpha and beta rays. The alpha rays proved to be positively charged particles identical to ionized helium atoms. Beta rays are much less massive negatively charged particles; they were shown to be the same as the electrons discovered by J.J. Thomson in cathode rays in 1897. A third kind of ray, designated gamma, consists of high-frequency electromagnetic radiation.

Rutherford's investigations of radioactivity

Rutherford proposed that radioactivity involves a transmutation of one element into another. This proposal called into question one of the basic assumptions of 19th-century chemistry: that the elements consist of qualitatively different substances—92 of them by the end of the century. It implied a return to the ideas of Prout and the ancient atomists—namely, that everything in the world is composed of only one or a few basic substances.

Transmutation, according to Rutherford and his colleagues, was governed by certain empirical rules. For example, in alpha decay the atomic number of the "daughter" element is two less than that of the "mother" element, and its atomic weight is four less; this seems consistent with the fact that the alpha ray, identified as helium, has atomic number 2 and atomic weight 4, so that total atomic number and total atomic weight are conserved in the decay reaction.

Using these rules, Rutherford and his colleagues could determine the atomic numbers and atomic weights of many substances formed by radioactive decay, even though the substances decayed so quickly into others that these properties could not be measured directly. The atomic number of an element determines its place in Mendeleyev's periodic table (and thus its chemical properties; see above). It was found that substances of different atomic weight could have the same atomic number; such substances were called isotopes of an element.

Although the products of radioactive decay are determined by simple rules, the decay process itself seems to occur at random. All one can say is that there is a certain probability that an atom of a radioactive substance will decay during a certain time interval, or, equivalently, that half of the atoms of the sample will have decayed after a certain time—i.e., the half life of the material.

The nucleus. At the University of Manchester (England), Rutherford led a group that rapidly developed new ideas about atomic structure. On the basis of an experiment conducted by Hans Geiger and Ernest Marsden in which alpha particles were scattered by a thin film of metal, Rutherford proposed a nuclear model of the atom (1911). In this model, the atom consists mostly of empty space, with a tiny, positively charged nucleus that contains most of the mass, surrounded by one or more negatively charged electrons. Henry G.J. Moseley, an English physicist, showed by an analysis of X-ray spectra that the electric charge on the nucleus is simply proportional to the atomic number of the element.

During the 1920s physicists thought that the nucleus was composed of two particles: the proton (the positively charged nucleus of hydrogen) and the electron. In 1932 the English physicist James Chadwick discovered the neutron, a particle with about the same mass as the proton but no electric charge. Since there were technical difficulties with the proton-electron model of the nucleus, physicists were willing to accept Heisenberg's hypothesis that it consists instead of protons and neutrons. The atomic number is then simply the number of protons in the nucleus, while the mass number, the integer closest to the atomic weight,

Discovery of the neutron

is equal to the total number of neutrons and protons. As mentioned above, this simple model of nuclear structure provided the basis for Hans Bethe's theory of the formation of elements from hydrogen in stars.

Splitting
of the
uranium
atom

In 1938 the German physicists Otto Hahn and Fritz Strassmann found that, when uranium is bombarded by neutrons, lighter elements such as barium and krypton are produced. This phenomenon was interpreted by Lise Meitner and her nephew Otto Frisch as a breakup, or fission, of the uranium nucleus into smaller nuclei. Other physicists soon realized that since fission produces more neutrons, a chain reaction could result in a powerful explosion. World War II was about to begin, and physicists who had emigrated from Germany, Italy, and Hungary to the United States and Great Britain feared that Germany might develop an atomic bomb that could determine the outcome of the war. They persuaded the U.S. and British governments to undertake a major project to develop such a weapon first. The U.S. Manhattan Project did eventually produce atomic bombs based on the fission of uranium or of plutonium, a new artificially created element, and these were used against Japan in August 1945. Later, an even more powerful bomb based on the fusion of hydrogen atoms was developed and tested by both the United States and the Soviet Union. Thus nuclear physics began to play a major role in world history.

Einstein's 1905 trilogy. In a few months during the years 1665–66, Newton discovered the composite nature of light, analyzed the action of gravity, and invented the mathematical technique now known as calculus—or so he recalled in his old age. The only person who has ever matched Newton's amazing burst of scientific creativity—three revolutionary discoveries within a year—was Albert Einstein, who in 1905 published the special theory of relativity, the quantum theory of radiation, and a theory of Brownian movement that led directly to the final acceptance of the atomic structure of matter.

Relativity theory has already been mentioned several times in this article, an indication of its close connection with several areas of physical science. There is no room here to discuss the subtle line of reasoning that Einstein followed in arriving at his amazing conclusions; a brief summary of his starting point and some of the consequences will have to suffice.

Relativity
of space
and time

In his 1905 paper on the electrodynamics of moving bodies, Einstein called attention to an apparent inconsistency in the usual presentation of Maxwell's electromagnetic theory as applied to the reciprocal action of a magnet and a conductor. The equations are different depending on which is "at rest" and which is "moving," yet the results must be the same. Einstein located the difficulty in the assumption that absolute space exists; he postulated instead that the laws of nature are the same for observers in any inertial frame of reference and that the speed of light is the same for all such observers.

From these postulates Einstein inferred: (1) an observer in one frame would find from his own measurements that lengths of objects in another frame are contracted by an amount given by the Lorentz–FitzGerald formula; (2) each observer would find that clocks in the other frame run more slowly; (3) there is no absolute time—events that are simultaneous in one frame of reference may not be so in another; and (4) the observable mass of any object increases as it goes faster.

Closely connected with the mass-increase effect is Einstein's famous formula $E = mc^2$: mass and energy are no longer conserved but can be interconverted. The explosive power of the atomic and hydrogen bombs derives from the conversion of mass to energy.

Quantum
theory of
radiation

In a paper on the creation and conversion of light (usually called the "photoelectric effect paper"), published earlier in 1905, Einstein proposed the hypothesis that electromagnetic radiation consists of discrete energy quanta that can be absorbed or emitted only as a whole. Although this hypothesis would not replace the wave theory of light, which gives a perfectly satisfactory description of the phenomena of diffraction, reflection, refraction, and dispersion, it would supplement it by also ascribing particle properties to light.

Until recently the invention of the quantum theory of radiation was generally credited to another German physicist, Max Planck, who in 1900 discussed the statistical distribution of radiation energy in connection with the theory of blackbody radiation (see below *The methodology of physics*). Although Planck did propose the basic hypothesis that the energy of a quantum of radiation is proportional to its frequency of vibration, it is not clear whether he used this hypothesis merely for mathematical convenience or intended it to have a broader physical significance. In any case, he did not explicitly advocate a particle theory of light before 1905. Historians of physics still disagree on whether Planck or Einstein should be considered the originator of the quantum theory.

Einstein's paper on Brownian movement seems less revolutionary than the other 1905 papers because most modern readers assume that the atomic structure of matter was well established at that time. Such was not the case, however. In spite of the development of the chemical atomic theory and of the kinetic theory of gases in the 19th century, which allowed quantitative estimates of such atomic properties as mass and diameter, it was still fashionable in 1900 to question the reality of atoms. This skepticism, which does not seem to have been particularly helpful to the progress of science, was promoted by the empiricist, or "positivist," philosophy advocated by Auguste Comte, Ernst Mach, Wilhelm Ostwald, Pierre Duhem, Henri Poincaré, and others. It was the French physicist Jean Perrin who, using Einstein's theory of Brownian movement, finally convinced the scientific community to accept the atom as a valid scientific concept.

Quantum mechanics. The Danish physicist Niels Bohr pioneered the use of the quantum hypothesis in developing a successful theory of atomic structure. Adopting Rutherford's nuclear model, he proposed in 1913 that the atom is like a miniature solar system, with the electrons moving in orbits around the nucleus just as the planets move around the Sun. Although the electrical attraction between the electrons and nucleus is mathematically similar to the gravitational attraction between the planets and the Sun, the quantum hypothesis is needed to restrict the electrons to certain orbits and to forbid them from radiating energy except when jumping from one orbit to another.

Bohr's
model of
atomic
structure

Bohr's model provided a good description of the spectra and other properties of atoms containing only one electron—neutral hydrogen and singly ionized helium—but could not be satisfactorily extended to multi-electron atoms or molecules. It relied on an inconsistent mixture of old and new physical principles, hinting but not clearly specifying how a more adequate general theory might be constructed.

The nature of light was still puzzling to those who demanded that it should behave either like waves or like particles. Two experiments performed by American physicists seemed to favour the particle theory: Robert A. Millikan's confirmation of the quantum theory of the photoelectric effect proposed by Einstein; and Arthur H. Compton's experimental demonstration that X rays behave like particles when they collide with electrons. The findings of these experiments had to be considered along with the unquestioned fact that electromagnetic radiation also exhibits wave properties such as interference and diffraction.

Louis de Broglie, a French physicist, proposed a way out of the dilemma: accept the wave–particle dualism as a description not only of light but also of electrons and other entities previously assumed to be particles. In 1926 the Austrian physicist Erwin Schrödinger constructed a mathematical "wave mechanics" based on this proposal. His theory tells how to write down an equation for the wave function of any physical system in terms of the masses and charges of its components. From the wave function, one may compute the energy levels and other observable properties of the system.

Schrödinger's
so-called
wave
mechanics

Schrödinger's equation, the most convenient form of a more general theory called quantum mechanics to which the German physicists Werner Heisenberg and Max Born also contributed, was brilliantly successful. Not only did it yield the properties of the hydrogen atom but it also allowed the use of simple approximating methods for more

complicated systems even though the equation could not be solved exactly. The application of quantum mechanics to the properties of atoms, molecules, and metals occupied physicists for the next several decades.

Heisenberg's indeterminacy principle

The founders of quantum mechanics did not agree on the philosophical significance of the new theory. Born proposed that the wave function determines only the probability distribution of the electron's position or path; it does not have a well-defined instantaneous position and velocity. Heisenberg made this view explicit in his indeterminacy principle: the more accurately one determines the position, the less accurately the velocity is fixed; the converse is also true. Heisenberg's principle is often called the uncertainty principle, but this is somewhat misleading. It tends to suggest incorrectly that the electron really has a definite position and velocity and that they simply have not been determined.

Einstein objected to the randomness implied by quantum mechanics in his famous statement that God "does not play dice." He also was disturbed by the apparent denial of the objective reality of the atomic world: Somehow the electron's position or velocity comes into existence only when it is measured. Niels Bohr expressed this aspect of the quantum worldview in his complementarity principle, building on de Broglie's resolution of the wave-particle dichotomy: A system can have such properties as wave or particle behaviour that would be considered incompatible in Newtonian physics but that are actually complementary; light exhibits either wave behaviour or particle behaviour, depending on whether one chooses to measure the one property or the other. To say that it is really one or the other, or to say that the electron really has both a definite position and momentum at the same time, is to go beyond the limits of science.

Bohr's viewpoint, which became known as the Copenhagen Interpretation of quantum mechanics, was that reality can be ascribed only to a measurement. Einstein argued that the physical world must have real properties whether or not one measures them; he and Schrödinger published a number of thought experiments designed to show that things can exist beyond what is described by quantum mechanics. During the 1970s and 1980s, advanced technology made it possible to actually perform some of these experiments, and quantum mechanics was vindicated in every case.

Chemistry. The long-standing problem of the nature of the force that holds atoms together in molecules was finally solved by the application of quantum mechanics. Although it is often stated that chemistry has been "reduced to physics" in this way, it should be pointed out that one of the most important postulates of quantum mechanics was introduced primarily for the purpose of explaining chemical facts and did not originally have any other physical justification. This was the so-called exclusion principle put forth by the Austrian physicist Wolfgang Pauli, which forbids more than one electron occupying a given quantum state in an atom. The state of an electron includes its spin, a property introduced by the Dutch-born American physicists George E. Uhlenbeck and Samuel A. Goudsmit. Using that principle and the assumption that the quantum states in a multi-electron atom are essentially the same as those in the hydrogen atom, one can postulate a series of "shells" of electrons and explain the chemical valence of an element in terms of the loss, gain, or sharing of electrons in the outer shell.

Some of the outstanding problems to be solved by quantum chemistry were: (1) The "saturation" of chemical forces. If attractive forces hold atoms together to form molecules, why is there a limit on how many atoms can stick together (generally only two of the same kind)? (2) Stereochemistry—the three-dimensional structure of molecules, in particular the spatial directionality of bonds as in the tetrahedral carbon atom. (3) Bond length—*i.e.*, there seems to be a well-defined equilibrium distance between atoms in a molecule that can be determined accurately by experiment. (4) Why some atoms (*e.g.*, helium) normally form no bonds with other atoms, while others form one or more. (These are the empirical rules of valence.)

Soon after J.J. Thomson's discovery of the electron in 1897, there were several attempts to develop theories of chemical bonds based on electrons. The most successful was that proposed in the United States by G.N. Lewis in 1916 and Irving Langmuir in 1919. They emphasized shared pairs of electrons and treated the atom as a static arrangement of charges. While the Lewis-Langmuir model as a whole was inconsistent with quantum theory, several of its specific features continued to be useful.

The key to the nature of the chemical bond was found to be the quantum-mechanical exchange effect, first described by Heisenberg in 1926–27. Resonance is related to the requirement that the wave function for two or more identical particles must have definite symmetry properties with respect to the coordinates of those particles—it must have plus or minus the same value (symmetric or antisymmetric, respectively) when those particles are interchanged. Particles such as electrons and protons, according to a hypothesis proposed by Enrico Fermi and P.A.M. Dirac, must have antisymmetric wave functions. Exchange may be imagined as a continual jumping back and forth or interchange of the electrons between two possible states. In 1927 the German physicists Walter Heitler and Fritz London used this idea to obtain an approximate wave function for two interacting hydrogen atoms. They found that with an antisymmetric wave function (including spin) there is an attractive force, while with a symmetric one there is a repulsive force. Thus two hydrogen atoms can form a molecule if their electron spins are opposite, but not if they are the same.

The Heitler-London approach to the theory of chemical bonds was rapidly developed by John C. Slater and Linus C. Pauling in the United States. Slater proposed a simple general method for constructing multiple-electron wave functions that would automatically satisfy the Pauli exclusion principle. Pauling introduced a valence-bond method, picking out one electron in each of the two combining atoms and constructing a wave function representing a paired-electron bond between them. Pauling and Slater were able to explain the tetrahedral carbon structure in terms of a particular mixture of wave functions that has a lower energy than the original wave functions, so that the molecule tends to go into that state.

About the same time another American scientist, Robert S. Mulliken, was developing an alternative theory of molecular structure based on what he called molecular orbitals. (The idea had been used under a different name by John E. Lennard-Jones of England in 1929 and by Erich Hückel of Germany in 1931.) Here, the electron is not considered to be localized in a particular atom or two-atom bond, but rather it is treated as occupying a quantum state (an "orbital") that is spread over the entire molecule (see below *Studies of molecular structure*).

In treating the benzene molecule by the valence-bond method in 1933, Pauling and George W. Wheland constructed a wave function that was a linear combination of five possible structures—*i.e.*, five possible arrangements of double and single bonds. Two of them are the structures that had been proposed by the German chemist August Kekulé (later Kekule von Stradonitz) in 1865, with alternating single and double bonds between adjacent carbon atoms in the six-carbon ring. The other three (now called Dewar structures for the British chemist and physicist James Dewar, though they were first suggested by H. Wichelhaus in 1869) have one longer bond going across the ring. Pauling and Dewar described their model as involving resonance between the five structures. According to quantum mechanics, this does not mean that the molecule is sometimes "really" in one state and at other times in another, but rather that it is always in a composite state.

The valence-bond method, with its emphasis on resonance between different structures as a means of analyzing aromatic molecules, dominated quantum chemistry during the 1930s. The method was comprehensively presented and applied in Pauling's classic treatise *The Nature of the Chemical Bond* (1939), the most important work on theoretical chemistry in the 20th century. One reason for its popularity was that ideas similar to resonance had

The quantum-mechanical exchange effect

Pauling's valence-bond method

Increasing preference for the molecular-orbital method

been developed by organic chemists, notably F.G. Arndt in Germany and Christopher K. Ingold in England, independently of quantum theory during the late 1920s. After World War II there was a strong movement away from the valence-bond method toward the molecular-orbital method, led by Mulliken in the United States and by Charles Coulson, Lennard-Jones, H.C. Longuet-Higgins, and Michael J.S. Dewar in England. The advocates of the molecular-orbital method argued that their approach was simpler and easier to apply to complicated molecules, since it allowed one to visualize a definite charge distribution for each electron. (S.G.B.)

Physics

Physics is the basic physical science. Until rather recent times the terms physics and natural philosophy were used interchangeably for the science whose aim is the discovery and formulation of the fundamental laws of nature. As the modern sciences developed and became increasingly specialized, physics came to denote that part of physical science not included in astronomy, chemistry, geology, and engineering. Physics plays an important role in all the natural sciences, however, and all such fields have branches in which physical laws and measurements receive special emphasis, bearing such names as astrophysics, geophysics, biophysics, and even psychophysics. Physics can, at base, be defined as the science of matter, motion, and energy. Its laws are typically expressed with economy and precision in the language of mathematics.

Both experiment, the observation of phenomena under conditions that are controlled as precisely as possible, and theory, the formulation of a unified conceptual framework, play essential and complementary roles in the advancement of physics. Physical experiments result in measurements, which are compared with the outcome predicted by theory. A theory that reliably predicts the results of experiments to which it is applicable is said to embody a law of physics. However, a law is always subject to modification, replacement, or restriction to a more limited domain, if a later experiment makes it necessary.

Ultimate aim of physics

The ultimate aim of physics is to find a unified set of laws governing matter, motion, and energy at small (microscopic) subatomic distances, at the human (macroscopic) scale of everyday life, and out to the largest distances (*e.g.*, those on the extragalactic scale). This ambitious goal has been realized to a notable extent. Although a completely unified theory of physical phenomena has not yet been achieved (and possibly never will be), a remarkably small set of fundamental physical laws appears able to account for all known phenomena. The body of physics developed up to about the turn of the 20th century, known as classical physics, can largely account for the motions of macroscopic objects that move slowly with respect to the speed of light and for such phenomena as heat, sound, electricity, magnetism, and light. The modern developments of relativity and quantum theory modify these laws insofar as they apply to higher speeds, very massive objects, and to the tiny elementary constituents of matter, such as electrons, protons, and neutrons.

THE SCOPE OF PHYSICS

The traditionally organized branches or fields of classical and modern physics are delineated below.

Mechanics. Mechanics is generally taken to mean the study of the motion of objects (or their lack of motion) under the action of given forces. Classical mechanics is sometimes considered a branch of applied mathematics. It consists of kinematics, the description of motion, and dynamics, the study of the action of forces in producing either motion or static equilibrium (the latter constituting the science of statics). The 20th-century subjects of quantum mechanics, crucial to treating the structure of matter, subatomic particles, superfluidity, superconductivity, neutron stars, and other major phenomena, and relativistic mechanics, important when speeds approach that of light, are forms of mechanics that will be discussed later in this section.

In classical mechanics the laws are initially formulated for

point particles in which the dimensions, shapes, and other intrinsic properties of bodies are ignored. Thus in the first approximation even objects as large as the Earth and the Sun are treated as pointlike—*e.g.*, in calculating planetary orbital motion. In rigid-body dynamics, the extension of bodies and their mass distributions are considered as well, but they are imagined to be incapable of deformation. The mechanics of deformable solids is elasticity; hydrostatics and hydrodynamics treat, respectively, fluids at rest and in motion.

The three laws of motion set forth by Isaac Newton form the foundation of classical mechanics, together with the recognition that forces are directed quantities (vectors) and combine accordingly. The first law, also called the law of inertia, states that, unless acted upon by an external force, an object at rest remains at rest, or if in motion, it continues to move in a straight line with constant speed. Uniform motion therefore does not require a cause. Accordingly, mechanics concentrates not on motion as such but on the change in the state of motion of an object that results from the net force acting upon it. Newton's second law equates the net force on an object to the rate of change of its momentum, the latter being the product of the mass of a body and its velocity. Newton's third law, that of action and reaction, states that when two particles interact, the forces each exerts on the other are equal in magnitude and opposite in direction. Taken together, these mechanical laws in principle permit the determination of the future motions of a set of particles, providing their state of motion is known at some instant, as well as the forces that act between them and upon them from the outside. From this deterministic character of the laws of classical mechanics, profound (and probably incorrect) philosophical conclusions have been drawn in the past and even applied to human history.

Lying at the most basic level of physics, the laws of mechanics are characterized by certain symmetry properties, as exemplified in the aforementioned symmetry between action and reaction forces. Other symmetries, such as the invariance (*i.e.*, unchanging form) of the laws under reflections and rotations carried out in space, reversal of time, or transformation to a different part of space or to a different epoch of time, are present both in classical mechanics and in relativistic mechanics, and with certain restrictions, also in quantum mechanics. The symmetry properties of the theory can be shown to have as mathematical consequences basic principles known as conservation laws, which assert the constancy in time of the values of certain physical quantities under prescribed conditions. The conserved quantities are the most important ones in physics; included among them are mass and energy (in relativity theory, mass and energy are equivalent and are conserved together), momentum, angular momentum, and electric charge.

The study of gravitation. This field of inquiry has in the past been placed within classical mechanics for historical reasons, because both fields were brought to a high state of perfection by Newton and also because of its universal character. Newton's gravitational law states that every material particle in the universe attracts every other one with a force that acts along the line joining them and whose strength is directly proportional to the product of their masses and inversely proportional to the square of their separation. Newton's detailed accounting for the orbits of the planets and the Moon, as well as for such subtle gravitational effects as the tides and the precession of the equinoxes (a slow cyclical change in direction of the Earth's axis of rotation) through this fundamental force was the first triumph of classical mechanics. No further principles are required to understand the principal aspects of rocketry and space flight (although, of course, a formidable technology is needed to carry them out).

The modern theory of gravitation was formulated by Albert Einstein and is called the general theory of relativity. From the long-known equality of the quantity "mass" in Newton's second law of motion and that in his gravitational law, Einstein was struck by the fact that acceleration can locally annul a gravitational force (as occurs in the so-called weightlessness of astronauts in an Earth-orbiting

Newton's laws of motion

Conservation laws

Modern theory of gravitation

spacecraft) and was led thereby to the concept of curved space-time. Completed in 1915, the theory was valued for many years mainly for its mathematical beauty and for correctly predicting a small number of phenomena, such as the gravitational bending of light around a massive object. Only in recent years, however, has it become a vital subject for both theoretical and experimental research. (Relativistic mechanics, discussed below, refers to Einstein's special theory of relativity, which is not a theory of gravitation.)

The study of heat, thermodynamics, and statistical mechanics. Heat is a form of internal energy associated with the random motion of the molecular constituents of matter or with radiation. Temperature is an average of a part of the internal energy present in a body (it does not include the energy of molecular binding or of molecular rotation). The lowest possible energy state of a substance is defined as the absolute zero of temperature. An isolated body eventually reaches uniform temperature, a state known as thermal equilibrium, as do two or more bodies placed in contact. The formal study of states of matter at (or near) thermal equilibrium is called thermodynamics; it is capable of analyzing a large variety of thermal systems without considering their detailed microstructures.

First law. The first law of thermodynamics is the energy conservation principle of mechanics (*i.e.*, for all changes in an isolated system, the energy remains constant) generalized to include heat.

Second law. The second law of thermodynamics asserts that heat will not flow from a place of higher temperature to one where it is lower without the intervention of an external device (*e.g.*, a refrigerator). The concept of entropy involves the measurement of the state of disorder of the particles making up a system. For example, if tossing a coin many times results in a random-appearing sequence of heads and tails, the result has a higher entropy than if heads and tails tend to appear in clusters. Another formulation of the second law is that the entropy of an isolated system never decreases with time.

Third law. The third law of thermodynamics states that the entropy at the absolute zero of temperature is zero, corresponding to the most ordered possible state.

Statistical mechanics. The science of statistical mechanics derives bulk properties of systems from the mechanical properties of their molecular constituents, assuming molecular chaos and applying the laws of probability. Regarding each possible configuration of the particles as equally likely, the chaotic state (the state of maximum entropy) is so enormously more likely than ordered states that an isolated system will evolve to it, as stated in the second law of thermodynamics. Such reasoning, placed in mathematically precise form, is typical of statistical mechanics, which is capable of deriving the laws of thermodynamics but goes beyond them in describing fluctuations (*i.e.*, temporary departures) from the thermodynamic laws that describe only average behaviour. An example of a fluctuation phenomenon is the random motion of small particles suspended in a fluid, known as Brownian motion.

Quantum
statistical
mechanics

Quantum statistical mechanics plays a major role in many other modern fields of science, as, for example, in plasma physics (the study of fully ionized gases), in solid-state physics, and in the study of stellar structure. From a microscopic point of view the laws of thermodynamics imply that, whereas the total quantity of energy of any isolated system is constant, what might be called the quality of this energy is degraded as the system moves inexorably, through the operation of the laws of chance, to states of increasing disorder until it finally reaches the state of maximum disorder (maximum entropy), in which all parts of the system are at the same temperature, and none of the state's energy may be usefully employed. When applied to the universe as a whole, considered as an isolated system, this ultimate chaotic condition has been called the "heat death."

The study of electricity and magnetism. Although conceived of as distinct phenomena until the 19th century, electricity and magnetism are now known to be components of the unified field of electromagnetism. Particles with electric charge interact by an electric force, while

charged particles in motion produce and respond to magnetic forces as well. Many subatomic particles, including the electrically charged electron and proton and the electrically neutral neutron, behave like elementary magnets. On the other hand, in spite of systematic searches undertaken, no magnetic monopoles, which would be the magnetic analogues of electric charges, have ever been found.

The field concept plays a central role in the classical formulation of electromagnetism, as well as in many other areas of classical and contemporary physics. Einstein's gravitational field, for example, replaces Newton's concept of gravitational action at a distance. The field describing the electric force between a pair of charged particles works in the following manner: each particle creates an electric field in the space surrounding it, and so also at the position occupied by the other particle; each particle responds to the force exerted upon it by the electric field at its own position.

Classical electromagnetism is summarized by the laws of action of electric and magnetic fields upon electric charges and upon magnets and by four remarkable equations formulated in the latter part of the 19th century by James Clerk Maxwell. The latter equations describe the manner in which electric charges and currents produce electric and magnetic fields, as well as the manner in which changing magnetic fields produce electric fields, and vice versa. From these relations Maxwell inferred the existence of electromagnetic waves—associated electric and magnetic fields in space, detached from the charges that created them, traveling at the speed of light, and endowed with such "mechanical" properties as energy, momentum, and angular momentum. The light to which the human eye is sensitive is but one small segment of an electromagnetic spectrum that extends from long-wavelength radio waves to short-wavelength gamma rays and includes X rays, microwaves, and infrared (or heat) radiation.

Optics. Because light consists of electromagnetic waves, the propagation of light can be regarded as merely a branch of electromagnetism. However, it is usually dealt with as a separate subject called optics: the part that deals with the tracing of light rays is known as geometrical optics, while the part that treats the distinctive wave phenomena of light is called physical optics. More recently, there has developed a new and vital branch, quantum optics, which is concerned with the theory and application of the laser, a device that produces an intense coherent beam of unidirectional radiation useful for many applications.

Quantum
optics

The formation of images by lenses, microscopes, telescopes, and other optical devices is described by ray optics, which assumes that the passage of light can be represented by straight lines, that is, rays. The subtler effects attributable to the wave property of visible light, however, require the explanations of physical optics. One basic wave effect is interference, whereby two waves present in a region of space combine at certain points to yield an enhanced resultant effect (*e.g.*, the crests of the component waves adding together); at the other extreme, the two waves can annul each other, the crests of one wave filling in the troughs of the other. Another wave effect is diffraction, which causes light to spread into regions of the geometric shadow and causes the image produced by any optical device to be fuzzy to a degree dependent on the wavelength of the light. Optical instruments such as the interferometer and the diffraction grating can be used for measuring the wavelength of light precisely (about 500 micrometres) and for measuring distances to a small fraction of that length.

Atomic and chemical physics. One of the great achievements of the 20th century has been the establishment of the validity of the atomic hypothesis, first proposed in ancient times, that matter is made up of relatively few kinds of small, identical parts—namely, atoms. However, unlike the indivisible atom of Democritus and other ancients, the atom, as it is conceived today, can be separated into constituent electrons and nucleus. Atoms combine to form molecules, whose structure is studied by chemistry and chemical physics; they also form other types of compounds, such as crystals, studied in the field of condensed-matter physics. Such disciplines study the most important

Signifi-
cance of
the field
concept

attributes of matter (not excluding biologic matter) that are encountered in normal experience—namely, those that depend almost entirely on the outer parts of the electronic structure of atoms. Only the mass of the atomic nucleus and its charge, which is equal to the total charge of the electrons in the neutral atom, affect the chemical and physical properties of matter.

Although there are some analogies between the solar system and the atom due to the fact that the strengths of gravitational and electrostatic forces both fall off as the inverse square of the distance, the classical forms of electromagnetism and mechanics fail when applied to tiny, rapidly moving atomic constituents. Atomic structure is comprehensible only on the basis of quantum mechanics, and its finer details require as well the use of quantum electrodynamics (QED) (see below).

Spectroscopy

Atomic properties are inferred mostly by the use of indirect experiments. Of greatest importance has been spectroscopy, which is concerned with the measurement and interpretation of the electromagnetic radiations either emitted or absorbed by materials. These radiations have a distinctive character, which quantum mechanics relates quantitatively to the structures that produce and absorb them. It is truly remarkable that these structures are in principle, and often in practice, amenable to precise calculation in terms of a few basic physical constants: the mass and charge of the electron, the speed of light, and Planck's constant h , the fundamental constant of the quantum theory named for the German physicist Max Planck.

Condensed-matter physics. This field, which treats the thermal, elastic, electrical, magnetic, and optical properties of solid and liquid substances, has grown at an explosive rate in recent years and has scored numerous important scientific and technical achievements, including the transistor. Among solid materials, the greatest theoretical advances have been in the study of crystalline materials whose simple repetitive geometric arrays of atoms are multiple-particle systems that allow treatment by quantum mechanics. Because the atoms in a solid are coordinated with each other over large distances, the theory must go beyond that appropriate for atoms and molecules. Thus conductors, such as metals, contain some so-called free (or conduction) electrons, which are responsible for the electrical and most of the thermal conductivity of the material and which belong collectively to the whole solid rather than to individual atoms. Semiconductors and insulators, either crystalline or amorphous, are other materials studied in this field of physics.

Research on superfluidity and superconductivity

Other aspects of condensed matter involve the properties of the ordinary liquid state, of liquid crystals, and, at temperatures near absolute zero, of the so-called quantum liquids. The latter exhibit a property known as superfluidity (completely frictionless flow), which is an example of a macroscopic quantum phenomena. Such phenomena are also exemplified by superconductivity (completely resistance-less flow of electricity), a low-temperature property of certain metallic and ceramic materials. Besides their significance to technology, macroscopic liquid and solid quantum states are important in astrophysical theories of stellar structure in, for example, neutron stars.

Nuclear physics. This branch of physics deals with the structure of the atomic nucleus and the radiation from unstable nuclei. About 10,000 times smaller than the atom, the constituent particles of the nucleus, protons and neutrons, attract one another so strongly by the nuclear forces that nuclear energies are approximately 1,000,000 times larger than typical atomic energies. Quantum theory is needed for understanding nuclear structure.

Like excited atoms, unstable radioactive nuclei (either naturally occurring or artificially produced) can emit electromagnetic radiation. The energetic nuclear photons are called gamma rays. Radioactive nuclei also emit other particles: negative and positive electrons (beta rays), accompanied by neutrinos, and helium nuclei (alpha rays).

A principal research tool of nuclear physics involves the use of beams of particles (*e.g.*, protons or electrons) directed as projectiles against nuclear targets. Recoiling particles and any resultant nuclear fragments are detected, and their directions and energies are analyzed to reveal details

of nuclear structure and to learn more about the strong nuclear force. A much weaker nuclear force, the so-called weak interaction, is responsible for the emission of beta rays. Nuclear collision experiments use beams of higher-energy particles, including those of unstable particles called mesons produced by primary nuclear collisions in accelerators dubbed meson factories. Exchange of mesons between protons and neutrons is directly responsible for the strong nuclear force. (For the mechanism underlying mesons, see below *Fundamental forces and fields*.)

In radioactivity and in collisions leading to nuclear breakup, the chemical identity of the nuclear target is altered whenever there is a change in the nuclear charge. In fission and fusion nuclear reactions in which unstable nuclei are, respectively, split into smaller nuclei or amalgamated into larger ones, the energy release far exceeds that of any chemical reaction.

Particle physics. One of the most significant branches of contemporary physics is the study of the fundamental subatomic constituents of matter, the elementary particles. This field, also called high-energy physics, emerged in the 1930s out of the developing experimental areas of nuclear and cosmic-ray physics. Initially investigators studied cosmic rays, the very-high-energy extraterrestrial radiations that fall upon the Earth and interact in the atmosphere (see below *The methodology of physics*). However, after World War II, scientists gradually began using high-energy particle accelerators to provide subatomic particles for study. Quantum field theory, a generalization of QED to other types of force fields, is essential for the analysis of high-energy physics.

High-energy physics

During recent decades a coherent picture has evolved of the underlying strata of matter involving three types of particles called leptons, quarks, and field quanta, for whose existence evidence is good. (Other types of particles have been hypothesized but have not yet been detected.) Subatomic particles cannot be visualized as tiny analogues of ordinary material objects such as billiard balls, for they have properties that appear contradictory from the classical viewpoint. That is to say, while they possess charge, spin, mass, magnetism, and other complex characteristics, they are nonetheless regarded as pointlike. Leptons and quarks occur in pairs (*e.g.*, one lepton pair consists of the electron and the neutrino). Each quark and each lepton have an antiparticle with properties that mirror those of its partner (the antiparticle of the negatively charged electron is the positive electron, or positron; that of the neutrino is the antineutrino). In addition to their electric and magnetic properties, quarks have very strong nuclear forces and also participate in the weak nuclear interaction, while leptons take part in only the weak interaction.

Ordinary matter consists of electrons surrounding the nucleus, which is composed of neutrons and protons, each of which is believed to contain three quarks. Quarks have charges that are either positive two-thirds or negative one-third of the electron's charge, while antiquarks have the opposite charges. Mesons, responsible for the nuclear binding force, are composed of one quark and one antiquark. In addition to the particles in ordinary matter and their antiparticles, which are referred to as first-generation, there are probably two or more additional generations of quarks and leptons, more massive than the first. Evidence exists at present for the second generation and all but one quark of the third, namely the *t* (or top) quark, which may be so massive that a new higher-energy accelerator may be needed to produce it.

The quantum fields through which quarks and leptons interact with each other and with themselves consist of particle-like objects called quanta (from which quantum mechanics derives its name). The first known quanta were those of the electromagnetic field; they are also called photons because light consists of them. A modern unified theory of weak and electromagnetic interactions, known as the electroweak theory, proposes that the weak nuclear interaction involves the exchange of particles about 100 times as massive as protons. These massive quanta have been observed—namely, two charged particles, W^+ and W^- , and a neutral one, W^0 .

In the theory of strong nuclear interactions known as

Quantum
chromo-
dynamics

quantum chromodynamics (QCD), eight quanta, called gluons, bind quarks to form protons and neutrons and also bind quarks to antiquarks to form mesons, the force itself being dubbed the "colour force." (This unusual use of the term colour is a somewhat forced analogue of ordinary colour mixing.) Quarks are said to come in three colours—red, blue, and green. (The opposites of these imaginary colours, minus-red, minus-blue, and minus-green, are ascribed to antiquarks.) Only certain colour combinations, namely colour-neutral, or "white" (*i.e.*, equal mixtures of the above colours cancel out one another, resulting in no net colour), are conjectured to exist in nature in an observable form. The gluons and quarks themselves, being coloured, are permanently confined (deeply bound within the particles of which they are a part), while the colour-neutral composites such as protons can be directly observed. One consequence of colour confinement is that the observable particles are either electrically neutral or have charges that are integral multiples of the charge of the electron. A number of specific predictions of QCD have been experimentally tested and found correct.

Quantum mechanics. Although the various branches of physics differ in their experimental methods and theoretical approaches, certain general principles apply to all of them. The forefront of contemporary advances in physics lies in the submicroscopic regime, whether it be in atomic, nuclear, condensed-matter, plasma, or particle physics, or in quantum optics, or even in the study of stellar structure. All are based upon quantum theory (*i.e.*, quantum mechanics and quantum field theory) and relativity; which together form the theoretical foundations of modern physics. Many physical quantities whose classical counterparts vary continuously over a range of possible values are in quantum theory constrained to have discontinuous, or discrete, values. The intrinsically deterministic character of classical physics is replaced in quantum theory by intrinsic uncertainty.

According to quantum theory, electromagnetic radiation does not always consist of continuous waves; instead it must be viewed under some circumstances as a collection of particle-like photons, the energy and momentum of each being directly proportional to its frequency (or inversely proportional to its wavelength, the photons still possessing some wavelike characteristics). Conversely, electrons and other objects that appear as particles in classical physics are endowed by quantum theory with wavelike properties as well, such a particle's quantum wavelength being inversely proportional to its momentum. In both instances, the proportionality constant is the characteristic quantum of action (action being defined as energy \times time)—that is to say, Planck's constant h .

In principle, all of atomic and molecular physics, including the structure of atoms and their dynamics, the periodic table of elements and their chemical behaviour, as well as the spectroscopic, electrical, and other physical properties of atoms, molecules, and condensed matter, can be accounted for by quantum mechanics. Roughly speaking, the electrons in the atom must fit around the nucleus as some sort of standing wave (the Schrödinger wave function; see above) analogous to the waves on a plucked violin or guitar string. As the fit determines the wavelength of the quantum wave, it necessarily determines its energy state. Consequently, atomic systems are restricted to certain discrete, or quantized, energies. When an atom undergoes a discontinuous transition, or quantum jump, its energy changes abruptly by a sharply defined amount, and a photon of that energy is emitted when the energy of the atom decreases, or is absorbed in the opposite case.

Although atomic energies can be sharply defined, the positions of the electrons within the atom cannot be, quantum mechanics giving only the probability for the electrons to have certain locations. This is a consequence of the feature that distinguishes quantum theory from all other approaches to physics, the indeterminacy (or uncertainty) principle of Werner Heisenberg. As was explained earlier in the article, this principle holds that measuring a particle's position with increasing precision necessarily increases the uncertainty as to the particle's momentum, and conversely. The ultimate degree of uncertainty is con-

trolled by the magnitude of Planck's constant, which is so small as to have no apparent effects except in the world of microstructures. In the latter case, however, because both a particle's position and its velocity or momentum must be known precisely at some instant in order to predict its future history, quantum theory precludes such certain prediction and thus escapes determinism.

The complementary wave and particle aspects, or wave-particle duality, of electromagnetic radiation and of material particles furnish another illustration of the uncertainty principle. When an electron exhibits wavelike behaviour, as in the phenomenon of electron diffraction, this excludes its exhibiting particle-like behaviour in the same observation. Similarly, when electromagnetic radiation in the form of photons interacts with matter, as in the Compton effect in which X-ray photons collide with electrons, the result resembles a particle-like collision and the wave nature of electromagnetic radiation is precluded. The principle of complementarity, asserted by Niels Bohr, who pioneered the theory of atomic structure, states that the physical world presents itself in the form of various complementary pictures, no one of which is by itself complete, all of these pictures being essential for our total understanding. Thus both wave and particle pictures are needed for understanding either the electron or the photon.

Although it deals with probabilities and uncertainties, the quantum theory has been spectacularly successful in explaining otherwise inaccessible atomic phenomena and in thus far meeting every experimental test. Its predictions, especially those of QED, are the most precise and the best checked of any in physics; some of them have been tested and found accurate to better than one part per billion.

Relativistic mechanics. In classical physics, space is conceived as having the absolute character of an empty stage in which events in nature unfold as time flows onward independently; events occurring simultaneously for one observer are presumed to be simultaneous for any other; mass is taken as impossible to create or destroy; and a particle given sufficient energy acquires a velocity that can increase without limit. The special theory of relativity, developed principally by Einstein in 1905 and now so adequately confirmed by experiment as to have the status of physical law, shows that all these, as well as other apparently obvious assumptions, are false.

Specific and unusual relativistic effects flow directly from Einstein's two basic postulates, which are formulated in terms of so-called inertial reference frames. These are reference systems that move in such a way that in them Newton's first law, the law of inertia, is valid. The set of inertial frames consists of all those that move with constant velocity with respect to each other (accelerating frames therefore being excluded). Einstein's postulates are: (1) All observers, whatever their state of motion relative to a light source, measure the same speed for light; and (2) The laws of physics are the same in all inertial frames.

The first postulate, the constancy of the speed of light, is an experimental fact from which follow the distinctive relativistic phenomena of space contraction, time dilation, and the relativity of simultaneity: as measured by an observer assumed to be at rest, an object in motion is contracted along the direction of its motion, and moving clocks run slow; two spatially separated events that are simultaneous for a stationary observer occur sequentially for a moving observer. As a consequence, space intervals in three-dimensional space are related to time intervals, thus forming so-called four-dimensional space-time.

The second postulate is called the principle of relativity. It is equally valid in classical mechanics (but not in classical electrodynamics until Einstein reinterpreted it). This postulate implies, for example, that table tennis played on a train moving with constant velocity is just like table tennis played with the train at rest, the states of rest and motion being physically indistinguishable. In relativity theory, mechanical quantities such as momentum and energy have forms that are different from their classical counterparts but give the same values for speeds that are small compared to the speed of light, the maximum permissible speed in nature (about 300,000 kilometres per second, or 186,000 miles per second). According to rela-

theory

Equivalence of mass and energy

tivity, mass and energy are equivalent and interchangeable quantities, the equivalence being expressed by Einstein's famous equation $E = mc^2$, where m is an object's mass and c is the speed of light.

The general theory of relativity, as discussed above, is Einstein's theory of gravitation, which uses the principle of the equivalence of gravitation and locally accelerating frames of reference. Einstein's theory has special mathematical beauty; it generalizes the "flat" space-time concept of special relativity to one of curvature. It forms the background of all modern cosmological theories (see COSMOS: *Relativistic cosmologies*). In contrast to some vulgarized popular notions of it, which confuse it with moral and other forms of relativism, Einstein's theory does not argue that "all is relative." On the contrary, it is largely a theory based upon those physical attributes that do not change, or, in the language of the theory, that are invariant.

Conservation laws and symmetry. Since the early period of modern physics, there have been conservation laws, which state that certain physical quantities, such as the total electric charge of an isolated system of bodies, do not change in the course of time. In the 20th century it has been proved mathematically that such laws follow from the symmetry properties of nature, as expressed in the laws of physics. The conservation of mass-energy of an isolated system, for example, follows from the assumption that the laws of physics may depend upon time intervals but not upon the specific time at which the laws are applied. The symmetries and the conservation laws that follow from them are regarded by modern physicists as being even more fundamental than the laws themselves, since they are able to limit the possible forms of laws that may be proposed in the future.

Conservation laws are valid in classical, relativistic, and quantum theory for mass-energy, momentum, angular momentum, and electric charge. (In nonrelativistic physics, mass and energy are separately conserved.) Momentum, a directed quantity equal to the mass of a body multiplied by its velocity or to the total mass of two or more bodies multiplied by the velocity of their centre of mass, is conserved when, and only when, no external force acts. Similarly angular momentum, which is related to spinning motions, is conserved in a system upon which no net turning force, called torque, acts. External forces and torques break the symmetry conditions from upon which the respective conservation laws follow.

In quantum theory, and especially in the theory of elementary particles, there are additional symmetries and conservation laws, some exact and others only approximately valid, which play no significant role in classical physics. Among these are the conservation of so-called quantum numbers related to left-right reflection symmetry of space (called parity) and to the reversal symmetry of motion (called time reversal). These quantum numbers are conserved in all processes other than the weak nuclear interaction.

Internal symmetries

Other symmetry properties not obviously related to space and time (and referred to as internal symmetries) characterize the different families of elementary particles and, by extension, their composites. Quarks, for example, have a property called baryon number, as do protons, neutrons, nuclei, and unstable quark composites. All of these except the quarks are known as baryons. A failure of baryon-number conservation would exhibit itself, for instance, by a proton decaying into lighter non-baryonic particles. Indeed, intensive search for such proton decay has been conducted, but so far it has been fruitless. Similar symmetries and conservation laws hold for an analogously defined lepton number, and they also appear, as does the law of baryon conservation, to hold absolutely.

Fundamental forces and fields. The four basic forces of nature, in order of increasing strength, are thought to be: (1) the gravitational force between particles with mass; (2) the electromagnetic force between particles with charge or magnetism or both; (3) the colour force between quarks; and (4) the weak nuclear interaction by which, for example, quarks can change their type, so that a neutron decays into a proton, an electron, and an antineutrino. The strong nuclear interaction that binds protons and

neutrons into nuclei and is responsible for fission, fusion, and other nuclear reactions is in principle derived from the colour force. Nuclear physics is thus related to QCD as chemistry is to atomic physics.

According to quantum field theory, each of the four fundamental interactions is mediated by the exchange of quanta, called vector gauge bosons, which share certain common characteristics. All have an intrinsic spin of one unit, measured in terms of Planck's constant \hbar . (Leptons and quarks each have one-half unit of spin.) The term gauge refers to a special type of symmetry they possess. This symmetry was first seen in the equations for electromagnetic potentials, quantities from which electromagnetic fields can be derived. It is possessed in pure form by the eight massless gluons of QCD, but in the electroweak theory, the unified theory of electromagnetic and weak interactions, gauge symmetry is partially broken, so that only the photon remains massless, with the other gauge bosons (W^+ , W^- , and Z) acquiring large masses. At present, theoretical physicists are trying to produce a further unification of QCD with the electroweak theory and, more ambitiously still, to unify them with a quantum version of gravity in which the force would be transmitted by massless quanta of two units of spin called gravitons.

THE METHODOLOGY OF PHYSICS

Physics has evolved and continues to evolve without any single strategy. Essentially an experimental science, refined measurements can reveal unexpected behaviour. On the other hand, mathematical extrapolation of existing theories into new theoretical areas, critical reexamination of apparently obvious but untested assumptions, argument by symmetry or analogy, aesthetic judgment, pure accident, and hunch—each of these plays a role (as in all of science). Thus, for example, the quantum hypothesis proposed by Planck was based on observed departures of the character of blackbody radiation (radiation emitted by a heated body that absorbs all radiant energy incident upon it) from that predicted by classical electromagnetism. P.A.M. Dirac predicted the existence of the positron in making a relativistic extension of the quantum theory of the electron. The elusive neutrino, without mass or charge, was hypothesized by Wolfgang Pauli as an alternative to abandoning the conservation laws in the beta-decay process. Maxwell conjectured that if changing magnetic fields create electric fields (which was known to be so), then changing electric fields might create magnetic fields, leading him to the electromagnetic theory of light. Einstein's special theory of relativity was based on a critical reexamination of the meaning of simultaneity, while his general theory rests on the equivalence of inertial and gravitational mass.

Although the tactics may vary from problem to problem, the physicist invariably tries to make unsolved problems more tractable by constructing a series of idealized models, with each successive model being a more realistic representation of the actual physical situation. Thus, in the theory of gases, the molecules are at first imagined to be particles that are as structureless as billiard balls with vanishingly small dimensions. This ideal picture is then improved on step by step.

The correspondence principle, a useful guiding principle for extending theoretical interpretations, was formulated by Niels Bohr in the context of the quantum theory. It asserts that when a valid theory is generalized to a broader arena, the new theory's predictions must agree with the old one in the overlapping region in which both are applicable. For example, the more comprehensive theory of physical optics must yield the same result as the more restrictive theory of ray optics whenever wave effects proportional to the wavelength of light are negligible on account of the smallness of that wavelength. Similarly, quantum mechanics must yield the same results as classical mechanics in circumstances when Planck's constant can be considered as negligibly small. Likewise, for speeds small compared to the speed of light (as for baseballs in play), relativistic mechanics must coincide with Newtonian classical mechanics.

Some ways in which experimental and theoretical physi-

Underlying principles of quantum field theory

Correspondence principle

cists attack their problems are illustrated by the following examples.

The modern experimental study of elementary particles began with the detection of new types of unstable particles produced in the atmosphere by primary radiation, the latter consisting mainly of high-energy protons arriving from space. The new particles were detected in Geiger counters and identified by the tracks they left in instruments called cloud chambers and in photographic plates. After World War II, particle physics, then known as high-energy nuclear physics, became a major field of science. Today's high-energy particle accelerators can be several kilometres in length, cost hundreds (or even thousands) of millions of dollars, and accelerate particles to enormous energies (trillions of electron volts). Experimental teams, such as those that discovered the W^+ , W^- , and Z quanta of the weak force at the European Laboratory for Particle Physics (CERN) in Geneva can have 100 or more physicists from many countries, along with a larger number of technical workers serving as support personnel. A variety of visual and electronic techniques are used to interpret and sort the huge amounts of data produced by their efforts, and particle-physics laboratories are major users of the most advanced technology, be it superconductive magnets or supercomputers.

Theoretical physicists use mathematics both as a logical tool for the development of theory and for calculating predictions of the theory to be compared with experiment. Newton, for one, invented integral calculus to solve the following problem, which was essential to his formulation of the law of universal gravitation: Assuming that the attractive force between any pair of point particles is inversely proportional to the square of the distance separating them, how does a spherical distribution of particles, such as the Earth, attract another nearby object? Integral calculus, a procedure for summing many small contributions, yields the simple solution that the Earth itself acts as a point particle with all its mass concentrated at the centre. In modern physics, Dirac predicted the existence of the then-unknown positive electron (or positron) by finding an equation for the electron that would combine quantum mechanics and the special theory of relativity.

RELATIONS BETWEEN PHYSICS AND OTHER DISCIPLINES AND SOCIETY

Influence of physics on related disciplines. Because physics elucidates the simplest fundamental questions in nature on which there can be a consensus, it is hardly surprising that it has had a profound impact on other fields of science, on philosophy, on the worldview of the developed world, and, of course, on technology.

Indeed, whenever a branch of physics has reached such a degree of maturity that its basic elements are comprehended in general principles, it has moved from basic to applied physics and thence to technology. Thus almost all current activity in classical physics consists of applied physics, and its contents form the core of many branches of engineering. Discoveries in modern physics are converted with increasing rapidity into technical innovations and analytical tools for associated disciplines. There are, for example, such nascent fields as nuclear and biomedical engineering, quantum chemistry and quantum optics, and radio, X-ray, and gamma-ray astronomy, as well as such analytic tools as radioisotopes, spectroscopy, and lasers, which all stem directly from basic physics.

Apart from its specific applications, physics—especially Newtonian mechanics—has become the prototype of the scientific method, its experimental and analytic methods sometimes being imitated (and sometimes inappropriately so) in fields far from the related physical sciences. Some of the organizational aspects of physics, based partly on the successes of the radar and atomic-bomb projects of World War II, also have been imitated in large-scale scientific projects, as, for example, in astronomy and space research.

The great influence of physics on the branches of philosophy concerned with the conceptual basis of human perceptions and understanding of nature, such as epistemology, is evidenced by the earlier designation of physics itself as natural philosophy. Present-day philosophy of

science deals largely, though not exclusively, with the foundations of physics. Determinism, the philosophical doctrine that the universe is a vast machine operating with strict causality whose future is determined in all detail by its present state, is rooted in Newtonian mechanics, which obeys that principle. Moreover, the schools of materialism, naturalism, and empiricism have in large degree considered physics to be a model for philosophical inquiry. An extreme position is taken by the logical positivists, whose radical distrust of the reality of anything not directly observable leads them to demand that all significant statements must be formulated in the language of physics.

The uncertainty principle of quantum theory has prompted a reexamination of the question of determinism, and its other philosophical implications remain in doubt. Particularly problematic is the matter of the meaning of measurement, for which recent theories and experiments confirm some apparently noncausal predictions of standard quantum theory. It is fair to say that though physicists agree that quantum theory works, they still differ as to what it means.

Influence of related disciplines on physics. The relationship of physics to its bordering disciplines is a reciprocal one. Just as technology feeds on fundamental science for new practical innovations, so physics appropriates the techniques and instrumentation of modern technology for advancing itself. Thus experimental physicists utilize increasingly refined and precise electronic devices. Moreover, they work closely with engineers in designing basic scientific equipment, such as high-energy particle accelerators. Mathematics has always been the primary tool of the theoretical physicist, and even abstruse fields of mathematics such as group theory and differential geometry have become invaluable to the theoretician classifying subatomic particles or investigating the symmetry characteristics of atoms and molecules. Much of contemporary research in physics depends on the high-speed computer. It allows the theoretician to perform computations that are too lengthy or complicated to be done with paper and pencil. Also, it allows experimentalists to incorporate the computer into their apparatus, so that the results of measurements can be provided nearly instantaneously on-line as summarized data while an experiment is in progress.

The physicist in society. Because of the remoteness of much of contemporary physics from ordinary experience and its reliance on advanced mathematics, physicists have sometimes seemed to the public to be initiates in a latter-day secular priesthood who speak an arcane language and can communicate their findings to laymen only with great difficulty. Yet, the physicist has come to play an increasingly significant role in society, particularly since World War II. Governments have supplied substantial funds for research at academic institutions and at government laboratories through such agencies as the National Science Foundation and the Department of Energy in the United States, which has also established a number of national laboratories, including the Fermi National Accelerator Laboratory in Batavia, Ill., with the world's largest particle accelerator. CERN, mentioned above, is composed of 14 European countries and operates a large accelerator at the Swiss-French border. Physics research is supported in the Federal Republic of Germany by the Max Planck Society for the Advancement of Science and in Japan by the Japan Society for the Promotion of Science. In Trieste, Italy, there is the International Center for Theoretical Physics, which has strong ties to developing countries. These are only a few examples of the widespread international interest in fundamental physics.

Basic research in physics is obviously dependent on public support and funding, and with this development has come, albeit slowly, a growing recognition within the physics community of the social responsibility of scientists for the consequences of their work and for the more general problems of science and society. philosophy

Principal concerns

challenge in chemistry is the development of a coherent explanation of the complex behaviour of materials, why they appear as they do, what gives them their enduring properties, and how interactions among different substances can bring about the formation of new substances and the destruction of old ones. From the earliest attempts to understand the material world in rational terms, chemists have struggled to develop theories of matter that satisfactorily explain both permanence and change. The ordered assembly of indestructible atoms into small and large molecules, or extended networks of intermingled atoms, is generally accepted as the basis of permanence, while the reorganization of atoms or molecules into different arrangements lies behind theories of change. Thus chemistry involves the study of the atomic composition and structural architecture of substances, as well as the varied interactions among substances that can lead to sudden, often violent reactions.

Practical applications

Chemistry also is concerned with the utilization of natural substances and the creation of artificial ones. Cooking, fermentation, glass making, and metallurgy are all chemical processes that date from the beginnings of civilization. Today, vinyl, Teflon, liquid crystals, semiconductors, and superconductors represent the fruits of chemical technology. The 20th century has seen dramatic advances in the comprehension of the marvelous and complex chemistry of living organisms, and a molecular interpretation of health and disease holds great promise. Modern chemistry, aided by increasingly sophisticated instruments, studies materials as small as single atoms and as large and complex as DNA (deoxyribonucleic acid), which contains millions of atoms. New substances can even be designed to bear desired characteristics and then synthesized. The rate at which chemical knowledge continues to accumulate is remarkable. Over time more than 8,000,000 different chemical substances, both natural and artificial, have been characterized and produced. The number was less than 500,000 as recently as 1965.

Intimately interconnected with the intellectual challenges of chemistry are those associated with industry. In the mid-19th century the German chemist Justus von Liebig commented that the wealth of a nation could be gauged by the amount of sulfuric acid it produced. This acid, essential to many manufacturing processes, remains today the leading chemical product of industrialized countries. As Liebig recognized, a country that produces large amounts of sulfuric acid is one with a strong chemical industry and a strong economy as a whole. The production, distribution, and utilization of a wide range of chemical products is common to all highly developed nations. In fact, one can say that the "iron age" of civilization is being replaced by a "polymer age," for in some countries the total volume of polymers now produced exceeds that of iron.

THE SCOPE OF CHEMISTRY

The days are long past when one person could hope to have a detailed knowledge of all areas of chemistry. Those pursuing their interests into specific areas of chemistry communicate with others who share the same interests. Over time a group of chemists with specialized research interests become the founding members of an area of specialization. The areas of specialization that emerged early in the history of chemistry, such as organic, inorganic, physical, analytical, and industrial chemistry, along with biochemistry, remain of greatest general interest. There has been, however, much growth in the areas of polymer, environmental, and medicinal chemistry during the 20th century. Moreover, new specialties continue to appear, as, for example, pesticide, forensic, and computer chemistry.

Analytical chemistry. Most of the materials that occur on Earth, such as wood, coal, minerals, or air, are mixtures of many different and distinct chemical substances. Each pure chemical substance (e.g., oxygen, iron, or water) has a characteristic set of properties that gives it its chemical identity. Iron, for example, is a common silver-white metal that melts at 1,535° C, is very malleable, and readily combines with oxygen to form the common substances hematite and magnetite. The detection of iron in a mixture of metals, or in a compound such as magnetite, is

a branch of analytical chemistry called qualitative analysis. Measurement of the actual amount of a certain substance in a compound or mixture is termed quantitative analysis. Quantitative analytic measurement has determined, for instance, that iron makes up 72.3 percent, by mass, of magnetite, the mineral commonly seen as black sand along beaches and stream banks. Over the years, chemists have discovered chemical reactions that indicate the presence of such elemental substances by the production of easily visible and identifiable products. Iron can be detected by chemical means if it is present in a sample to an amount of 1 part per million or greater. Some very simple qualitative tests reveal the presence of specific chemical elements in even smaller amounts. The yellow colour imparted to a flame by sodium is visible if the sample being ignited has as little as one-billionth of a gram of sodium. Such analytic tests have allowed chemists to identify the types and amounts of impurities in various substances and to determine the properties of very pure materials. Substances used in common laboratory experiments generally have impurity levels of less than 0.1 percent. For special applications, one can purchase chemicals that have impurities totaling less than 0.001 percent. The identification of pure substances and the analysis of chemical mixtures enable all other chemical disciplines to flourish.

The importance of analytical chemistry has never been greater than it is today. The demand in modern societies for a variety of safe foods, affordable consumer goods, abundant energy, and labour-saving technologies places a great burden on the environment. All chemical manufacturing produces waste products in addition to the desired substances, and waste disposal has not always been carried out carefully. Disruption of the environment has occurred since the dawn of civilization, and pollution problems have increased with the growth of global population. The techniques of analytical chemistry are relied on heavily to maintain a benign environment. The undesirable substances in water, air, soil, and food must be identified, their point of origin fixed, and safe, economical methods for their removal or neutralization developed. Once the amount of a pollutant deemed to be hazardous has been assessed, it becomes important to detect harmful substances at concentrations well below the danger level. Analytical chemists seek to develop increasingly accurate and sensitive techniques and instruments.

Sophisticated analytic instruments, often coupled with computers, have improved the accuracy with which chemists can identify substances and have lowered detection limits. An analytic technique in general use is gas chromatography, which separates the different components of a gaseous mixture by passing the mixture through a long, narrow column of absorbent but porous material. The different gases interact differently with this absorbent material and pass through the column at different rates. As the separate gases flow out of the column, they can be passed into another analytic instrument called a mass spectrometer, which separates substances according to the mass of their constituent ions. A combined gas chromatograph-mass spectrometer can rapidly identify the individual components of a chemical mixture whose concentrations may be no greater than a few parts per billion. Similar or even greater sensitivities can be obtained under favourable conditions using techniques such as atomic absorption, polarography, and neutron activation. The rate of instrumental innovation is such that analytic instruments often become obsolete within 10 years of their introduction. Newer instruments are more accurate and faster and are employed widely in the areas of environmental and medicinal chemistry.

Inorganic chemistry. Modern chemistry, which dates more or less from the acceptance of the law of conservation of mass in the late 18th century, focused initially on those substances that were not associated with living organisms. Study of such substances, which normally have little or no carbon, constitutes the discipline of inorganic chemistry. Early work sought to identify the simple substances—namely, the elements—that are the constituents of all more complex substances. Some elements, such as gold and carbon, have been known since antiquity, and

Qualitative analysis and quantitative analysis

Gas chromatography and mass spectrometry

many others were discovered and studied throughout the 19th and early 20th centuries. Today, more than 100 are known. The study of such simple inorganic compounds as sodium chloride (common salt) has led to some of the fundamental concepts of modern chemistry, the law of definite proportions providing one notable example. This law states that for most pure chemical substances the constituent elements are always present in fixed proportions by mass (*e.g.*, every 100 grams of salt contains 39.3 grams of sodium and 60.7 grams of chlorine). The crystalline form of salt, known as halite, consists of intermingled sodium and chlorine atoms, one sodium atom for each one of chlorine. Such a compound, formed solely by the combination of two elements, is known as a binary compound. Binary compounds are very common in inorganic chemistry, and they exhibit little structural variety. For this reason, the number of inorganic compounds is limited in spite of the large number of elements that may react with each other. If three or more elements are combined in a substance, the structural possibilities become greater.

After a period of quiescence in the early part of the 20th century, inorganic chemistry has again become an exciting area of research. Compounds of boron and hydrogen, known as boranes, have unique structural features that forced a change in thinking about the architecture of inorganic molecules. Some inorganic substances have structural features long believed to occur only in carbon compounds, and a few inorganic polymers have even been produced. Ceramics are materials composed of inorganic elements combined with oxygen. For centuries ceramic objects have been made by strongly heating a vessel formed from a paste of powdered minerals. Although ceramics are quite hard and stable at very high temperatures, they are usually brittle. Currently, new ceramics strong enough to be used as turbine blades in jet engines are being manufactured. There is hope that ceramics will one day replace steel in components of internal-combustion engines. In 1987 a ceramic containing yttrium, barium, copper, and oxygen, with the approximate formula $\text{YBa}_2\text{Cu}_3\text{O}_7$, was found to be a superconductor at a temperature of about 100 K. A superconductor offers no resistance to the passage of an electrical current, and this new type of ceramic could very well find wide use in electrical and magnetic applications. A superconducting ceramic is so simple to make that it can be prepared in a high school laboratory. Its discovery illustrates the unpredictability of chemistry, for fundamental discoveries can still be made with simple equipment and inexpensive materials.

Many of the most interesting developments in inorganic chemistry bridge the gap with other disciplines. Organometallic chemistry investigates compounds that contain inorganic elements combined with carbon-rich units. Many organometallic compounds play an important role in industrial chemistry as catalysts, which are substances that are able to accelerate the rate of a reaction even when present in only very small amounts. Some success has been achieved in the use of such catalysts for converting natural gas to related but more useful chemical substances. Chemists also have created large inorganic molecules that contain a core of metal atoms, such as platinum, surrounded by a shell of different chemical units. Some of these compounds, referred to as metal clusters, have characteristics of metals, while others react in ways similar to biologic systems. Trace amounts of metals in biologic systems are essential for processes such as respiration, nerve function, and cell metabolism. Processes of this kind form the object of study of bioinorganic chemistry. Although organic molecules were once thought to be the distinguishing chemical feature of living creatures, it is now known that inorganic chemistry plays a vital role as well.

Organic chemistry. Organic compounds are based on the chemistry of carbon. Carbon is unique in the variety and extent of structures that can result from the three-dimensional connections of its atoms. The process of photosynthesis converts carbon dioxide and water to oxygen and compounds known as carbohydrates. Both cellulose, the substance that gives structural rigidity to plants, and starch, the energy storage product of plants, are polymeric

carbohydrates. Simple carbohydrates produced by photosynthesis form the raw material for the myriad organic compounds found in the plant and animal kingdoms. When combined with variable amounts of hydrogen, oxygen, nitrogen, sulfur, phosphorus, and other elements, the structural possibilities of carbon compounds become limitless, and their number far exceeds the total of all nonorganic compounds. A major focus of organic chemistry is the isolation, purification, and structural study of these naturally occurring substances. Many natural products are simple molecules. Examples include formic acid (HCO_2H) in ants, ethyl alcohol ($\text{C}_2\text{H}_5\text{OH}$) in fermenting fruit, and oxalic acid ($\text{C}_2\text{H}_2\text{O}_4$) in rhubarb leaves. Other natural products, such as penicillin, vitamin B_{12} , proteins, and nucleic acids, are exceedingly complex. The isolation of pure natural products from their host organism is made difficult by the low concentrations in which they may be present. Once they are isolated in pure form, however, modern instrumental techniques can reveal structural details for amounts weighing as little as one-millionth of a gram. The correlation of the physical and chemical properties of compounds with their structural features is the domain of physical organic chemistry. Once the properties endowed upon a substance by specific structural units termed functional groups are known, it becomes possible to design novel molecules that may exhibit desired properties. The preparation, under controlled laboratory conditions, of specific compounds is known as synthetic chemistry. Some products are easier to synthesize than to collect and purify from their natural sources. Tons of vitamin C, for example, are synthesized annually. Many synthetic substances have novel properties that make them especially useful. Plastics are a prime example, as are many drugs and agricultural chemicals. A continuing challenge for synthetic chemists is the structural complexity of most organic substances. To synthesize a desired substance, the atoms must be pieced together in the correct order and with the proper three-dimensional relationships. Just as a given pile of lumber and bricks can be assembled in many ways to build houses of several different designs, so too can a fixed number of atoms be connected together in various ways to give different molecules. Only one structural arrangement out of the many possibilities will be identical with a naturally occurring molecule. The antibiotic erythromycin, for example, contains 37 carbon, 67 hydrogen, and 13 oxygen atoms, along with one nitrogen atom. Even when joined together in the proper order, these 118 atoms can give rise to 262,144 different structures, only one of which has the characteristics of natural erythromycin. The great abundance of organic compounds, their fundamental role in the chemistry of life, and their structural diversity have made their study especially challenging and exciting. Organic chemistry is the largest area of specialization among the various fields of chemistry.

Biochemistry. As understanding of inanimate chemistry grew during the 19th century, attempts to interpret the physiological processes of living organisms in terms of molecular structure and reactivity gave rise to the discipline of biochemistry. Biochemists employ the techniques and theories of chemistry to probe the molecular basis of life. An organism is investigated on the premise that its physiological processes are the consequence of many thousands of chemical reactions occurring in a highly integrated manner. Biochemists have established, among other things, the principles that underlie energy transfer in cells, the chemical structure of cell membranes, the coding and transmission of hereditary information, muscular and nerve function, and biosynthetic pathways. In fact, related biomolecules have been found to fulfill similar roles in organisms as different as bacteria and human beings. The study of biomolecules, however, presents many difficulties. Such molecules are often very large and exhibit great structural complexity; moreover, the chemical reactions they undergo are usually exceedingly fast. The separation of the two strands of DNA, for instance, occurs in one-millionth of a second. Such rapid rates of reaction are possible only through the intermediary action of biomolecules called enzymes. Enzymes are proteins that owe their remarkable rate-accelerating abilities to their three-dimen-

Probing the molecular basis of life

Development of new ceramics

Organometallic chemistry

Bioinorganic chemistry

sional chemical structure. Not surprisingly, biochemical discoveries have had a great impact on the understanding and treatment of disease. Many ailments due to inborn errors of metabolism have been traced to specific genetic defects. Other diseases result from disruptions in normal biochemical pathways.

Concern
with
therapeutic
agents

Frequently, symptoms can be alleviated by drugs, and the discovery, mode of action, and degradation of therapeutic agents is another of the major areas of study in biochemistry. Bacterial infections can be treated with sulfonamides, penicillins, and tetracyclines, and research into viral infections has revealed the effectiveness of acyclovir against the herpes virus. There is much current interest in the details of carcinogenesis and cancer chemotherapy. It is known, for example, that cancer can result when cancer-causing molecules, or carcinogens as they are called, react with nucleic acids and proteins and interfere with their normal modes of action. Researchers have developed tests that can identify molecules likely to be carcinogenic. The hope, of course, is that progress in the prevention and treatment of cancer will accelerate once the biochemical basis of the disease is more fully understood.

Methods
of gene
synthesis

The molecular basis of biologic processes is an essential feature of the fast-growing disciplines of molecular biology and biotechnology. Chemistry has developed methods for rapidly and accurately determining the structure of proteins and DNA. In addition, efficient laboratory methods for the synthesis of genes are being devised. Ultimately, the correction of genetic diseases by replacement of defective genes with normal ones may become possible.

Polymer chemistry. The simple substance ethylene is a gas composed of molecules with the formula CH_2CH_2 . Under certain conditions, many ethylene molecules will join together to form a long chain called polyethylene, with the formula $(\text{CH}_2\text{CH}_2)_n$, where n is a variable but large number. Polyethylene is a tough, durable solid material quite different from ethylene. It is an example of a polymer, which is a large molecule made up of many smaller molecules (monomers), usually joined together in a linear fashion. Many naturally occurring substances, including cellulose, starch, cotton, wool, rubber, leather, proteins, and DNA, are polymers. Polyethylene, nylon, and acrylics are examples of synthetic polymers. The study of such materials lies within the domain of polymer chemistry, a specialty that has flourished in the 20th century. The investigation of natural polymers overlaps considerably with biochemistry, but the synthesis of new polymers, the investigation of polymerization processes, and the characterization of the structure and properties of polymeric materials all pose unique problems for polymer chemists.

Polymer chemists have developed and synthesized polymers that vary in hardness, flexibility, softening temperature, solubility in water, and biodegradability. They have produced polymeric materials that are as strong as steel yet lighter and more resistant to corrosion. Oil, natural gas, and water pipelines are now routinely constructed of plastic pipe. In recent years, automakers have increased their use of plastic components to build lighter vehicles that consume less fuel. Other industries such as those involved in the manufacture of textiles, rubber, paper, and packaging materials are built upon polymer chemistry.

Developing
special
catalysts

Besides producing new kinds of polymeric materials, researchers are concerned with developing special catalysts that are required by the large-scale industrial synthesis of commercial polymers. Without such catalysts, the polymerization process would be very slow in certain cases.

Physical chemistry. Many chemical disciplines, such as those already discussed, focus on certain classes of materials that share common structural and chemical features. Other specialties may be centred not on a class of substances but rather on their interactions and transformations. The oldest of these fields is physical chemistry, which seeks to measure, correlate, and explain the quantitative aspects of chemical processes. The Anglo-Irish chemist Robert Boyle, for example, discovered in the 17th century that at room temperature the volume of a fixed quantity of gas decreases proportionally as the pressure on it increases. Thus, for a gas at constant temperature, the product of its volume V and pressure P equals a constant

number—i.e., $PV = \text{constant}$. Such a simple arithmetic relationship is valid for nearly all gases at room temperature and at pressures equal to or less than one atmosphere. Subsequent work has shown that the relationship loses its validity at higher pressures, but more complicated expressions that more accurately match experimental results can be derived. The discovery and investigation of such chemical regularities, often called laws of nature, lie within the realm of physical chemistry. For much of the 18th century the source of mathematical regularity in chemical systems was assumed to be the continuum of forces and fields that surround the atoms making up chemical elements and compounds. Developments in the 20th century, however, have shown that chemical behaviour is best interpreted by a quantum mechanical model of atomic and molecular structure (see above *Quantum mechanics*). The branch of physical chemistry that is largely devoted to this subject is theoretical chemistry. Theoretical chemists make extensive use of computers to help them solve complicated mathematical equations. Other branches of physical chemistry include chemical thermodynamics, which deals with the relationship between heat and other forms of chemical energy, and chemical kinetics, which seeks to measure and understand the rates of chemical reactions. Electrochemistry investigates the interrelationship of electric current and chemical change. The passage of an electric current through a chemical solution causes changes in the constituent substances that are often reversible—i.e., under different conditions the altered substances themselves will yield an electric current. Common batteries contain chemical substances that, when placed in contact with each other by closing an electrical circuit, will deliver current at a constant voltage until the substances are consumed. At present there is much interest in devices that can use the energy in sunlight to drive chemical reactions whose products are capable of storing the energy. The discovery of such devices would make possible the widespread utilization of solar energy.

Electro-
chemistry

There are many other disciplines within physical chemistry that are concerned more with the general properties of substances and the interactions among substances than with the substances themselves. Photochemistry is a specialty that investigates the interaction of light with matter. Chemical reactions initiated by the absorption of light can be very different from those that occur by other means. Vitamin D, for example, is formed in the human body when the steroid ergosterol absorbs solar radiation; ergosterol does not change to vitamin D in the dark.

A rapidly developing subdiscipline of physical chemistry is surface chemistry. It examines the properties of chemical surfaces, relying heavily on instruments that can provide a chemical profile of such surfaces. Whenever a solid is exposed to a liquid or a gas, a reaction occurs initially on the surface of the solid, and its properties can change dramatically as a result. Aluminum is a case in point: it is resistant to corrosion precisely because the surface of the pure metal reacts with oxygen to form a layer of aluminum oxide, which serves to protect the interior of the metal from further oxidation. Numerous reaction catalysts perform their function by providing a reactive surface on which substances can react.

Surface
chemistry

Industrial chemistry. The manufacture, sale, and distribution of chemical products is one of the cornerstones of a developed country. Chemists play an important role in the manufacture, inspection, and safe handling of chemical products, as well as in product development and general management. The manufacture of basic chemicals such as oxygen, chlorine, ammonia, and sulfuric acid provides the raw materials for industries producing textiles, agricultural products, metals, paints, and pulp and paper. Specialty chemicals are produced in smaller amounts for industries involved with such products as pharmaceuticals, foodstuffs, packaging, detergents, flavours, and fragrances. To a large extent, the chemical industry takes the products and reactions common to "bench-top" chemical processes and scales them up to industrial quantities.

The monitoring and control of bulk chemical processes, especially with regard to heat transfer, pose problems usually tackled by chemists and chemical engineers. The

Concept of wave functions

Applied research

disposal of by-products also is a major problem for bulk chemical producers. These and other challenges of industrial chemistry set it apart from the more purely intellectual disciplines of chemistry discussed above. Yet, within the chemical industry, there is a considerable amount of fundamental research undertaken within traditional specialties. Most large chemical companies have research-and-development capability. Pharmaceutical firms, for example, operate large research laboratories in which chemists test molecules for pharmacological activity. The new products and processes that are discovered in such laboratories are often patented and become a source of profit for the company funding the research. A great deal of the research conducted in the chemical industry can be termed applied research because its goals are closely tied to the products and processes of the company concerned. New technologies often require much chemical expertise. The fabrication of, say, electronic microcircuits involves close to 100 separate chemical steps from start to finish. Thus, the chemical industry evolves with the technological advances of the modern world and at the same time often contributes to the rate of progress.

THE METHODOLOGY OF CHEMISTRY

Chemistry is to a large extent a cumulative science. Over time the number and extent of observations and phenomena studied increase. Not all hypotheses and discoveries endure unchallenged, however. Some of them are discarded as new observations or more satisfying explanations appear. Nonetheless, chemistry has a broad spectrum of explanatory models for chemical phenomena that have endured and been extended over time. These now have the status of theories, interconnected sets of explanatory devices that correlate well with observed phenomena. As new discoveries are made, they are incorporated into existing theory whenever possible. However, as the discovery of high-temperature superconductors in 1986 illustrates, accepted theory is never sufficient to predict the course of future discovery. Serendipity, or chance discovery, will continue to play as much a role in the future as will theoretical sophistication.

Studies of molecular structure. The chemical properties of a substance are a function of its structure, and the techniques of X-ray crystallography now enable chemists to determine the precise atomic arrangement of complex molecules. A molecule is an ordered assembly of atoms. Each atom in a molecule is connected to one or more neighbouring atoms by a chemical bond. The length of bonds and the angles between adjacent bonds are all important in describing molecular structure, and a comprehensive theory of chemical bonding is one of the major achievements of modern chemistry. Fundamental to bonding theory is the atomic-molecular concept.

Atoms and elements. As far as general chemistry is concerned, atoms are composed of the three fundamental particles: the proton, the neutron, and the electron. Although the proton and the neutron are themselves composed of smaller units, their substructure has little impact on chemical transformation. As was explained in an earlier section, the proton carries a charge of +1, and the number of protons in an atomic nucleus distinguishes one type of chemical atom from another. The simplest atom of all, hydrogen, has a nucleus composed of a single proton. The neutron has very nearly the same mass as the proton, but it has no charge. Neutrons are contained with protons in the nucleus of all atoms other than hydrogen. The atom with one proton and one neutron in its nucleus is called deuterium. Because it has only one proton, deuterium exhibits the same chemical properties as hydrogen but has a different mass. Hydrogen and deuterium are examples of related atoms called isotopes. The third atomic particle, the electron, has a charge of -1, but its mass is 1,836 times smaller than that of a proton. The electron occupies a region of space outside the nucleus termed an orbital. Some orbitals are spherical with the nucleus at the centre. Because electrons have so little mass and move about at speeds close to half that of light, they exhibit the same wave-particle duality as photons of light. This means that some of the properties of an electron are best described

by considering the electron to be a particle, while other properties are consistent with the behaviour of a standing wave. The energy of a standing wave, such as a vibrating string, is distributed over the region of space defined by the two fixed ends and the up-and-down extremes of vibration. Such a wave does not exist in a fixed region of space as does a particle. Early models of atomic structure envisioned the electron as a particle orbiting the nucleus, but electron orbitals are now interpreted as the regions of space occupied by standing waves called wave functions (see above *Quantum mechanics*). These wave functions represent the regions of space around the nucleus in which the probability of finding an electron is high. They play an important role in bonding theory, as will be discussed later.

Each proton in an atomic nucleus requires an electron for electrical neutrality. Thus, as the number of protons in a nucleus increases, so too does the number of electrons. The electrons, alone or in pairs, occupy orbitals increasingly distant from the nucleus. Electrons farther from the nucleus are attracted less strongly by the protons in the nucleus, and they can be removed more easily from the atom. The energy required to move an electron from one orbital to another, or from one orbital to free space, gives a measure of the energy level of the orbitals. These energies have been found to have distinct, fixed values; they are said to be quantized. The energy differences between orbitals give rise to the characteristic patterns of light absorption or emission that are unique to each chemical atom.

A new chemical atom—that is, an element—results each time another proton is added to an atomic nucleus. Consecutive addition of protons generates the whole range of elements known to exist in the universe. Compounds are formed when two or more different elements combine through atomic bonding. Such bond formation is a consequence of electron pairing and constitutes the foundation of all structural chemistry.

Ionic and covalent bonding. When two different atoms approach each other, the electrons in their outer orbitals can respond in two distinct ways. An electron in the outermost atomic orbital of atom A may move completely to an outer but stabler orbital of atom B. The charged atoms that result, A^+ and B^- , are called ions, and the electrostatic force of attraction between them gives rise to what is termed an ionic bond. Most elements can form ionic bonds, and the substances that result commonly exist as three-dimensional arrays of positive and negative ions. Ionic compounds are frequently crystalline solids that have high melting points (e.g., table salt).

The second way in which the two outer electrons of atoms A and B can respond to the approach of A and B is to pair up to form a covalent bond. In the simple view known as the valence-bond model, in which electrons are treated strictly as particles, the two paired electrons are assumed to lie between the two nuclei and are shared equally by atoms A and B, resulting in a covalent bond. Atoms joined together by one or more covalent bonds constitute molecules. Hydrogen gas is composed of hydrogen molecules, which consist in turn of two hydrogen atoms linked by a covalent bond. The notation H_2 for hydrogen gas is referred to as a molecular formula. Molecular formulas indicate the number and type of atoms that make up a molecule. The molecule H_2 is responsible for the properties generally associated with hydrogen gas. Most substances on Earth have covalently bonded molecules as their fundamental chemical unit, and their molecular properties are completely different from those of the constituent elements. The physical and chemical properties of carbon dioxide, for example, are quite distinct from those of pure carbon and pure oxygen.

The interpretation of a covalent bond as a localized electron pair is an oversimplification of the bonding situation. A more comprehensive description of bonding that considers the wave properties of electrons is the molecular-orbital theory. According to this theory, electrons in a molecule, rather than being localized between atoms, are distributed over all the atoms in the molecule in a spatial distribution described by a molecular orbital. Such orbitals result when the atomic orbitals of bonded atoms combine with each other. The total number of molecular

Valence-bond model

The molecular-orbital theory

Basic concepts of modern bonding theory

orbitals present in a molecule is equal to the sum of all atomic orbitals in the constituent atoms prior to bonding. Thus, for the simple combination of atoms A and B to form the molecule AB, two atomic orbitals combine to generate two molecular orbitals. One of these, the so-called bonding molecular orbital, represents a region of space enveloping both the A and B atoms, while the other, the anti-bonding molecular orbital, has two lobes, neither of which occupies the space between the two atoms. The bonding molecular orbital is at a lower energy level than are the two atomic orbitals, while the anti-bonding orbital is at a higher energy level. The two paired electrons that constitute the covalent bond between A and B occupy the bonding molecular orbital. For this reason, there is a high probability of finding the electrons between A and B, but they can be found elsewhere in the orbital as well. Because only two electrons are involved in bond formation and both can be accommodated in the lower energy orbital, the anti-bonding orbital remains unpopulated. This theory of bonding predicts that bonding between A and B will occur because the energy of the paired electrons after bonding is less than that of the two electrons in their atomic orbitals prior to bonding. The formation of a covalent bond is thus energetically favoured. The system goes from a state of higher energy to one of lower energy.

Another feature of this bonding picture is that it is able to predict the energy required to move an electron from the bonding molecular orbital to the anti-bonding one. The energy required for such an electronic excitation can be provided by visible light, for example, and the wavelength of the light absorbed determines the colour displayed by the absorbing molecule (e.g., violets are blue because the pigments in the flower absorb the red rays of natural light and reflect more of the blue). As the number of atoms in a molecule increases, so too does the number of molecular orbitals. Calculation of molecular orbitals for large molecules is mathematically difficult, but computers have made it possible to determine the wave equations for several large molecules. Molecular properties predicted by such calculations correlate well with experimental results.

Isomerism. Many elements can form two or more covalent bonds, but only a few are able to form extended chains of covalent bonds. The outstanding example is carbon, which can form as many as four covalent bonds and can bond to itself indefinitely. Carbon has six electrons in total, two of which are paired in an atomic orbital closest to the nucleus. The remaining four are farther from the nucleus and are available for covalent bonding. When there is sufficient hydrogen present, carbon will react to form methane, CH_4 . When all four electron pairs occupy the four molecular orbitals of lowest energy, the molecule assumes the shape of a tetrahedron, with carbon at the centre and the four hydrogen atoms at the apexes. The C-H bond length is 110 picometres (1 picometre = 10^{-12} metre), and the angle between adjacent C-H bonds is close to 110° . Such tetrahedral symmetry is common to many carbon compounds and results in interesting structural possibilities. If two carbon atoms are joined together, with three hydrogen atoms bonded to each carbon atom, the molecule ethane is obtained. When four carbon atoms are joined together, two different structures are possible: a linear structure designated *n*-butane and a branched structure called iso-butane. These two structures have the same molecular formula, C_4H_{10} , but a different order of attachment of their constituent atoms. The two molecules are termed structural isomers. Each of them has unique chemical and physical properties, and they are different compounds. The number of possible isomers increases rapidly as the number of carbon atoms increases. There are five isomers for C_6H_{14} , 75 for $\text{C}_{10}\text{H}_{22}$, and 6.2×10^{13} for $\text{C}_{40}\text{H}_{82}$. When carbon forms bonds to atoms other than hydrogen, such as oxygen, nitrogen, and sulfur, the structural possibilities become even greater. It is this great potential for structural diversity that makes carbon compounds essential to living organisms.

Even when the bonding sequence of carbon compounds is fixed, further structural variation is still possible. When two carbon atoms are joined together by two bonding pairs of electrons, a double bond is formed. A double bond

forces the two carbon atoms and attached groups into a rigid, planar structure. As a result, a molecule such as $\text{CHCl}=\text{CHCl}$ can exist in two nonidentical forms called geometric isomers. Structural rigidity also occurs in ring structures, and attached groups can be on the same side of a ring or on different sides. Yet another opportunity for isomerism arises when a carbon atom is bonded to four different groups. These can be attached in two different ways, one of which is the mirror image of the other. This type of isomerism is called optical isomerism, because the two isomers affect plane-polarized light differently. Two optical isomers are possible for every carbon atom that is bonded to four different groups. For a molecule bearing 10 such carbon atoms, the total number of possible isomers will be $2^{10} = 1,024$. Large biomolecules often have 10 or more carbon atoms for which such optical isomers are possible. Only one of all the possible isomers will be identical to the natural molecule. For this reason, the laboratory synthesis of large organic molecules is exceedingly difficult. Only in the last few decades of the 20th century have chemists succeeded in developing reagents and processes that yield specific optical isomers. They expect that new synthetic methods will make possible the synthesis of ever more complex natural products.

Investigations of chemical transformations. *Basic factors.* The structure of ionic substances and covalently bonded molecules largely determines their function. As noted above, the properties of a substance depend on the number and type of atoms it contains and on the bonding patterns present. Its bulk properties also depend, however, on the interactions among individual atoms, ions, or molecules. The force of attraction between the fundamental units of a substance dictate whether, at a given temperature and pressure, that substance will exist in the solid, liquid, or gas phase. At room temperature and pressure, for example, the strong forces of attraction between the positive ions of sodium (Na^+) and the negative ions of chlorine (Cl^-) draw them into a compact solid structure. The weaker forces of attraction among neighbouring water molecules allow the looser packing characteristic of a liquid. Finally, the very weak attractive forces acting among adjacent oxygen molecules are exceeded by the dispersive forces of heat; oxygen, consequently, is a gas. Interparticle forces thus affect the chemical and physical behaviour of substances, but they also determine to a large extent how a particle will respond to the approach of a different particle. If the two particles react with each other to form new particles, a chemical reaction has occurred. Notwithstanding the unlimited structural diversity allowed by molecular bonding, the world would be devoid of life if substances were incapable of change. The study of chemical transformation, which complements the study of molecular structure, is built on the concepts of energy and entropy.

Energy and the first law of thermodynamics. The concept of energy is a fundamental and familiar one in all the sciences. In simple terms, the energy of a body represents its ability to do work, and work itself is a force acting over a distance.

Chemical systems can have both kinetic energy (energy of motion) and potential energy (stored energy). The kinetic energy possessed by any collection of molecules in a solid, liquid, or gas is known as its thermal energy. Since liquids expand when they have more thermal energy, a liquid column of mercury, for example, will rise higher in an evacuated tube as it becomes warmer. In this way a thermometer can be used to measure the thermal energy, or temperature, of a system. The temperature at which all molecular motion comes to a halt is known as absolute zero.

Energy also may be stored in atoms or molecules as potential energy. When protons and neutrons combine to form the nucleus of a certain element, the reduction in potential energy is matched by the production of a huge quantity of kinetic energy. Consider, for instance, the formation of the deuterium nucleus from one proton and one neutron. The fundamental mass unit of the chemist is the mole, which represents the mass, in grams, of 6.02×10^{23} individual particles, whether they be atoms or molecules.

Concerns
of nuclear
chemistry

One mole of protons has a mass of 1.007825 grams and one mole of neutrons has a mass of 1.008665 grams. By simple addition the mass of one mole of deuterium atoms (ignoring the negligible mass of one mole of electrons) should be 2.016490 grams. The measured mass is 0.00239 gram less than this. The missing mass is known as the binding energy of the nucleus and represents the mass equivalent of the energy released by nucleus formation. By using Einstein's formula for the conversion of mass to energy ($E = mc^2$), one can calculate the energy equivalent of 0.00239 gram as 2.15×10^8 kilojoules. This is approximately 240,000 times greater than the energy released by the combustion of one mole of methane. Such studies of the energetics of atom formation and interconversion are part of a specialty known as nuclear chemistry.

The energy released by the combustion of methane is about 900 kilojoules per mole. Although much less than the energy released by nuclear reactions, the energy given off by a chemical process such as combustion is great enough to be perceived as heat and light. Energy is released in so-called exothermic reactions because the chemical bonds in the product molecules, carbon dioxide and water, are stronger and stabler than those in the reactant molecules, methane and oxygen. The chemical potential energy of the system has decreased, and most of the released energy appears as heat, while some appears as radiant energy, or light. The heat produced by such a combustion reaction will raise the temperature of the surrounding air and, at constant pressure, increase its volume. This expansion of air results in work being done. In the cylinder of an internal-combustion engine, for example, the combustion of gasoline results in hot gases that expand against a moving piston. The motion of the piston turns a crankshaft, which then propels the vehicle. In this case, chemical potential energy has been converted to thermal energy, some of which produces useful work. This process illustrates a statement of the conservation of energy known as the first law of thermodynamics. This law states that, for an exothermic reaction, the energy released by the chemical system is equal to the heat gained by the surroundings plus the work performed. By measuring the heat and work quantities that accompany chemical reactions, it is possible to ascertain the energy differences between the reactants and the products of various reactions. In this manner, the potential energy stored in a variety of molecules can be determined, and the energy changes that accompany chemical reactions can be calculated.

Measuring

Entropy and the second law of thermodynamics. Some chemical processes occur even though there is no net energy change. Consider a vessel containing a gas, connected to an evacuated vessel via a channel wherein a barrier obstructs passage of the gas. If the barrier is removed, the gas will expand into the evacuated vessel. This expansion is consistent with the observation that a gas always expands to fill the volume available. When the temperature of both vessels is the same, the energy of the gas before and after the expansion is the same. The reverse reaction does not occur, however. The spontaneous reaction is the one that yields a state of greater disorder. In the expanded volume, the individual gas molecules have greater freedom of movement and thus are more disordered. The measure of the disorder of a system is a quantity termed entropy. At a temperature of absolute zero, all movement of atoms and molecules ceases, and the disorder—and entropy—of such perfectly compacted substances is zero. (Zero entropy at zero temperature is in accord with the third law of thermodynamics.) All substances above absolute zero will have a positive entropy value that increases with temperature. When a hot body cools down, the thermal energy it loses passes to the surrounding air, which is at a lower temperature. As the entropy of the cooling body decreases, the entropy of the surrounding air increases. In fact, the increase in entropy of the air is greater than the decrease in entropy of the cooling body. This is consistent with the second law, which states that the total entropy of a system and its surroundings always increases in a spontaneous reaction. Thus the first and second laws of thermodynamics indicate that, for all processes of chem-

ical change throughout the universe, energy is conserved but entropy increases.

Application of the laws of thermodynamics to chemical systems allows chemists to predict the behaviour of chemical reactions. When energy and entropy considerations favour the formation of product molecules, reagent molecules will act to form products until an equilibrium is established between products and reagents. The ratio of products to reagents is specified by a quantity known as an equilibrium constant, which is a function of the energy and entropy differences between the two. What thermodynamics cannot predict, however, is the rate at which chemical reactions occur. For fast reactions an equilibrium mixture of products and reagents can be established in one millisecond or less; for slow reactions the time required could be hundreds of years.

Rates of reaction. When the specific rates of chemical reactions are measured experimentally, they are found to be dependent on the concentrations of reacting species, temperature, and a quantity called activation energy. Chemists explain this phenomenon by recourse to the collision theory of reaction rates. This theory builds on the premise that a reaction between two or more chemicals requires, at the molecular level, a collision between two rapidly moving molecules. If the two molecules collide in the right way and with enough kinetic energy, one of the molecules may acquire enough energy to initiate the bond-breaking process. As this occurs, new bonds may begin to form, and ultimately reagent molecules are converted into product molecules. The point of highest energy during bond breaking and bond formation is called the transition state of the molecular process. The difference between the energy of the transition state and that of the reacting molecules is the activation energy that must be exceeded for a reaction to occur. Reaction rates increase with temperature because the colliding molecules have greater energies, and more of them will have energies that exceed the activation energy of reaction. The modern study of the molecular basis of chemical change has been greatly aided by lasers and computers. It is now possible to study short-lived collision products and to better determine the molecular mechanisms that fix the rate of chemical reactions. This knowledge is useful in designing new catalysts that can accelerate the rate of reaction by lowering the activation energy. Catalysts are important for many biochemical and industrial processes because they speed up reactions that ordinarily occur too slowly to be useful. Moreover, they often do so with increased control over the structural features of the product molecules. A rhodium phosphine catalyst, for example, has enabled chemists to obtain 96 percent of the correct optical isomer in a key step in the synthesis of L-dopa, a drug used for treating Parkinson's disease.

CHEMISTRY AND SOCIETY

For the first two-thirds of the 20th century, chemistry was seen by many as the science of the future. The potential of chemical products for enriching society appeared to be unlimited. Increasingly, however, and especially in the public mind, the negative aspects of chemistry have come to the fore. Disposal of chemical by-products at waste-disposal sites of limited capacity has resulted in environmental and health problems of enormous concern. The legitimate use of drugs for the medically supervised treatment of diseases has been tainted by the growing misuse of mood-altering drugs. The very word chemicals has come to be used all too frequently in a pejorative sense. There is, as a result, a danger that the pursuit and application of chemical knowledge may be seen as bearing risks that outweigh the benefits.

It is easy to underestimate the central role of chemistry in modern society, but chemical products are essential if the world's population is to be clothed, housed, and fed. The world's reserves of fossil fuels (*e.g.*, oil, natural gas, and coal) will eventually be exhausted, some as soon as the 21st century, and new chemical processes and materials will provide a crucial alternative energy source. The conversion of solar energy to more concentrated, useful forms, for example, will rely heavily on discoveries in chemistry.

Long-term, environmentally acceptable solutions to pollution problems are not attainable without chemical knowledge. There is much truth in the aphorism that "chemical problems require chemical solutions." Chemical inquiry will lead to a better understanding of the behaviour of both natural and synthetic materials and to the discovery of new substances that will help future generations better supply their needs and deal with their problems.

Progress in chemistry can no longer be measured only in terms of economics and utility. The discovery and manufacture of new chemical goods must continue to be economically feasible but must be environmentally acceptable as well. The impact of new substances on the environment can now be assessed before large-scale production begins, and environmental compatibility has become a valued property of new materials. For example, compounds consisting of carbon fully bonded to chlorine and fluorine, called chlorofluorocarbons (or Freons), were believed to be ideal for their intended use when they were first discovered. They are nontoxic, nonflammable gases and volatile liquids that are very stable. These properties led to their widespread use as solvents, refrigerants, and propellants in aerosol containers. Time has shown, however, that these compounds decompose in the upper regions of the atmosphere and that the decomposition products act to destroy stratospheric ozone. Limits have now been placed on the use of chlorofluorocarbons, but it is impossible to recover the amounts already dispersed into the atmosphere.

The chlorofluorocarbon problem illustrates how difficult it is to anticipate the overall impact that new materials can have on the environment. Chemists are working to develop methods of assessment, and prevailing chemical theory provides the working tools. Once a substance has been identified as hazardous to the existing ecological balance, it is the responsibility of chemists to locate that substance and neutralize it, limiting the damage it can do or removing it from the environment entirely. The last years of the 20th century will see many new, exciting discoveries in the processes and products of chemistry. Inevitably, the harmful effects of some substances will outweigh their benefits, and their use will have to be limited. Yet, the positive impact of chemistry on society as a whole seems beyond doubt. (M.C.U.)

Astronomy

Astronomy comprises the study of all extraterrestrial objects. Until the invention of the telescope and the discovery of the laws of motion and gravity in the 17th century, astronomy was primarily concerned with noting and predicting the positions of the Sun, Moon, and planets, initially for calendrical and astrological purposes and later for navigational applications and scientific interest. The catalog of objects now studied is much broader and includes, in order of increasing distances, the solar system, the stars that make up the Milky Way Galaxy, and other more distant stellar objects and galaxies. With the advent of scientific space probes, the Earth also has come to be studied as one of the planets, though its more detailed investigation remains the domain of the geologic sciences.

THE SCOPE OF ASTRONOMY

During the 20th century astronomy has expanded to include astrophysics, the application of physical and chemical knowledge to an understanding of the nature of celestial objects and the physical processes that control their formation, evolution, and emission of radiation. Study of the nuclear reactions that provide the energy radiated by stars has shown how the diversity of atoms found in nature can be derived from a universe that originally consisted exclusively of hydrogen. Concerned with phenomena on the largest scale is cosmology, the study of the evolution of the universe. Astrophysics has transformed cosmology from an almost purely speculative activity to a modern science capable of predictions that can be tested.

Its great advances notwithstanding, astronomy is still subject to a major constraint; it is inherently an observational rather than an experimental science. Almost all

measurements must be performed at great distances from the objects of interest, with no control over such quantities as their temperature, pressure, or chemical composition. There are a few exceptions to this limitation—namely, meteorites, rock and soil samples brought back from the Moon, and interplanetary dust particles collected in or above the stratosphere. These can be examined with laboratory techniques to provide information that cannot be obtained in any other way. Future space missions may yield samples of comet-tail dust or surface materials from Mars, but much of astronomy appears otherwise confined to Earth-based observations.

Determining astronomical distances. A central problem in astronomy is the determination of distances. Without a knowledge of distances, sizes would remain nothing more than angular diameters, and stellar brightness could not be converted into true radiated power or luminosity. Astronomical distance measurement began with a knowledge of the Earth's diameter, which provided a base for triangulation. Within the inner solar system, some distances can now be better determined through the timing of radar reflections. For the outer planets, triangulation is still used. Beyond the solar system, distances to the closest stars are determined through triangulation, with the diameter of the Earth's orbit serving as the baseline and shifts in stellar parallax being the measured quantities. Stellar distances are commonly expressed by astronomers in parsecs (pc; 1 pc = 3.086×10^{18} centimetres) or in kiloparsecs. They can be measured out to about 50 parsecs by trigonometric parallax (see STARS AND STAR CLUSTERS: *Determining stellar distances*). Less direct measurements must be used for more distant stars and galaxies.

Only two general methods for galactic distances are described here. In the first, a clearly identifiable type of star is used as a reference standard because its luminosity (total radiated power) has been well determined. Such a star is termed a "standard candle." The distance to a standard candle can be calculated from its known luminosity and its measured intensity. Identification of the standard candle can be made through its spectrum or regular variations in brightness. (Corrections may have to be made for the absorption of starlight over great distances.) This method forms the basis of measurements of distances to the closest galaxies. It has been found that such distances generally correlate with the speeds of recession (as determined from Doppler-shifted wavelengths; see above). This correlation is expressed in the Hubble law, velocity = $H \times$ distance, with H denoting Hubble's constant, the best value of which is thought to lie between 50 and 100 kilometres per second per megaparsec (km/sec/Mpc). It is currently used to determine distances to remote galaxies in which standard candles have not been found. Application of the Hubble law, however, has been questioned as it relates to some quasars (energetic galactic nuclei), and the value of Hubble's constant cited above is still a subject of disagreement.

Study of the solar system. The solar system took shape 4,600,000,000 years ago, when it condensed within a large cloud of gas and dust. Gravitational attraction holds the planets in their elliptical orbits around the Sun. Besides the Earth, five major planets (Mercury, Venus, Mars, Jupiter, and Saturn) have been known from ancient times. Since then, only three others have been discovered: Uranus by accident in 1781, and Neptune and Pluto in 1846 and 1930, respectively, after deliberate searches.

The average Earth-Sun distance was originally defined as the astronomical unit (a.u.) and provides a convenient measure for distances within the solar system. The astronomical unit is now defined dynamically (using Kepler's third law), and it has the value $1.49597870 \times 10^{13}$ centimetres. The semimajor axis of the Earth's orbit is $1 + (3.1 \times 10^{-8})$ a.u. Mercury, at 0.39 a.u., is the closest planet to the Sun, while Pluto, at 39.5 a.u., is the farthest. The planes of the planetary orbits (other than that of Pluto) are all within a few degrees of the ecliptic, the plane that contains the Earth's orbit around the Sun. As viewed from far above the Earth's North Pole, all planets move in the same (counterclockwise) direction in their orbits.

Sun (Mercury and Venus), have satellites whose great diversity in appearance, size, and structure has been revealed through closeup observations from long-range space probes. Three planets—Jupiter, Saturn, and Uranus—have rings consisting of small rocks and particles that are confined to disklike systems as they orbit their parent planets.

Most of the mass of the solar system is concentrated in the Sun, with its 1.99×10^{33} grams. Together, all of the planets amount to about 2.7×10^{30} grams, with Jupiter alone accounting for 71 percent of this. The solar system also contains a very large number of much smaller objects. In order of decreasing size, these are the asteroids (also called minor planets), comets, meteoroids, and dust particles.

Planetary
data

The four terrestrial planets, Mercury, Venus, Earth, and Mars, along with the Moon, have average densities in the range 3.9–5.5 grams per cubic centimetre (g/cm^3), setting them apart from the outer planets, whose densities are all close to 1 g/cm^3 , the density of water. The compositions of these two groups of planets must therefore be significantly different. This is probably attributable to the conditions that prevailed during the early development of the solar system (see below *Theories of origin*). Planetary temperatures now range from about 500°C on Mercury's surface through the typical 20°C on Earth to -135°C on Jupiter and down to -230°C on Pluto.

The surfaces of the terrestrial planets and many satellites show extensive cratering produced by high-speed impacts. On Earth, with its large quantities of water and an active atmosphere, many of these cosmic footprints have eroded, but remnants of very large craters can be seen in satellite and aerial photographs of the terrestrial surface. On Mercury, Mars, and the Moon, the absence of water and any significant atmosphere has left the craters unchanged for billions of years, apart from disturbances produced by infrequent later impacts. Cratering on the largest scale seems to have ceased about 3,000,000,000 years ago, but there is clear evidence for a continued cosmic drizzle of small particles, with the larger objects churning (gardening) the lunar surface and the smallest producing microscopic impact pits in crystals in the lunar rocks.

Signifi-
cance of
the lunar
missions

Lunar exploration. During the U.S. Apollo missions, a total sample weight of 381 kilograms was collected; 300 grams of lunar material also was returned by three unmanned Soviet Luna space vehicles. Less than 10 percent of the samples has so far been distributed for analysis, but planetary science has been revolutionized by these expeditions. A wide range of laboratory techniques has been employed on the lunar samples. The results of the analysis have enabled investigators to determine the composition and age of the lunar surface. Seismic techniques have made it possible to probe the lunar interior. In addition, a retroreflector left on the Moon's surface by Apollo astronauts returns a high-power laser beam emitted from the Earth, enabling researchers to monitor on a regular basis the Earth–Moon distance to an accuracy of a few centimetres. This experiment provides data that can be used in calculations of the dynamics of the Earth–Moon system.

Planetary studies. Mercury is too hot to retain an atmosphere, but Venus' brilliant white appearance is the result of its being completely enveloped by thick clouds of carbon dioxide. Below the upper clouds it has a hostile atmosphere containing clouds of sulfuric acid droplets. The cloud cover shields the planet's surface from direct sunlight, but the energy that does filter through warms the surface, which then radiates at infrared wavelengths. The long waves of infrared radiation are trapped by the dense clouds, resulting in a very high surface temperature of almost 480°C . Radar can penetrate the thick Venusian clouds and has been used to map the planet's surface. The Martian atmosphere is very thin, only about 0.006 that of the Earth, and composed mostly of carbon dioxide (95 percent), with very little water vapour. The outer planets have atmospheres composed largely of light gases. For example, hydrogen and helium, along with some methane and ammonia, have been detected on Jupiter.

Each of the planets rotates on its axis, and nearly all of them rotate in the same (counterclockwise) direction, as viewed from above the ecliptic. The two exceptions are

Venus, which rotates in the clockwise direction beneath its cloud cover, and Uranus, which has its rotational axis very nearly in the plane of the ecliptic.

Some of the planets have magnetic fields. The Earth's field extends outward until it is disturbed by the solar wind, an outward flow of protons and electrons from the Sun that carries a magnetic field along with it. Through processes not yet fully understood, protons and electrons from the solar wind and cosmic rays populate two doughnut-shaped regions called the Van Allen radiation belts, the inner of which extends from about 1,000 to 5,000 kilometres above the Earth's surface and the outer from roughly 15,000 to 25,000 kilometres. In these belts, trapped particles spiral along paths that take them around the Earth while bouncing back and forth between the Northern and Southern hemispheres. During periods of increased solar activity, these regions of trapped particles are disturbed, and some of the particles move down into the Earth's atmosphere where they collide with atoms and molecules to produce auroras.

Jupiter has a stronger magnetic field than the Earth's and many more trapped electrons, whose synchrotron radiation (electromagnetic radiation of the kind produced by electrons in accelerators called synchrotrons) is detectable from Earth. Saturn has a magnetic field that is not quite as strong as Jupiter's, but it, too, has a region of trapped particles. Mercury has a weak magnetic field that is only about 1 percent as strong as the Earth's and contains no discernible trapped particles. No magnetic field has been detected around any of the other planets.

Investigations of the minor bodies. Approximately 3,500 asteroids have now been identified. Most have orbits close to the ecliptic and move in the asteroid belt located between 2.3 and 3.3 a.u. from the Sun. Only about 250 of these objects are larger than 100 kilometres, and their total mass is thought to be roughly $1/2,000$ that of the Earth.

Asteroids,
comets,
and
meteoroids

Comets are considered to come from a vast reservoir, the Oort cloud, which orbits the Sun at distances of 30,000 to 100,000 a.u. More than 600 comets have so far been discovered. Most make only a single pass through the inner solar system, but some are deflected by Jupiter or Saturn into orbits that allow them to return at predictable times. Comet Halley is the best known of these periodic comets, with its next return predicted for AD 2060. About 30 comets have periods of less than 100 years. Comet masses have not been well determined, but most are thought to be less than 10^{18} grams, or 1,000,000,000 times smaller than the Earth.

Even smaller than comets are the meteoroids, lumps of stony material. Meteoroids vary in size from small rocks to large boulders weighing a ton or more. A few have orbits that bring them into the Earth's atmosphere and down to the ground as meteorites. These are classified into three broad groups: stony or chondrites (about 93 percent), iron (5.7 percent), and stony-iron (1.5 percent). Smaller meteoroids that enter the atmosphere may heat up sufficiently to vaporize and appear as meteors. Many, perhaps most, of the meteors occur in showers and follow orbits that seem to be identical with those of certain comets, thus pointing to a cometary origin. For example, each May the Earth crosses the orbit of Comet Halley, and the Eta Aquarid meteor shower becomes visible. Micrometeorites, the smallest meteoroidal particles, can be detected from Earth-orbiting satellites or be sufficiently slowed by atmospheric friction to be collected by specially equipped aircraft flying in the stratosphere and returned for laboratory inspection.

Determinations of age and chemical composition. The age of the solar system, about 4,500,000,000 years, has been derived from measurements of radioactivity in meteorites, lunar samples, and the Earth's crust. Abundances of the isotopes of uranium, thorium, and rubidium and their decay products, lead and strontium, are the measured quantities.

Assessment of the chemical composition of the solar system is based on data from the Earth, Moon, and meteorites, as well as on the spectral analysis of light from the Sun and planets. In broad outline, the solar system abundances of the elements decrease with increasing atomic

Measure-
ment of
radio-
isotope
abundance

weight. Hydrogen atoms are by far the most abundant, with 93 percent; helium is next, with 6.7 percent; and all other types of atoms together amount to only 2.3 percent.

Theories of origin. The origin of the Earth, Moon, and solar system as a whole is a problem that has not yet been settled in detail. The Sun probably formed by condensation of the central region of a large cloud of gas and dust, with the planets and other solar-system bodies forming soon after, their composition strongly influenced by the temperature and density gradients in the evolving solar nebula. Less-volatile materials could condense into solids relatively close to the Sun to form the terrestrial planets. The abundant, volatile lighter elements could condense only at much greater distances.

The origin of the planetary satellites is not settled. There is still the question as to the origin of the Moon, and professional opinion has been oscillating between theories that see its origin and condensation simultaneous with the formation of the Earth, to an explanation in terms of a large impact on the Earth resulting in the expulsion of material that subsequently formed the Moon. For the outer planets with their multiple satellites, many very small and quite unlike one another, the picture is even less clear. Some of the objects have icy surfaces, while others are heavily cratered, and at least one, Jupiter's Io, is volcanic. Some of the satellites may have formed along with their parent planets, and others may have formed elsewhere and been captured. (For an in-depth treatment of the solar system and its components, see SOLAR SYSTEM.)

Study of the stars. *Measuring observable stellar properties.* The measurable quantities in stellar astrophysics include the externally observable features of the stars: distance, temperature spectrum and luminosity, composition (of the outer layers), diameter, mass, and variability in any of these. Theoretical astrophysicists use these observations to model the structure of stars and to devise theories for their formation and evolution.

In a system dating back at least to the Greek astronomer-mathematician Hipparchus in the 2nd century BC, apparent stellar brightness (m) is measured in magnitudes. Magnitudes are now defined so that a first-magnitude star is 100 times brighter than a star of sixth magnitude. The human eye cannot see stars fainter than about sixth magnitude, but modern instruments used with large telescopes can record stars as faint as about 26th magnitude. By convention, the absolute magnitude (M) is the magnitude that a star would appear to have if it were located at a standard distance of 10 parsecs. These quantities are related through the expression: $m - M = 5 \log_{10} r - 5$, where r is the star's distance in parsecs.

The magnitude scale is anchored on a group of standard stars. An absolute measure of radiant power is luminosity, usually expressed in ergs per second. This can be calculated when m and r are known. Correction might be necessary for the interstellar absorption of starlight.

There are several methods of measuring a star's diameter. From the brightness and distance, the luminosity (L) can be calculated; and from observations of the brightness at different wavelengths, the temperature (T) can be calculated. As the radiation from many stars can be well approximated by a Planck blackbody spectrum, these measured quantities can be related through the expression $L = 4\pi R^2 \sigma T^4$, thus providing a means of calculating R , the star's radius. In this expression, σ is Stefan's constant, 5.67×10^{-5} erg/cm²deg⁴sec. (The radius R refers to the star's photosphere, the region where the star becomes effectively opaque to outside observation.) Stellar angular diameters can be measured through interference effects. Alternatively, it is possible to monitor the intensity of the starlight during occultation by the Moon, which produces diffraction fringes whose pattern depends on the angular diameter of the star. Stellar angular diameters of several milliarcseconds can be measured, but so far only for relatively bright and close stars.

Many stars occur in binary systems, with the two partners in orbits around their mutual centre of mass. Such a system provides the best measurement of stellar masses. The period (P) of a binary system is related to the masses of the two stars ($m_1 + m_2$), and the orbital semimajor axis

a via Kepler's third law: $P^2 = 4\pi^2 a^3 / G[m_1 + m_2]$. (G is, as before, the universal gravitational constant.) From diameters and masses, average values of the stellar density can be calculated, and thence the central pressure. With the assumption of an equation of state, the central temperature can then be calculated. Thus, for example, in the Sun the central density is 158 g/cm³, and the pressure is calculated to be more than 1,000,000,000 atmospheres and the temperature about 15,000,000 K. At this temperature, all atoms are ionized, and so the solar interior consists of a plasma, an ionized gas, with hydrogen and helium nuclei and electrons as major constituents. A small fraction of the hydrogen nuclei possess such high speeds that, upon colliding, their electrostatic repulsion is overcome, resulting in the formation by fusion of helium nuclei and a release of energy. Some of this energy is carried away by neutrinos, but most of it is carried by photons to the surface of the Sun to maintain its luminosity.

Other stars, both more and less massive than the Sun, have broadly similar structures, but the size, central pressure and temperature, and fusion rate are functions of a star's mass and composition. Stars and their internal fusion (and resultant luminosity) are held stable against collapse through a delicate balance between the inward pressure produced by gravitational attraction and the outward pressure supplied by the photons produced in the fusion reactions.

Stars that are in this condition of hydrostatic equilibrium are termed main-sequence stars, and they occupy a well-defined band on the Hertzsprung–Russell (H–R) diagram, in which luminosity is plotted against colour index or temperature. Temperature is deduced from broad-band spectral measurements in several standard wavelength intervals. Measurement of apparent magnitudes in the B and V bands (centred on 4350 and 5550 angstroms [Å], respectively) permits calculation of the colour index, $CI = m_B - m_V$, from which the temperature can be calculated.

For a given temperature, there are stars that have luminosity much greater than main-sequence stars. Given the $R^2 T^4$ dependence of luminosity, greater luminosity implies a larger radius, and such stars are called giants or supergiants. Conversely, stars with a luminosity much less than that of main-sequence stars of the same temperature must be smaller and are termed dwarfs. White dwarfs are stars with temperatures that typically range from 10,000 to 12,000 K, and they appear visually as white or blue-white.

Spectral classification, based initially on the colour index, has major spectral types O, B, A, F, G, K, and M, each subdivided into 10 parts. The strength of spectral lines of the more abundant elements in a star's atmosphere allows additional subdivisions within a class. Thus the Sun, a main-sequence star, is classified as G2 V, where the V denotes main sequence. Betelgeuse, a red supergiant with a surface temperature about half that of the Sun but with a luminosity of about 10,000 solar units, is classified as M2 Iab. (For more specific information about stellar spectra and bulk stellar properties, see STARS AND STAR CLUSTERS.)

Stellar formation and evolution. The range of physically allowable masses for stars is very narrow. If the star's mass is too small, the central temperature will be too low to sustain fusion reactions. The theoretical minimum stellar mass is about 0.08 solar mass. An upper theoretical limit of approximately 100 solar masses has been suggested, but this value is not firmly defined. Stars as massive as this will have luminosities about 1,000,000 times greater than that of the Sun.

A general model of star formation and evolution has been developed, and the major features seem to be established. This model shows that a large cloud of gas and dust can contract under its own gravitational attraction if its temperature is sufficiently low. Gravitational energy is released, and the contracting central material heats up until a point is reached where the outward radiation pressure balances the inward gravitational pressure and contraction ceases. Fusion reactions take over as the star's primary source of energy, and the star is then on the main sequence. The time required to pass through these

Basis for theoretical work

Methods of measuring stellar diameter

Determining stellar mass

formative stages and onto the main sequence is less than 100,000,000 years for a star with as much mass as the Sun. It takes longer for less massive stars and a much shorter time for those much more massive.

Once a star has reached its main-sequence stage, it evolves relatively slowly, with the fusion of the hydrogen nuclei in its core to form helium nuclei. Continued fusion not only releases the energy that is radiated but also involves nucleosynthesis, the production of heavier nuclei.

Computer
modeling
of stellar
evolution

Stellar evolution has been followed through computer modeling because the time scales for most stages are generally too extended for measurable changes to be seen even over a period of many years. One exception is the supernova, where major changes have been seen on a scale of hours, and computations have shown that some changes take place on a scale of milliseconds. Calculation of nucleosynthesis during stable and explosive stellar stages has yielded abundances of nuclei in general agreement with observed abundances.

The nature of the terminal products of stellar evolution depend on stellar mass. Some stars pass through an unstable stage in which their dimensions, temperature, and luminosity change cyclically over periods of hours or days. These so-called Cepheid variables serve as standard candles for distance measurements. Some stars may blow off their outer layers to produce planetary nebulas. The expanding material can be seen glowing in a thin shell as it disperses into the interstellar medium, while the remnant core, initially with a surface temperature of as high as 100,000 K, cools to become a white dwarf. The maximum stellar mass that can exist as a white dwarf is about 1.4 solar masses and is called the Chandrasekhar limit. More massive stars may end up as either neutron stars or black holes (see below).

The average density of a white dwarf is calculated to exceed 1,000,000 g/cm³. Further compression is limited by a quantum condition called degeneracy, in which only certain energies are allowed for electrons. Under sufficiently great pressure, the electrons combine with protons to form neutrons. The resulting neutron star will have a density in the range 10^{14} – 10^{15} g/cm³, which is comparable to the density within atomic nuclei. The behaviour of large masses having nuclear densities is not yet sufficiently understood to be able to set a limit on the maximum size of a neutron star, but it is thought to be in the region of five solar masses.

Still more massive remnants of stellar evolution would have smaller dimensions and would be even denser than neutron stars. Such remnants are conceived to be black holes, objects so compact that no radiation can escape from their gravitational force within a characteristic distance called the Schwarzschild radius. This critical dimension is defined by $R_s = 2GM/c^2$. (Here, R_s is the Schwarzschild radius, G is the gravitational constant, M is the object's mass, and c is the speed of light.) For an object of three solar masses, the R_s would be about three kilometres.

Search for
black holes

Although no light can be detected from a black hole, the presence of such an object may be manifested in the effects of its gravitational field, as, for example, in a binary star system. If a black hole is a member of a double star, it may pull matter from its companion—a normal visible star—toward itself. This matter is accelerated as it approaches the black hole and becomes so intensely heated that it radiates large amounts of X rays from the periphery of the black hole outside the Schwarzschild radius. A few candidates for black holes have been found (e.g., the X-ray source Cygnus X-1). Each of them has an estimated mass clearly exceeding that allowable for a neutron star, a factor crucial in the identification of possible black holes. (For further information on black holes, as well as on stellar evolution, see STARS AND STAR CLUSTERS; COSMOS: The end states of stars: Black-hole model for active galactic nuclei.)

Whereas the detection of black holes still needs to be confirmed, the existence of neutron stars was proved in 1968 when they were identified with the then newly discovered pulsars, objects characterized by the emission of radiation at short and extremely regular intervals generally between one and 1,000 pulses per second and stable to

better than one part per billion. Pulsars are regarded as rotating neutron stars, the remnants of some supernovas.

Study of the Milky Way Galaxy. *General properties.* Stars are not distributed randomly throughout space. Many stars occur in systems consisting of two or three members with separations of less than 1,000 a.u. On a larger scale, clusters may contain many thousands of stars. Galaxies are much larger systems of stars and usually include clouds of gas and dust.

The solar system is located within the Milky Way Galaxy close to the equatorial plane and about 8.7 kiloparsecs (kpc) from the galactic centre. The galactic diameter is about 30 kiloparsecs, as indicated by luminous matter. There is evidence, however, for nonluminous matter—the so-called dark matter—extending out nearly twice this distance. The entire galactic system is rotating so that, at the position of the Sun, the orbital speed is about 220 kilometres per second, and a complete circuit will take roughly 240,000,000 years. Application of Kepler's third law leads to an estimate of the galactic mass of about 100,000,000,000 solar masses. The rotational velocity can be measured from the Doppler shifts observed in the 21-centimetre emission line of neutral hydrogen and the lines of millimetre wavelengths from various molecules, especially carbon monoxide. At great distances from the galactic centre, the rotational velocity does not drop off as expected but rather increases slightly. This condition appears to require a much larger galactic mass than can be accounted for by the known (luminous) matter. Additional evidence for the presence of dark matter comes from a variety of other observations. The nature and extent of the dark matter (or missing mass) constitutes one of today's major astronomical puzzles.

The
problem
of dark
matter

There are about 100,000,000,000 stars in the Milky Way Galaxy. Star concentrations within the Galaxy fall into three types: open clusters, globular clusters, and associations. Open clusters lie primarily in the disk of the Galaxy and contain from 50 to 1,000 stars within a region of no more than 10 parsecs. Associations tend to have somewhat fewer stars; moreover, the constituent stars are not as closely grouped as those in the clusters and are for the most part hotter. Globular clusters may extend up to about 100 parsecs in size and may have as many as 100,000 stars. The importance of the globular clusters lies in their use as indicators of the age of the Galaxy. Because massive stars evolve more rapidly than do smaller stars, the age of a cluster can be estimated from its H-R diagram. In a young cluster the main sequence will be well populated, but in an old cluster the heavier stars will have evolved away from the main sequence. The extent of the depopulation of the main sequence provides an index of age. In this way, the oldest globular clusters have been found to be about 15,000,000,000 years old, which must therefore be the minimum age of the Galaxy.

Investigations of interstellar matter. The interstellar medium (ISM) occupies the regions that lie between the stars. On average, it contains less than one atom per cubic centimetre, with about 1 percent as much mass in the form of minute dust grains. The gas, mostly hydrogen, has been mapped through its 21-centimetre emission line. The gas also contains numerous molecules. Some of these have been detected by the visible-wavelength absorption lines they impose on the spectra of more distant stars, while others have been identified by their own emission lines at millimetre wavelengths. Many of the interstellar molecules occur in giant molecular clouds, wherein complex organic molecules have been discovered.

In the vicinity of a very hot O- or B-type star, the intensity of ultraviolet radiation is sufficiently high to ionize the surrounding hydrogen out to a distance as large as 100 parsecs to produce an HII region known as a Strömgren sphere. Such regions are strong and characteristic emitters of radiation at radio wavelengths, and their dimensions are well calibrated in terms of the luminosity of the central star. Using radio interferometers, astronomers are able to measure the angular diameters of HII regions even in some external galaxies and can thereby deduce the great distances to those remote systems. This method can be used for distances up to about 30 megaparsecs.

Measuring
the angular
diameters
of HII
regions

Interstellar dust grains scatter and absorb starlight, with the effect being roughly inversely proportional to wavelength from the infrared to the near ultraviolet. As a result, stellar spectra tend to be reddened. Absorption amounts typically to about one magnitude per kiloparsec but varies considerably in different directions. Some dusty regions contain silicate materials, identified by a broad absorption feature around 10-micrometre wavelengths. Another prominent feature around 2200 angstroms has sometimes but not conclusively been attributed to graphite grains.

Starlight often shows a small degree of polarization (a few percent), with the effect increasing with stellar distance. This is attributed to the scattering of the starlight from dust grains that have been partially aligned in a weak interstellar magnetic field. The strength of this field is estimated to be a few microgauss, very close to the strength inferred from observations of nonthermal cosmic radio noise. This radio background has been identified as synchrotron radiation, emitted by highly relativistic cosmic-ray electrons (*i.e.*, those traveling at nearly the speed of light) that pass through the interstellar magnetic field. The spectrum of the cosmic radio noise is close to what is calculated on the basis of measurements of the cosmic rays near the Earth.

The cosmic rays constitute another component of the interstellar medium. Cosmic rays that are detected in the vicinity of the Earth consist of high-speed nuclei and electrons. Individual particle energies, expressed in electron volts (eV; $1 \text{ eV} = 1.6 \times 10^{-12} \text{ erg}$), range with decreasing numbers from about 10^6 to more than 10^{20} eV. Among the nuclei, hydrogen (protons) are the most plentiful at 89 percent, helium next with 9 percent, and all other nuclei at about 1 percent. Electrons are roughly 2 percent as abundant as the nuclear component.

A minority of the cosmic rays are produced in the Sun, especially at times of increased solar activity (as indicated by sunspots and flares). The origin of the galactic cosmic rays has not yet been conclusively identified, but they are thought to be produced in stellar processes such as supernova explosions, perhaps with additional acceleration occurring in the interstellar regions.

Observations of the galactic centre. The central region of the Milky Way Galaxy is so heavily obscured by large quantities of dust that direct observation has become possible only with the development of astronomy for wavelengths that penetrate to or relatively near the Earth's surface—namely, radio, infrared, and more recently X rays and gamma rays. Together, these observations have revealed a nuclear region of intense activity, with a large number of separate sources and a great deal of dust. Detection of gamma-ray emission at a line energy of 511,000 eV, which corresponds to the annihilation of electrons and positrons, along with radio mapping of a region no more than 20 a.u. across, points to a very compact and energetic source at the centre of the Galaxy. Whether this is powered by a black hole or some very close and hot stars remains to be determined. (For more specific information on this matter, see *COSMOS: Galaxies*.)

Study of other galaxies and related phenomena. Galaxies are generally classified into three principal types according to their appearance: spiral, elliptical, and irregular. Galactic dimensions are typically in the tens of kiloparsecs and the distances between galaxies typically in megaparsecs.

Spiral galaxies (of which the Milky Way system is a characteristic example) tend to be flattened, roughly circular systems, with their constituent stars strongly concentrated along spiral arms. These arms are thought to be produced by traveling density waves, which compress and expand the galactic material. (For an explanation of the density-wave theory, see *COSMOS: Dynamics of ellipticals and spirals*.) Between the spiral arms exists a diffuse interstellar medium of gas and dust, mostly at very low temperatures (below 100 K). Spiral galaxies are typically a few kiloparsecs in thickness; they have a central bulge and taper gradually toward the outer edges.

Ellipticals show none of the spiral features. They are more densely packed stellar systems, ranging from the nearly spherical (type E0) to the very flattened (E7), and they contain little interstellar matter. Irregular galaxies

account for only a few percent of all stellar systems and exhibit none of the regular features associated with either spirals or ellipticals.

Properties vary considerably between the different types of galaxies. Spirals generally have masses in the range 10^9 – 10^{12} solar masses, with ellipticals having values from 10 times smaller to 10 times larger and the irregulars, generally 10 times larger. The visual galactic luminosities show similar spreads, but the irregulars tend to be less luminous. In contrast, at radio wavelengths the maximum luminosity of spirals is usually 100,000 times less than for ellipticals or irregulars.

Quasars are objects whose spectra display very large redshifts, implying that they lie at the greatest distances (see above). They were discovered in 1963, but they remained enigmatic for many years. Quasars are now considered to be the exceedingly luminous cores of distant galaxies.

The Milky Way Galaxy is a member of the Local Group of galaxies, which contains about two dozen members and extends out to a distance of about one megaparsec. Two of the closest members are the Large and Small Magellanic Clouds, irregular galaxies about 50 kiloparsecs away. At 680 kiloparsecs, the Andromeda Galaxy is one of the most distant in the Local Group. Some members of the Local Group are moving toward the Milky Way system, while others are traveling away from it. At greater distances, all galaxies are moving away from the Milky Way Galaxy. Their speeds (as determined from the redshifted wavelengths in their spectra) are proportional to their distances. As explained earlier, the Hubble law relates these two quantities. In the absence of any other method, the Hubble law continues to be used for distance determinations to the farthest objects—that is, galaxies and quasars for which redshifts can be measured. (For a detailed treatment of the properties, structures, and distribution of galaxies, see *GALAXIES*.)

Cosmology. The currently accepted cosmological model is the big bang. In this picture, the expansion of the universe began with an intense explosion roughly 15,000,000,000 years ago. In this primordial fireball, the temperature exceeded 10^{12} K and most of the energy was in the form of radiation. As the expansion proceeded (accompanied by cooling), the role of the radiation became diminished and other physical processes dominated in turn. Thus, after about one minute, the temperature had dropped to the 1,000,000,000 K range, making it possible for nuclear reactions to take place and produce deuterons and helium nuclei. (At the higher temperatures that prevailed earlier, these nuclei would have been promptly disrupted by high-energy photons.) With further expansion, the time between nuclear collisions would have increased and the proportion of deuterons and helium nuclei would have stabilized. After a few hundred thousand years, the temperature must have dropped sufficiently for electrons to remain attached to nuclei to constitute atoms. Galaxies are thought to have begun forming after a few million years, but this stage is still very poorly understood. Star formation probably started much later, after some billions of years, and the process continues today.

The observational support for this general model comes from several independent directions. The expansion has been documented by the galactic redshifted spectra. The radiation left over from the original fireball would have cooled with the expansion. One of the most striking discoveries of the 20th century came in 1965 with the observation of a widespread cosmic radiation corresponding to a temperature of close to 3 K. The spectrum of this cosmic radio noise peaks at approximately one-millimetre wavelength in the far infrared, a difficult region to observe; however, the spectrum has been well mapped at many wavelengths from that point through the radio region. Additional support for the big-bang theory comes from the observed cosmic abundances of deuterium and helium. Normal stellar nucleosynthesis cannot produce the measured quantities, which fit well with calculations of production during the early stages of the big bang.

Surveys of the cosmic 3 K radiation have indicated that it is extremely uniform in all directions. Calculations have shown that it is difficult to achieve this degree of isotropy

Observations of nonthermal cosmic radio noise

Identification of quasars

The big-bang model and observational support

Classification of galaxies

unless there was a very early and rapid inflationary period before the expansion settled into its present mode. However, the isotropy poses problems for models of galaxy formation. It has been conjectured that galaxies originate from turbulent conditions that produce local fluctuations of density toward which matter would then be gravitationally attracted. Such density variations are difficult to reconcile with the isotropy required by observations of the 3 K background radiation.

The very earliest stages of the big bang are less well understood. The conditions of temperature and density that prevailed prior to the first microsecond require the introduction of theoretical ideas of subatomic particles. Such particles are usually studied in laboratories with giant accelerators, but the region of particle energies of potential significance to the question at hand lies beyond the range of accelerators currently available. Fortunately, some important conclusions can be drawn from the observed cosmic helium abundance, which is dependent on conditions during the early big bang. This observed helium abundance serves to set a limit to the number of families of certain types of subatomic particles that can exist.

Finally, there is the question of the future behaviour of the universe: Is it open? That is to say, will the expansion continue indefinitely? Or is it closed, so that the expansion will slow down and eventually reverse, resulting in contraction? The outcome hinges on the total mass of the universe. For this reason, the extent of the dark matter (the missing mass) may be decisive. The amount of luminous mass currently known to exist is insufficient to close the universe, but if dark matter is universally present in the quantities suggested by galactic rotation or galactic-cluster dynamics, then the universe will be closed. An additional factor might be the mass of neutrinos. Theoretically postulated to have zero mass, neutrinos are now experimentally known to have a mass less than $1/10,000$ that of the electron. Because there are so many neutrinos in the universe, neutrino masses even as small as this might render the universe closed. The issue remains unresolved, although the detection of neutrinos (albeit only 19 of them) associated with a supernova observed in 1987 suggests that neutrino mass is probably less than the critical value postulated. (For a full discussion of the big-bang theory, including conceptions about the ultimate fate of the universe, see COSMOS: *Cosmological models*.)

THE METHODOLOGY OF ASTRONOMY

Astronomical observations involve a sequence of stages, each of which may impose constraints on the type of information attainable. Radiant energy is collected with telescopes and brought to a focus on a detector, which is calibrated so that its sensitivity and spectral response are known. Accurate pointing is required to permit the correlation of observations made with different systems in different wavelength intervals. The radiation must be spectrally analyzed so that the emission processes can be identified.

Telescopic observations. Before Galileo's use of telescopes for astronomical investigations in 1609, all observations were made by naked eye, with corresponding limits on the faintness and degree of detail that could be seen. Since that time, telescopes have become central to astronomy. With apertures much larger than the pupil of the human eye, telescopes permit the study of faint and distant objects. In addition, sufficient radiant energy can be collected in short time intervals to permit rapid fluctuations in intensity to be detected.

Optical telescopes are either refractors or reflectors that use lenses or mirrors, respectively, for their main light-collecting elements (objectives). Refractors are effectively limited to apertures with a diameter of 102 centimetres (40 inches) or less because of problems inherent in the use of large lenses. These distort under their own weight and can be supported only around the perimeter; an appreciable amount of light is lost due to absorption in the glass. Large-aperture refractors are extremely long and require large and expensive domes. The largest modern telescopes are all reflectors. They are not subject to the chromatic problems of refractors, can be better supported mechan-

ically, and can be housed in smaller domes because of their more compact dimensions.

The angular resolving power of a single telescope is limited by the wave nature of light. For a telescope having an objective with diameter D and operating at a wavelength λ , the angular resolution (in radians) can be approximately described by the ratio (λ/D) . Optical telescopes can have very high intrinsic resolving powers; in practice, however, these are not attained. Atmospheric effects limit the resolution to about one arc second.

The atmosphere does not transmit radiation of all wavelengths equally well. This restricts ground-based astronomy to the visible and radio regions of the spectrum, with some relatively narrow "windows" in the nearer infrared. Longer infrared wavelengths are heavily absorbed by atmospheric water vapour and carbon dioxide. Atmospheric effects can be reduced by careful site selection and by carrying out observations at high altitudes. Most major optical observatories are now located on high mountains, well away from cities and their reflected lights. Infrared telescopes have been constructed atop Mauna Kea in Hawaii and in the Canary Islands where atmospheric humidity is very low. Airborne telescopes designed mainly for infrared observations, such as the one aboard the Kuiper Airborne Observatory, operate at an altitude of about 12,000 metres (40,000 feet), with flight durations limited to a few hours. Telescopes for infrared-, X-, and gamma-ray observations have been carried to altitudes of more than 30,000 metres by balloons. Higher altitudes can be attained during short-duration rocket flights for ultraviolet observations. Telescopes for all wavelengths from infrared to gamma rays have been carried by remote-controlled Earth-orbiting satellites as well as by some manned space vehicles.

Angular resolution better than one milliarcsecond has been achieved at radio wavelengths by using several telescopes in an array. In such an arrangement, the effective aperture (D) becomes the greatest distance between component telescopes. For example, in the Very Large Array (VLA), operated near Socorro, N.M., by the National Radio Astronomy Observatory, 27 movable radio dishes are set out along tracks that extend for nearly 21 kilometres. In a technique called very long baseline interferometry (VLBI), simultaneous observations are made with radio telescopes thousands of kilometres apart.

The Earth is a moving platform for astronomical observations. It is important that the specification of precise celestial coordinates be made in ways that correct for telescope location, the position of the Earth in its orbit around the Sun, and the epoch of observation, since the Earth's axis of rotation moves slowly over the years. Time measurements are now based on atomic clocks rather than on the Earth's rotation, and telescopes can be driven continuously to compensate for the planet's rotation so as to permit tracking of a given astronomical object.

Use of radiation detectors. While the human eye remains an important astronomical tool, detectors capable of greater sensitivity and more rapid response are needed at visible wavelengths and especially to extend observations beyond that region of the electromagnetic spectrum. Photography has been used for more than 100 years and continues to be an essential tool. Long time exposures may be needed to reveal faint objects. This integrative property of photography smooths out rapid variations in intensity, for which electronic methods must otherwise be used. Furthermore, photography provides an archival record. A photograph of a particular celestial object may include the images of many other objects that were not of interest when the picture was taken but that become the focus of study years later. When quasars were discovered in 1963, for example, photographic plates dating to before 1900, held by the Harvard College Observatory, were examined to trace possible changes in the position or intensity of quasar 3C273. Also, major photographic surveys, such as those of the National Geographic Society and Palomar Observatory, can provide a historic base for long-term studies.

Photographic film converts only a few percent of the incident photons into its images, whereas efficiencies of better than 50 percent can be achieved by several electronic meth-

Observations from aircraft, balloons, rockets, and Earth-orbiting spacecraft

Very long baseline interferometry

Photography in astronomical research

Optical telescopes

ods of detection. The greater sensitivity and intrinsically rapid response of such methods are exploited for tracking exceedingly rapid intensity variations. For example, pulsars that emit their radiation at millisecond intervals can be followed and their pulse shapes monitored. The arrival of individual photons can be recorded with phototubes or more recent devices, such as the charge-coupled device (CCD). Special photographic materials can be employed for the shortest infrared wavelengths, but, for wavelengths longer than a few micrometres, semiconductor detectors that operate at temperatures of liquid nitrogen (77 K) or liquid helium (below 4 K) have to be used. In detectors of this kind, photons are absorbed in small semiconducting crystals to produce a minute temperature increase or a change in electrical resistance. Individual photons are not recorded. Reception of radio waves is based on the production of a small voltage in an antenna rather than on photon counting. Individual X-ray and gamma-ray photons possess sufficient energy to be detected through the ionization they produce.

Spectral
analysis

Spectral analysis involves measuring intensity as a function of wavelength or frequency. In some detectors, such as those for X and gamma rays, the energy of each photon can be measured directly. Photographic film is sensitive to photons over a wide range of wavelengths. For low-resolution spectroscopy, broad-band filters suffice. Greater resolution can be obtained with prisms, gratings, and interferometers.

As a departure from the traditional astronomical approach of remote observing, certain more recent lines of research involve the analysis of actual samples under laboratory conditions. These include studies of meteorites, rock samples returned from the Moon, and interplanetary dust particles collected by aircraft in the stratosphere or by Earth-orbiting spacecraft. In all such cases, a wide range of highly sensitive laboratory techniques can be adapted for the often microscopic samples. It is possible to supplement chemical analysis with mass spectroscopy, so that the isotopic composition can be determined. Radioactivity and collisions between cosmic-ray particles can produce minute quantities of gas that remain trapped in crystals. Heating under laboratory conditions releases this gas, which then is analyzed in a mass spectrometer. X-ray spectrometers, electron microscopes, and microprobes are employed to determine crystal structure and composition, from which temperature and pressure conditions at the time of formation can be inferred.

Theoretical approaches. Theory is just as important as observation in astronomy. It is required for the interpretation of observational data, for the construction of models of celestial objects and their properties, and for guiding further observations. Theoretical astrophysics is based on the laws of physics that have been validated with great precision through controlled experiments. Application of these laws to specific astrophysical problems, however, may yield equations too complex for direct solution. Two general approaches are then available. In the traditional method, an idealized description of the problem is formulated, incorporating only the major physical components, to provide equations that can be either solved directly or evaluated numerically. Alternatively, a computer program that will explore the problem numerically can be devised. Computational science is taking its place as a major division alongside theory and experiment.

Theoretical
astro-
physics

IMPACT OF ASTRONOMY

No area of science is totally self-contained. Discoveries in one field find applications in others, often unpredictably. There are various notable examples of this involving astronomical studies. Newton's laws of motion and gravity emerged from the analysis of planetary and lunar orbits. Observations during the 1919 solar eclipse provided dramatic confirmation of Einstein's general theory of relativity, which has gained further support with the recent discovery and tracking of the binary pulsar designated PSR 1913 + 16. The behaviour of nuclear matter and of some elementary particles is now better understood as a result of measurements of neutron stars and the cosmological helium abundance, respectively. Study of the

theory of synchrotron radiation was greatly stimulated by its detection in radiation emitted by the Crab Nebula, and machines are now being used to produce synchrotron radiation to probe the structure of materials.

Astronomical knowledge also has had impact outside of science. The earliest calendars were based on astronomical observations of the cycles of repeated solar and lunar positions. Also, for centuries, familiarity with the positions and apparent motions of the stars enabled sea voyagers to navigate with reasonable accuracy. Perhaps the single greatest effect that astronomical studies have had on modern society has been in molding the attitude of its members. The development of what is known as the scientific method was strongly influenced by astronomical observations. The power of science to provide the basis for accurate predictions of such phenomena as eclipses and the positions of the planets and later, so dramatically, of comets has generated an attitude toward science that remains an important social force today. (M.W.Fr.)

BIBLIOGRAPHY

History of physical sciences: A. RUPERT HALL and MARIE BOAS HALL, *A Brief History of Science* (1964, reprinted 1988), provides a good introduction to the subject; A.E.E. MCKENZIE, *The Major Achievements of Science*, 2 vol. (1960, reprinted 1988), concentrates on developments from the 16th century, with brief extracts from original sources; and CECIL J. SCHNEER, *The Search for Order: The Development of the Major Ideas in the Physical Sciences from the Earliest Times to the Present* (1960, reissued 1984 as *The Evolution of Physical Science*), accounts for the developments from the 17th through the 19th centuries. Comprehensive surveys include STEPHEN F. MASON, *A History of the Sciences*, new rev. ed. (1962); and STEPHEN TOULMIN and JUNE GOODFIELD, *The Architecture of Matter* (1962, reissued 1982). THOMAS S. KUHN, *The Structure of Scientific Revolutions*, 2nd enl. ed. (1970), presents the "paradigm" theory of science, based on historical examples; GERALD HOLTON, *Thematic Origins of Scientific Thought: Kepler to Einstein*, rev. ed. (1988), offers a new interpretation of the history of science, with case studies of the work of Einstein and others; and I. BERNARD COHEN, *Revolution in Science* (1985), is a comparative study. See also STEPHEN G. BRUSH, *The History of Modern Science: A Guide to the Second Scientific Revolution, 1800–1950* (1988). CHARLES COULSTON GILLISPIE (ed.), *Dictionary of Scientific Biography*, 16 vol. (1970–80), is an excellent source for authoritative biographical data. For references to the scholarly literature in the history of science, consult the "Critical Bibliography of the History of Science and Its Cultural Influences," an annual feature in *Isis*, an international review of the history of science. Cumulations of this bibliography appeared as MAGDA WHITROW (ed.), *Isis Cumulative Bibliography: 1913–65*, 6 vol. (1971–84); and JOHN NEU (ed.), *Isis Cumulative Bibliography 1966–1975*, 2 vol. (1980–85).

Physics: I. BERNARD COHEN, *The Birth of a New Physics*, rev. ed. (1985), is an account of the work of Galileo, Newton, and other 17th-century scientists. See also EMILIO SEGRÈ, *From Falling Bodies to Radio Waves: Classical Physicists and Their Discoveries* (1984), and *From X-Rays to Quarks: Modern Physicists and Their Discoveries* (1980; originally published in Italian, 1976). HENRY A. BOORSE and LLOYD MOTZ (eds.), *The World of the Atom*, 2 vol. (1966), is a comprehensive anthology of historical sources on 19th- and 20th-century developments in atomic physics. For recent history, see STEPHEN G. BRUSH, "Resource Letter HP-1: History of Physics," *American Journal of Physics*, 55:683–691 (August 1987). An interesting collection of writings by physicists is presented in JEFFERSON HANE WEAVER (ed.), *The World of Physics: A Small Library of the Literature of Physics from Antiquity to the Present*, 3 vol. (1987).

Reference works surveying the scope and methodology of physics include ROBERT M. BESANÇON (ed.), *The Encyclopedia of Physics*, 3rd ed. (1985); and CESARE EMILIANI, *Dictionary of the Physical Sciences: Terms, Formulas, Data* (1987). Other works include DAVID HALLIDAY and ROBERT RESNICK, *Fundamentals of Physics*, 3rd extended ed., 2 vol. (1988), a good standard text; GERALD HOLTON, *Introduction to Concepts and Theories in Physical Science*, 2nd ed., rev. by STEPHEN G. BRUSH (1973, reprinted 1985), analyzing the physical theories from a historical standpoint; RICHARD P. FEYNMAN, ROBERT B. LEIGHTON, and MATTHEW SANDS, *The Feynman Lectures on Physics*, 3 vol. (1963–65), and RICHARD P. FEYNMAN, *QED: The Strange Theory of Light and Matter* (1985), works by a modern master; FRANK CLOSE, MICHAEL MARTEN, and CHRISTINE SUTTON, *The Particle Explosion* (1987), a discussion of the latest developments in fundamental physics, written for the general reader; STEVEN WEINBERG, *The Discovery of Subatomic Particles* (1983), and *The First Three Minutes: A Modern View of the Origin*

of the Universe, updated ed. (1988); P.C.W. DAVIES, *Space and Time in the Modern Universe* (1977); and PETER G. BERGMANN, *The Riddle of Gravitation*, rev. ed. (1987). An unusual social history of the U.S. scientific community is presented in DANIEL J. KEVLES, *The Physicists* (1978, reprinted 1987).

Chemistry: Historical developments in chemistry through the 17th century are explored in ROBERT P. MÜLTHAUF, *The Origins of Chemistry* (1966). CECIL J. SCHNEER, *Mind and Matter: Man's Changing Concepts of the Material World* (1970, reprinted 1988), gives an interesting account of the history of chemistry in relation to the structure of matter; AARON J. IHDE, *The Development of Modern Chemistry* (1964, reprinted 1984), is a comprehensive history covering the 18th to the middle of the 20th century; and FREDERIC LAWRENCE HOLMES, *Lavoisier and the Chemistry of Life: An Exploration of Scientific Creativity* (1985), is a study of chemical experimentation.

Concise explanations of chemical terms can be found in DOUGLAS M. CONSIDINE and GLENN D. CONSIDINE (eds.), *Van Nostrand Reinhold Encyclopedia of Chemistry*, 4th ed. (1984), a specialized reference work. Comprehensive treatment of chemical theories and reactivity is presented in DONALD A. MCQUARRIE and PETER A. ROCK, *General Chemistry*, 2nd ed. (1987); and in JOHN C. KOTZ and KEITH F. PURCELL, *Chemistry & Chemical Reactivity* (1987). Studies of common applications of chemistry, intended for the general reader, include WILLIAM R. STINE *et al.*, *Applied Chemistry*, 2nd ed. (1981); and JOHN W. HILL, *Chemistry for Changing Times*, 5th ed. (1988). An overview of modern chemistry and discussion of its prospects is found in GEORGE C. PIMENTEL and JANICE A. COONROD, *Opportunities in Chemistry: Today and Tomorrow* (1987). P.W. ATKINS, *Molecules* (1987), is a pictorial examination of chemical structure. LIONEL SALEM, *Marvels of the Molecule*, trans. from French (1987), presents the molecular orbital theory of chemical bonding in simple terms. The extent to which molecular structure has become central to biochemistry is demonstrated in the articles in *The Molecules of Life: Readings from Scientific American* (1985). The fundamental principles governing chemical change and the laws of thermodynamics are presented, with a minimum of mathematics, in P.W. ATKINS, *The Second Law* (1984); and JOHN B. FENN, *Engines, Energy, and Entropy: A Thermodynamics Primer* (1982). Social aspects of developments in chemistry, especially the environmental costs of use of chemical products, are studied in LUCIANO CAGLIOTI, *The Two Faces of Chemistry*, trans. from Italian (1983).

Astronomy: ANTONIE PANNEKOEK, *A History of Astronomy* (1961, reissued 1969; originally published in Dutch, 1951); and STEPHEN TOULMIN and JUNE GOODFIELD, *The Fabric of the Heavens* (1961), are comprehensive surveys. THOMAS S. KUHN, *The Copernican Revolution: Planetary Astronomy in the Development of Western Thought* (1957), discusses the ancient geo-

centric theory of the universe and the heliocentric system that replaced it. CHARLES A. WHITNEY, *The Discovery of Our Galaxy* (1971, reprinted 1988), explains theories and observations in stellar astronomy from the 18th through the 20th centuries. OTTO STRUVE and VELTA ZEBERGS, *Astronomy of the 20th Century* (1962), studies the developments and achievements of the first 50 years of the century. The same period is covered in a later study from the ongoing series "The General History of Astronomy": OWEN GINGERICH (ed.), *Astrophysics and Twentieth-Century Astronomy to 1950* (1984).

Literature on current knowledge in astronomy is voluminous. C.W. ALLEN, *Astrophysical Quantities*, 3rd ed. (1973, reprinted 1983), provides a compact compilation of data; and KENNETH R. LANG, *Astrophysical Formulae: A Compendium for the Physicist and Astrophysicist*, 2nd rev. ed. (1980), is a comprehensive reference source, with extensive formulas and background data. ROBERT BURNHAM, JR., *Burnham's Celestial Handbook: An Observer's Guide to the Universe Beyond the Solar System*, rev. ed., 3 vol. (1978), is a guide to stars, nebulae, and galaxies. ARTHUR P. NORTON, *Norton's Star Atlas and Reference Handbook (Epoch 1950.0)*, 17th ed., edited by GILBERT E. SATTERTHWAIT (1978, reprinted 1986), is a popular atlas. Introductory texts include GEORGE O. ABELL, DAVID MORRISON, and SIDNEY C. WOLFF, *Exploration of the Universe*, 5th ed. (1987), a comprehensive classic; and A.E. ROY and D. CLARKE, *Astronomy: Principles and Practice*, 3rd ed. (1988), a survey of experimental basics.

The scope and methodology of astronomy are explored in specialized works: J. KELLY BEATTY, BRIAN O'LEARY, and ANDREW CHAIKIN, *The New Solar System*, 2nd ed. (1982); PETER H. CADOGAN, *The Moon: Our Sister Planet* (1981); JOHN C. BRANDT and ROBERT D. CHAPMAN, *Introduction to Comets* (1981); GORDON WALKER, *Astronomical Observations: An Optical Perspective* (1987); R.J. TAYLER, *The Stars: Their Structure and Evolution* (1970, reissued 1981); CARL E. FICHTEL and JACOB I. TROMBKA, *Gamma Ray Astrophysics: New Insights into the Universe* (1981); CLAUD E. ROLFS and WILLIAM S. RODNEY, *Cauldrons in the Cosmos: Nuclear Astrophysics* (1988); DIMITRI MIHALAS and JAMES BINNEY, *Galactic Astronomy: Structure and Kinematics*, 2nd ed. (1981); JOHN D. KRAUS *et al.*, *Radio Astronomy*, 2nd ed. (1986); M.S. LONGAIR, *High Energy Astrophysics: An Informal Introduction for Students of Physics and Astronomy* (1981); MICHAEL ROWAN-ROBINSON, *The Cosmological Distance Ladder: Distance and Time in the Universe* (1985); and EDWARD R. HARRISON, *Cosmology, the Science of the Universe* (1981). For up-to-date reviews of specialized subjects and for current listings of observational information, consult the *Annual Review of Astronomy and Astrophysics*, *Annual Review of Earth and Planetary Sciences*, *The Astronomical Almanac* (annual), and *The Observer's Handbook* (annual).

Picasso

The enormous body of Picasso's work, including painting, sculpture, works on paper, ceramics, and poetry, remains; and the legend lives on—a tribute to the vitality of the “disquieting” Spaniard with the “sombre . . . piercing” eyes who superstitiously believed that work would keep him alive. For nearly 80 of his 91 years Picasso devoted himself to an artistic production that contributed significantly to and paralleled the whole development of modern art in the 20th century.

LIFE AND CAREER

Early years. Pablo Picasso, son of José Ruiz Blasco, a professor of drawing, and Maria Picasso López, was born in Málaga, Spain, on Oct. 25, 1881. His unusual adeptness for drawing began to manifest itself early, around the age of 10, when he became his father's pupil in La Coruña, where the family moved in 1891. From that point his ability to experiment with what he learned and to develop new expressive means quickly allowed him to surpass his father's abilities. In La Coruña his father shifted his own ambitions to those of his son, providing him with models and support for his first exhibition there at the age of 13.

The family moved to Barcelona in the autumn of 1895, and Pablo entered the local art academy (La Llotja), where his father had assumed his last post as professor of drawing. The family hoped that their son would achieve success as an academic painter, and in 1897 his eventual fame in Spain seemed assured; in that year his painting “Science and Charity,” for which his father modeled for the doctor, was awarded an honorable mention in Madrid at the Fine Arts Exhibition.

The Spanish capital was the obvious next stop for the young artist intent on gaining recognition and fulfilling family expectations. Pablo Ruiz duly set off for Madrid in the autumn of 1897 and entered the Royal Academy of San Fernando. But finding the teaching there stupid, he increasingly spent his time recording life around him, in the cafés, on the streets, in the brothels, and in the Prado, where he discovered Spanish painting. He wrote: “The Museum of paintings is beautiful. Velázquez first

class; from El Greco some magnificent heads, Murillo does not convince me in every one of his pictures.” Works by these and other artists would capture Picasso's imagination at different times during his long career. Goya, for instance, was an artist whose works Picasso copied in the Prado in 1898 (a portrait of the bullfighter Pepe Illo and the drawing for one of the *Caprichos*, “Bien tirada está,” which shows a Celestina [procuress] checking a young maja's stockings). These same characters reappear in his late work—Pepe Illo in a series of engravings (1957) and Celestina as a kind of voyeuristic self-portrait, especially in the series of etchings and engravings known as “Suite 347” (1968).

Picasso fell ill in the spring of 1898 and spent most of the remaining year convalescing in the Catalan village of Horta de Ebro in the company of his Barcelona friend Manuel Pallarès. When Picasso returned to Barcelona in early 1899, he was a changed man: he had put on weight, he had learned to live on his own in the open countryside, he spoke Catalan, and most importantly he had made the decision to break with his art school training and to reject his family's plans for his future. He even began to show a decided preference for his mother's surname, and more often than not he signed his works P.R. Picasso (by late 1901 he had dropped the Ruiz altogether).

In Barcelona Picasso moved among a circle of Catalan artists and writers whose eyes were turned toward Paris. These were his friends at the café Els Quatre Gats (“The Four Cats,” styled after the Chat Noir [“Black Cat”] in Paris), where Picasso had his first Barcelona exhibition in February 1900, and they were the subjects of more than 50 portraits (in mixed media) in the show. In addition, there was a dark, moody “modernista” painting, “Last Moments” (later painted over), showing the visit of a priest to the bedside of a dying woman, a work that was accepted for the Spanish section of the Exposition Universelle in Paris in that year. Eager to see his own work in place and to experience Paris firsthand, Picasso set off in the company of his studio-mate Carles Casagemas (“Portrait of Carles Casagemas,” 1899) to conquer, if not Paris, at least a corner of Montmartre.

Discovery of Paris. One of Picasso's principal artistic discoveries on that trip (October–December) was colour—not the drab colours of the Spanish palette, the black of the shawls of Spanish women, or the ochres and browns of the Spanish landscape, but brilliant colour—the colour of Van Gogh, of new fashion, of a city celebrating a world's fair. Using charcoal, pastels, watercolours, and oils, Picasso recorded life in the French capital (“Lovers in the Street,” 1900). In “Moulin de la Galette” (1900) he paid tribute to French artists such as Toulouse-Lautrec and Steinlen as well as his Catalan compatriot Ramon Casas.

After just two months Picasso returned to Spain with Casagemas, who had become despondent about a failed love affair. Having tried unsuccessfully to amuse his friend in Málaga, Picasso took off for Madrid, where he worked as an art editor for a new journal, *Arte Joven*. Casagemas returned to Paris and attempted to shoot the woman he loved, then turned the gun on himself and died. The impact on Picasso was deep: it was not just that he had lost his loyal friend and perhaps felt a sense of guilt for having abandoned him; more importantly, he had gained the emotional experience and the material that would stimulate the powerful expressiveness of the works of the so-called Blue Period. Picasso made two death portraits of Casagemas several months later in 1901 as well as two funeral scenes (“Mourners” and “Evocation”), and in 1903 Casagemas appeared as the artist in the enigmatic painting “La Vie.”

Blue Period. Between 1901 and mid-1904, when blue was the predominant colour in his paintings, Picasso

Picasso.

moved back and forth between Barcelona and Paris, taking material for his work from one place to the other. For example, his visits to the Women's Prison of Saint-Lazare in Paris in 1901–02, which provided him with free models and compelling subject matter ("The Soup," 1902), were reflected in his depictions of Barcelona street people—blind or lonely beggars and castaways in 1902–03 ("Crouching Woman," 1902; "Blind Man's Meal," 1903; "Old Jew and a Boy," 1903). The subject of maternity (women were allowed to keep nursing children with them at the prison) also preoccupied Picasso at a time when he was searching for material that would best express traditional art-historical subjects in 20th-century terms.

Friendship
with
Apollinaire

The move to Paris. Picasso finally made the decision to move permanently to Paris in the spring of 1904, and his work reflects a change of spirit and especially a change of intellectual and artistic currents. The traveling circus and saltimbanques became a subject he shared with a new and important friend, Guillaume Apollinaire. To both the poet and the painter these rootless wandering performers ("Girl Balancing on a Ball," 1905; "The Actor," 1905) became a kind of evocation of the artist's position in modern society. Picasso specifically made this identification in "Family of Saltimbanques" (1905), where he assumes the role of Harlequin and Apollinaire is the strongman (according to their mutual friend, the writer André Salmon).

Picasso's personal circumstances also changed at the end of 1904, when Fernande Olivier became his mistress. Her presence inspired many works during the years leading up to Cubism, especially on their trip to Gosol in 1906 ("Woman with Loaves"), including the sculpture "Head of a Woman" (1909) and several paintings related to it ("Woman with Pears," 1909).

Colour never came easily to Picasso, and he reverted to a generally more Spanish (*i.e.*, monochromatic) palette. The tones of the Blue Period were replaced from late 1904 to 1906 in the so-called Rose Period by those of pottery, of flesh, and of the earth itself ("The Harem," 1906). Picasso seems to have been working with colour in an attempt to come closer to sculptural form, especially in 1906 ("Two Nudes"; "La Toilette"). His "Portrait of Gertrude Stein" (1906) and a "Self-Portrait with Palette" (1906) show this development as well as the influence of his discovery of primitive Iberian sculpture.

Les Femmes d'Alger (O.J.). Toward the end of 1906 Picasso began work on a large composition that came to be called "Les Femmes d'Alger" (1907). His violent treatment of the female body and masklike painting of the faces (influenced by a study of African art) have made this work controversial. Yet the work was firmly based upon art-historical tradition: a renewed interest in El Greco contributed to the fracturing of the space and the gestures of the figures, while the overall composition owed much to Cézanne's "Bathers" as well as to Ingres's harem scenes. The "Femmes," however, named by Picasso's friend Max Jacob (to refer to Avignon Street in Barcelona, where sailors found popular brothels), was perceived as a shocking and direct assault: these women were not conventional images of beauty but prostitutes who challenged the very tradition from which they were born. Although he had his collectors by this date (Leo and Gertrude Stein, the Russian merchant Sergey Shchukin) and a dealer (Daniel-Henry Kahnweiler), Picasso chose to roll up the canvas of the "Femmes" and to keep it out of sight for several years.

In 1908 the African-influenced striations and masklike heads were superseded by a technique that incorporated elements he and his new friend Georges Braque found in the work of Cézanne, whose shallow space and characteristic planar brushwork are especially evident in Picasso's work of 1909. Still lifes, inspired by Cézanne, also became an important subject for the first time in Picasso's career.

Cubism. Picasso and Braque worked together closely during the next few years (1909–12)—the only time Picasso ever worked with another painter in this way—and they developed what came to be known as Analytical Cubism. Early Cubist paintings were often misunderstood by critics and viewers because they were thought to be merely geometric art. Yet the painters themselves believed

they were presenting a new kind of reality that broke away from Renaissance tradition, especially from the use of perspective and illusion. For example, they showed multiple views of an object on the same canvas to convey more information than could be contained in a single, limited illusionistic view.

As Kahnweiler saw it, Cubism signified the opening up of closed form by the "re-presentation" of the form of objects and their position in space instead of their imitation through illusionistic means; and the analytic process of fracturing objects and space, light and shadow, and even colour was likened by Apollinaire to the way in which the surgeon dissects a cadaver. This type of analysis is characteristic of Picasso's work beginning in 1909, especially in the landscapes he made on a trip to Spain that summer ("Factory at Horta de Ebro"). These were followed in 1910 with a series of hermetic portraits ("Ambroise Vollard"; "Daniel-Henry Kahnweiler"); and in his 1911–12 paintings of seated figures, often playing musical instruments ("The Accordionist," 1911), Picasso merged figures, objects, and space on a kind of grid. The palette was once again limited to monochromatic ochres, browns, and grays.

Neither Braque nor Picasso desired to move into the realm of total abstraction in their Cubist works, although they implicitly accepted inconsistencies such as different points of view, different axes, and different light sources in the same picture. Furthermore, the inclusion of abstract and representational elements on the same picture plane led both artists to reexamine what two-dimensional elements, such as newspaper lettering, signified. A song title, "Ma Jolie," for instance, could point to events outside the painting; it could refer narratively to Picasso's new mistress, Eva (Marcelle Humbert). But it could also point to compositional elements within the painting, to the function of flat pictorial elements that play off other flat planes or curvilinear motifs. The inclusion of lettering also produced the powerful suggestion that Cubist pictures could be read coming forward from the picture plane rather than receding (in traditional perspective) into it. And the Cubists' manipulation of the picture shape—their use of the oval, for example—redefined the edge of the work in a way that underlined the fact that in a Cubist picture the canvas provides the real space.

Abstract
elements in
Cubism

Collage. By 1912 Picasso and Braque were gluing real paper (*papier collé*) and other materials (collage) onto their canvases, taking a stage further the Cubist conception of a work as a self-contained, constructed object. This Synthetic phase (1912–14) saw the reintroduction of colour, while the actual materials often had an industrial reference (*e.g.*, sand or printed wallpaper). Still lifes and, occasionally, heads were the principal subjects for both artists. And in Picasso's works the multiple references inherent in his Synthetic compositions—curves that refer to guitars and at the same time to ears, for instance—introduce an element of play that is characteristic of so much of his work ("Student with a Pipe," 1913) and lead to the suggestion that one thing becomes transformed into another. "Absinthe glass" (1914; six versions), for example, is in part sculpture (cast bronze), in part collage (a real silver sugar strainer is welded onto the top), and in part painting (Neo-Impressionist brushstrokes cover planes of white paint). But the work is neither sculpture, nor collage, nor painting; planes refer to two-dimensionality, while the object indeed possesses three dimensions. The work of art thus hovers between reality and illusion.

By 1915 Picasso's life had changed and so, in a sense, had the direction of his art. At the end of that year his beloved Eva died, and the painting he had worked on during her illness ("Harlequin," 1915; Museum of Modern Art, New York City) gives testimony to his grief—a half-Harlequin, half-Pierrot artist before an easel holds an unfinished canvas against a black background.

Parade. World War I dispersed Picasso's circle; Apollinaire, Braque, and others left for the front, while most of Picasso's Spanish compatriots returned to their neutral homeland. Picasso stayed in France, and from 1916 his friendship with the composer Erik Satie took him into a new avant-garde circle that remained active during the

Jean
Cocteau

war. The self-appointed leader of this nucleus of talents who frequented the Café de la Rotonde was the young poet Jean Cocteau. His idea to stage a wartime theatrical event in collaboration with Sergey Diaghilev's Ballets Russes resulted in the production of *Parade*, a work about a circus sideshow that incorporated imagery of the new century, such as skyscrapers and airplanes. Cocteau went to Satie for the music and then to Picasso for the sets and costumes. Work began in 1917, and although Picasso intensely disliked travel, he agreed to go with Cocteau to Rome where they joined Diaghilev and the choreographer of *Parade*, Léonide Massine. It was on this occasion that Picasso also met his future wife, Olga Kokhlova, among the dancers.

Parade was first performed in May 1917 at the Théâtre du Châtelet in Paris, where it was considered no less than an attempt to undermine the solidarity of French culture. Satie seems to have been the principal target of abuse (partly because of his inclusion of airplane propellers and typewriters in the score), while Picasso disarmed the public with the contrast between his basically realistic stage curtain and the startling Synthetic Cubist constructions worn by the characters, the sideshow managers, in the ballet.

New Mediterraneanism. Picasso's paintings and drawings of the late teens often seem unexpectedly naturalistic in contrast to the Cubist works that preceded or sometimes coincided with them ("Passeig de Colom," 1917). After his travels to Italy and a return to Barcelona in 1917 (*Parade* was performed there in November), a new spirit of Mediterraneanism made itself felt in his work, especially in the use of classical forms and drawing techniques. This was reinforced by a conscious looking back to Ingres (for example, in Picasso's portrait drawings of Jacob and Volland, 1915) and to late Renoir. Even the direction of Picasso's Cubist work was affected. By clarifying planes, forms, and colour, the artist imparted to his Cubist paintings a classical expression (Saint-Raphaël still lifes, 1919; two versions of the "Three Musicians," 1921).

Picasso's only legitimate child, Paulo, was born in 1921. As part of his new status as darling of the socialites (encouraged particularly by his wife and Jean Cocteau) Picasso continued his collaborations with the Ballets Russes and produced designs for Manuel de Falla's *Three-Cornered Hat* (1919); Igor Stravinsky's *Pulcinella* (1920); De Falla's *Cuadro Flamenco* (1921); and Satie's ballet *Mercury* (1924). André Breton called Picasso's designs for this ballet "tragic toys for adults" created in the spirit of Surrealism.

Surrealism. Although Picasso never became an official member of the group, he had intimate connections with the most important art movement between the two world wars, Surrealism. The Surrealist establishment, including its main propagandist, André Breton, claimed him as one of their own, and Picasso's art gained a new dimension from contact with his Surrealist friends, particularly the writers. Inherent in Picasso's work since the "Demoiselles" were many elements that the official circle advocated. The creation of monsters, for instance, could certainly be perceived in the disturbing juxtapositions and broken contours of the human figure in Cubist works; Breton specifically pointed to the strange "Woman in a Chemise" (1913). Moreover, the idea of reading one thing for another, an idea implicit in Synthetic Cubism, seemed to coincide with the dreamlike imagery the Surrealists championed.

What the Surrealist movement gave to Picasso were new subjects—especially erotic ones—as well as a reinforcement of disturbing elements already in his work. The many variations on the subject of bathers with their overtly sexual and contorted forms (Dinard series, 1929) show clearly the impact of Surrealism, while in other works the effect of distortion on the emotions of the spectator can also be interpreted as fulfilling one of the psychological aims of Surrealism (drawings and paintings of the "Crucifixion," 1930–35). In the 1930s Picasso, like many of the Surrealist writers, often played with the idea of metamorphosis. For example, the image of the minotaur, the monster of Greek mythology—half bull and half human—that traditionally has been seen as the embodiment of the struggle between the human and the bestial, becomes in Picasso's

work not only an evocation of that idea but also a kind of self-portrait.

Finally, Picasso's own brand of Surrealism found its strongest expression in poetry. He began writing poetry in 1934, and during one year, from February 1935 to the spring of 1936, Picasso virtually gave up painting. Collections of poems were published in *Cahiers d'Art* (1935) and in *La Gaceta de Arte* (1936, Tenerife), and some years later he wrote the Surrealist play *Le Désir attrapé par la queue* (1941, *Desire Caught by the Tail*).

Sculpture. Picasso's reputation as a major 20th-century sculptor came only after his death, because he had kept much of his sculpture in his own collection. Beginning in 1928, Picasso began to work in iron and sheet metal in Julio González's studio in Paris. Then, in 1931, with his new mistress, Marie-Thérèse Walter, he left his wife and moved to a country home at Boisgeloup, where he had room for sculpture studios. There, with Marie-Thérèse as his muse, Picasso began working on large-scale plaster heads. He also began to make constructions incorporating found objects, and until the end of his life Picasso continued working in sculpture in a variety of materials.

The 1930s. The privacy of his life with the undemanding Marie-Thérèse formed a contrast to the hectic pace of life kept by Olga and her bourgeois circle of society friends. Once in Boisgeloup, Picasso lived openly with Marie-Thérèse (with whom he had a child, Maya, in 1935), and she became the subject of his often lyrical, sometimes erotic paintings, in which he combined intense colour with flowing forms ("Girl Before a Mirror," 1932).

Picasso never completely dissociated himself from the women who had shared his life once a new lover occupied his attention. This is evident in his work, in which one mistress often turns into another; for instance, in a private sketchbook (number 99, 1929) Picasso's portrait drawings betray his double life, for the pictures of his then secret mistress evolve into horrific images of screaming Olgas. And in 1936, while money and a certain amount of attention were given to both Olga and Marie-Thérèse, Picasso moved back to Paris and began to live with the Yugoslav photographer Dora Maar. This change in his own life coincided with a period of personal preoccupation with the Spanish Civil War, which had begun in that year.

Although Picasso never returned to his native country after a visit in 1934, his sympathies always lay with Spain (the short-lived Republican government named him honorary director of the Prado), and in early 1937 he produced a series of etchings and aquatints ("Dream and Lie of Franco") to be sold in support of the Republican cause. His major contribution, of course, was the mural painting "Guernica" (named for the Basque town bombed in 1937 by the Fascists) commissioned by the Republican government for the Spanish pavilion at the 1937 World's Fair in Paris. As compensation Picasso was provided with a studio in Paris on rue des Grands Augustins large enough to accommodate the enormous canvas (11.5 × 25.5 feet; 3.49 × 7.77 metres). Dora Maar worked with him to complete the final work, which was realized in just over three weeks. The imagery in "Guernica"—the gored horse, the fallen soldier, and screaming mothers with dead babies (representing the bullfight, war, and female victims, respectively)—was employed to condemn the useless destruction of life, while at the same time the bull represented the hope of overcoming the unseen aggressor, Fascism.

World War II and after. The expressive quality of both the forms and gestures in the basically monochromatic composition of "Guernica" found its way into Picasso's other work, especially in the intensely coloured versions of "Weeping Woman" (1937) as well as in related prints and drawings, in portraits of Dora Maar and Nusch Éluard (wife of Picasso's friend, the French poet Paul Éluard), and in still lifes ("Still Life with Red Bull's Head," 1938). These works led to the claustrophobic interiors and skull-like drawings (sketchbook number 110, 1940) of the war years, which Picasso spent in France with Dora Maar as well as with Jaime Sabartés, a friend of his student days in Barcelona. Thereafter Sabartés shared Picasso's life as secretary, biographer, and companion, and more often than not as the butt of endless jokes ("Portrait of Jaime

Marie-
Thérèse
Walter

"Guernica"

Sabartés," 1939; "Retour de Bruxelles," sketchbook number 137, 1956).

Member-
ship in the
Communist Party

After the war Picasso resumed exhibiting his work, which included painting and sculpture as well as work in lithography and ceramics. At the Autumn Salon of 1944 ("Salon de la Liberation") Picasso's canvases and sculpture of the preceding five years were received as a shock. This plus the announcement that Picasso had just joined the Communist Party led to demonstrations against his political views in the gallery itself. At the same time Picasso opened up his studio to both new and old writer and artist friends, including Jean-Paul Sartre, Pierre Reverdy, Éluard, the photographer Brassai, the English artist Roland Penrose, and the American photographer Lee Miller, as well as many American GI's.

Already in 1943 a young painter, Françoise Gilot, had presented herself at the studio, and within months she became the successor to Dora Maar. In 1946 Picasso moved to the Mediterranean with Gilot (with whom he was to have two children, Claude in 1947 and Paloma in 1949). First they moved to Antibes, where Picasso spent four months painting at the Château Grimaldi ("Joie de Vivre," 1946). The paintings of this time and the ceramics he decorated at the studio in nearby Vallauris, beginning in 1947, vividly express Picasso's sense of identification with the classical tradition and with his Mediterranean origins. They also celebrate his new-found happiness with Gilot, who in works of this period is often nymph to Picasso's fauns and centaurs.

Ceramics. Picasso's ceramics are usually set apart from his main body of work and are treated as less important, because at first glance they seem a somewhat frivolous exercise in the decoration of ordinary objects. Plates, jugs, and vases, mostly made by craftsmen at the Madoura pottery in Vallauris, were reshaped or painted, gouged out, scratched, or marked by fingerprints, and, for the most part, were rendered useless. In turning to craft, Picasso worked with a sense of liberation, experimenting with the play between decoration and form (between two and three dimensions) and between personal and universal meaning.

During this period Picasso's fame increasingly attracted numerous visitors, including artists and writers, some of whom (Hélène Parmelin, Édouard Pignon, Éluard, and especially Louis Aragon) encouraged Picasso's further political involvement. Although he contributed designs willingly (his dove was used for the World Peace Congress poster in Wrocław, Pol., in 1949), it was not so much from a commitment to the Communists as from a sincere and lifelong sympathy with any group of repressed people. "War" and "Peace," two panels painted in 1952 to adorn the Temple of Peace attached to an old chapel in Vallauris, reflect Picasso's personal optimism of those years.

The Picasso myth. After World War II an aura of myth grew up around the name of Picasso, and in the last decades of his life his work had, in a sense, moved beyond criticism. Although there were few critics able to keep pace with his latest work, there were few who attacked him. One exception was the British critic John Berger (*The Success and Failure of Picasso*, 1965), who raised questions about Picasso's economic motives and speculated about his inflated public reputation. Picasso's enormous output (especially in printing and drawing) kept his name before the public, even though his work seemed at the time to be far from mainstream, nonfigurative imagery. For example, in the series that characterized the working methods of his late years he used figurative imagery to weave a kind of narrative within each series' numerous variations.

Jacqueline
Roque

In 1953 Françoise Gilot with their two children left Picasso, and he spent several years as a bachelor, dividing his time between Paris and his home at La Californie, near Cannes. In 1954 he had met Jacqueline Roque, who worked in the pottery shop in Vallauris, and they married in 1961; she not only became his steadfast companion, but also, as his muse, she became the principal image and source of inspiration for practically all of the late work. They are both buried in the castle at Vauvenargues, which Picasso purchased in 1958. But the years from their marriage to Picasso's death they spent at Mougins.

History of art. In his late work Picasso repeatedly

turned toward the history of art for his themes. He seemed at times obsessed with the need to create variations on the works of earlier artists; thus in his many prints, drawings, and paintings of that period, reference is made to artists such as Altdorfer, Manet, Rembrandt, Delacroix, and Courbet. Repeatedly Picasso did a complete series of variations on one particular work, the most famous being perhaps the series on "Las Meninas" of Velázquez consisting of 58 discrete pictures. At times Picasso reworked a specific work because he identified personally with it. For example, he was attracted to Delacroix's "Femmes d'Alger" because the figure on the right bore resemblance to his wife. More often he seemed moved by the challenge to rework in his own way the complex pictorial and narrative problems the older artists had originally posed for themselves. In a sense Picasso was writing himself into the history of art by virtue of such an association with a number of his predecessors.

There is a renewed sense of play in the work of Picasso's later years. He transformed paper cutouts into monumental sculptures, and in Henri-Georges Clouzot's film "Le Mystère Picasso" (1955), the artist, the sole star, behaves like a conjurer, performing tricks with light as well as with his brush. And finally, just as he turned to the paintings of earlier masters, redoing their works in many variations, so he turned to his own earlier oeuvre, prompted by the same impulse. The circus and the artist's studio became once again the stage for his characters, among whom he often placed himself portrayed as an old acrobat or king.

Picasso died in Mougins, Fr., at the age of 91, on April 8, 1973.

"Le
Mystère
Picasso"

ASSESSMENT

Because Picasso's art from the time of the "Demoiselles" was radical in nature, virtually no 20th-century artist could escape his influence. Moreover, while other masters such as Matisse or Braque tended to stay within the bounds of a style they had developed in their youth, Picasso continued to be an innovator into the last decade of his life. This led to misunderstanding and criticism both in his lifetime and since, and it was only in the 1980s that his last paintings began to be appreciated both in themselves and for their profound influence on the rising generation of young painters. Since Picasso was able from the 1920s to sell works at very high prices, he could keep most of his oeuvre in his own collection. At the time of his death he owned some 50,000 works in various media from every period of his career, which passed into possession of the French state and his heirs. Their exhibition and publication has served to reinforce the highest estimates of Picasso's astonishing powers of invention and execution over a span of more than 80 years.

MAJOR WORKS

PAINTINGS: "Girl with Bare Feet" (1895; Picasso Museum, Paris); "Science and Charity" (1897; Picasso Museum, Barcelona); "Portrait of Carles Casagemas" (1899; Picasso Museum, Barcelona); "Lovers in the Street" (1900; Picasso Museum, Barcelona); "Moulin de la Galette" (1900; Solomon R. Guggenheim Museum, New York City); "Mourners" (1901; private collection, United States); "Evocation" (1901; Museum of Modern Art of the City of Paris); "Self-Portrait" (1901; Picasso Museum, Paris); "El Bock (Portrait of Jaime Sabartés)" (1901; State Pushkin Museum of Fine Arts, Moscow); "The Soup" (1902; Art Gallery of Ontario, Toronto); "Crouching Woman" (1902; Art Gallery of Ontario); "The Two Sisters" (1902; Hermitage, Leningrad); "Blind Man's Meal" (1903; Metropolitan Museum of Art, New York City); "Old Jew and a Boy" (1903; State Pushkin Museum of Fine Arts); "La Vie" (1903; Cleveland Museum of Art); "The Old Guitarist" (1903; Art Institute of Chicago); "The Tragedy" (1903; National Gallery of Art, Washington, D.C.); "Family of Saltimbanques" (1905; National Gallery of Art); "Girl Balancing on a Ball" (1905; State Pushkin Museum of Fine Arts); "The Actor" (1905; Metropolitan Museum of Art); "The Harem" (1906; Cleveland Museum of Art); "La Toilette" (1906; Albright-Knox Art Gallery, Buffalo); "Portrait of Gertrude Stein" (1906; Metropolitan Museum of Art); "Two Nudes" (1906; Museum of Modern Art, New York City); "Seated Female Nude with Crossed Legs" (1906; National Gallery, Prague); "Self-Portrait with Palette" (1906; Philadelphia Museum of Art); "Woman with Loaves" (1906; Philadelphia Museum of Art); "Les Demoiselles d'Avignon" (1907; Museum of Modern Art); "Three Women" (1908–09;

Hermitage); "Bread and Fruit Dish on a Table" (1909; Public Art Collection, Basel, Switz.); "Factory at Horta de Ebro" (1909; Hermitage); "Woman with Pears" (1909; State Pushkin Museum of Fine Arts); "Portrait of Ambroise Vollard" (1910; State Pushkin Museum of Fine Arts); "Portrait of Daniel-Henry Kahnweiler" (1910; Art Institute of Chicago); "The Accordionist" (1911; Solomon R. Guggenheim Museum); "Ma Jolie" (1911-12; Museum of Modern Art); "Still Life with Chair Caning" (1911-12; Picasso Museum, Paris); "Student with a Pipe" (1913; Museum of Modern Art); "Woman in a Chemise" (1913; private collection, United States); "Harlequin" (1915; Museum of Modern Art); "Portrait of Olga" (1917; Picasso Museum, Paris); "Harlequin" (1917; Picasso Museum, Barcelona); "Passeig de Colom" (1917; Picasso Museum, Barcelona); "Three Musicians" (1921; Philadelphia Museum of Art); "Three Musicians" (1921; Museum of Modern Art); "Pipes of Pan" (1923; Picasso Museum, Paris); "Three Dancers" (1925; Tate Gallery, London); "Woman in an Armchair" (1929; Picasso Museum, Paris); "Crucifixion" (1930; Picasso Museum, Paris); "Seated Bather" (1930; Museum of Modern Art); "Bather with Beach Ball" (1932; private collection, United States); "Girl Before a Mirror" (1932; Museum of Modern Art); "The Female Swimmer" (1934; Marina Picasso Collection, Geneva); "Nude Asleep in a Landscape" (1934; Picasso Museum, Paris); "Guernica" (1937; Casón del Buen Retiro, Prado, Madrid); "Weeping Woman" (1937; private collection, England); "Still Life with Red Bull's Head" (1938; Museum of Modern Art); "Portrait of Jaime Sabartés" (1939; Picasso Museum, Barcelona); "Woman Dressing Her Hair" (1940; private collection, United States); "L'Aubade" (1942; National Museum of Modern Art, Beaubourg Centre, Paris); "The Charnel House" (1944-45; Museum of Modern Art); "Joie de Vivre" (1946; Picasso Museum, Antibes, Fr.); "Femme Fleur" (1946; private collection, France); "Peace" (1952; National Picasso Museum, Vallauris, Fr.); "War" (1952; National Picasso Museum); "Women of Algiers, After Delacroix" (series, 1954-55); "Las Meninas, After Velázquez" (series 1957; Picasso Museum, Barcelona); "Rape of the Sabinas" (1963; Museum of Fine Arts, Boston); "Man with Pipe and Cupid" (1969; Am Rhyn-Haus, Luzern, Switz.); "The Kiss" (1969; Picasso Museum, Paris); "Young Bather with Sand Shovel" (1971; private collection, France).

SCULPTURE: (Works without ownership identification exist in multiple castings.) "The Jester" (bronze, 1905); "Head of a Woman" (bronze, 1909); "Guitar" (sheet metal and wire, 1912; Museum of Modern Art); "Absinthe Glass" (painted bronze and silver sugar strainer, 1914; six versions); "Guitar" (floorcloth, string, nails, and newspaper, 1926; Picasso Museum, Paris); "Construction" (iron wire, 1928; Picasso Museum, Paris); "Bust of a Woman" (bronze, 1932; Picasso Museum, Paris); "Bull's Head" (saddle and handlebars, 1943; Picasso Museum, Paris); "Death's Head" (bronze, 1942; Picasso Museum, Paris); "Man with a Sheep" (bronze, 1944); "She-Goat" (plaster, later bronze, 1950); "Bathers" (wood, 1956; State Gallery, Stuttgart, W.Ger.); "Head" (steel, 1967; Daley Center Plaza, Chicago).

WORKS ON PAPER: "The Frugal Repast" (etching, 1904); "Portrait of Max Jacob" (pencil, 1915; private collection, France); "Sleeping Peasants" (tempera with coloured pencil, 1919; Museum of Modern Art); "Portrait of Erik Satie" (pencil, 1920; Picasso Museum, Paris); "Portrait of Igor Stravinsky" (pencil, 1920; Picasso Museum, Paris); illustrations for Balzac's *Chef-d'œuvre inconnu* (13 etchings and 67 wood engravings, 1927 [published 1931]); illustrations for Ovid's *Metamorphoses* (30 etchings, 1930 [published 1931]); "Crucifixion, After Grünewald" (India ink series, 1932; Picasso Museum, Paris); cover of *Minotaure* (collage, 1933; Museum of Modern Art); "Model and Surrealist Sculpture" (etching, 1933); "Sculptor's Studio" (etchings, 1933-34); "Minotauremachie"

(etching, 1935); "Minotaur" (ink and gouache series, 1936; Picasso Museum, Paris); "Dream and Lie of Franco" (etchings and aquatints, 1937); "David and Bathsheba, After Cranach the Elder" (lithograph series, 1947); "Luncheon on the Grass, After Manet" (sketchbook number 163, 1962; private collection, Paris); "Suite 347" (etchings and engravings, 1968); "Man and Seated Nude, Mougins" (ink, 1970; Ludwig Museum, Cologne); "Self-Portrait" (crayons, 1972; Fuji TV Company Gallery, Japan).

CERAMICS: "Bullfight" series (plates, 1949); "Centaur" series (plates, 1949); "Visage de Femme" (jug with spout, 1951; private collection, England); "Hands Holding Fish" (plate, 1953; State Pushkin Museum of Fine Arts).

BIBLIOGRAPHY

Biography and criticism: JAIME SABARTÉS, *Picasso: An Intimate Portrait*, trans. from Spanish (1948), is a fundamental biographical source, although many Picasso legends begin here. Picasso himself approved the biography by ANTONINA VALENTIN, *Picasso* (1963). Other biographies and memoirs are DORE ASHTON (comp.), *Picasso on Art: A Selection of Views* (1972); BRASSAI, *Picasso and Company* (1966; U.K. title, *Picasso & Co.*, 1967; originally published in French, 1964), conversations with the artist; PIERRE DAIX, *La Vie de peintre de Pablo Picasso* (1977), a well-documented chronological study of his work; FRANÇOISE GILOT and CARLTON LAKE, *Life with Picasso* (1964, reissued 1981), informative and sometimes biased memoirs; PATRICK O'BRIAN, *Picasso: Pablo Ruiz Picasso: A Biography* (U.K. title, *Pablo Ruiz Picasso*, 1976); FERNANDE OLIVIER, *Picasso and His Friends* (1964; originally published in French, 1933), early memoirs; ROLAND PENROSE, *Picasso: His Life and Work*, 3rd ed. (1981); and GERTRUDE STEIN, *Picasso* (1938). More specific works of criticism are ALFRED H. BARR, JR., *Picasso: Fifty Years of His Art* (1946, reprinted 1984); MARILYN MCCULLY (ed.), *A Picasso Anthology: Documents, Criticism, Reminiscences* (1981, reissued 1982); JOSEF PALAU I FABRE, *Picasso, the Early Years: 1881-1907* (1981; originally published in Catalan, 1980), containing more than 1,500 illustrations; and GERT SCHIFF (ed.), *Picasso in Perspective* (1976), a collection of essays about his work. See also RAY ANNE KIBBEY, *Picasso: A Comprehensive Bibliography* (1977), with limited general coverage through 1976.

Catalogs: GEORGES BLOCH, *Pablo Picasso*, 4 vol. (1968-79), including printed graphic work from 1904 to 1972 and painted ceramics from 1949 to 1971; DOUGLAS COOPER and GARY TINTEROW, *The Essential Cubism 1907-1920: Braque, Picasso & Their Friends* (1983); DOUGLAS COOPER, *Picasso Theatre* (1968; originally published in French, 1967); PIERRE DAIX and GEORGES BOUDAILLE, *Picasso: A Catalogue Raisonné, 1900-1906*, rev. ed. (1967; originally published in French, 1966); PIERRE DAIX, *Picasso: The Cubist Years, 1907-1916: A Catalogue Raisonné of the Paintings and Related Works* (1979; originally published in French, 1979); CHRISTIAN GEELHAAR et al., *Pablo Picasso: Das Spätwerk: Themen 1964-1972* (1981); BERNHARD GEISER (ed.), *L'Oeuvre gravé de Picasso* (1955); JÜRGEN GLAESEMER (ed.), *Der Junge Picasso: Frühwerk und blaue Periode* (1984); ARNOLD GLIMCHER and MARK GLIMCHER (eds.), *Je Suis le Cahier: The Sketchbooks of Picasso* (1986); SEBASTIAN GOEPFERT, HERMA GOEPFERT-FRANK, and PATRICK CRAMER, *Pablo Picasso: The Illustrated Books* (1983; originally published in French, 1983); WILLIAM RUBIN (ed.), *Pablo Picasso: A Retrospective* (1980); GERT SCHIFF, *Picasso: The Last Years, 1963-1973* (1983); WERNER SPIES, *Picasso: Pastelle, Zeichnungen, Aquarelle* (1986); GARY TINTEROW, *Master Drawings by Picasso* (1981); and CHRISTIAN ZERVOS, *Pablo Picasso*, 33 vol. (1932-78), a basic work reproducing the works in black and white.

(M.McCu.)

Planck

Max Planck made many contributions to theoretical physics, but his fame rests primarily on his role as originator of the quantum theory. This theory revolutionized our understanding of atomic and subatomic processes, just as Albert Einstein's theory of relativity revolutionized our understanding of space and time. Together they constitute the fundamental theories of 20th-century physics. Both have forced man to revise some of his most cherished philosophical beliefs, and both have led to industrial and military applications that affect every aspect of modern life.

EB, Inc.

Planck.

Early life. Max Karl Ernst Ludwig Planck was born on April 23, 1858, in Kiel, Germany, the sixth child of a distinguished jurist and professor of law at the University of Kiel. The long family tradition of devotion to church and state, excellence in scholarship, incorruptibility, conservatism, idealism, reliability, and generosity became deeply ingrained in Planck's own life and work. When Planck was nine years old, his father received an appointment at the University of Munich, and Planck entered the city's renowned Maximilian Gymnasium, where a teacher, Hermann Müller, stimulated his interest in physics and mathematics. But Planck excelled in all subjects, and after graduation at age 17 he faced a difficult career decision. He ultimately chose physics over classical philology or music because he had dispassionately reached the conclusion that it was in physics that his greatest originality lay. Music, nonetheless, remained an integral part of his life. He possessed the gift of absolute pitch and was an excellent pianist who daily found serenity and delight at the keyboard, enjoying especially the works of Schubert and Brahms. He also loved the outdoors, taking long walks each day and hiking and climbing in the mountains on vacations, even in advanced old age.

Planck entered the University of Munich in the fall of 1874 but found little encouragement there from physics professor Philipp von Jolly. During his *Wanderjahr* (1877–78) at the University of Berlin, he was unimpressed by the lectures of Hermann von Helmholtz and Gustav Robert Kirchhoff, despite their eminence as research scientists. His intellectual capacities were, however, brought to a focus as the result of his independent study, especially of Rudolf Clausius' writings on thermodynamics. Returning to Munich, he received his doctoral degree in July 1879 (the year of Einstein's birth) at the unusually young age of 21. The following year he completed his *Habilitationsschrift* (qualifying dissertation) at Munich and became a *Privatdozent* (lecturer). In 1885, with the help of his fa-

ther's professional connections, he was appointed *ausserordentlicher Professor* (associate professor) at the University of Kiel. In 1889, after the death of Kirchhoff, Planck received an appointment to the University of Berlin, where he came to venerate Helmholtz as mentor and colleague. In 1892 he was promoted to *ordentlicher Professor* (full professor). He had only nine doctoral students altogether, but his Berlin lectures on all branches of theoretical physics went through many editions and exerted great influence. He remained in Berlin for the rest of his active life.

Planck recalled that his "original decision to devote myself to science was a direct result of the discovery . . . that the laws of human reasoning coincide with the laws governing the sequences of the impressions we receive from the world about us; that, therefore, pure reasoning can enable man to gain an insight into the mechanism of the [world]. . . ." He deliberately decided, in other words, to become a theoretical physicist at a time when theoretical physics was not yet recognized as a discipline in its own right. But he went further: he concluded that the existence of physical laws presupposes that the "outside world is something independent from man, something absolute, and the quest for the laws which apply to this absolute appeared . . . as the most sublime scientific pursuit in life."

The first instance of an absolute in nature that impressed Planck deeply, even as a *Gymnasium* student, was the law of the conservation of energy, the first law of thermodynamics. Later, during his university years, he became equally convinced that the entropy law, the second law of thermodynamics, was also an absolute law of nature. The second law became the subject of his doctoral dissertation at Munich, and it lay at the core of the researches that led him to discover the quantum of action, now known as Planck's constant h , in 1900.

In 1859–60 Kirchhoff had defined a blackbody as an object that re-emits all of the radiant energy incident upon it; i.e., it is a perfect emitter and absorber of radiation. There was, therefore, something absolute about blackbody radiation, and by the 1890s various experimental and theoretical attempts had been made to determine its spectral energy distribution—the curve displaying how much radiant energy is emitted at different frequencies for a given temperature of the blackbody. Planck was particularly attracted to the formula found in 1896 by his colleague Wilhelm Wien at the Physikalisch-Technische Reichsanstalt (PTR) in Berlin-Charlottenburg, and he subsequently made a series of attempts to derive "Wien's law" on the basis of the second law of thermodynamics. By October 1900, however, other colleagues at the PTR, the experimentalists Otto Richard Lummer, Ernst Pringsheim, Heinrich Rubens, and Ferdinand Kurlbaum, had found definite indications that Wien's law, while valid at high frequencies, broke down completely at low frequencies.

Planck learned of these results just before a meeting of the German Physical Society on October 19. He knew how the entropy of the radiation had to depend mathematically upon its energy in the high-frequency region if Wien's law held there. He also saw what this dependence had to be in the low-frequency region in order to reproduce the experimental results there. Planck guessed, therefore, that he should try to combine these two expressions in the simplest way possible, and to transform the result into a formula relating the energy of the radiation to its frequency.

Planck's formulation was hailed as indisputably correct. To Planck, however, it was simply a guess, a "lucky intuition." If it was to be taken seriously, it had to be derived somehow from first principles. That was the task to which Planck immediately directed his energies, and by December 14, 1900, he had succeeded—but at great cost. To achieve his goal, Planck found that he had to

Develop-
ment of
quantum
theory

relinquish one of his own most cherished beliefs, that the second law of thermodynamics was an absolute law of nature. Instead he had to embrace Ludwig Boltzmann's interpretation, that the second law was a statistical law. In addition, Planck had to assume that the oscillators comprising the blackbody and re-emitting the radiant energy incident upon them could not absorb this energy continuously but only in discrete amounts, in quanta of energy; only by statistically distributing these quanta, each containing an amount of energy $h\nu$ proportional to its frequency, over all of the oscillators present in the blackbody could Planck derive the formula he had hit upon two months earlier. He adduced additional evidence for the importance of his formula by using it to evaluate the constant h (his value was 6.55×10^{-27} erg-second, close to the modern value), as well as the so-called Boltzmann constant (the fundamental constant in kinetic theory and statistical mechanics), Avogadro's number, and the charge of the electron. As time went on physicists recognized ever more clearly that—because Planck's constant was not zero but had a small but finite value—the microphysical world, the world of atomic dimensions, could not in principle be described by ordinary classical mechanics. A profound revolution in physical theory was in the making.

Planck's concept of energy quanta, in other words, conflicted fundamentally with all past physical theory. He was driven to introduce it strictly by the force of his logic; he was, as one historian put it, a reluctant revolutionary. Indeed, it was years before the far-reaching consequences of Planck's achievement were generally recognized, and in this Einstein played a central role. In 1905, independently of Planck's work, Einstein argued that under certain circumstances radiant energy itself seemed to consist of quanta (light quanta, later called photons), and in 1907 he showed the generality of the quantum hypothesis by using it to interpret the temperature dependence of the specific heats of solids. In 1909 he introduced the wave-particle duality into physics. In October 1911 he was among the group of prominent physicists who attended the first Solvay conference in Brussels. The discussions there stimulated Henri Poincaré to provide a mathematical proof that Planck's radiation law necessarily required the introduction of quanta—a proof that converted James (later Sir James) Jeans and others into supporters of the quantum theory. In 1913 Niels Bohr also contributed greatly to its establishment through his quantum theory of the hydrogen atom. Ironically, Planck himself was one of the last to struggle for a return to classical theory, a stance he later regarded not with regret but as a means by which he had thoroughly convinced himself of the necessity of the quantum theory. Opposition to Einstein's radical light quantum hypothesis of 1905 persisted until after the discovery of the Compton effect in 1922.

Later life. Planck was 42 years old in 1900 when he made the famous discovery that in 1918 won him the Nobel Prize for Physics and that brought him many other honours. It is not surprising that he subsequently made no discoveries of comparable importance. Nevertheless, he continued to contribute at a high level to various branches of optics, thermodynamics and statistical mechanics, physical chemistry, and other fields. He was also the first prominent physicist to champion Einstein's special theory of relativity (1905). "The velocity of light is to the Theory of Relativity," Planck remarked, "as the elementary quantum of action is to the Quantum Theory; it is its absolute core." In 1914 Planck and the physical chemist Walther Hermann Nernst succeeded in bringing Einstein to Berlin, and after the war, in 1919, arrangements were made for Max von Laue, Planck's favourite student, to come to Berlin as well. When Planck retired in 1928, another prominent theoretical physicist, Erwin Schrödinger, the originator of wave mechanics, was chosen as his successor. For a time, therefore, Berlin shone brilliantly as a centre of theoretical physics—until darkness enveloped it in January 1933 with the ascent of Adolf Hitler to power.

In his later years, Planck devoted more and more of his writings to philosophical, aesthetic, and religious questions. Together with Einstein and Schrödinger, he remained adamantly opposed to the indeterministic, sta-

tistical worldview introduced by Bohr, Max Born, Werner Heisenberg, and others into physics after the advent of quantum mechanics in 1925–26. Such a view was not in harmony with Planck's deepest intuitions and beliefs. The physical universe, Planck argued, is an objective entity existing independently of man; the observer and the observed are not intimately coupled, as Bohr and his school would have it.

Planck became permanent secretary of the mathematics and physics sections of the Prussian Academy of Sciences in 1912 and held that position until 1938; he was also president of the Kaiser Wilhelm Society (now the Max Planck Society) from 1930 to 1937. These offices and others placed Planck in a position of great authority, especially among German physicists; seldom were his decisions or advice questioned. His authority, however, stemmed fundamentally not from the official appointments he held but from his personal moral force. His fairness, integrity, and wisdom were beyond question. It was completely in character that Planck went directly to Hitler in an attempt to reverse Hitler's devastating racial policies, and that he chose to remain in Germany during the Nazi period to try to preserve what he could of German physics.

Planck was a man of indomitable will. Had he been less stoic, and had he had less philosophical and religious conviction, he could scarcely have withstood the tragedies that entered his life after age 50. In 1909, his first wife, Marie Merck, the daughter of a Munich banker, died after 22 years of happy marriage, leaving Planck with two sons and twin daughters. The elder son, Karl, was killed in action in 1916. The following year, Margarete, one of his daughters, died in childbirth, and in 1919 the same fate befell Emma, his other daughter. World War II brought further tragedy. Planck's house in Berlin was completely destroyed by bombs in 1944. Far worse, the younger son, Erwin, was implicated in the attempt made on Hitler's life on July 20, 1944, and in early 1945 he died a horrible death at the hands of the Gestapo. That merciless act destroyed Planck's will to live. At war's end, American officers took Planck and his second wife, Marga von Hoesslin, whom he had married in 1910 and by whom he had had one son, to Göttingen. There, on October 4, 1947, in his 89th year, he died. Death, in the words of James Franck, came to him "as a redemption."

BIBLIOGRAPHY. Technical books that treat Planck's work and the history of quantum physics include MAX JAMMER, *The Conceptual Development of Quantum Mechanics* (1966); EDMUND T. WHITTAKER, *A History of the Theories of Aether and Electricity*, rev. and enlarged ed., vol. 2, *The Modern Theories: 1900–1926* (1954); HANS KANGRO, *Early History of Planck's Radiation Law* (1976); ARMIN HERMANN, *The Genesis of Quantum Theory (1899–1913)* (1971); THOMAS S. KUHN, *Black-Body Theory and the Quantum Discontinuity: 1894–1912* (1978); JAGDISH MEHRA and HELMUT RECHENBERG, *The Historical Development of Quantum Theory*, 4 vol. (1982); and ROGER H. STUEWER, *The Compton Effect: Turning Point in Physics* (1975). Nontechnical books include BARBARA LOVETT CLINE, *The Questioners: Physicists and the Quantum Theory* (1965); EMILIO SEGRÈ, *From X-Rays to Quarks: Modern Physicists and Their Discoveries* (1980); and ALEX KELLER, *The Infancy of Atomic Physics: Hercules in His Cradle* (1983). Especially noteworthy are three articles by MARTIN J. KLEIN, "Max Planck and the Beginnings of Quantum Theory," *Archive for History of Exact Sciences*, 1:459–479 (1962), "Planck, Entropy, and Quanta, 1901–1906," *The Natural Philosopher*, 1:83–108 (1963), and "Thermodynamics and Quanta in Planck's Work," *Physics Today*, 19:23–32 (1966). Planck described his life and work in his *Scientific Autobiography, and Other Papers* (1949). Insights may be found in the obituary notices of Planck by MAX BORN, *Obituary Notices of Fellows of the Royal Society of London*, 6:161–188 (1948–49); JAMES FRANCK, *Science*, 107:534–537 (1948); WALTER MEISSNER, *Science*, 113:75–81 (1951); and LISE MEITNER, "Max Planck als Mensch," *Naturwissenschaften*, 45:406–408 (1958). The short biography by HANS KANGRO in the *Dictionary of Scientific Biography*, vol. 11, pp. 7–17 (1975), is excellent. ARMIN HERMANN, *Max Planck in Selbstzeugnissen und Bilddokumenten* (1973); and HANS HARTMANN, *Max Planck als Mensch und Denker* (1953), are biographies in German. See also HENRY LOWOOD (comp.), *Max Planck: A Bibliography of His Non-Technical Writings* (1977), listing more than 600 articles published between 1879 and 1976; and ILSE ROSENTHAL-SCHNEIDER, *Reality and Scientific Truth: Discussions with Einstein, von Laue, and Planck* (1980). Plants

Plants, as members of the kingdom Plantae, share the following features common to all living things. Their cells undergo complex metabolic reactions that result in the production of chemical energy, nutrients, and new structural components. They respond to internal and external stimuli in a self-preserving manner. They reproduce by passing their genetic information to descendants that resemble them. They have evolved over geologic time by the process of natural selection into a wide array of forms and life-history strategies.

Plants range in size from diminutive duckweeds only a few millimetres in length to the giant sequoias of California that reach 90 metres (300 feet) or more in height. There are approximately 275,000 to 300,000 different species of plants, and new species are continuously being described, particularly from unexplored tropical areas of the world. Having evolved from aquatic ancestors, plants have subsequently migrated over the entire surface of the Earth, inhabiting tropical, Arctic, desert, and Alpine regions. Some plants have returned to an aquatic habitat in either fresh or salt water.

Plants play a vital role in the maintenance of life on Earth. All energy used by living organisms depends on the complex process of photosynthesis, which is carried out by green plants. Radiant energy from the Sun is transformed into organic chemical energy in the form of sugar through a fundamental series of chemical reactions called photosynthesis. In nature all food chains begin with green plants (primary producers). Primary producers, represented by trees, shrubs, and herbs, are a prolific source of energy in the form of carbohydrates (sugars) stored in

the leaves. These carbohydrates, produced in photosynthesis, are broken down in a process called respiration; the smaller units of the sugar molecule and its products fuel numerous metabolic processes. Various parts of the plant (e.g., leaves) are the energy sources that support animal life in different community habitats. A by-product of photosynthesis, oxygen, is essential to animals.

The daily existence of human beings is also directly influenced by plants. Plants furnish food and flavourings; raw materials for industry, such as wood, resins, oils, and rubber; fibres for the manufacture of fabrics and cordage; medicines; insecticides; and fuels. More than half of the Earth's population relies on the grasses rice, corn (maize), and wheat as their primary source of food. Apart from their commercial and aesthetic value, plants conserve other natural resources by protecting soils from erosion, by controlling water levels and quality, and by producing a favourable atmosphere.

The following article summarizes the morphological, physiological, and ecological features of plants. The principal focus is on structure and function, physiology, life histories, and ecology, and on how the various plant groups have evolved, dispersed, and become adapted to life on land. The features that define each major plant group and the role they play in the wider ecosystem also are discussed.

For further information, see PHOTOSYNTHESIS and BIOCHEMICAL COMPONENTS OF ORGANISMS.

DEFINITION OF THE KINGDOM

The kingdom Plantae includes organisms that range in size from a tiny moss to a giant tree. Despite this enormous variation, all plants are multicellular and eukaryotic (i.e., each cell possesses a membrane-bound nucleus that contains the chromosomes). They generally possess pigments (chlorophylls *a* and *b* and carotenoids), which play a central role in converting the radiant energy of sunlight into chemical energy (in the form of sugar) by means of photosynthesis. Plants, therefore, are independent in their nutritional needs (autotrophic) and store their excess food in the form of macromolecules of starch. The relatively few plants that are not autotrophic have lost pigments and are dependent on other organisms for nutrients (parasitism). Plants are nonmotile organisms, although some produce motile cells (gametes) propelled by whiplike flagella. Plant cells are surrounded by a more or less rigid cell wall composed of the carbohydrate cellulose, and adjacent cells are interconnected by microscopic strands of cytoplasm called plasmodesmata, which traverse the cell walls. Many plants have the capacity for unlimited growth at localized regions

of cell division, called meristems. Plants, unlike animals, can use inorganic forms of the element nitrogen (N), such as nitrates and ammonia, and thus do not require an external source of protein (in which nitrogen is a major constituent) to survive.

The life histories of plants include two phases, or generations, one of which is diploid (the nuclei of the cells contain two sets of chromosomes), while the other is haploid (with one set of chromosomes). The diploid generation is known as the sporophyte, which literally means spore-producing plant. The haploid generation, called the gametophyte, produces the sex cells, or gametes. The complete life cycle of a plant thus involves an alternation of haploid and diploid generations. The sporophyte and gametophyte generations of plants are structurally quite dissimilar.

The concept of what constitutes a plant has undergone significant change over time. At one time the photosynthetic aquatic organisms commonly referred to as algae were considered members of the plant kingdom. The various major algal groups, such as the green algae, brown algae, and red algae, are now placed in the kingdom Pro-

Changes
in classification

tista because they lack one or more of the features that are characteristic of plants. The organisms known as fungi also were once considered to be plants since they reproduce by spores and possess a cell wall. The fungi, however, uniformly lack chlorophyll (thus they are heterotrophic) and are chemically distinct from the plants; they are now placed in a separate kingdom, Fungi.

The earliest plants undoubtedly evolved from an aquatic, green algal ancestor (as evidenced by similarities in pigmentation, cell wall chemistry, biochemistry, and method of cell division), and different plant groups have become adapted to terrestrial life to varying degrees. Land plants face severe environmental threats or difficulties, such as desiccation, drastic changes in temperature, support, nutrient availability to each of the cells of the plant, regulation of gas exchange between the plant and the atmosphere, and successful reproduction. Thus, many adaptations to land existence have evolved in the plant kingdom and are reflected among the different major plant groups. An example is the development of a waxy covering (the cuticle) that covers the plant body, preventing excess water loss. Specialized tissues and cells (vascular tissue) enabled early land plants to absorb and transport water and nutrients to distant parts of the body more effectively and, eventually, to develop a more complex body composed of organs called stems, leaves, and roots. The evolution and incorporation of the substance lignin into the cell walls of plants provided strength and support. Details of the life history are often a reflection of a plant's adaptation to a terrestrial mode of life and may characterize a particular group; for example, the most highly evolved plants reproduce by means of seeds, and, in the most advanced of all plants (angiosperms), a reproductive organ called a flower is formed.

NONVASCULAR PLANTS

Definition of the category. The plant division Bryophyta includes tiny plants that lack specialized vascular tissue (xylem and phloem) for internal water and food conduction and support. Bryophytes are, therefore, nonvascular plants and, correlatively, possess no true roots, stems, or leaves. Some larger mosses, however, contain a central core of elongated, thick-walled cells called hydroids that are involved in water conduction and that have been compared to the xylem elements of other plants. The Bryophyta are second in diversity among the land plants only to the flowering plants (angiosperms) and are generally regarded as composed of three classes; some evidence indicates, however, that these groups may not be so closely related: Musci (the mosses), Hepaticae (the liverworts), and Anthocerotae (the hornworts).

Since bryophytes generally lack conducting cells and a well-developed cuticle that would limit dehydration, they depend on their immediate surroundings for an adequate supply of moisture. As a result, most bryophytes live in moist or wet, shady locations, growing on rocks, trees, and soil. Some, however, have become adapted to totally aquatic habitats; others have become adapted to alternately wet and dry environments by growing during wet periods and becoming dormant during dry intervals. Although bryophytes are widely distributed, occurring in practically all parts of the world, none are found in salt water. Ecologically, some mosses are considered pioneer plants because they can invade bare areas.

Bryophytes are typically land plants but seldom attain a height of more than a few centimetres. They possess the photosynthetic pigment chlorophyll (both *a* and *b* forms) and carotenoids in cell organelles called chloroplasts. The life histories of these plants show a well-defined alternation of generations, with the independent and free-living gametophyte as the dominant photosynthetic phase in the life cycle. (This is in contrast to the vascular plants, in which the dominant photosynthetic phase is the sporophyte.) The sporophyte generation develops from, and is almost entirely parasitic on, the gametophyte. The gametophyte produces multicellular sex organs (gametangia). Female gametangia are called archegonia; and male gametangia, antheridia. At maturity, archegonia each contain one egg, and antheridia produce many sperm. Because the egg is

retained and fertilized within the archegonium, the early stages of the developing sporophyte are protected and nourished by the gametophytic tissue. The young undifferentiated sporophyte is called an embryo. Although bryophytes have become adapted to life on land, an apparent vestige of their aquatic ancestry is that the motile (flagellated) sperm depend on water to effect gamete transport and fertilization.

Bryophytes are widely believed to have evolved from complex green algae that invaded land more than 400 million years ago. Bryophytes share some traits with green algae, such as motile sperm, similar photosynthetic pigments, and the general absence of vascular tissue. However, bryophytes have multicellular reproductive structures, whereas those of green algae are unicellular, and bryophytes are mostly terrestrial and have complex plant bodies, while the green algae are primarily aquatic and have less complex forms. An alternative view envisions the bryophytes as directly derived from early vascular plants or as an early offshoot of the lineage that gave rise to vascular plants.

Representative members. *Class Musci.* Moss is a term erroneously applied to many different plants (Spanish moss, a flowering plant; Irish moss, a red alga; pond moss, filamentous algae; and reindeer moss, a lichen). Mosses are classified as the class Musci in the division Bryophyta. Two major groups of mosses are recognized, the true mosses and the commercially important peat mosses (*Sphagnum*). (The granite mosses form a small group comprising the genera *Andreaea* and *Andreaebryum*.) *Sphagnum* often grows in dense mats in acidic boglands. Because the peat mosses are very absorbent, they are widely used to improve soil texture and to surround plant roots during shipment and replanting in order to prevent desiccation.

The moss gametophyte possesses leaflike structures (phylloids) that usually are a single cell layer thick, have a costa (midrib), and are spirally arranged on a stemlike axis (caulid). The moss gametophyte is an independent plant and is the familiar, erect "leafy" shoot. Multicellular rhizoids anchor the gametophyte to the substrate. The sporophyte plant develops from the tip of the fertile leafy shoot. After repeated cell divisions, the young sporophyte (embryo) transforms into a mature sporophyte consisting of foot, elongate seta, and capsule. The capsule is often covered by a calyptra, which is the enlarged remains of the archegonium. The capsule is capped by an operculum (lid), which falls off, exposing a ring of teeth (the peristome) that regulates the dispersal of spores.

Class Hepaticae. Liverworts, the second major class of bryophytes, are found in the same types of habitat as mosses, and species of the two classes are often intermingled on the same site. The curious name "liverwort" is a relic of the medieval belief in the "doctrine of signatures," which held that the external form of a plant provided a clue to which diseased body organ could be cured by a preparation made from that particular plant. There are two types of liverworts (also called hepatics) based on reproductive features and thallus structure. The more numerous "leafy" liverworts superficially resemble mosses, but most notably differ in having lobed or divided leaves that are without a midrib and which are positioned in three rows. Thalloid (thallose) liverworts have a ribbonlike, or strap-shaped, body that grows flat on the ground. They have a high degree of internal structural differentiation into photosynthetic and storage zones. Liverwort gametophytes have unicellular rhizoids. Liverworts have an alternation of generations similar to that of mosses and, as with mosses, the gametophyte generation is dominant. The sporophytes, however, are not microscopic and are often borne on specialized structures. They sometimes resemble small umbrellas and are called antheridiophores and archegoniophores.

Class Anthocerotae. The third class of bryophytes comprises the hornworts, a minor group numbering fewer than 100 species. The gametophyte is a small, ribbonlike thallus that resembles a thallose liverwort. The name hornwort is derived from the unique, slender, upright sporophytes, which are about three to four centimetres long at maturity and dehisce longitudinally into two valves that twist in

Moss

response to changing humidity, thereby releasing spores in small numbers over a fairly long period of time.

VASCULAR PLANTS

Xylem and
phloem

Definition of the category. Vascular plants (tracheophytes) differ from the nonvascular bryophytes in that they possess specialized supporting and water-conducting tissue, called xylem, and food-conducting tissue, called phloem. The xylem is composed of nonliving cells (tracheids and vessel elements) that are stiffened by the presence of lignin, a hardening substance that reinforces the cellulose cell wall. The living sieve elements that comprise the phloem are not lignified. Xylem and phloem are collectively called vascular tissue and form a central column (stele) through the plant axis. The ferns, gymnosperms, and flowering plants are all vascular plants. Because they possess vascular tissues, these plants have true stems, leaves, and roots. Before the development of vascular tissues, the only plants of considerable size existed in aquatic environments where support and water conduction were not necessary. A second major difference between the vascular plants and bryophytes is that the larger, more conspicuous generation among vascular plants is the sporophytic phase of the life cycle.

The vegetative body of vascular plants is adapted to terrestrial life in various ways. In addition to vascular tissue, the aerial body is covered with a well-developed waxy layer (cuticle) that decreases water loss. Gases are exchanged through numerous pores (stomata) in the outer cell layer. The root system is involved in the uptake from the soil of water and minerals that are used by the root system as well as the stem and leaves. Roots also anchor the plant and store food. The stem conducts water and minerals absorbed by the root system upward to various parts of the stem and leaves; stems also conduct carbohydrates manufactured through the process of photosynthesis from the leaves to various parts of the stem and root system. Leaves are supported by the stem and are oriented in a manner conducive to maximizing the amount of leaf area involved in trapping sunlight for use in photosynthesis.

Modifications of roots, stems, and leaves have enabled species of vascular plants to survive in a variety of habitats encompassing diverse and even extreme environmental conditions. The ability of vascular plants to flourish in so many different habitats is a key factor in their having become the dominant group of terrestrial plants.

Major
divisions

The vascular plants are divisible into the nonseed plants (lower vascular plants, or cryptogams) and those that reproduce by seeds (higher vascular plants, or phanerogams). The ferns (Filicophyta) are a group of the lower vascular plants; other groups include the whisk ferns (Psilotophyta), club and spike mosses (Lycopphyta), and horsetails (Sphenophyta, or Arthropphyta). Collectively, the latter four groups are sometimes referred to as pteridophytes, since each reproduces by spores liberated from dehiscent sporangia (free sporing). Although the lower vascular plants have adapted to terrestrial life, they are similar to bryophytes in that, as an apparent vestige of their aquatic ancestry, all produce motile (flagellated) male gametes (antherozoids, or sperm) and must rely on water for fertilization to be effected.

Nonseed plants. *Division Filicophyta.* Ferns are a diverse group of plants technically classified in the division Filicophyta. Although they have a worldwide distribution, ferns are more common in tropical and subtropical regions. They range in size and complexity from small floating aquatic plants less than 2 centimetres long to tall tree ferns 20 metres (65 feet) high. Tropical tree ferns possess erect, columnar trunks and large, compound (divided) leaves more than 5 metres long. As a group, ferns are either terrestrial or epiphytic (growing upon another plant). Fern stems never become woody (composed of secondary tissue containing lignin) since all tissues of the plant body originate at the stem apex.

Ferns typically possess a rhizome (horizontal stem) that grows partially underground; the deeply divided fronds (leaves) and the roots grow out of the rhizome. Fronds are characteristically coiled in the bud (fiddleheads) and uncurl in a type of leaf development called circinate vernation. Fern leaves are either whole or variously divided.

The leaf types are differentiated into rachis (axis of a compound leaf), pinnae (primary divisions), and pinnules (ultimate segments of a pinna). Fern leaves often have prominent epidermal hairs and large chaffy scales. Venation of fern leaves is usually open dichotomous (forking into two equal parts).

Each frond is a potential sporophyll (spore-bearing leaf) and as such can bear structures that are associated with reproduction. When growth conditions are favourable, a series of brown patches appear on the undersurface of the sporophylls. Each one of the patches (called a sorus) is composed of many sporangia, or spore cases, which are joined by a stalk to the sporophyll. The spore case is flattened, with a layer of sterile, or nonfertile, cells surrounding the spore mother cells. Each spore mother cell divides by reduction division (meiosis) to produce haploid spores, which are shed in a way characteristic to the ferns.

Spores

Each fern spore has the potential to grow into a green, heart-shaped, independent gametophyte plant (prothallus) capable of photosynthesis. In contrast to bryophytes, in which the sporophyte is nutritionally dependent on the gametophyte during its entire existence, the fern sporophyte is dependent on the gametophyte for nutrition only during the early phase of its development; thereafter, the fern sporophyte is free-living. In some ferns the sexes are separate, meaning a gametophyte will bear only male or female sex organs. Other species have gametophytes bearing both sex organs. Features important in the identification of ferns include such aspects of the mature sporophyte plant as differences in the stem, frond, sporophyll, sporangium, and position of the sporangium and the absence or presence, as well as shape, of the indusium (a membranous outgrowth of the leaf) covering the sporangia.

Division Psilotophyta. Psilotophyta (whisk ferns) is a division represented by two living genera (*Psilotum* and *Tmesipteris*) and several species that are restricted to the subtropics. This unusual group of small herbaceous plants is characterized by a leafless and rootless body possessing a stem that exhibits a primitive dichotomous type of branching: it forks into equal halves. The photosynthetic function is assumed by the stem, and the underground rhizome anchors the plant. The vascular tissue is organized into a poorly developed central cylinder in the stem.

Division Lycopphyta. This division is represented by four or more living genera, with the principal genera being *Lycopodium* (club mosses), *Selaginella* (spike mosses), and *Isoetes* (quillworts). Extant members of Lycopphyta occur in both temperate and tropical regions and represent the survivors of a group of vascular plants that was extremely diverse and numerous. As a group, the lycopods were prominent in the great coal-forming swamp forests of the Carboniferous Period (360 to 280 million years ago). Although all living lycopods are small herbaceous plants, some extinct types were large trees. Lycopods are differentiated into stem, root, and leaf (microphylls). Sporangia are positioned on the upper (adaxial) surface of the leaf (sporophyll). Some species form distinct cones or strobili, while others do not.

Division Sphenophyta. Sphenophyta (also called horsetails and scouring rushes) is a division represented by a single living genus (*Equisetum*). It has a worldwide distribution but occurs in greater variety in the Northern Hemisphere. Like the lycopods, the sphenophytes were a diverse and prominent group of vascular plants during the Carboniferous Period, when some genera attained great size in the coal-forming swamp forests. Sphenophytes are differentiated into stem, leaf (microphylls), and root. Green aerial stems have longitudinal ridges and furrows extending the length of the internodes, and stems are jointed (articulated). Surface cells are characteristically filled with silica. Branches, when they occur, are borne in whorls at the node, as are the scale leaves. Sporangia are borne in terminal strobili. The Sphenophyta are an independent line of vascular plant evolution that had its origin in the Devonian Period (408 to 360 million years ago).

Seed plants. Gymnosperms and angiosperms (flowering plants) share with ferns a dominant, independent sporophyte generation; the presence of vascular tissue; differentiation of the plant body into root, stem, and leaf

derived from a bipolar embryo (having stem and root-growing apices); and similar photosynthetic pigments. Unlike ferns, however, the seed plants have stems that branch laterally and vascular tissue that is arranged in strands (bundles) around the pith (eustele). Among seed plants, as in ferns, the stem tissues that arise directly from the shoot apex are called primary tissues. Primary tissues contribute to the longitudinal growth of the stem, or primary growth. Secondary growth, resulting in an increase in the width of the axis, is produced by meristematic tissue between the primary xylem and phloem called vascular cambium. This meristem consists of a narrow zone of cells that form new secondary xylem (wood) and secondary phloem (secondary vascular tissues).

Major evolutionary advancements of these plants are demonstrated by the generally more complex plant body and by reproduction via seeds. Seeds represent an important evolutionary innovation within the plant kingdom. Each seed has an embryonic plant (sporophyte), food-storage tissue, and hardened protective covering (seed coat). The seed thus contains and protects the embryonic plant and, as the primary dispersal unit of the seed plants, represents a significant improvement over the spore, with its limited capacity for survival.

In comparing ferns and seed plants and their life histories, certain significant differences are seen. The gametophyte in seed plants has been reduced in size, usually consisting of a few to a dozen cells. Thus, it is no longer itself a plant body, as in the bryophytes and ferns. The gametophyte is not free-living but is embedded in the sporophyte and is thus less vulnerable to environmental stress than the gametophytes of bryophytes and ferns. Finally, the spores of seed plants are male and female, as are the sporangia that contain them. The spores are not dispersed as in the bryophytes and ferns but develop into gametophytes within the sporangia. In the most advanced seed plants, the male gametes (sperm) are carried to the egg by a later extension of the pollen grain called the pollen tube. The advantage of this system is that the nonflagellated sperm are no longer dependent on water to reach the egg.

Another terrestrial adaptation of the seed plants not found in ferns is pollen dispersed by wind or animals. Pollen is a unit of genetic material as well as part of the seed formation process. The dispersal of pollen by wind or insects, in addition to dispersal of seeds, promotes genetic recombination and distribution of the species over a wide geographic area.

Gymnosperms. The term gymnosperm ("naked seeds") represents four extant divisions of vascular plants whose ovules (seeds) are exposed on the surface of cone scales. The cone-bearing gymnosperms are among the largest and oldest living organisms in the world. They dominated the landscape about 200 million years ago. Today gymnosperms are of great economic value as major sources of lumber products, pulpwood, turpentine, and resins.

Conifer stems are composed of a woody axis containing primitive water- and mineral-conducting cells called tracheids. Tracheids are interconnected by passages called bordered pits. Leaves are often needlelike or scalelike and typically contain canals filled with resin. The leaves of pine are borne in bundles (fascicles), and the number of leaves per fascicle is an important distinguishing feature. Most gymnosperms are evergreen, but some, such as larch and bald cypress, are deciduous (the leaves fall after one growing season). The leaves of many gymnosperms are adapted to water conservation in having a thick cuticle and in having a stomata below the leaf surface.

The tree or shrub is the sporophyte generation. In conifers, the male and female sporangia are produced on separate structures called cones or strobili. Individual trees are typically monoecious (male and female cones are borne on the same tree). A cone is a modified shoot with a single axis, on which is borne a spirally arranged series of pollen- or ovule-bearing scales or bracts. The male cone, or microstrobilus, is usually smaller than the female cone (megastrobilus) and is essentially an aggregation of many small structures (microsporophylls) that encase the pollen in microsporangia.

The extant cycads (division Cycadophyta) are a group of

ancient seed plants that are survivors of a complex which has existed since the Mesozoic Era (beginning 245 million years ago). They are presently distributed in the tropics and subtropics of both hemispheres. Cycads are palmlike in general appearance, with an unbranched, columnar trunk and a crown of large, pinnately compound (divided) leaves. The sexes are always separate, resulting in male and female plants (*i.e.*, cycads are dioecious). Most species produce conspicuous cones (strobili) on both male and female plants, and the seeds are very large.

The ginkgophytes (division Ginkgophyta), although abundant, diverse, and widely distributed in the past, are represented now by a sole surviving species, *Ginkgo biloba* (maidenhair tree). The species was formerly restricted to southeastern China, but it is now probably extinct in the wild. The plant is commonly cultivated worldwide, however, and is particularly resistant to disease and air pollution. The ginkgo is multibranched, with stems that are differentiated into long shoots and dwarf (spur) shoots. A cluster of fan-shaped, deciduous leaves with open dichotomous venation occurs at the end of each lateral spur shoot. Sexes are separate, and distinct cones are not produced. Female trees produce plumlike seeds with a fleshy outer layer and are noted for their foul smell when mature.

The gnetophytes (division Gnetophyta) comprise a group of three unusual genera. *Ephedra* occurs as a shrub in dry regions in tropical and temperate North and South America and in Asia, from the Mediterranean Sea to China. Species of *Gnetum* occur as woody shrubs, vines, or broad-leaved trees and grow in moist tropical forests of South America, Africa, and Asia. *Welwitschia*, restricted to extreme deserts (less than 25 millimetres [1 inch] of rain per year) in a narrow belt about 1,000 kilometres (600 miles) long in southwestern Africa, is an unusual plant composed of an enormous underground stem and a pair of long, strap-shaped leaves that lie along the ground. The three genera differ from all other gymnosperms in possessing vessel elements (as compared to tracheids) in the xylem and in specializations in reproductive morphology. The gnetophytes have figured prominently in the theories about gymnospermous origins of the angiosperms.

Angiosperms. Approximately 130 million years ago flowering plants (angiosperms) evolved from gymnosperms, although the identity of the specific gymnospermous ancestral group remains unresolved. The primary distinction between gymnosperms and angiosperms is that angiosperms reproduce by means of flowers. Flowers are modified shoots bearing a series of leaflike, modified appendages and containing ovules (immature seeds) surrounded and protected by the female reproductive structure, the carpel or pistil. Along with other features, angiospermy, the enclosed condition of the seed, gave the flowering plants a competitive advantage and enabled them to come to dominate the extant flora. Flowering plants have also fully exploited the use of insects and other animals as agents of pollination (the transfer of pollen from male to female floral structures). In addition, the water-conducting cells and food-conducting tissue are more complex and efficient in flowering plants than in other land plants. Finally, flowering plants possess a specialized type of nutritive tissue in the seed, endosperm. Endosperm is the chief storage tissue in the seeds of grasses; hence, it is the primary source of nutrition in corn, rice, wheat, and other cereals that have been utilized as major food sources by humans and other animals.

The flowering plants are represented by two divergent evolutionary lines, the monocotyledons and the dicotyledons, treated as separate classes within the division. These two major groups are distinguished by the number of embryonic seed leaves (cotyledons), arrangement of vascular tissue in the stem, leaf venation, and manner of leaf attachment to the stem. A further distinction between the two is in the number of flower parts. Generally, monocots have flower parts in multiples of three, and dicots have flower parts in multiples of four or five. The pollen of monocots is uniaperturate (with a single germinal aperture or germ pore), whereas the pollen of dicots is most commonly triaperturate or a derived form.

The plant body of angiosperms consists of a central axis

Seeds

Naked seeds

Ginkgo

of two parts, the shoot and root. Shoots have two kinds of organs, the stem and the leaves, while roots have one type of organ, the root itself. Systems of classification are often based upon the longevity of the portions of plant above ground. Woody plants are trees and shrubs whose shoots are durable and survive over a period of years. They are further classified into deciduous and evergreen plants. Deciduous plants drop their leaves at the end of every growing season, while evergreens keep their leaves until the leaves of the following year are produced. Herbaceous plants have soft, flexible aerial portions that die each year.

Annuals,
biennials,
and
perennials

Another system of classification, based on the duration of the life history, is particularly applicable to angiosperms of the temperate region. Annuals are plants that complete the entire life history (germinate from seeds, mature, flower, and produce seed) in one growing season. Examples of annuals are corn, wheat, peas, and tobacco. Biennials complete their life history in two seasons, blooming during the second season. Beets, celery, cabbage, carrots, and turnips are biennials, but their flowers are rarely seen since they are harvested during the first season. Annuals and biennials are both generally herbaceous plants. Perennials are plants that live from year to year. Trees and shrubs are perennial, but some herbaceous plants are also perennials.

A number of modifications of the stem occur in angiosperms, and many of these modifications provide a means for herbs to become dormant and survive for a period of years. Rhizomes are horizontally growing underground stems that serve as organs of asexual reproduction and food storage. Tubers are rhizomes with thickened portions (for example, the Irish potato). Corms are short, upright underground stems surrounded by a few thin scale leaves (as in *Crocus* and *Gladiolus*). Bulbs have a greatly reduced stem with thick, fleshy scale leaves surrounding it (as in the onion). Runners are thin, surface stems characteristic of such plants as strawberries; new plants may form on the runner as it spreads along the ground. Stolons are like runners and extend along the ground. Many of the most prolific weeds have stolons by which they propagate asexually.

In herbaceous dicotyledonous stems the vascular conducting tissue (xylem and phloem) is organized into discrete strands or vascular bundles, each containing both xylem and phloem. The cells between the vascular bundles are thin-walled and often store starch. The peripheral region of cells in the stem is called the cortex; cells of the central portion make up the pith. The outermost cells of the stem compose the epidermis. No bark is formed on the herbaceous stem. In contrast, woody dicot stems develop an outer layer of dead, thick-walled cells called cork cells, which together with the underlying phloem compose the bark of the tree. The major portion of the woody stem's diameter is a cylinder of xylem (wood) that originates from a region of cell division called the vascular cambium. The water-conducting cells that make up the xylem are nonliving. The accumulated xylem forms annual rings composed of two zones: a relatively wide zone of spring wood (made up of large cells, characteristic of rapid growth) and a narrower zone of summer wood (smaller cells). Xylem rays, radiating like spokes of a wagon wheel, are formed in the xylem and connect with the peripheral phloem. Stems of monocotyledons are composed of numerous vascular bundles that are arranged in a seemingly scattered manner within the ground tissue. Monocot vascular bundles lack a vascular cambium, and thus monocot stems do not become woody in a manner comparable to dicots.

Leaves and
roots

Leaves are the other plant organ that, along with stems, constitutes the shoot of the vascular plant body. Their principal function is to act as the primary site of photosynthesis in the plant. Leaves of dicots possess a network of interconnecting veins and veinlets between the larger veins of the leaf (a pattern called net venation). Leaves of monocots possess major veins that extend parallel to the long axis of the leaf (parallel venation). Leaves are classified based on leaf arrangement and on whether they are simple or compound. A leaf may be deeply lobed but still simple; a compound leaf is composed of two or more distinctly separate leaflets.

Structurally, leaves are composed of an outermost layer of cells called the epidermis. Epidermal cells secrete a waxy substance (cutin) that forms a cuticle impermeable to water. The pores (stomates) in the epidermis that allow for gas exchange are formed between specialized epidermal cells called guard cells. Vascular bundles (veins) are embedded in the mesophyll, the tissue that includes all of the cells between the upper and lower epidermis. The cells of the mesophyll contain the photosynthetic pigments.

The root system begins its development from the embryonic root (radicle), which grows out of the seed after the seed has absorbed water. This is the primary root of a new plant. The tip of the root is covered by a mass of loose cells called the root cap. Just beneath the root cap is the region of cell division of the root. Epidermal outgrowths just above the root tip are root hairs that are active in water and mineral absorption. Two types of root system are commonly distinguished, fibrous roots and taproots. Fibrous root systems are composed of large numbers of roots nearly equal in size; root systems of this type are found, for example, in the grasses. A taproot system is one in which the primary root remains the largest, and a number of smaller secondary roots are formed from it; taproots are found in such plants as carrots and dandelions. Roots that arise other than by branching from the primary roots are called adventitious roots. The prop roots of corn, for example, are adventitious.

Flowers

As noted above, a primary distinction between the gymnosperms and angiosperms is that the latter have flowers. Flowers represent modified shoots that have become differentiated for reproduction. The flower bears whorls of floral organs attached to a receptacle, the expanded end of a flower stalk on which the flower parts are borne. Sepals (collectively called the calyx) are modified leaves that encase the developing flower. They are sterile floral parts and may be either green or leaflike or composed of petallike tissue. Petals (collectively called the corolla) are also sterile floral parts that usually function as visually conspicuous elements serving to attract specific pollinators to the flower. The calyx and corolla together are referred to as the perianth. Flowers that lack one or both of the above perianth parts are called incomplete. Stamens (collectively called the androecium) are the male parts of the flower. Stamens are composed of saclike anthers (microsporangia) and filaments, which are stalks that support the anthers. Anthers are usually compartmentalized and contain the pollen grains (microgametophytes). The pistil, or female part of the flower, is composed of one or a number of carpels (collectively called the gynoecium) that fuse to form an essentially enclosed chamber. The three regions of the pistil (from the base up) are the ovary, which contains the ovules; the style, a stalked structure atop the ovary that elevates the stigma; and the stigma, a sticky knob whose surface receives the pollen during pollination.

Flowers may contain both male and female parts (a condition called perfect) or parts related to just one sex (imperfect), or they may have no sexual parts (sterile). Female and male flowers may be located on separate plants (dioecious) or on the same plant (monoecious). Flowers can also be borne singly or in aggregations called inflorescences.

Primitive flowers are radially symmetrical (actinomorphic) and characterized by numerous spirally arranged floral parts. Floral parts are free (unfused) and borne on an elongated floral axis. Sepals, petals, and stamens are attached below the ovary. Advanced flowers are bilaterally symmetrical and are characterized by a reduction in the number of floral parts. Floral parts are fused (often forming a long floral tube). Sepals, petals, and stamens are attached to the floral tube above the ovary.

Pollination is the transfer of pollen to the stigma of the same or another flower. Agents of pollination encompass a vast and diverse array of animals, including insects, birds, bats, and slugs. Flowers exhibit various adaptations to pollinators, such as showy corollas, the production of nectar (a sugary liquid), and even visual cues visible only to insects that can perceive ultraviolet wavelengths of light. Flowers pollinated by wind generally are small and lack petals. The stigma is the pollen receptor site and must be

chemically compatible with any pollen that lands on it for the pollen grain to germinate. This ensures that only genetically compatible sperm are transferred to the egg.

Fruits and seeds

In flowering plants, ovules are enclosed and protected in an ovary. As the ovule develops into a seed, the ovary matures into a fruit. The formation of fruits is a characteristic feature of the flowering plants. Fruits are extremely variable. In some fruits the ovary wall (pericarp) is thick and fleshy; in others it is thin and dry.

Angiosperms have evolved many different adaptations for seed dispersal involving such agents as wind, water, and animals. Adaptations to wind dispersal include wings or plumes attached to the seed or as part of the fruit, or simply very minute seeds that are easily windborne. Adaptations to water dispersal are seeds that float or fruits that float and carry the seeds with them. Some seeds are a source of food to animals, which bury the seeds in the ground, where they later germinate. Other plants produce a fleshy fruit that is eaten along with the seeds inside it by animals, which pass the seeds through their digestive tracts unharmed. Another adaptation for animal dispersal is the development of barbed fruits or seeds that stick to the coats or skins of wandering animals. Some plants, such as witch hazels or jewelweed, can project their seeds through the air some distance from the parent plant.

Seeds have many adaptations that enable them to survive long periods of harsh conditions. Seeds can remain viable in a dormant condition for a few days or, in some species, for hundreds of years. (W.C.D.)

REPRODUCTION AND LIFE HISTORIES

Each organism from inception to death goes through a sequence of genetically programmed developmental events constituting a life history. In eukaryotic organisms, development involves cellular events such as mitosis, meiosis, and syngamy (fertilization), which variously proceed by nuclear division (karyokinesis), cytoplasmic division (cytokinesis), cytoplasmic fusion without the union of nuclei (plasmogamy), or nuclear fusion (karyogamy).

This discussion focuses on the life histories of land plants—that is, nonvascular (bryophytes) and vascular plants, the latter comprising nonseed vascular plants (pteridophytes) and seed plants (gymnosperms and angiosperms). Although algae and fungi were traditionally regarded as plants, fungi are now universally considered as constituting the kingdom Fungi, whereas algae are often included in the kingdom Protista.

Life histories. The chromosome number in cells may be haploid, with one set of chromosomes per cell (written $1n$); diploid, with two sets ($2n$); polyploid, with three or more sets; or dikaryotic, with a pair of nuclei in a cell ($n + n$), a condition that occurs mainly in fungi. Three types of sexual life histories have been recognized for the eukaryotic organisms: $1n$, or haplontic; $2n$, or diplontic; and $1n-2n$ ($2n-1n$). The former two types have collectively been called haplobiontic or monobiontic, because the life histories include only one phase; the third type has been called haplodiplontic, diplohaplontic, diplobiontic, dibiontic, or sporic, because the life history involves two alternating multicellular phases, or generations. Algae and fungi have many variants of all three types, especially the first, while land plants have the third type exclusively. In addition, all land plants are strictly oogamous, having motile sperm and nonmotile eggs. (In contrast, the algae and fungi may be oogamous or, frequently, isogamous or anisogamous, the latter conditions characterized by morphologically similar gametes that are either of the same size or with the female gametes of a larger size, respectively.)

The $1n-2n$ life history of bryophytes and vascular plants comprises the entire sequence of developmental events from zygote formation via syngamy (fertilization) to spore formation via meiosis. Syngamy and meiosis are successive events in a sexual life history. Syngamy involves the union of two $1n$ gametes to form a $2n$ zygote, which eventually develops into a $2n$ sporophyte. Meiosis involves the division of a $2n$ sporocyte (meiocyte, spore mother cell, pollen mother cell) to produce four $1n$ spores. These four spores constitute a tetrad. Gametes are $1n$ cells that fuse to form a zygote, whereas spores are $1n$ cells that de-

velop into gametophytes without uniting with another cell.

Syngamy and meiosis are generally inseparable and alternate; consequently, the sporophyte develops from a zygote formed via syngamy, whereas the haploid gametophyte results after the sporophyte undergoes meiosis to form spores. These two phases, or generations, are multicellular in land plants. This type of life history involves an alternation of generations, a phenomenon not occurring in haplobiontic ($1n$ or $2n$) life histories. In the latter, such alternation is evident in both the morphological and the nuclear (chromosomal) changes that occur.

Meiosis and syngamy (fertilization) are the critical events that separate the sporophytic and gametophytic generations. (All nonmeiotic cell divisions involved in development are mitotic, in which chromosomes replicate, giving each daughter cell a full complement.) The zygote is the first stage and the sporocyte the last stage of the sporophytic generation, whereas the spore is the first stage and the gametes (eggs, sperm) the last stage of the gametophytic generation. The sporocytes of the multicellular $2n$ sporophyte divide meiotically to form $1n$ spores (sporogenesis). Each meiotic division results in a tetrad of four spores. (The land plants produce only sexual spores resulting from meiosis.) Each spore divides mitotically to form a multicellular $1n$ gametophyte, which eventually produces gametes mitotically (gametogenesis). The gametes (an egg and a sperm) fuse in the process of syngamy to form a $2n$ zygote. The zygote divides mitotically to form a multicellular embryo (embryogenesis), which is protected by either gametophytic tissues (such as remnants of archegonia in the nonseed land plants) or sporophytic tissues (the seed in the seed plants). An embryo, which is actually an immature sporophyte, is universally found among the land plants and often becomes dormant, but eventually grows into the mature sporophyte. During organogenesis in vascular plants the embryo develops into the mature sporophyte, with its vegetative organs (root and shoot, the latter consisting of stem and leaves) and reproductive structures (cones or strobili, flowers, etc.).

In all land plants, the two alternating generations are morphologically dissimilar, and the gametophyte is initially dominant over the sporophyte. In all bryophytes the gametophyte remains dominant, and the sporophyte is physiologically dependent on it. A homosporous life history, in which only one morphological type of spore is produced, is found in most bryophytes, although a few (e.g., *Macromitrium*) exhibit an anisoporous life history, in which the same sporangium produces morphologically similar spores of two different sizes.

In vascular plants, the sporophyte ultimately becomes physiologically independent of the gametophyte. A homosporous life history occurs in *Psilotum* (Psilotophyta), *Lycopodium* (Lycophyta), *Equisetum* (Sphenophyta), and most ferns (Filicophyta). A functionally heterosporous life history, in which the same sporangium produces morphologically similar but physiologically different spores, has been reported in a few pteridophytes—e.g., *Equisetum*. Finally, a heterosporous life history, in which different sporangia produce morphologically different types of spores, occurs in *Selaginella*, *Isoetes* (Lycophyta), a few aquatic ferns (Filicophyta), and all seed plants.

Homosporous life histories. A homosporous life history occurs in nearly all bryophytes and in most pteridophytes. It is characterized by morphologically identical spores that germinate to produce bisexual (both male and female) gametophytes in pteridophytes, but either bisexual or more usually unisexual (either male or female) gametophytes in bryophytes. Each mature gametophyte bears gametangia (sex organs) that produce gametes. Each antheridium (male gametangium) forms many motile, flagellate sperm, and each archegonium (female gametangium) forms one nonmotile egg. Fusion of an egg and sperm (syngamy) creates a zygote and restores the $2n$ ploidy level. Various mechanisms prevent the fusion of eggs and sperm from a bisexual gametophyte (inbreeding). For example, the sex organs may mature at different times (usually antheridia mature first), or inbreeding may be chemically or genetically inhibited. The zygote divides mitotically to form the embryo, which then develops into the sporophyte.

Morphological differences among generations

Syngamy and meiosis

Gametangia and gametes

This eventually produces sporangia, which bear meiocytes (sporocytes) that divide meiotically to form spores. The number of spores produced per sporangium ranges from 16 or 32 in some pteridophytes to more than 65,000,000 in some mosses. The sporangia may be borne in specialized structures, such as sori in ferns or as cones (strobili) in many other pteridophytes. The leaflike structures that bear sporangia are called sporophylls.

In most homosporous life histories of pteridophytes the spores are both morphologically and physiologically identical and produce bisexual gametophytes. In some species of horsetail (*Equisetum*) the spores may be physiologically different and produce male or female gametophytes. This uncommon situation is called functional heterospory and may represent the means by which the heterosporous condition (see below) in vascular plants evolved from the homosporous condition.

Anisosporous life histories. In anisosporous life histories, an unusual phenomenon in bryophytes, there is a size difference among spores produced in the same sporangium. Each meiotic division results in a tetrad of two small spores that produce male gametophytes and two larger spores that produce female gametophytes.

Heterosporous life histories. A heterosporous life history occurs in some pteridophytes and in all seed plants. It is characterized by morphologically dissimilar spores produced from two types of sporangia: microspores, or male spores, and megaspores (macrospores), or female spores. In pteridophytes, megaspores are typically larger than microspores, but the opposite is true in most seed plants.

The spores produce two types of gametophytes: each microspore develops into a microgametophyte (male gametophyte), which ultimately produces male gametes (sperm), and each megaspore produces a megagametophyte (female gametophyte), which ultimately produces female gametes (eggs). Fusion of an egg and a sperm creates a zygote and restores the $2n$ ploidy level. The zygote divides mitotically to form the embryo, which then develops into the sporophyte. Eventually the sporophyte produces sporangia, which bear sporocytes (meiocytes) that undergo meiosis to form spores. Microsporangia (male sporangia) produce microsporocytes (micromeiocytes) that yield microspores. Megasporangia (female sporangia) produce megasporocytes (megameiocytes) that yield megaspores. The sporangia may be borne in specialized structures such as sori in ferns, cones (strobili) in some pteridophytes and most gymnosperms, or flowers in angiosperms. The leaflike structures bearing microsporangia and megasporangia are called, respectively, microsporophylls and megasporophylls. In angiosperms these sporophylls represent, respectively, the stamens and carpels of the flower; in gymnosperms these sporophylls may constitute parts of, respectively, microstrobili (male cones, or pollen cones) and megastrobili (female cones, ovule cones, or seed cones).

The essential difference between the homosporous and heterosporous life history is the presence in the latter of two spore types (microspores and megaspores) and their concomitant precursory structures (microsporocytes and megasporocytes; microsporangia and megasporangia; etc.) and subsequent structures (microgametophytes and megagametophytes).

Variations involving seed plants. The gymnosperms and angiosperms not only lack some reproductive structures found in the homosporous and heterosporous pteridophytes but also have certain reproductive structures peculiar to the seed plants. Heterosporous pteridophytes, like their homosporous counterparts, have archegonia, antheridia, and motile, flagellate sperm. The seed plants completely lack antheridia, and of the extant groups only the ginkgo and the cycads have flagellate sperm. Archegonia occur in most gymnosperms except *Gnetum* and *Welwitschia*, but they are lacking in all angiosperms.

Pollen grains and pollen tubes (male reproductive structures), ovules and seeds (female reproductive structures), and seedlings are structures unique to all seed plants. The ovule is a single megasporangium (in seed plants this is called the nucellus) surrounded by one or two integuments (in rare cases, none or three) and containing inside the nucellus a single megasporocyte (spore mother cell).

The megasporocyte undergoes meiosis to form four megaspores, three of which typically degenerate, the remaining one developing into the megagametophyte (female gametophyte). Ovules never dehisce to release their megaspores, unlike the megasporangia of most pteridophytes. The pollen grain is the partly or completely developed microgametophyte (male gametophyte). It is usually multicellular, consisting of two or three cells in angiosperms and usually two to five cells in gymnosperms, although in conifers it is occasionally one cell (for example, the families Taxaceae and some Cupressaceae) or 6 to 43 cells (the families Araucariaceae and some Podocarpaceae).

During pollination, pollen is transferred from its source to a receptive surface: in gymnosperms from the microsporangium to the integument or, especially, the pollination droplet of the ovule (rarely to the cone scale); in angiosperms from the microsporangium (pollen sac) of the anther to the stigma of the carpel. Once pollen has reached the appropriate receptive source, it germinates to form the pollen tube, a structure that grows toward the megagametophyte and in so doing conveys the sperm directly to the egg. All angiosperms and most gymnosperms, except the ginkgo, cycads, and some fossil seed plants, lack swimming sperm. The presence of swimming sperm apparently represents a more primitive, transitional evolutionary condition. After fertilization, the ovule transforms into a seed. The integument or integuments become modified into the seed coat. The seed typically becomes dormant for a period of time before it germinates to produce a seedling.

Double fertilization is a phenomenon unique to angiosperms. Each pollen grain produces two sperm; one fuses with an egg to form the zygote, and the other fuses with one or more polar nuclei in the female gametophyte (megagametophyte, or also "embryo sac") to form an endosperm, which has a ploidy level that varies from $2n$ to $15n$. In approximately 70 percent of the known cases, the second sperm fuses with two endosperm nuclei to produce a $3n$ (triploid) endosperm. The endosperm is a special nutritive tissue for the embryo and, after seed germination, for the seedling. In contrast, the megagametophyte is the comparable nutritive tissue in the gymnosperms.

Asexual reproduction. Both homosporous and heterosporous life histories may exhibit various types of asexual reproduction (vegetative reproduction, somatic reproduction). Asexual reproduction is any reproductive process that does not involve meiosis or the union of nuclei, sex cells, or sex organs. Depending on the type of life history, asexual reproduction can involve the $1n$ or $2n$ generation.

The significance of sexual reproduction is that it is responsible for the genetic variation arising in a population as a result of the segregation and recombination of genetic material via meiosis and syngamy, respectively (the cells that result from sexual reproduction are genetically different from their parent cells). The significance of asexual reproduction is that it is a means for a rapid and significant increase in the numbers of individuals. (Weeds, for instance, are successful partly due to their great capacity for vegetative reproduction.) The cells that result from asexual reproduction are genetically identical to their parent cells. In addition, vegetative reproduction in the bryophytes and pteridophytes is a means of bypassing the somewhat lengthy and moisture-dependent sexual process—that is, the motile, swimming sperm characteristic of these groups require the presence of water, which may be a limiting factor in drier times.

Deviations from the usual life history. In most life histories, a $2n$ sporophyte typically alternates with a $1n$ gametophyte, but there are significant deviations. Apospory is the development of $2n$ gametophytes, without meiosis and spores, from vegetative, or nonreproductive, cells of the sporophyte. In contrast, apogamy is the development of $1n$ sporophytes without gametes and syngamy from vegetative cells of the gametophyte. The $2n$ aposporous gametophytes and $1n$ apogamous sporophytes are usually infertile under natural conditions because of disruption of cytological events. Various compensating genetic mechanisms, however, may occur to complete the life history. Parthenogenesis is the formation of a $1n$ embryo directly

Double fertilization

Significance of reproductive method

Structures unique to seed plants

from an unfertilized egg. Apospory and apogamy occur in bryophytes, pteridophytes, and angiosperms, whereas parthenogenesis occurs in ferns and angiosperms. Apogamy is more common in pteridophytes, but apospory is more common in bryophytes.

Some ferns (certain species of *Trichomanes* and *Vittaria*) have lost the ability to produce sporophytes. The species exist as gametophytes that spread by gemmae (units of asexual reproduction); although gametangia are produced, no sporophytes result. (Ru.Sc.)

PLANT PHYSIOLOGY

General features of plant nutrition. Plant nutrition includes the nutrients necessary for the growth, maintenance, and reproduction of individual plants; the mechanisms by which plants acquire such nutrients; and the structural, physiological, and biochemical roles these nutrients play in metabolism.

Mode of nutrition. All organisms obtain their nutrients from the environment, but not all organisms require the same nutrients, nor do they assimilate these nutrients in the same way. There are two basic nutritional types, autotrophs and heterotrophs. Heterotrophs require both inorganic and organic (carbon-containing) compounds as nutrient sources. Autotrophs obtain their nutrients from inorganic compounds, and their sole source of carbon is carbon dioxide (CO₂). An autotroph is photoautotrophic if light energy is required to assimilate CO₂ into the organic constituents of the cell. Furthermore, a photoautotroph that also uses water as a nutrient source and liberates oxygen in the energy-trapping process of photosynthesis is an oxygenic photoautotroph. The Earth's first such organisms are believed to have been the major sources of the present-day oxygen content of the atmosphere (approximately 21 percent). All plants, as well as many monerans and protists, are characteristically oxygenic photoautotrophs.

Plants, as autotrophic organisms, use light energy to photosynthesize sugars from CO₂ and water. They also synthesize amino acids and vitamins from carbon fixed in photosynthesis and from inorganic elements garnered from the environment. (Animals, as heterotrophic organisms, cannot synthesize many nutrients, including certain amino acids and vitamins, and so must take them from the environment.)

Essential elements and minerals. Certain key elements are required, or essential, for the complex processes of metabolism to take place in plants. Plant physiologists generally consider an element to be essential if the plant is unable to complete its life cycle (*i.e.*, grow and reproduce) in its absence; the particular structural, physiological, or biochemical roles of the element cannot be satisfied by any other element; and the element is directly involved in the plant's metabolism (*e.g.*, as part of an enzyme or other essential organic cellular constituent). Beneficial elements are those that stimulate plant growth by ameliorating the toxic effects of other elements or by substituting for an element in a less essential role (*e.g.*, as a nonspecific osmotic solute). Some elements are beneficial in that they are necessary for the growth of some, but not all, plant species.

The required concentrations of each essential and beneficial element vary over a wide range. The essential elements required in relatively large quantities for adequate growth are called macroelements. Nine minerals make up this group: carbon (C), hydrogen (H), oxygen (O), nitrogen (N), potassium (K), calcium (Ca), magnesium (Mg), phosphorus (P), and sulfur (S). Seven other essential mineral elements are required in smaller amounts (0.01 percent or less) and are called microelements. These are iron (Fe), chlorine (Cl), manganese (Mn), boron (B), copper (Cu), molybdenum (Mo), and zinc (Zn). The specific required percentages may vary considerably with species, genotype (or variety), age of the plant, and environmental conditions of growth.

A macronutrient is the actual chemical form or compound in which the macroelement enters the root system of a plant. The macronutrient source of the macroelement nitrogen, for example, is the nitrate ion (NO₃⁻). Carbon dioxide from the atmosphere provides the carbon atoms and two-thirds of the oxygen required by plants. Water

taken from the soil provides about one-third of the oxygen and much of the hydrogen. Soil provides macroelements and microelements from mineral complexes, parent rock, and decaying organisms. Factors that determine plant root uptake include the solubility of the chemical in question, the adsorptive properties of the charged soil surfaces, and the metabolic uptake capabilities of the individual plant.

The macroelements carbon, hydrogen, oxygen, and nitrogen constitute more than 96 percent of the dry weight of plants. Thus, they are the major constituents of the structural and metabolic compounds of the plant. Their presence within cells also helps regulate osmotic pressure. Microelements are generally either activators or components of enzymes, although the macroelement potassium also serves these roles.

General overview of metabolic cycles. Metabolism denotes the sum of the chemical reactions in the cell that provide the energy and synthesized materials required for growth, reproduction, and maintenance of structure and function. In plants the ultimate source of all organic chemicals and the energy stored in their chemical bonds is the conversion of CO₂ into organic compounds (CO₂ fixation) by either photosynthesis or chemosynthesis. The general and specific features of plant metabolism ultimately derive from oxygenic photosynthesis, which underlies the autotrophic nutrition of plants.

Pathways and cycles. Chemical reactions in the cell occur in a sequence of stages called a metabolic pathway. Each stage is catalyzed by an enzyme, a protein that changes (usually increases) the rate at which the reaction proceeds but does not alter the reactants or end products. Certain thermodynamic conditions must be met for a reaction to proceed, even in the presence of enzymes. If the end product of the reaction is also the reactant (or substrate) that starts the pathway, then the sequence of reactions is called a metabolic cycle. The intermediate chemicals that are formed and used in the various stages of the sequence are called intermediary metabolites.

Metabolic pathways and cycles are either catabolic (energy-releasing) or anabolic (energy-consuming). Catabolic reactions break down complex metabolites into simpler ones, while anabolic reactions build up (biosynthesize) new molecules. When chemical bonds are broken, energy is released, which drives anabolic reactions to form new bonds. The energy released generally has been stored in high-energy bonds of an intermediate energy carrier molecule, such as the terminal phosphate bond of adenosine triphosphate (ATP). (When the terminal phosphate is split from the ATP molecule, adenosine diphosphate, or ADP, is formed and inorganic phosphate is released, along with energy.) The simpler metabolites formed via catabolic reactions are often the building-block metabolites used in anabolic reactions to synthesize more complex molecules (*e.g.*, starch, proteins, or lipids).

Control mechanisms. The cells of all plants are eukaryotic, since they possess a nucleus and membrane-bound organelles, such as chloroplasts, mitochondria, glyoxysomes, peroxisomes, and vacuoles. The thousands of metabolic reactions that take place in the cell are regulated within these organelles and their subcompartments. When compared with cells of other eukaryotic organisms, plant cells may have the highest degree of metabolic compartmentalization.

The primary mechanism of metabolic control, however, remains the enzymes themselves. Although all enzymes of the pathway help determine the net and directional flow of carbon, certain key stages are controlled by regulatory enzymes. Regulatory enzymes may catalyze either the first stage in the metabolic pathway, or they may catalyze reactions in which key branch points occur. The activity of such enzymes, in turn, may be controlled by the amount synthesized (coarse control)—in that further action by the enzyme is inhibited when some critical concentration of the reaction product is reached—or by special metabolites, called effectors, that interact directly with the enzyme (fine control). The latter metabolites may be either part of, or totally unrelated to, the metabolites of the pathway.

Another mechanism by which metabolic reactions are regulated is through transport systems in the membranes

Autotrophs
and
hetero-
trophs

and
anabolic
reactions

Macro-
and micro-
elements

of organelles. These systems control the nature, direction, and amount of metabolites entering the metabolic pathways and are often uniquely related to the autotrophic nutrition of plants.

Principal pathways and cycles. The 6-carbon sugar glucose, a product of photosynthesis, may be translocated in the form of sucrose (a 12-carbon sugar) to nourish nonphotosynthesizing parts of the plant, or it may be polymerized into starch for storage. (Trehalose, another 12-carbon sugar, replaces sucrose in some nonvascular plants.) When required, sucrose and starch are hydrolyzed to glucose and then enter glycolysis or the pentose phosphate pathway. The reactions of both pathways take place in the cytoplasm of the cell.

Result of
glycolysis

The net result of glycolysis is the metabolism of glucose into two molecules of the three-carbon organic acid pyruvate. This 10-reaction metabolic pathway involves phosphate-containing intermediates and is regulated by two enzymes, which catalyze those reactions that contain the substrates fructose phosphate and phosphoenolpyruvate (PEP). Glycolysis yields ATP molecules and hydrogen; the latter is accepted by the coenzyme (coenzymes are smaller, nonprotein participants associated with certain enzymes) nicotinamide adenine dinucleotide (NAD) to form NADH. The hydrogen on NADH then reacts either with molecular oxygen (O_2) to catalyze the release of energy (trapped in the high-energy bonds of ATP) or with another metabolite to reduce the molecule by the addition of hydrogen. Some intermediates are used in the biosyntheses of fat or certain amino acids.

The pentose phosphate pathway, an alternative pathway for the catabolism of glucose, operates in the presence of oxygen. It furnishes reducing power (*i.e.*, it accepts hydrogen atoms and carries them on the coenzyme nicotinamide adenine dinucleotide phosphate [NADP]) for use in the synthesis of fat and five-carbon (pentose) sugars that are required as components of nucleic acids, some vitamins, and key metabolites. It is regulated by the rate at which the product of the pentose pathway, NADPH, is oxidized. The end products are cycled back into the glycolytic pathway.

Pyruvate is transported into the mitochondria, where it enters a sequence of 10 reactions called the tricarboxylic acid (TCA) cycle, or Krebs cycle. Pyruvate is metabolized into the two-carbon intermediate, acetyl coenzyme A (CoA), which combines with a four-carbon acid, oxaloacetate. The product, citrate, has three acid (or carboxylic) groups; hence the name tricarboxylic acid cycle. Citrate is systematically catabolized (broken down) with progressive losses of successive carbon atoms as CO_2 into five-carbon and, finally, four-carbon, acids. The latter acid, oxaloacetate, begins the cycle again. With each oxidation reaction, a hydrogen atom is transferred to the coenzyme NAD or, in one reaction, the coenzyme flavin adenine dinucleotide (FAD) to form NADH and FADH, respectively. The reduced coenzymes NADH and FADH enter into a sequence of reactions called the respiratory chain on the inner membrane of the mitochondrion. This chain is a series of carriers (ubiquinone and several iron-containing chemicals called cytochromes) that ultimately transfer the hydrogen and electrons of these coenzymes to molecular oxygen, forming water. The energy generated from the oxidation by the respiratory chain is trapped in the three ATP molecules formed per NADH molecule oxidized. The mechanism is chemiosmotic in that it involves building a hydrogen ion (proton) gradient on one side of the mitochondrial membrane.

A net of 36 ATP molecules are gained from all hydrogen-carrying coenzymes formed in glycolysis and the TCA cycle, and they represent the principal energy source for most anabolic (biosynthetic) reactions in plants. In addition, the TCA cycle furnishes metabolites for the biosynthesis of important organic molecules of the cell.

Isoprenoid
pathway

Another metabolic cycle, the isoprenoid pathway, produces essential oils, carotenoid pigments, certain plant hormones, and rubber. These metabolites (often called secondary metabolites) are unique to plants and serve such functions as attracting pollinating insects, photosynthesis, and growth and development. Plant seedlings use the gly-

oxylic acid cycle to convert fats (principally from seeds) into glucose. This occurs initially in the glyoxysome and subsequently in the mitochondria and cytoplasm.

Unique features of plant metabolism. The pathways outlined above exist in essentially the same form in all organisms, but metabolism in plants does have certain unique features. Plant mitochondria, for example, have specific transport systems for the NADH produced in glycolysis and for the oxaloacetate produced from a direct fixation of CO_2 into PEP. Unlike animal mitochondria, plant mitochondria metabolize malate and the amino acid glycine. A special enzyme converts malate to pyruvate, thereby allowing an alternative to the glycolytic pathway. Glycine is a product of the unique plant pathway of photorespiration II (see below *Photosynthesis*).

Plant mitochondria possess a cyanide-resistant cytochrome-respiratory chain in addition to the cyanide-sensitive respiratory chain also found in other organisms. Oxidation of NADH through this alternative pathway produces energy in the form of heat, but no ATP. Some physiologists suggest that this pathway is a mechanism for burning off excess carbohydrate. Others believe that this pathway allows a TCA cycle, in times of increased need, to produce more than the usual amount of metabolites for biosyntheses, which, in the presence of ATP acting as a feedback inhibitor, could not normally be produced. This system functions at a high rate in the flowers of the arum (*Araceae*) lily. Temperatures of this organ may reach $40^\circ C$ ($104^\circ F$) and may contribute to the attraction of pollinators. The overall function of the cyanide-insensitive respiratory pathway, however, is not clearly understood.

Photosynthesis. As discussed above, the autotrophic mode of nutrition of plants is derived from oxygenic photosynthesis. Energy-rich organic compounds are synthesized from low-energy atmospheric CO_2 using the energy of absorbed sunlight. (Some bacteria are nonoxygenic photosynthesizers, utilizing hydrogen sulfide, H_2S , rather than water.) The resultant organic compounds initiate the flow of energy and carbon through the food chains of agricultural and natural ecosystems, intrinsically linking plants with the heterotrophic life-forms of the remaining four kingdoms of organisms. The oxygen liberated by plants (and certain photosynthetic protists and monerans) over geologic time, has oxygenated the Earth's atmosphere and has produced fossil fuels such as coal, gas, and oil.

This section describes the basic mechanisms of photosynthesis—the acquisition of energy and the fixation of carbon dioxide—used by plants of diverse evolutionary lines.

Basic mechanisms. Electromagnetic radiation having wavelengths between approximately 430 and 700 nanometres can be seen as light by the eye and constitutes the range absorbed by plants for photosynthesis. Blue light has a wavelength around 450 nanometres, and red light, a wavelength of 650–700 nanometres.

Double-membraned cell organelles called chloroplasts contain the photosynthetic apparatus: light-absorbing pigments, other electron-carrying chemicals (cytochromes and quinones), and enzymes. (Pigments absorb light of a particular wavelength; those wavelengths that are not absorbed are reflected and may be perceived as colour; hence, for example, the green colour of many plants.) The inner membrane of the chloroplast is folded into flat tubes, the edges of which are joined to hollow, sacklike disks called thylakoids. Stacks of thylakoids embedded with pigment molecules are called grana. The inner matrix of the chloroplast is called the stroma.

Photosynthesis consists of two interdependent series of reactions, the photochemical light reactions and the metabolic dark reactions; the former are dependent on light, the latter on temperature. Light reactions occur in the grana and dark reactions in the stroma. The overall formula for photosynthesis is:

The light reactions, the first stage of photosynthesis, convert light energy into chemical energy (ATP and NADPH). Light reactions comprise two interdependent systems, called photosystems I and II. The dark reactions,

Absorption
ranges for
plants

the second stage of photosynthesis, use the chemical energy products of the light reactions to convert carbon from carbon dioxide to simple sugars.

Light reactions consist of several hundred light-absorbing pigment molecules so arranged as to maximize the gathering of light energy. These "antennae" are coupled to a minicircuit of electron-carrying chemicals. The pigments are chlorophyll *a* and chlorophyll *b* and various carotenoids. Absorbed light energy is transferred to specialized chlorophyll molecules called P_{700} and P_{680} in photosystems I and II, respectively. Once these specialized chlorophyll molecules acquire sufficient energy, electrons are given up to the electron carriers within their photosystems, initiating an electron flow. (The carrier molecules include quinones and cytochromes.) The effect of this, when photosystems I and II function synchronously, is the formation of a chemiosmotic gradient of protons that phosphorylates (adds a phosphate group to) ADP, resulting in ATP. These electrons also effect the formation of NADPH from NADP. The P_{680} chlorophyll, upon loss of its electron, becomes a strong oxidizing agent that subsequently causes the water molecule to dissociate into protons and oxygen gas.

The dark reactions are responsible for the conversion of carbon dioxide to glucose. The essential reaction involves the combining of CO_2 with the five-carbon sugar ribulose 1,5-bisphosphate (RuBP) in a series of reactions called the Calvin-Benson cycle. This reaction yields an unstable intermediate, which breaks down into two molecules of phosphoglycerate (PGA), a three-carbon acid. Each reaction is catalyzed by a specific enzyme. Six revolutions of the cycle means that six CO_2 molecules react with six RuBP molecules to produce 12 molecules of PGA; two three-carbon PGA molecules combine to form the six-carbon glucose, and 10 PGAs are recycled to regenerate six molecules of RuBP. The ATP and NADPH from light reactions provide the energy and reducing power to form glucose and refurbish the CO_2 acceptor, RUBP.

Specific variations in photosynthesis. Chlorophylls *a* and *b* (bound to a protein) and carotenes constitute the principal light-absorbing complex of most plants. Differences in chloroplast structure, though not major, occur among phylogenetically diverse plant groups. All such variations, however, represent evolutionary adaptations to utilize more efficiently the light energy that drives the reactions common to all oxygenic photosynthesizers, *i.e.*, photosystems I and II.

The enzyme ribulose 1,5-bisphosphate carboxylase/oxygenase (rubisco) catalyzes the formation of organic molecules from CO_2 . As the major enzyme of all photosynthetic cells, rubisco is probably the most abundant protein on the Earth. There is, however, a major catalytic flaw in the ability of this enzyme to convert CO_2 to sugars. In the presence of molecular oxygen, rubisco catalyzes reactions in which oxygen is introduced (*i.e.*, it acts as an oxygenase), and CO_2 is formed rather than converted.

Rubisco evolved in photosynthetic organisms that lived in the atmosphere of primitive Earth, an atmosphere which contained only traces of molecular oxygen. As photosynthesis in the Cyanobacteria of Precambrian times (3.8 billion to 570 million years ago) oxygenated the atmosphere, the ratio of carbon dioxide to oxygen fell drastically, and rubisco began to function more and more as an oxygenase. This greatly reduces the net fixation of CO_2 into sugars and, therefore, photosynthetic efficiency. Rubisco as an oxygenase only splits RuBP into PGA and the two-carbon acid phosphoglycolate, which initiates the photorespiratory carbon-oxidation cycle, or photorespiration. (This cycle probably evolved to recycle PGA back into the photosynthetic pathway, thereby preventing an even greater loss of carbon.) Photorespiration involves three organelles (chloroplasts, peroxisomes, and mitochondria), each with unique transport mechanisms for the cycle's intermediates.

All plants are classified as C_3 (plants that use only the Calvin-Benson cycle), C_4 (plants that use an additional CO_2 -fixation mechanism and the Calvin-Benson cycle), C_3 - C_4 (plants intermediate between C_3 and C_4), and CAM (plants that have a variant of the C_4 pathway).

The majority of plants fix CO_2 directly into RuBP, and their first stable product is the three-carbon acid PGA, hence the designation C_3 . These plants have an active photorespiratory cycle, especially in high light intensity and warm temperatures.

Sometime during the later periods of the Cenozoic Era (66.4 million years ago to the present), certain of the angiosperms (grasses and the dicotyledonous plants) of mainly tropical climates evolved a CO_2 -fixation system that precedes the Calvin-Benson cycle. The first fixation is into the three-carbon acid phosphoenolpyruvate (PEP) by PEP carboxylase (an enzyme that has no oxygenase function) in the outer mesophyll cells of the leaf. The first stable fixation product is the four-carbon acid oxaloacetate, hence the designation C_4 plants. Oxaloacetate is converted to malate, which is transferred to a thick-walled bundle sheath cell that shields the subsequent reactions from the high concentration of molecular oxygen in the atmosphere. Malate is decarboxylated, and rubisco of the primitive and susceptible Calvin-Benson cycle functions more efficiently because here photorespiration is suppressed. There is thus a spatial separation of initial CO_2 fixation and the Calvin-Benson cycle. This efficiency is not without cost, however, as an additional ATP is required to recycle PEP. For this reason, C_3 plants may be more efficient in cold climates with less light (and, therefore, less photorespiration).

There are also plants with enzymatic and leaf anatomical characteristics intermediate between C_3 and C_4 plants, called C_3 - C_4 intermediate species. These plants are thought to be in the pathway of evolution to full C_4 photosynthetic status.

Succulent plants of the desert regions (*e.g.*, cacti) also initially fix CO_2 into oxaloacetate. This occurs only at night when conditions are cooler, however. Normally, the stomates in leaves or stems, through which plants lose water and acquire carbon dioxide, are open in the day and closed at night; those of the succulent plants do the opposite through a special mechanism that prevents great loss of water during the hot days. The resultant oxaloacetate is converted into malate, stored in the vacuole, and released during the day when the stomates are closed. Malate is decarboxylated, and the CO_2 that released is fixed by rubisco in the usual Calvin-Benson cycle. Both the C_4 and C_3 processes take place in the same cell. This process is called crassulacean acid metabolism (hence CAM plants) after a family of succulent plants (Crassulaceae). (J.H.Y.)

ECOLOGY

Plant geography. Plants occur over the surface of the Earth in well-defined patterns that are closely correlated with both climate and the history of the planet. Forests are the most important of these natural communities from the standpoint of area, carbon content, annual carbon fixation, the cycling of nutrient elements, and influence on energy and water budgets, as well as being the principal reservoir of biotic diversity on land. The most extensive forests are the boreal coniferous forests of North America, Scandinavia, northern Europe, and northern Asia. The moist forests of the tropics are the most diverse, often containing as many as 100 species of trees per hectare (1 hectare = 2.47 acres) and occasionally many more.

Forests are commonly distinguished from woodlands and savannas in having a closed canopy of trees that may be 10 metres to more than 50 metres in height. At their wetter and cooler limits, forests are replaced by tundra, a community of low-growing trees and shrubs with a ground cover of *Sphagnum* and other mosses, dwarfed shrubs, and perennial herbs. The transition from forest to tundra occurs at high latitudes and elevations and may extend over a considerable distance, throughout which trees are scattered, restricted to sheltered areas, and stunted in growth. Such taiga stands are common at the northern limit of trees throughout the Northern Hemisphere. The alpine transition tends to be more abrupt. Both are often determined locally by the distribution of snow.

Forests yield at their warmer and drier margins to grassland (called prairie in North America and steppe in Asia). In North America the rich grasslands of the eastern mid-continent, which is affected by moisture moving north-

Calvin-Benson cycle

C_3 , C_4 , and C_3 - C_4 plants

Importance of forests

ward from the Gulf of Mexico, once supported a diversity of herbaceous plants, including grasses that might reach several feet in height, and were known as tall-grass prairie. Westward, where water was less abundant, the grasses diminished in diversity and size to form the short-grass plains. Southward and westward the plains yielded under increasing aridity to desert, as old as any other zone in an evolutionary sense and very diverse in species. Similar patterns of vegetation occur across the broad waist of Asia.

The distinction between grassland and forest is blurred in many places, especially in the semiarid subtropics and in other regions where fires may be common. This transitional zone is savanna, an open, grassed woodland. The southeastern coastal plain of North America was originally such a region, a pine savanna that produced plants adapted to, in fact dependent on, burning for survival. The long-leaf pine (*Pinus palustris*), for instance, has a "grass" stage, which lasts for several years of early growth, with the bud protected at the very surface of the ground by a thick tuft of long, grasslike leaves that shield it from the heat of a fire. Once sufficient energy has been stored in the taproot and short stem, the tree virtually explodes into growth and passes rapidly through a period of vulnerability to fire. As a tree of 3 metres (10 feet) or more in height, it is safe from all but the hottest of fires. Oaks and other species are replacing pines as savannas disappear from the southeastern United States because of the continuing division of land ownership and protection from fire.

In contrast, the extensive savannas of eastern Africa have been maintained through climate, fires, and grazing and support an extraordinary diversity of migratory animals that have evolved to use different parts of the ecosystem. The patterns of use are complex and phased in time, and they work to maintain both the diversity and productivity of the savanna. These African populations are the last of the large and diverse mammalian and avian populations that once also grazed similar areas of North America, Europe, and Asia.

The forests of the moist tropics remain the most complex and fascinating of terrestrial ecosystems. They extend from mountain slopes to river swamps and occurred throughout the tropics wherever precipitation allowed trees to survive. Human activities have virtually eliminated forests from vast areas of the tropics and threaten to destroy the residual forests globally. The largest areas of tropical forest occur now in the Amazon basin of South America and in the Congo basin of west-central Africa. The extensive tropical forests of Southeast Asia have been reduced to fragments of the area they occupied as recently as 1950.

The forests of the Amazon basin have evolved as a part of a river system whose water level fluctuates annually by as much as 15 metres (50 feet) or more along the middle and lower Amazon. There are substantial further differences in the quality of water. The Negro River, for example, drains an area of sands low in nutrient elements, where organic matter has accumulated sufficiently in soils to produce the humic acids that give the river its dark colour and sufficient acidity to affect the plant and animal life it can support. The areas flooded in the annual cycle are forested and are known by the Portuguese word *várzea*. Trees in this zone survive flooding for several weeks annually and provide the basis of a food web that includes fish adapted for grazing on tree fruits and seeds. The grazing fish possess large flat molars adapted for masticating seeds and other coarse organic matter, and they compete for seeds dropped from pods in *várzea* trees on the river.

The distribution of the various zones of vegetation over the Earth has changed with climates throughout time. The greatest changes in the recent past have been due to the periods of glacial advance and retreat over the last several hundred thousand years. As recently as 15,000 years ago glacial ice covered much of eastern North America as far south as the present Hudson estuary and covered as well all of Scandinavia and northern Europe. Sea level was tens to hundreds of feet lower at various times, and extensive coastal areas now flooded were exposed. Such drastic changes in climate have sorted and resorted plant species, allowed the establishment of a diversity of forest types over time, and worked against the establishment or

preservation of the mutual dependencies among species so common in the tropics. These higher-latitude forests, while similar in form and genera and sometimes in species around the world, are apparently highly mutable, the antithesis of the stable and self-perpetuating "organism" they were once thought to be. Nonetheless, the concept of the plant community as an organism remains viable and useful in ecology and is the basis of much of the most progressive analysis of how to manage the Earth for successful support of large numbers of people.

Succession and zonation. It is known from studies of plant residues and pollen preserved in the highly acid sediments of bogs and from observations of contemporary glaciers that the vegetation southward from the glacial front in the Northern Hemisphere was banded in much the same way the vegetation is zoned today: tundra occurred in a zone closest to the ice; coniferous forests occurred in a warmer and drier zone southward; and deciduous forests occurred still farther southward. As the habitat changed—that is, as the glacial ice melted and the glacial front retreated—the vegetation migrated onto the new landscape: first the pioneer species of the tundra—a few hardy low-growing or crustose lichens and mosses of small stature—followed by dwarfed willows and birch and, ultimately, the full panoply of tundra plants. As the climate ameliorated further, the forest followed, always according to pattern, with a few pioneers followed by the full array of species characteristic of the forest.

The process of invasion of a new landscape not previously occupied by plants has long been called "primary succession." In this case the succession was in response to both the availability of a new habitat and a climatic warming that allowed the replacement of tundra by forest and of the coniferous forest ultimately by deciduous forest as the warming continued. Further warming might result in the replacement of deciduous forest by grassland, as has occurred worldwide at the steppe- or prairie-forest border in response to climatic changes over recent centuries. This boundary is strongly influenced by the fires that have swept grasslands throughout time. Disturbances such as clearings for agriculture, fires, diseases, and storms severe enough to open gaps in a forest may start secondary successional changes that also reestablish the normal vegetation for that climatic zone.

Throughout much of the tropics, where forests have been destroyed over large areas to make pasture, conditions appropriate for what might be a normal succession within disturbance-caused gaps in an otherwise intact forest do not exist, and the sites are permanently impoverished. The process generates grassland, shrublands, or sometimes bare earth. One-third of the land area of India has been impoverished in this way and is lost to agriculture, forests, or forestry. This class of land is the most rapidly growing class globally, according to interpretations of statistics of the United Nations Food and Agriculture Organization in 1985.

Ecosystems and the biosphere. The thin mantle of the Earth that supports life extends not more than a few feet into the sediments of the abyssal depths of the oceans and to a few tens of thousands of feet into the atmosphere, where pollen grains or other spores may survive. It is this thin layer at the surface of the Earth that is the biosphere, the place where life occurs. Human activity has changed the Earth irreversibly to form the present biosphere, and humans are now a force for further irreversible change.

Dispersal and colonization. The methods by which plants are distributed over the Earth are as diverse and complex as the plants themselves. The most widely occurring plants are the small-bodied, rapidly reproducing forms whose spores can be carried by wind and water and by birds and other animals.

Among the seed plants, whose spores are less mobile, explanations for the current distribution of plants become more complicated and include such profound changes over evolutionary time as the breakup of Pangaea some 300 million years ago, the opening of the Atlantic Ocean, and the isolation of North and South America, Australia, and Madagascar from larger continental landmasses. Progressive isolation produced endemism, evolutionary di-

Primary
succession

Glacial
advances

vergence sufficient to generate whole floras peculiar to a particular region, with many species, even genera, not known elsewhere. Volcanic islands are much younger than the continents and support floras derived from chance invaders carried by wind, sea, or animals, including humans. Island floras also come to exhibit endemism. Charles Darwin's observations of the fauna and flora of the Galápagos Islands off the western coast of South America led him to recognize the general process of biotic evolution. The islands are diverse in form and climate, isolated in varying degrees from each other and from the continent, and support a highly diversified flora and fauna clearly derived from South America, but modified over the time of isolation to contain forms peculiar to the islands.

Methods
of dispersal

Diverse mechanisms exist for dispersing spores and seeds at appropriate times and in appropriate habitats to ensure the survival of the new plant. In forests adapted to fire, pinecones may remain closed until a fire occurs. The heat of the fire opens the cones and releases the seeds into a fire-seared habitat, where the seedlings find soil with an abundance of nutrients left by the burning of organic matter and reduced competition from other plants. Seeds of trees frequently have "wings" that permit wider distribution by wind. Other plants, such as thistles and burdock, have awns or other appendages that catch on animals and obtain a wide distribution in areas frequented by them. Still others have elaborate mechanisms for spreading via rhizomes, stems, or other propagules.

Especially during the past two centuries, human activities have both deliberately and inadvertently spread the higher plants and microbial plagues of higher plants around the Earth. Examples among the higher plants are numerous; while many of the transfers of such plants have been benign and some clearly advantageous, others have been disastrous. Tree species have been moved freely around the world, sometimes with remarkable effectiveness. The Monterey pine (*Pinus radiata*), for instance, is a diminutive and unproductive tree on the coast of California, but it has become a major timber tree as a result of rapid growth in plantations in New Zealand. The rubber tree (*Hevea*) was carried in the 19th century from the moist tropics of Brazil to Java and elsewhere in the South Pacific, where its excellent growth, free of the diseases and competitors that affect it in its native American habitat, nearly destroyed the market for Brazilian rubber. Other inadvertent introductions have been far from benign; some have severely impoverished the landscape. *Bromus tectorum*, for example, is an annual grass introduced from Europe and the Transcasian steppes to the arid intermontane west in North America, probably as a contaminant in fodder in the latter part of the 19th century. It spread rapidly and became a continuous ground cover over extensive areas. The plant completes its life cycle early in the season, sets seeds, and stands through the rest of the year as a continuous cover of dry grass not useful for fodder. It does, however, carry fire, which changes and can even destroy the native vegetation.

Microbial diseases of plants have been inadvertently spread around the world by human activities. Such diseases continue to exact a high cost in that they progressively impoverish the vegetation. One of the most profound changes in any forested region was produced by the introduction of the chestnut blight (*Endothia parasitica*) to North America. The fungus, introduced from Asia, found a home in the Fagaceae of eastern North America but was lethal to the American chestnut (*Castanea dentata*), the dominant species of extensive stands in the southern Appalachians and elsewhere. Once a common and popular shade tree and a source of smooth-grained, easily worked wood and of the abundant mast that was one of the principal foods of indigenous wild turkeys and other animals, the American chestnut never developed resistance to this now widely distributed fungus, which has several hosts in the Fagaceae and which produces wind-borne spores.

The American elm (*Ulmus americana*), a magnificent tree of the moist forests of lowlands throughout eastern North America, has suffered a similar but less comprehensive loss through the ravages of another exotic fungus, Dutch elm disease (*Ceratocystis ulmi*), which was im-

ported from Europe on infected wood probably early in the 1900s. The fungus is spread by two elm bark beetles. Individual trees sometimes escape the fungus for many years but ultimately succumb before reaching the large sizes that were common throughout its range early in the 20th century.

Human effects on plants and natural communities. Humans have influenced the structure and development of natural communities for many thousands of years. The major influence has been through fire, which has been used deliberately in herding game, in rejuvenating plants used for fodder, in opening forested plots for agriculture, in maintaining savannas and grasslands, and in keeping forests open for easy passage for hunting. With the rapid expansion of human populations globally in recent decades, however, the changes in vegetation have been profound. Forests have advanced into grasslands and savannas. Succession has replaced pine forests with deciduous forests as in the southeastern coastal plain and piedmont regions of North America. In many instances, temporary protection from fire has resulted in the accumulation of a large mass of flammable vegetation that, when burning, makes a hot fire which kills the overstory trees and many species that normally survived the more frequent and less severe fires of the past. In such circumstances the vegetation may be impoverished, a condition that may prevail indefinitely, once established.

Domestication. The origins of domesticated plants and agriculture are buried in a dim and unrecorded past of 10,000 years and more. Recent experience with Stone Age cultures of the Amazon basin and elsewhere has shown that such cultures have a sophisticated knowledge of plants for such purposes as food, medicine, and the tools and poisons used for hunting and fishing. Amerindian cultures improved a wide range of species by deliberate selection of the more productive and useful forms. Manioc (*Manihot utilissima*) remains a staple of large sections of Latin America, especially Brazil and the Amazon basin. A woody, tuberous plant whose origin in the savannas of South America has long been lost, it is propagated vegetatively by planting a piece of tuber or a segment of stem. The tuber is ground to make a flour that must be washed to remove toxic quantities of hydrocyanic acid before being eaten directly or baked into a flat bread called *cazabi* (cassava).

Corn, or maize (*Zea mays*), was domesticated 10,000 to 8,000 years ago either from teosinte (a perennial *Zea* that exists today) or from a lost ancestor that existed in the highlands of what is now central Mexico. Its culture had spread as far north as southern Maine by the time of European settlement of North America. Corn is now the third largest plant-based food source in the world. Other plants domesticated from the region include the common bean, squash, chili, tomato, avocado, papaya, guava, sapodilla, cotton, sisal, and vanilla.

The process of domestication appears to have involved selection and cultivation of the most promising and productive of plants long harvested in the wild. Continued selection brought drastic shifts in the population, shifts in the frequency of genes, and the development of new races totally dependent on humans to maintain them. Races developed in this way have been called cultigens to emphasize their dependence on cultivation. Such is the case with corn: the original stock has probably been lost, although teosinte may offer clues as to the source.

Major crop plants have been domesticated over the last several thousand years from sources identified by the Russian botanist N.I. Vavilov. Common wheat (*Triticum vulgare*) and rye (*Secale cereale*) probably were first domesticated from the grasses of Central Asia. Various millets (*Panicum*) and barley (*Hordeum hexastichum*) originated in the mountainous regions of central and western China, rice (*Oryza sativa*) probably in the Indian region.

Changes in biosystems: pollution. There is no plant community anywhere on Earth that has not felt the direct influence of the expansion of the human enterprise. The influence has had the form of direct intrusion through hunting and gathering, cultivation, or extensive harvest of trees or other plants or has had indirect effects through the

Dutch elm
disease

Chemical pollutants

harvest of fish or other animals or through changes in the chemistry of the environment. The latter changes are now pervasive and range from the introduction of pesticides, such as DDT, and other industrial toxins, such as the PCBs, to the acidification of rain, with substantial modification of the sulfur, nitrogen, and hydrogen ion budgets of ecosystems over large areas. Widespread destruction of forest tree species occurred during the 1980s in eastern North America and throughout Europe because of the combined effects of acid rain and other air pollutants.

Symptoms of incipient damage from air pollution and other chronic disturbances are now common in forests and other types of vegetation around the world, although symptoms may be subtle and difficult to assign as being caused by a particular pollutant. They range from such changes as the elimination of populations of leafy lichens from the bark of trees to the mortality of the trees themselves. Under extreme circumstances, such as in regions around smelters in Sudbury, Ont., Can., virtually all higher plants have been eliminated from an area of hundreds of square miles.

One of the most spectacular and informative examples of the patterns of impoverishment of forests exposed to chronic disturbance was induced experimentally in an oak-pine forest at Brookhaven National Laboratory in central Long Island, N.Y., U.S., using ionizing radiation. A single radiation source was used in the centre of the forest. The exposure, begun in the fall of 1961, was sufficient within months to eliminate all plants from a central area within a few metres of the source and to produce a systematic zonation of the forest at lower exposures. The zones ranged through a lichen and moss community, followed at lower exposures by a continuous ground cover of a single species of sedge (*Carex pensylvanica*). At slightly lower exposures a community of low shrubs occurred, then high shrubs at still lower exposures. An impoverished forest of hardy oaks well within the normal range of variability of the oak-pine forest of the region occurred down the gradient of exposure and beyond that zone; at exposures of one roentgen or less daily, the pines survived and the forest appeared intact and normal. Effects could, however, be detected by careful measurements of growth down to exposures on the order of 0.1 roentgen per day. The experiment offered a specific example of the progressive impoverishment of vegetation where both cause and effect could be measured, something not possible in most instances of pollution. Such experience is useful not only in defining the effects of exposure to ionizing radiation but also in identifying stages in the impoverishment of natural communities as effects accumulate.

Similar changes occur in aquatic systems in response to chronic pollution. The early stages of pollution in bodies of water usually involve enrichment with nutrient elements, especially nitrogen and phosphorus, a process known as eutrophication.

General effects of pollution

The effects of pollution on land and in water are to favour small-bodied, rapidly reproducing organisms that do not depend on complex food webs. The process of simplification and impoverishment is now global and affects terrestrial and aquatic communities alike. It is the continuously expanding result of chronic intrusions on natural systems by human influences. The impoverishment threatens all life because it reduces systematically the capacity of the Earth to support plants.

Conservation. One of the most serious threats to life is the possibility of a rapid warming of the Earth from the accumulation of heat-trapping gases in the atmosphere. The most important of the gases is carbon dioxide, but methane, nitrous oxide, and the chlorofluorocarbon compounds (CFCs) also contribute significantly. The largest sources of carbon dioxide are the combustion of fossil fuels, the destruction of forests, and, probably, the warming itself. Methane is a product of the use of fossil fuels and of the decay of organic matter in soils and swamps and bogs. Its rate of evolution is accelerated by warming.

The effects of the warming are expected to be profound: If the warming occurs as rapidly as some suggest, there could be a change in the average temperature of the Earth of as much as 0.5°–1° C (0.9°–1.8° F) per decade during

the early part of the 21st century. A change of 1° in temperature is equivalent to 60–100 miles of latitudinal change in the middle latitudes. Such high rates of change in climatic zones would not only disrupt agriculture but also destroy forests and other natural communities at their warmer and drier margins more rapidly than they can be regenerated elsewhere. One of the effects would be to speed the decay of organic matter in soils and accelerate the accumulation of carbon dioxide and methane in the atmosphere, an effect that would further accelerate the warming. Avoiding such change will require abandoning fossil fuels as the major source of energy for industrial societies. An alternative is solar energy.

Classical approaches to conservation involve specific efforts at preserving species that are endangered. By far the most desirable approach to the preservation of the Earth's 5–30 million or more species is through management of natural ecosystems. Studies of tropical forests have emphasized that the area required to assure the habitat of bird populations as well as populations of other animals and plants is very large indeed, on the order of 10,000 hectares. There is evidence to support earlier experience that the best way to assure the preservation of the indigenous biota is to maintain a matrix of the indigenous vegetation with more than 50 percent of the land area undisturbed and an additional 25 to 50 percent in successional stages. This type of land-use planning exists in very few places around the world but offers the advantage of a landscape that maintains itself with stable, near-maximum flows of energy through living systems and offers, regionally, maximum sustainable support for people at low cost. The difficulty is that the apparently high stocks of land under light use—the forests, the water, and energy in various forms—are an open invitation to immediate, short-term exploitation, and their existence may suggest that the landscape can be more intensively occupied. (G.M.W.)

EVOLUTION AND PALEOBOTANY

The evolutionary history of plants is recorded in fossils preserved in lowland or marine sediments. Some fossils preserve the external form of plant parts, others show cellular features, and still others consist of microfossils such as pollen and spores. In rare instances, fossils may even display the ultrastructural or chemical features of the plants they represent. The fossil record reveals a pattern of accelerating rates of evolution coupled with increasing diversity and complexity of biological communities that began with the invasion of land and continued with the progressive colonization of the continents. At present, fossil evidence of land plants dates to the Ordovician Period (505 to 438 million years ago) of the Paleozoic Era.

By far the most diverse and conspicuous living members of the plant kingdom are vascular plants (tracheophytes), in which the sporophyte phase of the life history (see above *Reproduction and life histories*) is dominant. Fossil remains of vascular plants provide evidence for evolutionary changes in the structure of the plant body (sporophyte and gametophyte), in the variety of plant forms, in the complexity of the life history, in the tolerance for ecological conditions, and in systematic diversity. Nonvascular plants, or bryophytes (mosses, liverworts, and hornworts), are much smaller and less diverse than vascular plants. The first evidence for liverworts is from rocks of the Devonian Period (408 to 360 million years ago), while the earliest moss fossils are from the Permian Period (286 to 245 million years ago). In contrast to tracheophytes, most fossil bryophytes are relatively similar to living forms. Understanding of the evolution of nonvascular plants is, therefore, less complete than for tracheophytes.

Botanists now believe that plants evolved from the algae; the development of the plant kingdom may have resulted from evolutionary changes that occurred when photosynthetic multicellular organisms invaded the continents. The earliest evidence for land plants consists of isolated spores, tracheid-like tubes, and sheets of cells found in Ordovician rocks. The abundance and diversity of these fossils increases into the Silurian Period (438 to 408 million years ago), where the first macroscopic (megafossil) evidence for land plants has been found. These megafossils consist of

The fossil record

Evolution from algae

slender forking axes that are only a few centimetres long. Some of the axes terminate in sporangia that bear trilete spores (*i.e.*, spores that divide meiotically to form a tetrad). Since a trilete mark indicates that the spores are the product of meiosis, the fertile axes may be interpreted as the sporophyte phase of the life cycle.

Fossils of this type could represent either vascular plants or bryophytes. Another possibility is that they are neither but include ancestors of vascular plants, bryophytes, or both. The earliest fossils also include at least one or more additional plant groups that became extinct early in the colonization of the land and therefore have no living descendants. By the Early Devonian Period (408 to 360 million years ago), some of the fossils that consist of forking axes with terminal sporangia also produced a central strand of tracheids, the specialized water-conducting cells of the xylem. Tracheids are a diagnostic feature of vascular plants and are the basis for the division name, Tracheophyta.

The simplest and presumably most primitive vascular plants from the Late Silurian and Early Devonian periods (421 to 387 million years ago) were the Rhyniopsida. They included plants such as *Cooksonia* and *Rhynia*, which were herbaceous colonizers of moist habitats. Most were less than 30 centimetres (12 inches) tall. The plant body was not differentiated into stems, leaves, and roots; rather, the forking, above-ground axes bore terminal sporangia and produced stomata which demonstrate that the plants were green and photosynthetic. Surface or underground axes served to root the plant and were anchored by rhizoids. Because such plants produced only one type of spore, they were nonseed plants with a homosporous life cycle and free-living gametophytes. A small number of such gametophytes have been described from Devonian deposits.

Some plants of the Early Devonian had multicellular emergences of tissue along their above-ground axes, which are thought to have increased the light-capturing surface of the photosynthetic tissue. Such emergences (enations) gave rise to the leaves (microphylls) of the Lycopsidea, thus producing an above-ground shoot system that consisted of branching stems with leaves. Underground axes that lacked leaves would have become the roots. Lycophytes were the first plants with well-differentiated shoot systems, and they are the most ancient groups of vascular plants with living representatives.

The leaves of several other plant groups were derived from modifications of the forking axes. There was a variety in structure among Devonian plants. The axes of some plants forked equally, while other plants—*e.g.*, *Drepanophycus*—were more specialized, comprising a large, centrally located axis as well as smaller axes borne laterally. In plants where the lateral systems branched in only one plane, the side branches were flat like leaves. Filling in (webbing) of the spaces between forks of the laterals with photosynthetic tissue produced leaves called megaphylls. There is evidence for the evolution of megaphylls in several plant groups of the Late Devonian Period (374 to 360 million years ago) and Early Carboniferous Period (360 to 320 million years ago). Although most of these groups have no living representatives, by the Carboniferous Period they had given rise to homosporous ferns, sphenopsids (horsetails), and seed plants (gymnosperms).

As Devonian plants with microphylls and those with specialized branching systems diversified, many grew to the size of shrubs. By the Middle Devonian Period (387 to 374 million years ago) there were shrub-size representatives of several lineages, but a further increase in the size of herbaceous plants was restricted by the limited diameter that above-ground stems and rooting systems could achieve. The development of lateral (secondary) growth overcame this size restriction. The ability to produce secondary growth evolved independently in several groups. In the lycophytes, much of this secondary growth occurred in cortical tissues; in the ancestors of seed plants and several other lineages, however, the production of wood accounted for most of the growth in stem diameter. About the same time, downward-growing, central rooting systems evolved independently in lycophytes and other plant groups. As a result there were forests with a canopy of giant lycophyte

and gymnosperm trees near the beginning of the Early Carboniferous Period.

As plants developed more complex growth forms, they also underwent systematic diversification and evolved more specialized modes of sexual reproduction. The most primitive vascular plants had a homosporous life cycle, in which reproduction and dispersal involved a single type of spore. Extant homosporous plants include most ferns and many lycophytes. The homosporous life cycle is an effective means for long-distance dispersal of species. Although it permits the fertilization of an egg by a sperm from the same gametophyte plant, genetic recombination, considered important for more rapid evolution, is not possible. Moreover, because the gametophytes of homosporous plants are exposed to the environment for an extended period of time, mortality is relatively high.

By the Middle Devonian Period (387 to 374 million years ago), the heterosporous life cycle had evolved independently in several groups, including lycophytes and the ancestors of seed plants. In heterosporous plants there are two sizes of spores; the smaller (a microspore) produces a male gametophyte, and the larger (a megaspore) produces a female gametophyte. The incidence of genetic recombination is increased by this obligate cross-fertilization. Both types of gametophytes develop quickly within the protective spore wall. Compared with homosporous plants, reproduction is more rapid and mortality is reduced in heterosporous plants. By the end of the Devonian, heterosporous plants became the dominant species in most wetland environments; however, the need for an abundant source of water from the environment to effect fertilization prevented the heterosporous plants from establishing communities in drier habitats.

A series of changes in the reproductive biology among some heterosporous plants during the Late Devonian overcame this environmental restriction and allowed them to colonize a much wider range of habitats. These changes also led to the evolution of seed plants. In seed plants, the megaspore is retained in the megasporangium and the microspore is brought to a pollen chamber at the tip of this organ. The megasporangium is then sealed, and gametophyte development and fertilization occur within a protected environment. When such a megasporangium is enclosed in a seed coat, the structure with its enclosed embryo is called a seed. Seeds of the earliest such plants were exposed to the external environment; these “naked seed” plants are referred to as gymnosperms.

From the Late Devonian through the base of the Late Cretaceous Period (97.5 to 66.4 million years ago), gymnosperms underwent dramatic evolutionary radiations and became the dominant group of vascular plants in most habitats. Extant gymnosperms include conifers, cycads, and *Ginkgo biloba*, but these represent only a small fraction of the gymnosperms that inhabited the Earth during the Mesozoic Era (245 to 66.4 million years ago). Among the Mesozoic forms were species with a wide variety of mechanisms for effecting pollination, protecting the seeds, dispersing the seeds, and increasing the natural selection of the most successful varieties.

Primitive forms of the flowering plants (angiosperms) arose from among this diverse array of complex gymnosperms. From their earliest diversification in the Cretaceous Period (144 to 66.4 million years ago), angiosperms rapidly came to dominate the land flora. Today there are approximately 250,000 to 300,000 species of flowering plants, which account for more than 90 percent of the diversity of vascular plants. Among the many structures that contribute to this success are flowers, fruits, complex vein patterns in the leaves, and highly specialized cells of the conducting system.

Just as an ecological succession of plant forms can transform bare ground into a complex plant community, so an evolutionary succession can be thought of as having transformed bare continents into rich terrestrial biotas. In ecological succession, herbaceous weeds colonize bare earth and modify the environment for the development of more complete ground cover. This further modifies the environment for the successive establishment of larger herbs, perennial shrubs, fast-growing trees, and, finally, slower-

munities

growing trees, vines, and epiphytes (plants that grow on other plants rather than in soil).

As discussed above, primitive land plants of the Late Silurian and Early Devonian periods were primarily small herbs that inhabited the moist lowlands near oceans, lakes, and streams. The first of these grew on bare ground because there would have been little or no organic soil. They may be thought of as the evolutionary equivalent of primary colonizing weeds, and their establishment on land was responsible for the first of three dramatic increases in the diversity of land plants.

After the initial production of organic soils by these evolutionary colonizers, communities of larger herbs and shrubs were able to develop, and they became common in the Middle Devonian. In the Late Devonian these communities were themselves succeeded by communities dominated by heterosporous, tree-sized plants. During the Early Carboniferous Period, nonseed plants continued to dominate many wetland habitats, while communities dominated by gymnosperm trees colonized drier habitats than had been previously available to the heterosporous forms.

Communities dominated by trees were the first to provide suitable habitats for vines and for epiphytes. Such communities also provided habitats for herbivorous animals. As a result, biological communities of considerable complexity evolved by the Late Carboniferous Period (320 to 286 million years ago), giving rise to a second dramatic increase in the diversity of land plants.

With the rapid diversification of the gymnosperms and an increasing complexity of interactions between plants and animals, there was a significant evolutionary turnover among land plants during the Permian, Triassic, and Jurassic periods (286 to 144 million years ago). New groups of gymnosperms replaced some of the primitive gymnosperms as well as the most prominent nonseed plants from earlier periods. Among the most successful gymnosperms of these periods were conifers, cycads, *Ginkgo*, and several major groups with no extant representatives.

Flowering plants probably also originated during this time but did not become a significant part of the fossil flora until the middle of the Cretaceous Period. The fossil evidence provides a clear picture of the rapid diversification and spectacular rise to dominance of the angiosperms during the Late Cretaceous Period. This was accompanied by a dramatic increase in the complexity of plant community structure, produced at least in part by an expanding array of interactions between plants and animals. Improved pollination and seed dispersal were among the benefits of such interactions to plants. That animals equally benefited is evidenced by the coevolution of several groups of animals (particularly insects) and angiosperms during the Late Cretaceous and Tertiary periods. Such interactions contributed significantly to a third rapid increase in global plant diversity and helped angiosperms achieve the overwhelming dominance of the land flora characteristic of modern vegetation. (G.W.R.)

CLASSIFICATION

Annotated classification.

KINGDOM PLANTAE

Multicellular, photosynthetic, eukaryotic organisms containing chlorophylls *a* and *b* and carotenoids and forming true starch; chlorophyll contained in stacks of membranes (grana) within chloroplasts; cellulosic cell walls; aerial tissues covered with a waxy cuticle and provided with openings (stomata) in the epidermis bordered by two guard cells and serving in gas exchange; alternation of generations with multicellular gametangia and sporangia and possessing a multicellular embryo stage; motile sperm, when present, with whiplash flagellum; sperm with a microtubular cytoskeleton; cell division associated with the dispersal of the nuclear membrane and the formation of a cell plate across the mitotic spindle (phragmoplast).

Division Bryophyta

Small, mostly nonvascular, archegoniate plants with a dominant, photosynthetic, free-living gametophyte; sporophyte has little or no chlorophyll and is dependent on gametophyte; bi-flagellate sperm.

Class Musci (mosses)

Gametophytes "leafy" and radially symmetrical, with leaves arising spirally from stemlike axis; leaves rarely notched or

lobed, with thickened "midrib"; many chloroplasts per leaf cell; gametophyte with multicellular rhizoids; sporophytes with complex spore-containing capsule with peristome and operculum, columella, and stomata present, but elaters absent; between 10,000 and 14,000 species; representative genera include *Polytrichum*, *Mnium*, *Funaria*, and *Sphagnum*.

Class Hepaticae (liverworts)

Gametophytes either "leafy" or dorsiventrally flattened (strap-shaped) and thalloid; leafy forms with leaves in 3 rows, 2 lateral and 1 below; leaves usually notched or lobed, with thickened midrib lacking; gametophytes with unicellular rhizoids; many chloroplasts per cell; sporophytes ephemeral, surrounded by gametophytic tissue, lacking opercula, peristome, stomata, and columella; elaters mixed with spores in capsule; capsule opening into 4 or more valves; between 6,000 and 9,000 species; representative genera include *Porella*, *Frullania*, *Marchantia*, *Conocephalum*, and *Riccia*.

Class Anthocerotae (hornworts)

Gametophyte thalloid, with a single, large chloroplast per cell, mucilage cavities present; sporophytes persistent, erect (hornlike), photosynthetic, arising from upper surface of gametophyte, possessing stomata, columella, basal meristem, and pseudolaters opening by 2 valves but lacking an operculum; representative genus, *Anthoceros*.

Division Lycophyta (club mosses, spike mosses, quillworts)

Vascular plants; sporophyte differentiated into stem, leaf, and root; leaves spirally arranged on stem, of the microphyll type; sporangia borne on upper (adaxial) surface of leaves (sporophylls), one sporangium per sporophyll; vascular tissue basically forming a central core in stem (protostelic); homosporous or heterosporous; ligulate (having basal, leaflike protuberances) or eligulate; strobili (cones) present or lacking; all living genera with primary growth only; gametophytes subterranean or surface-dwelling; motile sperm; about 5 living genera and between 600 and 1,000 species; representative genera include *Lycopodium*, *Selaginella*, and *Isoetes*.

Division Psilotophyta (whisk ferns)

Vascular plants; sporophyte lacking roots and often leaves; stems with small enations, dichotomously branched; vascular tissue forming a central core in stem (protostelic); sporangia fused into synangiate structure, apparently terminal on short stem; homosporous; gametophytes subterranean, with motile sperm; representative genus, *Psilotum*.

Division Sphenophyta (horsetails, scouring rushes)

Vascular plants; sporophyte differentiated into stem, leaf, and root; stems ribbed and jointed, monopodial; minute leaves whorled at the nodes; vascular tissue organized into bundles; sole living genus with primary growth only; sporangia borne on specialized stalks (sporangiophores) in strobili; homosporous; gametophytes photosynthetic, surface-dwelling; motile sperm; 1 genus, *Equisetum*.

Division Filicophyta (ferns)

Vascular plants; sporophyte differentiated into stem (rhizome), roots, and leaves (fronds); leaves entire or, more often, divided; arrangement of vascular tissue in stem variable, primary growth only; sporangia usually clustered into sori, often located on the under (abaxial) surface of sporophylls; mostly homosporous; gametophytes (prothallia) either subterranean and nongreen or, more commonly, surface-dwelling and photosynthetic; sperm motile; between 9,000 and 12,000 species; representative genera include *Pteridium*, *Polypodium*, *Polystichum*, *Adiantum*, and *Cyathea*.

Division Cycadophyta (cycads)

Palmlike, gymnospermous plants with typically short, thick, unbranched aerial trunks, sometimes subterranean, and large, divided leaves; leaves usually thick and leathery; cones present, often large and terminal on the stem; pollen (male) and seed (female) cones borne on separate plants; gametophytes reduced, not free-living; sperm motile (flagellated), but brought to vicinity of egg by a pollen tube; 10 genera and about 120 species; representative genera include *Zamia* and *Cycas*.

Division Ginkgophyta (ginkgoes)

Gymnospermous plants; tall, much-branched tree with well-developed cylinder of wood; resin ducts present; xylem with tracheids only; stem differentiated into long shoots and short spur shoots; simple, fan-shaped leaves with open dichotomous venation terminate short shoots; leaves deciduous; sexes on separate trees; distinct cones lacking; gametophytes reduced, not free-living; sperm motile (flagellated); mature seeds with fleshy, foul-smelling outer region; 1 living species, *Ginkgo biloba*.

Division Coniferophyta (conifers)

Gymnospermous plants; mostly trees with abundant xylem composed of tracheids only; resin ducts present; leaves simple, needlelike, scalelike, with a single vein or, less commonly, strap-shaped with multiple veins; reproduction by well-defined cones; seeds exposed on ovuliferous scales; gametophyte gener-

Dominance of angiosperms

ation reduced, microscopic, not free-living; sperm nonmotile, transported to egg by pollen tube; approximately 50 to 55 genera and between 550 and 575 species; representative genera include *Pinus*, *Abies*, *Sequoia*, *Taxodium*, *Juniperus*, *Cupressus*, and *Agathis*.

Division Gnetaophyta (gnetophytes)

Diverse and unusual group of 3 gymnospermous genera; growth habits of all 3 are atypical among gymnosperms in possessing vessel elements in the xylem and reproductive structures that are somewhat flowerlike; gametophytes reduced as in other gymnosperms; sperm nonmotile; extant genera *Gnetum*, *Ephedra*, and *Welwitschia*.

Division Magnoliophyta (flowering plants, angiosperms)

Vascular plants, xylem typically with vessel elements; reproduction by flowers; ovules or young seeds enclosed by female reproductive structure (carpel); gametophyte generation extremely reduced, consisting of only a few cells; archegonia and antheridia lacking; nonmotile sperm transported to egg by pollen tube; pollen transported to specialized receptive surface (stigma) on carpel; double fertilization, one sperm uniting with the egg to form a zygote, another fusing with the polar nuclei to form the primary endosperm nucleus; nutritive tissue of seed triploid endosperm; seeds enclosed by mature ovary that ripens into a fruit; approximately 230,000 species worldwide, more than 300 families.

Class Magnoliopsida (Dicotyledonae; dicots)

Angiosperms with 2 seedling leaves (cotyledons); leaves with reticulate (net) venation; stem with vascular bundles arranged in a ring, each bundle with a functional vascular cambium; secondary growth common; flower parts in multiples of 4 or 5; pollen typically tricolpate (3 germinal apertures) or some derived type; about 165,000 species.

Class Liliopsida (Monocotyledonae; monocots)

Angiosperms with 1 seedling leaf (cotyledon); leaves with parallel venation; stem with scattered vascular bundles; bundles without a functional vascular cambium; secondary growth typically absent; flower parts in multiples of 3; pollen typically have a single germinal aperture; approximately 50,000 to 55,000 species; representative types include grasses, orchids, palms, and lilies.

Critical appraisal. In the classification above, only the major divisions and classes of living plants are listed, and a number of entirely extinct divisions are omitted. The classification outlined is somewhat conservative but is one that best conforms to available data and has gained wide acceptance.

Biological classifications were initially mechanical or "artificial"; that is to say, they had no basis in evolution. This was followed by a period of "natural system" construction, whereby plants were grouped together on the basis of their overall similarities or differences, using as many characteristics as possible. Contemporary systems of biological classification are phylogenetic, which means that various plants are arranged together because they are thought to be related by descent from a common ancestor. As more evidence is accumulated, it is to be expected that classifications also will change to accommodate this new information.

At the turn of the 19th century, the plant kingdom was frequently divided into two major groups, the cryptogamia (algae, fungi, bryophytes, and ferns) and the phanerogamia (gymnosperms and angiosperms). Subsequently, it was common practice among systematic botanists to group all vascular plants together under a single division, Tracheophyta. In contrast, all of the major individual groups of plants are now most often elevated to divisional rank, a view that interprets the individual major groups to be less closely related to one another than previously believed. Difficult and complex questions still exist in the definition and circumscription of certain groups. Although it is convenient to treat the Bryophyta (mosses, liverworts, and hornworts) as a single division, some authorities prefer to recognize three or five separate divisions for these plants, each representing an independent evolutionary lineage. Furthermore, the phylogenetic relationships, if any, of the bryophytic plants with primitive vascular plants remains unclear. The treatment of the Psilotophyta is controversial. Although here recognized as a separate division of lower vascular plants, some botanists prefer to include the group among the ferns (Filicophyta). The flowering plants

have classically been recognized as composed of two distinct classes; however, the origin of each class and the phylogenetic relationships of their component taxa have yet to be satisfactorily resolved. (W.C.D.)

Plate Tectonics

Plate tectonics is a theory dealing with the dynamics of the Earth's outer shell, the lithosphere. Resting on a broad synthesis of geologic and geophysical data, it dominates current thinking in the Earth sciences. According to the theory, the lithosphere consists of about a dozen large plates and several small ones. These plates move relative to each other and interact at their boundaries, where they diverge, converge, or slip relatively harmlessly past one another. Such interactions are thought to be responsible for most of the seismic and volcanic activity of the Earth, although earthquakes and volcanoes are not wholly absent in plate interiors. While moving about, the plates cause mountains to rise where they push together and continents to fracture and oceans to form where they pull apart. The continents, sitting passively on the backs of plates, drift with them and thereby bring about continual changes in the Earth's geography.

The theory of plate tectonics, formulated during the late 1960s, is now almost universally accepted and has had a major impact on the development of the Earth sciences. Its adoption represents a true scientific revolution, analogous in its consequences to the Rutherford and Bohr atomic models in physics or the discovery of the genetic code in biology. Incorporating the much older idea of continental drift, the theory of plate tectonics has made the study of the Earth more difficult by doing away with the notion of fixed continents, but it has at the same time provided the means of reconstructing the past geography of continents and oceans. While its impact has, to a considerable degree, run its course in marine geology and shows signs of reaching the limits of usefulness in the study of mountain-building processes, its influence on the scientific understanding of the Earth's history, of ancient oceans and climates, and of the evolution of life is only beginning to be felt.

For details on the specific effects of plate tectonics, see EARTHQUAKES, VOLCANISM, and GEOMORPHIC PROCESSES. A detailed treatment of the various land and submarine relief features associated with plate motion is provided in CONTINENTAL LANDFORMS: *Tectonic landforms* and OCEANS.

PRINCIPLES OF PLATE TECTONICS

The plate tectonics theory has a long and tortuous history. Yet, the theory itself is elegantly simple.

The surface layer of the Earth, from 50 to 100 kilometres (31 to 62 miles) thick, is assumed to be composed of a set of large and small plates, which together constitute the rigid lithosphere. The lithosphere rests on and slides

over an underlying, weaker layer of partially molten rock known as the asthenosphere. The constituent lithospheric plates move across the Earth's surface, driven by forces as yet not fully agreed upon, and interact along their boundaries, diverging, converging, or slipping past each other (Figure 1). While the interiors of the plates are presumed to remain essentially undeformed, their boundaries are the sites of many of the principal processes that shape the terrestrial surface, including earthquakes, volcanism, and orogeny (*i.e.*, the deformation that builds mountain ranges).

The most conspicuous feature of the Earth's surface is its division into continents and ocean basins, a division that owes its existence to differences in thickness and composition between the continental and the oceanic crust. The continents have a crust of granitic composition and hence are somewhat lighter than the basaltic ocean floor. Also, they are 30 to 40 kilometres thick as compared to the oceanic crust, which measures only 6 to 7 kilometres in thickness. Their greater buoyancy causes them to float much higher in the mantle than does the oceanic crust, thus accounting for the difference between the two principal levels of the Earth's surface. The boundary between the continental or oceanic crust and the underlying mantle, the Mohorovičić discontinuity, has been clearly defined by seismic studies.

Figure 1: Three-dimensional diagram showing crustal generation and destruction according to the theory of plate tectonics; included are the three kinds of plate boundaries—divergent, convergent (or collision), and strike-slip (or transform).

As conceived by the theory of plate tectonics, the lithospheric plates are much thicker than the oceanic or the continental crust; their boundaries do not usually coincide with those between oceans and continents; and their behaviour is only partly influenced by whether they carry oceans, continents, or both. The Pacific Plate, for example, is purely oceanic, but most of the others contain continents.

At a divergent plate boundary, magma wells up from below as the release of pressure produces partial melting of the underlying mantle and generates new crust. Because the partial melt is basaltic in composition, the new crust is oceanic. Consequently, diverging plate boundaries, even if they originate within continents, eventually come to lie in ocean basins of their own making. In fact, most divergent plate boundaries seem to have formed within continents rather than in oceans, probably because a hot, weak layer, sandwiched at a depth of about 15 kilometres between two stronger ones, renders the continental crust more vulnerable to fragmentation than its oceanic counterpart. The creation of the new crust is accompanied by much volcanic activity and by many shallow tension earthquakes as the crust repeatedly rifts, heals, and rifts again.

The continuous formation of new crust produces an excess that must be disposed of elsewhere. This is accomplished at convergent plate boundaries where one plate descends—*i.e.*, is subducted—beneath the other. At depths

Divergent
plate
boundaries

Convergent
plate
boundaries

between 300 and 700 kilometres, the subducted plate melts and is recycled into the mantle. Because the plates form an integrated system that completely covers the surface of the Earth, it is not necessary that new crust formed at any given divergent boundary be completely compensated at the nearest subduction zone, as long as the total amount of crust generated equals that destroyed.

It is in subduction zones that the difference between plates carrying oceanic and continental crust can be most clearly seen. If both plates have oceanic edges, either one may dive beneath the other; but, if one carries a continent, the greater buoyancy prevents this edge from sinking. Thus, it is invariably the oceanic plate that is subducted. Continents are permanently preserved in this manner, while the ocean floor continuously renews itself. If both plates possess a continental edge, neither can be subducted and a complex sequence of events from crumpling to under- and overthrusting raises lofty mountain ranges. Much later, after these ranges have been largely leveled by erosion, their remains continue as a reminder that this is the "suture" where continents were once fused.

The subduction process, which involves the descent into the mantle of a slab of cold rock about 100 kilometres thick, is marked by numerous earthquakes along a plane inclined 30° – 60° into the mantle—the Benioff zone. Most earthquakes in this planar dipping zone result from compression, and the seismic activity extends 300–700 kilometres below the surface. At a depth of 100 kilometres or more the subducted oceanic sediments, together with part of the upper basaltic crust, melt to an andesitic magma, which rises to the surface and gives birth to a line of volcanoes a few hundred kilometres behind the subducting boundary. This boundary is usually marked by an oceanic deep, or trench, where the overriding plate scrapes off the upper crust of the lower plate to create a zone of highly deformed, largely sedimentary rock. If both plates are oceanic, the deformed sediments and volcanoes form two island arcs parallel to the trench. If one plate is continental, the sediments are usually accreted against the continental margin and the volcanoes form inland, as they do in Mexico or western South America.

Strike-slip plate boundaries

Along the third type of plate boundary, two plates move laterally and pass each other without creating or destroying crust. Large earthquakes are common along such strike-slip, or transform, boundaries. Also known as fracture zones, these plate boundaries are perhaps best exemplified by the San Andreas fault in California and the North Anatolian fault system in Turkey.

Most of the seismic and volcanic activity on Earth is therefore concentrated along plate boundaries where mid-ocean ridges, trenches with island arcs, and mountain ranges are generated. Some seismic and volcanic activity also occurs within plates. Interesting examples of this interplate activity are linear volcanic chains in ocean basins, such as the Hawaiian Islands and their westward continuation as a string of reefs and submerged seamounts. An active volcano usually exists at one end of an island chain of this type, with progressively older extinct volcanoes occurring along the rest of the chain. Such topographic features have been explained by J. Tuzo Wilson of Canada and W. Jason Morgan of the United States as the product of "hot spots," magma-generating centres of controversial origin located deep in the mantle far below the lithosphere. A volcano builds at the surface of a plate positioned above a hot spot. As the plate moves on, the volcano dies, is eroded, and eventually sinks below the surface of the sea, while a new one forms above the hot spot. Hot spot volcanism is not restricted to the ocean basins; other manifestations occur within continents, as in the case of Yellowstone National Park in western North America.

The movement of a plate across the surface of the Earth can be described as a rotation around a pole, and it may be rigorously described with the theorem of spherical geometry formulated by the Swiss mathematician Leonhard Euler during the 18th century. Similarly, the motions of two plates with respect to each other may be described as rotations around a common pole, provided that the plates retain their shape (Figure 2). The requirement that plates are not internally deformed has become one of the

Figure 2: Movement on a sphere of two plates, A and B, can be described as a rotation around a common pole. Circles around that pole correspond to transform faults (single lines connecting divergent plate boundary marked by double line). Note that the pole of rotation of the two plates is not the same as the pole of rotation (spin axis) of the sphere.

postulates of plate tectonics. It is not totally supported by evidence, but it appears to be a reasonable approximation of what actually happens in most cases. It is needed to permit the mathematical reconstruction of past plate configurations.

The joint pole of rotation of two plates can be determined from their transform boundaries, which are by definition parallel to the direction of motion and so form small circles around the pole. The rate of motion can be computed from the increase in age of the crust away from the divergent plate boundary usually by means of magnetic anomalies (see below *Seafloor spreading*). Because all plates form a closed system, all movements can be defined by dealing with them two at a time.

It is, of course, conceivable that the entire lithosphere might slide around over the asthenosphere like a loose skin, altering the positions of all plates with respect to the spin axis of the Earth and the equator. To determine the true geographic positions of the plates in the past, which is so important in paleoclimatology and paleoceanography, investigators have to define their motions, relative not to each other but rather to this independent frame of reference. The hot spot island chains serve this purpose, their trends providing the direction of motion of a plate; the speed of the plate can be inferred from the increase in age of the volcanoes along the chain. It is assumed, of course, that the hot spots themselves remain fixed with respect to the Earth, an assumption that appears to be reasonably accurate for at least some hot spots.

Hot spot island chains as a frame of reference

Quite another method of determining absolute plate movements relies on the fact that the equatorial waters of the ocean are, and always have been, very fertile. The high biological productivity yields an enormous quantity of calcareous microfossils, which, like a gigantic natural chalk line, marks a narrow equatorial zone. The displacement of the equatorial deposits over time, traced by means of deep-sea drill cores, enables investigators to determine the direction and rate of plate movement.

Because the plates all interlock, any change in motion anywhere must reverberate throughout the entire system. If two continents collide, their edges will crumple and shorten, but eventually all motion must stop at this boundary and large parts of the system elsewhere will have to adjust. Earth scientists are thus able to reconstruct the positions and movements of plates in the past so long as they have the ancient oceanic crust to provide them with plate speeds and directions. Since old oceanic crust is continuously consumed to make room for new crust, this kind of evidence is eventually exhausted. Little oceanic crust of Early Cretaceous age (about 144 to 97.5 million years old) remains, and none is older than the Jurassic—the geologic period that began approximately 208 million

years ago. Consequently, this method fails for the history of drifting continents during earlier geologic periods (*i.e.*, the Paleozoic and Precambrian eras), making it necessary for investigators to turn to another, less effective technique (see below *Paleomagnetism, polar wandering, and continental drift*).

HISTORICAL OVERVIEW

Precursors. Any major new idea in science appears to lead instantly to a search of the past for those who might once have proposed similar concepts and with whom the current proponents should therefore share the credit. In the case of plate tectonics, the primary candidate is obvious: Alfred Wegener of Germany, who explicitly presented the concept of continental drift for the first time at the outset of the 20th century. Though plate tectonics is by no means synonymous with continental drift, it encompasses this idea and derives much of its impact from it.

There might have been predecessors even to Wegener. The outlines of the continents bordering the Atlantic Ocean are so similar that many probably noticed the correspondence, and some might have drawn the conclusion that the lands on both sides were once joined together. The earliest reference to this peculiar geographic feature was made by the English philosopher Francis Bacon. In his *Novum Organum* (1620), Bacon pointed out the correspondence but did not go beyond that. Such was also the extent of the contribution of the great French naturalist Georges-Louis Leclerc, Count du Buffon, a century later. Neither can François Paget qualify as a forerunner of continental drift theorists: even though he stated in 1666 that an undivided continent existed before Noah's flood, he explained the creation of the Atlantic Ocean by having part of that continent sink into the sea.

The first credible proponent of continental drift was Antonio Snider-Pellegrini, a belated advocate of catastrophism (the view that geologic history consists of a sequence of numerous violent catastrophic events), who in 1858 ascribed the biblical flood to the former existence of a single continent that was torn apart to restore the balance of a lopsided Earth. More recent and much more sophisticated was the work of the American geologist Frank B. Taylor, who, disdaining the then-prevailing contraction model of mountain building, postulated in 1908 that the arcuate mountain belts of Asia and Europe resulted from the equatorward creep of the continents. His analysis of tectonic features foreshadowed in many ways modern thought regarding plate collisions, and he anticipated Wegener's publications by only a few years. Curiously, however, his work instantly sank into oblivion.

Alfred Wegener and the concept of continental drift. Wegener was by training and profession a meteorologist (he was highly respected for his work in climatology and paleoclimatology), but he is best remembered for the foray into geology that led to his formulation of the concept of continental drift. In 1910, again because of the geography of the Atlantic coastlines, Wegener came to consider the existence of a single supercontinent during the late Paleozoic era (about 350 to 225 million years ago) and named it Pangaea. He searched the geologic and paleontological literature for evidence attesting to the continuity of geologic features across the Indian and Atlantic oceans, which he assumed had formed during the Mesozoic era (about 245 to 66.4 million years ago). His efforts proved rewarding, and he presented the idea of continental drift and some of the supporting evidence in a lecture in 1912. This was followed in 1915 by his major work, *Die Entstehung der Kontinente und Ozeane* (*The Origin of Continents and Oceans*).

The idea of large ancient continents composed of several of the present-day smaller ones had been put forth in the late 19th century by the Austrian geologist Eduard Suess. Suess, however, was not thinking of continental drift. In the spirit of his day, he assumed that portions of a single enormous southern continent—designated Gondwana, or Gondwanaland—foundered to become the Atlantic and Indian oceans. Such sunken lands, along with vanished land bridges, were frequently invoked in the late 1800s to explain sediment sources apparently present in the ocean

and to account for floral and faunal connections between continents. They remained popular until the 1950s, stimulated believers in ancient Atlantis, and even made their way into literary works.

Yet, it was already known that the concept of isostasy rendered large sunken continental blocks geophysically impossible, and Wegener characteristically introduced his continental drift proposal by pointing this out. Only then did he proceed to conclude that, if the continents had been once joined together, drift of their fragments rather than their foundering would have been the consequence. The assumption of a former single continent could be tested geologically, and Wegener next displayed a large array of data. Even today his evidence, ranging from the continuity of fold belts across oceans and similarities of sequences of strata on their opposite sides to paleobiogeographic and paleoclimatological arguments, would be judged worthy of serious consideration. He further argued that, if continents could move up and down in the mantle as a result of buoyancy changes produced by, say, erosion or deposition, they should be able to move horizontally as well. The driving forces he considered, however, were unconvincing: both pole fleeing and the westward tidal force appeared to most to be entirely inadequate.

Wegener's proposition was attentively received by many European geologists, and in England Arthur Holmes pointed out that the lack of a driving force was hardly sufficient grounds to scuttle the entire concept. As early as 1929, Holmes proposed an alternative mechanism—namely, convection of the mantle, which remains today a serious candidate for the force driving the plates. Wegener's ideas also were appreciated by geologists in the Southern Hemisphere. One of them, the South African Alexander Du Toit, remained a lifelong believer. After Wegener's death, Du Toit continued to amass further evidence in support of continental drift.

Evidence supporting the hypothesis. Much was thus to be said for the idea that the continents were joined together in the Paleozoic, and supporting evidence has continued to accumulate to this day. The opposing Atlantic shores match well, especially at the 1,000-metre (3,300-foot) depth contour, which is a better approximation of the edge of the continental block than the present shoreline, as Sir Edward Bullard cogently demonstrated in 1964 with the aid of computer analysis. Similarly, the structures and stratigraphic sequences of Paleozoic mountain ranges in eastern North America and northwestern Europe can be matched in detail. This fact was already known to Wegener and has been strengthened substantially in subsequent years.

Often cited as evidence have been the strikingly similar Paleozoic sequences on all southern continents and also in India. This Gondwana sequence—so called after one of Suess's large continents—consists of glacial tillites, followed by sandstones and finally coal measures. Placed on a reconstruction of Gondwana, the tillites mark two ice ages that occurred during the long march of this continent across the South Pole from its initial position north of Libya about 500 million years ago until its final departure from southern Australia 250 million years later (Figure 3). The first of these ice ages left its glacial deposits in the southern Sahara during the Silurian period (which extended from about 438 to 408 million years ago), and the second did the same in southern South America, South Africa, India, and Australia from 380 to 250 million years ago. At each location the tillites were subsequently covered by desert sands of the subtropics, and these in turn by coal measures, indicating that the region had arrived near the equator.

During the 1950s and '60s, patient work in isotopic dating showed that the massifs of Precambrian time (from about 3.8 billion to 570 million years ago) found on opposite sides of the South Atlantic did indeed closely correspond in age and composition, as Wegener had surmised. It is now evident that they originated as a single assemblage of Precambrian continental nuclei later torn apart by the breakdown of Pangaea.

Disbelief and opposition. More common than interest or approval, however, was a disbelief so strong that it often

Gondwana
sequence

The
super-
continent
Pangaea

bordered on indignation. One of the strongest opponents was the British geophysicist Sir Harold Jeffreys, who spent years attempting to demonstrate that continental drift is impossible because the strength of the mantle should be far greater than any conceivable driving force. He refused to abandon this viewpoint in spite of the massive evidence in favour of plate tectonics. It was in North America, however, that opposition to Wegener's ideas was vigorous to the point of excess and very nearly unanimous. This is illustrated by reports from a symposium on continental drift organized in 1928 by the American Association of Petroleum Geologists. The mood that prevailed at the gathering was expressed by an unnamed attendant quoted with sympathy by the great American geologist Thomas C. Chamberlin: "If we are to believe Wegener's hypothesis, we must forget everything which has been learned in the last 70 years and start all over again." The same reluctance to start anew was again displayed some 40 years later by the same organization when its publications provided the principal forum for the opposition to plate tectonics.

Wegener was attacked from virtually every possible vantage point, his paleontological evidence attributed to land bridges, the similarity of strata on both sides of the Atlantic called into question, the fit of Atlantic shores declared inaccurate, and his very competence doubted. It also did not escape attention that he did not possess proper credentials as a geologist.

What might have been the cause of this overwhelmingly negative response in the light of such a substantial amount of supporting evidence? The unsatisfactory quality of Wegener's driving mechanism has commonly been cited as the reason, but that seems too simple, especially since the absence of a mechanism did not delay the acceptance of plate tectonics. The roots of the resistance most certainly reached far deeper. It would be unusual for the practitioners of any science to flock to a new concept—particularly a revolutionary one of such profound consequences—before the need for a thorough overhaul of the existing conceptual edifice had become compelling and obvious to most, its supporting evidence daily crumbling, and its explanatory power reduced below any acceptable level.

Whatever the cause, continental drift, having been rejected by the vast majority of geologists the world over, retreated into obscurity and remained there for roughly three decades. Ironically, though, Du Toit so successfully kept the fires burning in the Southern Hemisphere that it remained quite respectable there to profess oneself an adherent of continental drift during the very years that such a confession north of the equator would have exposed one to ridicule and disbelief.

Renewed interest in continental drift. *Paleomagnetism,*

polar wandering, and continental drift. The fact that some rocks are strongly magnetized has been known for centuries, and geologists recognized more than 100 years ago that many rocks preserve the imprint of the Earth's magnetic field as it was at the time of their formation. Volcanic rocks such as basalt are especially good recorders of paleomagnetism, but some sediments also align their magnetic particles with the Earth's field at the time of deposition. Investigators therefore have at their disposal fossil compasses that indicate, like any magnet suspended in the Earth's field, the direction to the magnetic pole and that yield the latitude of their origin.

During the 1950s, paleomagnetic studies, notably those of Stanley K. Runcorn and his coworkers in England, showed that in the late Paleozoic the north magnetic pole—as seen from Europe—seems to have wandered from a Precambrian position near Hawaii to its present location by way of Japan. This, of course, might mean that the magnetic pole itself had migrated or that Europe had moved relative to a fixed pole. Either continental drift or polar wandering was therefore a reasonable explanation. Paleomagnetic data from other continents, however, soon yielded apparent polar wandering paths different from the European one. Separate wanderings of many magnetic poles are not acceptable, but the paths could be brought to coincide by joining the continents in the manner and at the time suggested by Wegener.

Impressed by this result, Runcorn became the first of a new generation of geologists and geophysicists to accept continental drift as a serious proposition worthy of careful testing. Yet, the band of the converted remained small, and most geologists found sufficient reason to doubt the paleomagnetic results, which were often conflicting due to the primitive nature of the early techniques. Since then, more sophisticated methods capable of removing the overprint of later magnetizations have made paleomagnetic data strong supporting evidence for continental drift and a major tool for reconstructing the geography of the past. In the meantime, however, much progress had been made on an entirely different and quite independent front. It was from evidence extracted from the oceanic crust that plate tectonics would be born.

Gestation and birth of plate tectonics. When Wegener developed his ideas, and for many years thereafter, relatively little was known regarding the nature of the ocean floor. After World War II, however, rapid advances were made in the study of the relief, geology, and geophysics of the ocean basins. Due in large part to the efforts of Bruce C. Heezen and Henry W. Menard of the United States, these features, which constitute more than two-thirds of the Earth's surface, became well enough known to permit serious geologic analysis.

Several major topographic and tectonic features distinguish the ocean basins from the continents. The first of these is the mid-ocean ridge system. Mid-ocean ridges are broad, elongated elevations of the ocean floor rising to about 2.5 or 3 kilometres below sea level, with widths ranging from a few hundred to more than 1,000 kilometres. Their crests tend to be rugged and are often endowed with a longitudinal rift valley where fresh lava flows, high heat flow, and shallow earthquakes of the extensional type are found. Mid-ocean ridges nearly girdle the globe.

Trenches constitute another type of seafloor feature. In contrast to mid-ocean ridges, they are long, narrow depressions containing the greatest depths of the ocean basins. Trenches virtually ring the Pacific; a few also occur in the northeastern part of the Indian, and some small ones are found in the Atlantic. Elsewhere they are absent. Trenches have low heat flow, are often filled with thick sediments, and lie at the upper edge of the Benioff zone of compressive earthquakes. Trenches border continents, as in the case of western Central and South America; but they also may occur in mid-ocean, as, for example, in the southwestern Pacific.

Mid-ocean ridges and, more rarely, trenches are offset by fracture zones—transverse features consisting of linear ridges and troughs approximately perpendicular to the ridge crest that they offset by a few to several hundred kilometres. Fracture zones often extend over long distances in

The paleomagnetic studies of Runcorn

Ocean basin studies

the ocean basins but generally end abruptly against continental margins. They are not volcanic, and their seismic activity is restricted to the area between offset ridge crests where earthquakes indicating horizontal slip are common.

The existence of these three types of striking, large seafloor features, which had gradually become evident during the late 1940s and '50s, clearly demanded a global rather than local tectonic explanation. The first comprehensive attempt at such an explanation was made by Harry H. Hess of the United States in a widely circulated manuscript that he had written in 1960 but not formally published for several years. In this paper Hess, drawing on Holmes's model of convective flow in the mantle, suggested that the mid-ocean ridges were the surface expressions of rising and diverging convective flow while trenches and Benioff zones with their associated island arcs marked descending limbs. At the ridge crests new oceanic crust would be generated and then carried away laterally to cool, subside, and finally be destroyed in the nearest trenches. Consequently, the age of the oceanic crust should increase with distance away from the ridge crests, and, because recycling was its ultimate fate, very old oceanic crust would not be preserved anywhere. This, incidentally, took care of an old and troubling paradox: only rocks younger than Mesozoic had ever been encountered in the oceans, whereas the continents bear ample evidence of the presence of oceans for more than three billion years.

Hess's model, later dubbed seafloor spreading by the American oceanographer Robert S. Dietz, appeared to account for most observations and was received with interest by many marine geologists. Confirmation of the production of oceanic crust at ridge crests and its subsequent lateral transfer was not long in coming. Fracture zones had thus far been widely regarded as transcurrent faults that gradually displaced one crestal block to the right or left relative to the other. Given this interpretation, the abrupt termination of many fracture zones against continental margins raised intractable problems. The aforementioned Canadian geologist J. Tuzo Wilson solved these problems in 1965 with a single ingenious stroke. Suppose, he argued, that the offset between two ridge crest segments is present at the outset. Each segment generates new crust, which moves laterally away. Along that part of the fracture zone lying between crests, the crustal slabs move in opposite directions, even though the axes or rift valleys themselves remain stationary. Beyond the crests, adjacent portions of crust move in parallel and are eventually absorbed in a trench. Wilson called this a transform fault and noted that on such a fault the seismicity should be confined to the part between ridge crests, as is indeed the case (Figure 4).

From T.H. van Andel, *New Views on an Old Planet* (1985), Cambridge University Press

Figure 4: Faults that horizontally offset two pieces of crust are called strike-slip faults (top). Fracture zones were initially regarded as classic strike-slip faults until J. Tuzo Wilson demonstrated that they result from the generation of new crust at already offset mid-ocean ridges. The concentration of earthquakes is in the axial part only, and the directions of motion confirm the hypothesis.

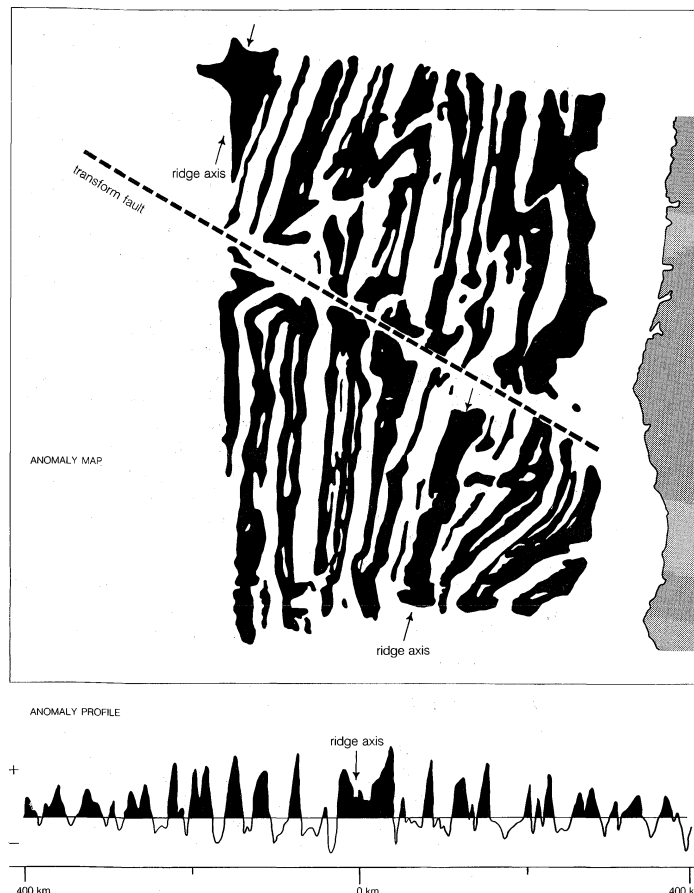

Figure 5: Map and profile of magnetic anomalies. (Top) Magnetically, the oceanic crust is distinguished by a pattern of values alternately higher (black) and lower (white) than the average of the Earth's field. Note the offset of the magnetic bands along a transform fault. (Bottom) A corresponding magnetic anomaly record showing the symmetry of anomalies on both sides of the ridge axis produced by seafloor spreading.

From T.H. van Andel, *New Views on an Old Planet* (1985), Cambridge University Press

Shortly afterward Lynn R. Sykes, an American seismologist, showed that the motions deduced from earthquakes on transform faults conform to the directions of motion postulated by Wilson and are opposite those observed on a transform fault.

The seafloor-spreading model also required that the oceanic crust should increase in age with distance from the ridge axis, and Wilson had already pointed out that volcanic islands in the Atlantic indeed show this pattern. Such islands are few, however, and it is in the nature of these piles of lava and ash that the moment of their birth is difficult to ascertain. Additional evidence was needed, and it soon came from magnetic surveys of the oceanic crust.

A magnetic survey of the eastern Pacific floor off the coast of Oregon and California had been published in 1961 by two geophysicists, Arthur D. Raff and Ronald G. Mason. The results were puzzling and gave rise to many farfetched interpretations. Unlike on the continents, where magnetic anomaly patterns tend to be confused and seemingly random except on a fine scale, the seafloor possesses a remarkably regular set of magnetic bands alternately higher and lower than the average Earth field. These positive and negative anomalies are strikingly linear and parallel with the mid-ocean ridge axis, show distinct offsets along fracture zones, and, when displayed in black and white, generally resemble the pattern of a zebra skin (Figure 5). The axial anomaly tends to be higher and wider than the adjacent ones, and in most cases the sequence on one side is the approximate mirror image of that on the other.

In his convection/seafloor-spreading model, Hess had attributed the formation of the oceanic crust mainly to the hydration of a peridotitic mantle, a process not judged

Magnetic anomalies

Hess's seafloor-spreading model

likely to produce such regular magnetic anomalies. Alternatively, it seemed possible that partial melting of the mantle might yield a basaltic magma, which, after congealing, would be a much better medium for retaining a strong imprint of the Earth's magnetic field. This second hypothesis has since been amply confirmed by deep-sea dredging and drilling.

It had further been known since early in the century that the polarity of the Earth's magnetic field reverses from time to time. Studies of the remanent magnetism of stacks of basalt lavas extruded in rapid succession on land had, since the late 1950s, begun to establish a sequence of reversals dated by isotopic methods.

Assuming that the oceanic crust is indeed made of basalt intruded in an episodically reversing geomagnetic field, Drummond H. Matthews of Cambridge University and a research student, Frederick J. Vine, postulated in 1963 that the new crust would assume a magnetization aligned with the field at the time of its formation. If the field were normal, as it is today, the magnetization of the crust would be added to that of the Earth and produce a positive anomaly. If intrusion had taken place during a period of reverse magnetic polarity, it would subtract from the present field and appear as a negative anomaly. Subsequent to intrusion, each new block would split and the halves, in moving aside, would generate the observed bilateral magnetic symmetry. Given a constant rate of crustal generation, the widths of individual anomalies should correspond to the intervals between magnetic reversals. Correlation of magnetic traverses from different mid-ocean ridges demonstrated in 1966 an excellent correspondence with the magnetic polarity-reversal time scale just then published by the American geologists Allan Cox, Richard Doell, and Brent Dalrymple in a series of timely papers. This reversal time scale went back some three million years, but since then further extrapolation based on marine magnetic anomalies (confirmed by deep-sea drilling) has extended the magnetic anomaly time scale far into the Cretaceous period, which spanned from about 144 to 66.4 million years ago.

As an aside, it is of interest to note that in Canada Laurence W. Morley, simultaneously with Vine and Matthews but entirely independently, had come to the same explanation for the marine magnetic anomalies, but publication of his paper, delayed by unsympathetic referees and technical problems, occurred long after Vine's and Matthews' work had already firmly taken root.

These confirmations persuaded a large number of marine

geologists that seafloor spreading was a reality. Continental drift, however, was not much in their minds, as they focused mainly on the explanations that the concept provided for a host of oceanic features. Land geologists were disinterested, viewing the affair as primarily an issue for their marine colleagues.

Two concerns, however, remained. The spreading seafloor was generally seen as a thin skin most likely having its base at the Mohorovičić discontinuity—*i.e.*, boundary between the crust and mantle considered of such major importance in the early 1960s that plans were undertaken to sample it by deep drilling in the oceans. If only oceanic crust were involved, as seemed to be the case in the Pacific Ocean, the thinness of the slab was not disturbing, even though the ever-increasing number of known fracture zones with their close spacing implied oddly narrow, long convection cells. More troubling was the fact that the Atlantic Ocean, though it had a well-developed mid-ocean ridge, lacked trenches adequate to dispose of the excess oceanic crust. There, the adjacent continents needed to travel with the spreading seafloor, a process that, given the thin but clearly undeformed slab, strained credulity.

Working independently but along very similar lines, Dan P. McKenzie and Robert L. Parker of Britain and W. Jason Morgan of the United States resolved these issues. McKenzie and Parker showed with a geometric analysis that, if the moving slabs of crust were thick enough to be regarded as rigid and thus to remain undeformed, their motions on a sphere would lead precisely to those divergent, convergent, and transform boundaries that are indeed observed. Morgan demonstrated that the directions and rates of movement had been faithfully recorded by magnetic anomaly patterns and transform faults. He also proposed that the plates extended approximately 100 kilometres to the base of a rigid lithosphere, which had long been known to be underlain by a weaker asthenosphere marked by strong attenuation of earthquake waves. In 1968 the French geophysicist Xavier Le Pichon refined these propositions with a computer analysis of all plate data and proved that they did indeed form an integrated system where the sum of all crust generated at mid-ocean ridges is balanced by the cumulative amount destroyed in all subduction zones. That same year, the American geophysicists Bryan Isacks, Jack Oliver, and Lynn R. Sykes showed that the theory, which they enthusiastically labeled the "new global tectonics," was capable of accounting for the larger part of the Earth's seismic activity. Almost immediately others began to consider seriously the abil-

hypothesis

ity of the theory to explain mountain building and sea-level changes.

Only a few years later, details of the processes of plate movement and of boundary interactions, along with much of the plate history of the Cenozoic era (the past 66.4 million years), had been worked out. Yet, the driving forces—*notwithstanding a brief flurry of discussion around 1970—*remained mysterious and continue as such. The vast accumulation of data bearing on plate history and plate processes has yielded surprisingly little information about what happens beneath them. Pull by the subducting slab, push at the spreading ridge, convection in the asthenosphere, and even tidal forces have been considered, but in every case the evidence has to be admitted as inconclusive. Many favour convection, but, if this indeed is the driving force, the flow pattern at depth is clearly not reflected in the surface movements of the plates, constrained as they are by each other.

PLATE TECTONICS AS AN EXPLANATION FOR EARTH PROCESSES

Since its inception in 1967–68, plate tectonics has had a pervasive impact on the Earth sciences. If it has not fully lived up to the proud name “new global tectonics,” it has nevertheless exerted enormous influence by clarifying areas of obscurity, reconciling seemingly conflicting evidence, unifying to a remarkable degree events occurring in distant parts of the globe, establishing new pathways toward knowledge, and opening the door to new subjects of investigation, all the while raising a myriad of new and important issues. A few examples may suffice to illustrate the dimensions of the revolution it has wrought.

Pangaea and its breakup. Magnetic anomalies, transform faults, and hot spot trails permit rigorous geometric reconstructions of past plate shapes, configurations, and movements. As previously noted, reasonable agreement on such reconstructions can be achieved as far back as the late Cretaceous, but beyond that time little oceanic crust remains. Much effort in reconstructing the geography of the past 100 million years or so has shown that, though some reconstructions are straightforward, others imply that the strict application of the assumption that plates are not internally deformed is not justified. Such is the case, for example, for the Pacific basin as opposed to the simple history of the Atlantic.

When dealing with geologic time beyond the Cretaceous, other means have to be applied in reconstructing ancient geography. Geologic data, for instance, can be used in the time-honoured manner to determine the proper fit of continents to make Pangaea. Only minor controversy continues here, such as in the vexing case of the position of Madagascar or of the many fragments that now constitute the Mediterranean, southeastern Europe, and the Middle East. Old collision boundaries are marked by sutures—*i.e.*, zones of deformation that betray points of contact between formerly separate continents even after much erosion. Good examples include the Urals between the old central European and Siberian continental blocks, and the Indus suture north of the Himalayas between India and Asia. Some sutures, on the other hand, are well concealed, as, for example, the one in northern Florida and southern Georgia that marks a collision between North America and northwestern Africa during the Paleozoic.

Having reconstructed Pangaea and identified the pieces that came together to form it through largely traditional means, investigators are able to trace continental migrations using paleomagnetic data to obtain their paleolatitudes and orientations for appropriate instants in time. What cannot be determined are their paleolongitudes, so that knowledge about the widths of intervening oceans remains limited. Paleolongitudes can be estimated only by relatively crude means such as faunal and floral affinities. Accordingly, Earth scientists will never know as much about the geography of the Precambrian, Paleozoic, or early Mesozoic as they do about the last 100 million years of Earth history. Yet, enough information has become available to permit some undoubtedly flawed but fascinating and useful reconstructions.

A widely used Paleozoic reconstruction by a group of

geologists at the University of Chicago shows that throughout the Paleozoic, and probably for some time before then, Gondwana existed, consisting of South America, Africa, and Australia. It was surrounded by an ever-shifting array of landmasses, some large—about the size of North America, China, or Siberia—and others small, though numerous and destined eventually to become parts of Europe and Asia.

Paleoclimates and ancient oceans. For Gondwana itself, geologic data suffice to recreate in broad outline form not only its coasts, plains, and mountain ranges but also its deserts, polar ice caps, and tropical jungles. These reflect broad climatic zones, which were themselves controlled mainly by insolation, seasonality, and the rotating of the Earth. Large landmasses may sometimes have modified climate to produce monsoons. Given the positions and sizes of continents, paleoclimatic zones may be inferred and then checked against climatic conditions deduced from the fossil record of sedimentary rocks. The results show a satisfactory correspondence between expectations and record, much better than the one obtained by plotting paleoclimatic data on the present-day configuration of continents. They leave little doubt that it is better to accept that the continents have drifted about than to assume that they have remained stationary.

The supercontinent Pangaea was completely surrounded by a world ocean extending from pole to pole and spanning 80 percent of the circumference of the Earth at the equator. The equatorial current system, driven by the trade winds, resided in warm latitudes much longer than it does today, and its waters were therefore warmer. The gyres that occupy most of the Southern and Northern hemispheres were also warmer, and consequently the temperature gradient from the equator to the poles was much reduced in comparison to the present.

Early in the Mesozoic, the equatorial current became circumglobal when the Tethys seaway split Gondwana from its northern counterpart, Laurasia. The equatorial surface waters, now able to circumnavigate the world one or more times, became even warmer; but whether the return flows continued to keep the high latitudes warm or diminished in strength and therefore somewhat increased the latitudinal temperature gradients is not certain. Nevertheless, in the middle and later Mesozoic the Arctic and Antarctic surface water temperatures were at or above 10° C (50° F), and the polar regions were warm enough to support forests. As the dispersal of continents following the breakup of Pangaea continued, however, the surface circulation of the oceans became much more complex. During the middle Cenozoic, the northward drift of Australia and South America created a new circumglobal seaway around Antarctica that remained centred on the South Pole. A vigorous circum-Antarctic current developed, isolating the southern continent from the warmer waters to the north. At the same time, the equatorial current system became blocked, first in the Indo-Pacific region, next in the Middle East and eastern Mediterranean, then at Gibraltar, and finally, about 5 million years ago, by the emergence of the Isthmus of Panama. As a result, the equatorial waters were heated less and the mid-latitude ocean gyres were not as effective in keeping the high latitudes warm. Because of this, an ice cap began to form on Antarctica some 20 million years ago and grew to roughly its present size about 5 million years later. This ice cap cooled the waters of the adjacent ocean to such a low temperature that the waters sank and initiated the north-directed abyssal flow that marks the present deep circulation. The Quaternary Ice Age arrived in full when the first ice caps appeared in the Northern Hemisphere about 2 million years ago.

There is no certainty that the changing configuration of continents and oceans can be held solely responsible for the onset of the Quaternary Ice Age, even if such factors as the drift of continents across the latitudes (with the associated changes in vegetation) and reflectivity for solar heat are included. There can be little doubt, however, that it was a major contributing factor and that recognition of its role has profoundly altered all concepts of paleoclimatology.

Plate tectonics and mountain building. Subduction and

The dispersal of the continents and its impact on oceanic current systems

Re-constructions of ancient geography

The significance of plate convergence in orogeny

continental collision raise mountain ranges. Consequently, the implications of plate tectonics for the processes of mountain building have attracted much attention. One of the earliest to apply the new theory was the Cambridge geologist John Dewey, who analyzed the Appalachian and Alpine orogenies. Many other researchers have subsequently undertaken similar work in the Mediterranean system and the American Cordilleran ranges, as well as in the Appalachians.

The collisions that gradually joined North America to Pangaea during the Paleozoic exemplify the role of plate convergence in mountain building. Some 500 million years ago, a subduction zone existed along what is now the eastern seaboard of North America. During the course of the next 67 million years or so—the Ordovician period—this region underwent a major phase of mountain building. When it was over, the direction of sediment transport had reversed, indicating that a large source area had appeared to the east of the subduction zone. The thick sequence of deposits from this source in eastern North America bears witness to its size, which is incommensurable with the island arcs that normally accompany a subduction zone. Subduction, sedimentation, and volcanism then continued until a small continent comprising what is today northwestern Europe collided with the northeastern tip of North America. This collision raised a major chain of folded mountains, the remains of which are now found from New England through eastern Canada and Scotland into Norway. This Caledonian range shed sediments to both sides, forming the Catskill delta in eastern North America and the Old Red Sandstone in northwestern Europe. Subsequently, the southern edge of North America collided with South America, and a little later Africa arrived, producing the southern Appalachians. Miscellaneous fragments, today part of central Europe and the western Mediterranean, filled in the gap and completed this portion of Pangaea.

This account fits the plate model fairly well except for two things: (1) the occurrence of paroxysms of mountain building when no continental collision can be assumed and (2) the need for sizable landmasses, presumably small continents, floating offshore to provide a necessary sediment source. Both problems appear quite often wherever plate movements are used to explain the details of the formation of major mountain ranges. Yet, the model itself is simple. It allows for three possible cases: ocean–ocean collisions, ocean–continent collisions, and continent–continent collisions. In the first two situations, oceanic crust is subducted either under other oceanic crust or under a continent—a steady process presumably accompanied by an equally steady scraping off and deforming of sediments and basaltic crust at the plate edge and by volcanism farther away. The New Hebrides trench and island arcs in the southwestern Pacific exemplify an ocean–ocean collision, while the Andes mountain ranges of South America represent a long-lasting collision of oceanic crust and continental crust at the leading edges of plates.

Even in these cases the process appears to be more complicated than the theory suggests, demanding modifications that, though eminently plausible and often proven, are ad hoc and thus diminish its value as a unifying principle. The South American Andes, for example, have had an episodic history not readily matched to the evidently uneventful spreading of the seafloor in the adjacent Pacific. The volcanism of the segments of the Cascade Range in Oregon and Washington in the northwestern United States is only a few million years old in its present form, whereas subduction along the Pacific coast dates back much farther than that. All along the west coast of North America, mountain building has occurred in distinct major phases, ultimately caused in all probability by changes in the rate and direction of plate movements that complicate the basically simple subduction process.

One of the complicating factors is much in evidence in the coast ranges that extend from California to southern Alaska. Large sections of these mountains fit poorly with the geology of the surrounding terrain and are thought to have originated somewhere in the ancient Pacific. Perhaps they once were oceanic plateaus, island arcs, or other

thick pieces of oceanic crust that would not subduct but instead became lodged against the continental edge, and so disturbed the processes of subduction and mountain building. Some of these “exotic terranes” have been shown by their paleomagnetic properties to have come a long way from their points of origin, perhaps as far as the Southern Hemisphere.

The Indus-Himalayan-Tibetan region in northern India and China represents a continent–continent collision that began 40 million years ago when all the oceanic crust between northward-drifting India and south-central Asia had been consumed and the continent-bearing edges of the two plates met. The suture of this collision, the site of the former subduction zone, lies inconspicuously in the high plateau region north of the Himalayas. This lofty mountain range itself formed long after the collision as India—its momentum not fully spent even today—drove another 2,000 kilometres into the underbelly of Asia. As a result, Asian lithosphere was displaced laterally along enormous transcurrent faults, which are the sites of the numerous devastating earthquakes in Iran, Afghanistan, and western China (Figure 7). The Himalayas themselves are the product of the northward, low-angle underthrusting of the upper slice of the Indian-Australian Plate under the Eurasian Plate, making it clear that a continent–continent collision involves a good deal more than the crumpling of opposing front edges.

Plate tectonics and life. Inevitably the continuous rearrangement over time of the size and shape of ocean basins and continents, followed by changes in ocean circulation and climate, have had a major impact on the development of life on Earth. Active interest in these aspects of the Earth science revolution has lagged behind that in other areas, even though as early as 1970 the American geologists James W. Valentine and Eldridge M. Moores

From T.H. van Andel, *New Views on an Old Planet* (1985); Cambridge University Press

The
effect
of plate
activity
on the
evolution
of life

attempted to show that the diversity of life increased as continents fragmented and dispersed and diminished when they were joined together.

Subsequently, however, the study of plate activity as a force in the evolution of life has leaped forward. A few simple examples of such research must suffice to illustrate the impact of the plate theory. Toward the end of the Paleozoic, during the Permian period (about 286 to 245 million years ago), there was a drastic drop in the variety of animal forms inhabiting the shallow seas around Pangaea. Well over half of the total number of known families became extinct. This drop can be attributed in large part simply to the decrease in biogeographic variety that marks a world consisting of a single continent rather than one comprising many widely dispersed landmasses. Other factors, such as a sharp decrease in the area of shallow-water habitats or a change in ocean fertility due to upwelling, have also been invoked. Moreover, the extinction had a complex history. High latitudes were affected first as a result of the waning of the Permian ice age when the South Pole slipped beyond the southern edge of Pangaea. The equatorial and subtropical zones appear to have been affected somewhat later by a global cooling. On the other hand, the extinctions were not felt so strongly on the continent itself. Instead, the vast semiarid and arid lands that emerged on so large a continent, the shortening of its moist coasts, and the many mountain ranges remaining from the collisions that led to the formation of the supercontinent provided strong incentives for evolutionary adaption to dry or high-altitude environments.

The impact of plate movements and interactions on life is perhaps most clearly demonstrated by what happens when continents diverge or collide. When the Atlantic Ocean began to open during the middle Mesozoic, the similarity between the faunas of opposite shores gradually decreased in almost linear fashion—the greater the distance, the smaller the number of families in common. The difference increased more rapidly in the South Atlantic than in the North Atlantic, where a land connection between Europe and North America persisted until well after the middle Cenozoic. The inverse, the effect of a collision between two hitherto separate landmasses, is illustrated by the consequences of the Pliocene emergence of the Isthmus of Panama. In South America a highly specialized fauna had evolved, rich in marsupials but with few predators. After the emergence of the isthmus had made it possible for land animals to cross, numerous herbivores migrated from north to south. They adapted well to the new environment and were more successful than the local fauna in competing for food. The invasion of highly adaptable carnivores from the north contributed to the extinction of no fewer than four orders of South American land mammals. Only a few species, notably the armadillo and the opossum, managed to migrate in the opposite direction. Ironically, many of the invading northerners, such as the llama and tapir, subsequently became extinct in their country of origin and found their last refuge in the south.

Early plate activity. Whatever the forces may be that drive the plates, they consume energy. By far the largest part of this energy is derived from the decay of radioactive isotopes within the Earth, and the energy flow has therefore declined through the 4.5 billion years of the Earth's history—rapidly at first and then at a slowly diminishing though not negligible rate. Accordingly, it is quite likely that the behaviour of the lithospheric plates on the early, more energetic Earth was different from what it is today, and what prevails at present will certainly differ from what will prevail in the future. A thickening lithosphere, a decreasing heat flow, a temperature gradient that decreases with depth within the Earth, and enlarging—though perhaps less vigorous—convection cells in the mantle have all been postulated as unidirectional changes that affected the behaviour of the lithosphere. It is possible, for example, that the initial plates were too small, too hot, and hence too light to be subducted. In this case, the first subduction would mark the coming of age of classical plate tectonics, and, indeed, clear evidence is lacking for subduction until rather late in the Precambrian.

The evidence that bears on the existence, nature, and

movements of possible lithospheric plates during the first several billion years of Earth history is very limited. The continental nuclei of the early and middle Precambrian seem to have been small and might be regarded as small plates on a more vigorously convecting mantle, though admittedly other explanations are equally possible. These nuclei are thought to have been embedded in strongly deformed complexes of sediments and basic igneous rocks, the greenstone belts reminiscent of the sutures that mark the closure of ancient oceans. In most cases, however, paleomagnetic data do not leave room for the existence of sizable oceanic areas between such nuclei. Investigators are thus forced to contemplate the possibility that, in the Precambrian, intensive deformation took place within plates, perhaps commensurate with the postulated thinner lithosphere and higher flow of heat toward the surface. On the other hand, current knowledge of this long but obscure portion of Earth history is so deficient that some geologists have emphatically denied that there might have been a remote past to which classical plate tectonics could not be applied.

DISSENTING OPINIONS AND UNANSWERED QUESTIONS

The dissenters. Scientific revolutions as far-reaching in their consequences as the plate tectonics revolution cannot be expected to be easily, or ever completely, accepted. Nevertheless, once the theory had fully emerged, acceptance was quick and widespread and by the late 1960s its influence in the West was pervasive. Such was, however, not the case in the Soviet Union, a country located largely in the continental interior far from present-day plate boundaries. Soviet scientists viewed as central to any issue of global tectonics the vertical movements of continental interiors, phenomena not satisfactorily dealt with by the plate tectonics theory. A leading spokesman for the Soviet position, the academician Vladimir Vladimirovich Belousov, strongly defended a model of the Earth that postulated stationary continents affected almost exclusively by vertical motions. The model, however, only vaguely defined the forces supposedly responsible for the motions. In recent years, a younger generation of Soviet geologists has very gradually come to regard plate tectonics as an attractive theory and a viable alternative to the concepts of Belousov and his followers.

Opposition to plate tectonics was by no means limited to the Soviet Union. Critics were heard—in fact, some quite loudly—elsewhere as well. Sir Harold Jeffreys continued his lifelong rejection of continental drift on grounds that his estimates of the properties of the mantle indicated the impossibility of plate movements. He did not, in general, deign to take note of the mounting geophysical and geologic arguments that were in favour of a mobile outer shell of the Earth.

Others proffered different explanations of the accumulating evidence, most of which were rather farfetched, as, for instance, the suggestion that new crust was formed at trenches and destroyed on mid-ocean ridges. Still others, notably the American geologists A.A. Meyerhoff and Howard A. Meyerhoff, attempted to assemble data that contradicted the theory and thereby show that the supporting evidence was wrong, insufficient, or simply misconstrued. Demonstrating a remarkable command of often quite obscure literature, they issued a series of negative commentaries in the early 1970s; but they failed to convince the majority of their colleagues, partly because they did not offer alternative explanations for the evidence.

The only serious alternative had been proposed in 1958 by the Australian geologist S. Warren Carey in the form of a new version of an old idea—namely, the expanding Earth model. Carey accepted the existence and early Mesozoic breakup of Pangaea and the subsequent dispersal of its fragments and formation of new ocean basins, but he attributed it all to the expansion of the Earth, the planet presumably having had a much smaller diameter in the late Paleozoic. In his view, the continents represented the pre-expansion crust, and the enlarged surface was to be entirely accommodated within the oceans. This model accounted for a spreading ocean floor and for the young age of the oceanic crust; however, it failed to deal adequately

Early
opposition
to plate
tectonics

Carey's
version
of the
expanding
Earth
model

with the evidence for subduction and compression. Carey's model also did not explain why the process should not have started until some four billion years after the Earth was formed, and it lacked a reasonable mechanism for so large an expansion. Finally, it disregarded the evidence for continental drift before the existence of Pangaea.

Unanswered questions. As the philosopher Thomas J. Kuhn has pointed out, science does not always advance in the gradual and stately fashion commonly attributed to it. Major breakthroughs often come from a leap forward that is at least in part intuitive and may fly in the face of conventional wisdom and widely accepted evidence while strict requirements for verification and proof are temporarily relaxed. Revolutions thus often become widely accepted before the verdict from rigorous analysis of evidence is completely in. Such was certainly the case with the geologic revolution, which also confirms Kuhn's view that a new paradigm is unlikely to supersede an existing one until there is little choice but to acknowledge that the conventional theory has failed. Thus, while Wegener did not manage to persuade the world, the successor theory was readily embraced 40 years later, even though it remained open to much of the same criticism that had caused the downfall of continental drift. What is the state of the new paradigm? Is it likely to suffer sooner rather than later the same fate that inevitably awaits all scientific theories?

In 1974, almost alone among the doubters who tried to discredit the new theory with contrary evidence, the American geologist John C. Maxwell, in a closely reasoned paper, enumerated all the points on which he believed plate tectonics had failed to offer an explanation. Many of these points have since been resolved, but more than a few remain to suggest that the theory, though in essence valid, may be incomplete.

The greatest successes of plate tectonics have been achieved in the ocean basins where additional decades of effort have confirmed its postulates and enabled investigators to construct a credible history of past plate movements. Inevitably in less rigorous form, the reconstruction of early Mesozoic and Paleozoic continental configurations has provided a powerful tool with which to resolve many important questions. On the other hand, the new paradigm has proved less useful in deciphering mountain-building processes or in offering explanations for the complex history of sea-level fluctuations. The American geologist L.L. Sloss has devoted a great deal of effort to demonstrating that continents do indeed rise and fall in unison, but the possible mechanisms for such a process remain elusive.

Where plate boundaries adjoin continents, matters often become very complex and have demanded an ever denser thicket of ad hoc modifications and amendments to the theory and practice of plate tectonics in the form of microplates, obscure plate boundaries, and exotic terranes. A good example is the Mediterranean, where the collisions between Africa and a swarm of microcontinents have produced a tectonic nightmare that is far from resolved. More disturbingly, some of the present plate boundaries, especially in the eastern Mediterranean, appear to be so diffuse and so anomalous that they cannot be compared to the three types of plate boundaries of the basic theory.

There is further evidence, as held by the American geophysicist Thomas H. Jordan, that the base of the plates

extends far deeper into the asthenosphere below the continents than below the oceans. How much of an impediment this might be for the free movement of plates and how it might affect their boundary interactions remain open questions. Others have postulated that the lower layer of the lithosphere peels off and sinks late in any collision sequence, producing high heat flow, volcanism, and an upper lithospheric zone vulnerable to contraction by thrusting.

It is understandable that any simple global tectonic model would work better in the oceans, which, being young, retain a record of only a brief and relatively uneventful history. On the continents, almost four billion years of growth and deformation, erosion, sedimentation, and igneous intrusion have produced a complex imprint that, with its intricate zones of varying strength, must directly affect the application of plate forces. Seismic reflection studies of the deep structure of the continents have demonstrated just how complex the events that form the continents and their margins may have been, and their findings sometimes are difficult to reconcile with the accretionary structures one would expect to see as a result of subduction and collision.

Notwithstanding these cautions and the continuing lack of an agreed-upon driving mechanism for the plates, one cannot help but conclude that the plate tectonics revolution has been fruitful and has immensely advanced scientific understanding of the Earth. Like all paradigms in science, it will most likely one day be replaced by a better one; yet there can be little doubt that, whatever the new theory may state, continental drift will be part of it.

BIBLIOGRAPHY. J. TUZO WILSON (ed.), *Continents Adrift and Continents Aground* (1976), contains an excellent and readable set of articles on the plate tectonics revolution drawn from *Scientific American*, many written by its protagonists, with fine introductions by the editor. Similarly, ALLAN COX (ed.), *Plate Tectonics and Geomagnetic Reversals* (1973), offers a well-chosen selection of the original classical papers that produced this revolution in the Earth sciences, from Holmes's work in the early 1900s to contributions in the late 1960s. An excellent explanation of the new Earth science is SEIYA UYEDA, *The New View of the Earth: Moving Continents and Moving Oceans* (1978), which discusses plate theory and its application to the study of the Earth's surface structures. Scholarly, but written for a lay audience, is TJEERD H. VAN ANDEL, *New Views on an Old Planet: Continental Drift and the History of Earth* (1985), an application of plate theory to the climatic, oceanographic, and geographic history of the Earth, and the relation of the theory to the history of life. The history of ideas pertaining to continental drift and plate tectonics has been thoughtfully analyzed in ANTHONY HALLAM, *A Revolution in the Earth Sciences: From Continental Drift to Plate Tectonics* (1973). The same subject is reviewed from a somewhat different vantage point—that of a science writer—in WALTER SULLIVAN, *Continents in Motion: The New Earth Debate* (1974). A summary of the revolution, mostly in a critical vein by many of its principal opponents, is CHARLES F. KAHLE (ed.), *Plate Tectonics: Assessments and Reassessments* (1974), a bit dated but a good substantive statement on the subject. More technical, though not forbiddingly so, are three books rich in detail and substance: PETER J. WYLLIE, *The Way the Earth Works: An Introduction to the New Global Geology and Its Revolutionary Development* (1976); ROBERT H. DOTT, JR., and ROGER L. BATTEN, *Evolution of the Earth*, 3rd ed. (1981), for the impact of the plate theory on research in Earth history; and STEPHEN STANLEY, *Earth and Life Through Time* (1985), a newer and more advanced treatment. (T.H.v.A.)

Plato and Platonism

Plato was the second of the great trio of ancient Greeks—Socrates, Plato, and Aristotle—who between them laid the philosophical foundations of Western culture. Building on the life and thought of Socrates, Plato developed a profound and wide-ranging system of philosophy. His thought has logical, epistemological, and metaphysical aspects; but its underlying motivation is ethical. It sometimes relies upon conjectures and myth, and it is occasionally mystical in tone; but funda-

mentally Plato is a rationalist, devoted to the proposition that reason must be followed wherever it leads. Thus the core of Plato's philosophy is a rationalistic ethics.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, Part Ten, Division V, especially Sections 51 and 53.

This article deals with the man, his works and influence, and the subsequent history of Platonism. It is divided into the following sections:

Plato and his thought

LIFE

Plato was born, the son of Ariston and Perictione, in Athens, or perhaps in Aegina, in about 428 BC, the year after the death of the great statesman Pericles. His family, on both sides, was among the most distinguished in Athens. Ariston is said to have claimed descent from the god Poseidon through Codrus, the last king of Athens; on the mother's side, the family was related to the early Greek lawmaker Solon. Nothing is known about Plato's father's death. It is assumed that he died when Plato was a

Distinguished family

Plato, Roman herm probably copied from a Greek original, 4th century BC. In the Staatliche Museen, Berlin.

boy. Perictione apparently married as her second husband her uncle Pyrilampes, a prominent supporter of Pericles; and Plato was probably brought up chiefly in his house. Critias and Charmides, leaders among the extremists of the oligarchic terror of 404, were, respectively, cousin and brother of Perictione; both were friends of Socrates, and through them Plato must have known the philosopher from boyhood.

His own early ambitions—like those of most young men of his class—were probably political. A conservative faction urged him to enter public life under its auspices, but he wisely held back. He was soon repelled by its members' violent acts. After the fall of the oligarchy, he hoped for better things from the restored democracy. Eventually, however, he became convinced that there was no place for a man of conscience in Athenian politics. In 399 BC the democracy condemned Socrates to death, and Plato and other Socratic men took temporary refuge at Megara with Euclides, founder of the Megarian school of philosophy. The next few years are said to have been spent in extensive travels in Greece, in Egypt, and in Italy. Plato himself (if the *Seventh Letter* is his; see below) states that he visited Italy and Sicily at the age of 40 and was disgusted by the gross sensuality of life there but found a kindred spirit in Dion, brother-in-law of Dionysius I, the ruler of Syracuse.

The Academy and Sicily. In about 387 Plato founded the Academy as an institute for the systematic pursuit of philosophical and scientific teaching and research. He presided over it for the rest of his life. The Academy's interests were not limited to philosophy in a narrow sense but also extended to the sciences: there is evidence that Plato encouraged research in such diverse disciplines as mathematics and rhetoric. He himself lectured (on at least one occasion he gave a celebrated public lecture "On the Good"), and he set problems for his pupils to solve. The Academy was not the only such "school" in Athens—there are traces of tension between the Academy and the rival school of Isocrates.

The one outstanding event in Plato's later life was his intervention in Syracusan politics. On the death of Dionysius I in 367, Dion conceived the idea of bringing Plato to Syracuse as tutor to his brother-in-law's successor, Dionysius II, whose education had been neglected. Plato was not

Political activity in Sicily

optimistic about the results; but because both Dion and Archytas of Tarentum, a philosopher-statesman, thought the prospect promising, he felt bound to risk the adventure. The plan was to train Dionysius II in science and philosophy and so to fit him for the position of a constitutional king who might hold Carthaginian encroachment on Sicily at bay. The scheme was crushed by Dionysius' natural jealousy of the stronger Dion, whom he drove into virtual banishment. Plato later paid a second and longer visit to Syracuse in 361–360, still in the hope of effecting an accommodation; but he failed, not without some personal danger. Dion then captured Syracuse by a coup de main in 357, but he was murdered in 354. Plato himself died in 348/347.

Of Plato's character and personality little is known, and little can be inferred from his writings. But it is worth recording that Aristotle, his most able pupil, described Plato as a man "whom it is blasphemy in the base even to praise," meaning that Plato was so noble a character that bad men should not even speak about him.

To his readers through the ages Plato has been important primarily as one of the greatest of philosophical writers; but to himself the foundation and organization of the Academy must have appeared to be his chief work. The *Seventh Letter* contrasts the impact of written works with that of the contact of living minds as a vehicle of philosophy, and it passes a comparatively unfavourable verdict on written works. Plato puts a similar verdict into the mouth of Socrates in the *Phaedrus*. He perhaps intended his dialogues in the main to interest an educated outside world in the more serious and arduous labours of his school.

All of the most important mathematical work of the 4th century was done by friends or pupils of Plato. The first students of conic sections, and possibly Theaetetus, the creator of solid geometry, were members of the Academy. Eudoxus of Cnidus—author of the doctrine of proportion expounded in Euclid's *Elements*, inventor of the method of finding the areas and volumes of curvilinear figures by exhaustion, and propounder of the astronomical scheme of concentric spheres adopted and altered by Aristotle—removed his school from Cyzicus to Athens for the purpose of cooperating with Plato; and during one of Plato's absences he seems to have acted as the head of the Academy. Archytas, the inventor of mechanical science, was a friend and correspondent of Plato.

Nor were other sciences neglected. Speusippus, Plato's nephew and successor, was a voluminous writer on natural history; and Aristotle's biological works have been shown to belong largely to the early period in his career immediately after Plato's death. The comic poets found matter for mirth in the attention of the school to botanical classification. The Academy was particularly active in jurisprudence and practical legislation. As Plutarch testifies,

Plato sent Aristonymus to the Arcadians, Phormion to Elis, Menedemus to Pyrrha. Eudoxus and Aristotle wrote laws for Cnidus and Stagirus. Alexander asked Xenocrates for advice about kingship; the man who was sent to Alexander by the Asiatic Greeks and did most to incite him to his war on the barbarians was Delios of Ephesus, an associate of Plato.

The Academy survived Plato's death. Though its interest in science waned and its philosophical orientation changed, it remained for two and a half centuries a focus of intellectual life. Its creation as a permanent society for the prosecution of both humane and exact sciences has been regarded—with pardonable exaggeration—as the first establishment of a university.

Formative influences. The most important formative influence to which the young Plato was exposed was Socrates. It does not appear, however, that Plato belonged as a "disciple" to the circle of Socrates' intimates. The *Seventh Letter* speaks of Socrates not as a "master" but as an older "friend," for whose character Plato had a profound respect; and he has recorded his own absence (through indisposition) from the death scene of the *Phaedo*. It may well be that his own vocation to philosophy dawned on him only afterward, as he reflected on the treatment of Socrates by the democratic leaders. Plato owed to Socrates his commitment to philosophy, his rational method, and his concern for ethical questions. Among other philosoph-

ical influences the most significant were those of Heraclitus and his followers, who disparaged the phenomenal world as an arena of constant change and flux, and of the Pythagoreans, with whose metaphysical and mystical notions Plato had great sympathy.

Plato had family connections with Pyrilampes, a Periclean politician, and with Critias, who became one of the most unscrupulous of the Thirty Tyrants who briefly ruled Athens after the collapse of the democracy.

Plato's early experiences covered the disastrous years of the Deceleian War, the shattering of the Athenian empire, and the fierce civil strife of oligarchs and democrats in the year of anarchy, 404–403. He was too young to have known anything by experience of the imperial democracy of Pericles and Cleon or of the tide of the Sophistic movement. It is certainly not from memory that he depicted Protagoras, the earliest avowed professional Sophist, or Alcibiades, a brilliant but unreliable Athenian politician and military commander. No doubt these early experiences helped to form the political views that were later expounded in the dialogues.

Political setting of Plato's life

GENERAL FEATURES OF THE DIALOGUES

The canon and text of Plato was apparently fixed at about the turn of the Christian Era. By reckoning the *Letters* as one item, the list contained 36 works, arranged in nine tetralogies. None of Plato's works has been lost, and there is a general agreement among modern scholars that a number of small items—*Alcibiades I*, *Alcibiades II*, *Theages*, *Erastae*, *Clitopho*, *Hipparchus*, and *Minos*—are spurious. Most scholars also believe that the *Epinomis*, an appendix to the *Laws*, was written by the mathematician Philippus of Opus. The *Hippias Major* and the *Menexenus* are regarded as doubtful by some, though Aristotle seems to have regarded them as Platonic. Most of the 13 *Letters* are certainly later forgeries. About the authenticity of the *Seventh Letter*, which is by far the most important from the biographical and the philosophical points of view, there exists a long and unsettled controversy.

Order of composition. Plato's literary career extended over the greater part of a long life. The *Apology* was probably written in the early 380s. The *Laws*, on the other hand, was the work of an old man, and the state of its text bears out the tradition that Plato never lived to give it its final revision. Since there is no evidence that Plato began his career with a fully developed system, and since there is every reason to believe that his thoughts changed, the order in which the various dialogues were written takes on importance. Only through it can the development of Plato's thought be adequately charted. Unfortunately, Plato himself has given few clues to the order: he linked the *Sophist* and the *Statesman* with the *Theaetetus* externally as continuations of the conversation reported in that dialogue. Similarly, he seems to have linked the *Timaeus* with the *Republic*. And Aristotle noted that the *Laws* was written after the *Republic*.

Modern scholars, by the use of stylistic criteria, have argued that the *Sophist*, *Statesman*, *Philebus*, *Timaeus* (with its fragmentary sequel *Critias*), and *Laws* form a distinct linguistic group, belonging to the later years of Plato's life. The whole group must be later than the *Sophist*, which professes to be a sequel to the *Theaetetus*. Since the *Theaetetus* commemorates the death of the eminent mathematician after whom it is named (probably in 369 BC), it may be ascribed to c. 368, the eve of Plato's departure for Syracuse.

Stylistic studies of the dialogues

The earlier group of dialogues is generally believed to have ended with the *Theaetetus* and the closely related *Parmenides*. Apart from this, perhaps all that can be said with certainty is that the great dialogues, *Symposium*, *Phaedo*, and *Republic* (and perhaps also *Protagoras*), in which Plato's dramatic power was at its highest, mark the culmination of this first period of literary activity. The later dialogues are often thought to lack the dramatic and literary merits of the earlier but to compensate for this by an increased subtlety and maturity of judgment.

Persons of the dialogues. One difficulty that initially besets the modern student is that created by the dramatic form of Plato's writings. Since Plato never introduced

Influence of the Academy

Dialogue
form

himself into his own dialogues, he is not formally committed to anything asserted in them. The speakers who are formally bound by the utterances of the dialogues are their characters, of whom Socrates is usually the protagonist. Since all of these are real historical persons, it is reasonable to wonder whether Plato is reporting their opinions or putting his own views into their mouths, and, more generally, to ask what was his purpose in writing dialogues.

Some scholars have suggested that Plato allowed himself to develop freely in a dialogue any view that interested him for the moment without pledging himself to its truth. Thus Plato can make Socrates advocate hedonistic utilitarianism in the *Protagoras* and denounce it in the *Gorgias*. Others argue that some of Plato's characters, notably Socrates and Timaeus, are "mouthpieces" through whom he inculcates tenets of his own without concern for dramatic or historical propriety. Thus it has often been held that the theory of Ideas, the doctrine of recollection, and the notion of the tripartite soul were originated by Plato after the death of Socrates and consciously fathered on the older philosopher.

Plato's
changing
views

Thought of the earlier and later dialogues. There are undeniable differences in thought between the dialogues that are later than the *Theaetetus* and those that are earlier. But there are no serious discrepancies of doctrine between individual dialogues of the same period. Plato perhaps announced his own personal convictions on certain doctrines in the second group of dialogues by a striking dramatic device. In the *Sophist* and *Statesman* the leading part is taken by a visitor from Elea and in the *Laws* by an Athenian. These are the only anonymous, indeed almost certainly the only imaginary, personages of any moment in the whole of Plato's writings. It seems likely, therefore, that these two characters were left anonymous so that the writer could be free to use them as mouthpieces for his own teaching. Plato thus took on himself the responsibility for the logic and epistemology of the *Sophist* and of the *Statesman* and for the ethics and the educational and political theory of the *Statesman* and of the *Laws*.

Doctrine of Forms. There is a philosophical doctrine running through the earlier dialogues that has as its three main features the theory of knowledge as recollection, the conception of the tripartite soul, and, most importantly, the theory of Forms. The theory that knowledge is recollection rests on the belief that the soul is not only eternal but also preexistent. The conception of the tripartite soul holds that the soul consists of reason, appetite, and spirit (or will). Each part serves a purpose and has validity, but reason is the soul's noblest part; in order for man to achieve harmony, appetite and spirit must be subjected to the firm control of reason. The theory of Forms has as its foundation the assumption that beyond the world of physical things there is a higher, spiritual realm of Forms, or Ideas, such as the Form of Beauty or Justice. This realm of Forms, moreover, has a hierarchical order, the highest level being that of the Form of the Good. Whereas the physical world, perceived with the senses, is in constant flux and knowledge derived from it restricted and variable, the realm of Forms, apprehensible only by the mind, is eternal and changeless. Each Form is the pattern of a particular category of things in this world; thus there are Forms of man, stone, shape, colour, beauty, and justice. Yet the things of this world are only imperfect copies of these perfect Forms.

In the *Phaedo* Socrates is made to describe the theory of Ideas as something quite familiar that he has for years constantly canvassed with his friends. In the dialogues of the second period, however, these tenets are less prominent, and the most important of them all, the theory of Forms, is in the *Parmenides* subjected to a searching set of criticisms. The question thus arises as to whether Plato himself had two distinct philosophies, an earlier and a later, or whether the main object of the first group of dialogues was to preserve the memory of Socrates, the philosophy there expounded being, in the main, that of Socrates—coloured, no doubt, but not consciously distorted, in its passage through the mind of Plato. On the second view, Plato had no distinctive Platonic philosophy until a late period in his life.

Socrates and Plato. It may be significant that the only dialogue later than the *Theaetetus* in which Socrates takes a leading part is the *Philebus*, the one work of the second group that deals primarily with the ethical problems on which the thought of Socrates had concentrated. This is usually explained by supposing that Plato was unwilling to make Socrates the exponent of doctrines that he knew to be his own property. It would, however, be hard to understand such misgivings if Plato had already been employing Socrates in that very capacity for years. It is notable, too, that Aristotle, who apparently knew nothing of an earlier and a later version of Platonism, attributed to Plato a doctrine that is quite unlike anything to be found in the first group of dialogues. It was also the view of Neoplatonic scholars that the theory of Ideas of the great earlier dialogues really originated with Socrates; and the fact that they did not find it necessary to argue the point may show that this had been the standing tradition of the Academy.

Few modern scholars, however, support this view. The differences between the early and late periods are not as great as they have sometimes been represented: although Plato's thought developed from the early to the late dialogues, it underwent no sudden dislocation. The ideas of the early period may have been inspired by Socrates, but they were Plato's own—for example, the theory of Forms could not have arisen with Socrates. Plato nevertheless attributed it to him because he saw it as the theoretical basis of what Socrates did teach.

THE EARLIER DIALOGUES

In the *Republic*, the greatest of all the dialogues that precede the *Theaetetus*, there are three main strands of argument deftly combined into an artistic whole—the ethical and political, the aesthetic and mystical, and the metaphysical. Other major dialogues belonging to this period give special prominence to one of these three lines of thought: the *Phaedo* to the metaphysical theme; the *Protagoras* and the *Gorgias* to the ethical and political; the *Symposium* and the *Phaedrus* to the aesthetic. But it should be noted that Plato's dialogues are not philosophical essays, let alone philosophical treatises, and they do not restrict themselves to a single topic or subject.

Dialogues of search. The shorter dialogues, dealing with more special problems, generally of an ethical character, mostly conform to a common type: a problem in moral philosophy, often that of the right definition of a virtue, is propounded, a number of tentative solutions are considered, and all are found to be vitiated by difficulties that cannot be dispelled. The reader is left, at the end of the conversation, aware of his ignorance of the very things that it is most imperative for a man to know. He has formally learned nothing but has been made alive to the confusions and fallacies in what he had hitherto been content to take as knowledge. The dialogues are "aporetic" and "elenctic": they pose puzzles (*aporiai* in Greek) without solving them, and Socrates' procedure consists in the successive refutation (*elenchos*) of the various views presented by his interlocutors.

The effect of these dialogues of search is thus to put the reader in tune with the spirit of Socrates, who had said that the one respect in which he was wiser than other men was in his keen appreciation of his own ignorance of the most important matters. The reader learns the meaning of Socrates' ruling principle that the supreme business of life is to "tend" the soul and his conviction that "goodness of soul" means knowledge of good and evil. The three dialogues directly concerned with the trial of Socrates have a further purpose. They are intended to explain to a puzzled public, as a debt of honour to his memory, why Socrates thought it a matter of conscience neither to withdraw from danger before his trial, nor to make a conciliatory defense, nor, after conviction, to avail himself of the opportunity of flight.

The *Apology*, or *Defense*, purports to give Socrates' speeches at his trial for impiety. In the *Crito* Socrates, in the condemned cell, explains why he will not try to escape paying the death penalty; the dialogue is a consideration of the source and nature of political obligation. The *Eu-*

of thought

Themes of
the shorter
dialogues

thyphro is represented as taking place just before Socrates' trial. Its subject is the virtue of "piety," or the proper attitude for men to take toward the gods. The *Hippias Major* propounds the question "What is the 'fine' (or 'beautiful')?" The *Hippias Minor* deals with the paradox that "wrongdoing is involuntary." The *Ion* discredits the poets, who create not "by science" but by a nonrational inspiration. The *Menexenus*, which professes to repeat a funeral oration learned from Aspasia, Pericles' mistress, is apparently meant as a satire on the patriotic distortion of history. The *Charmides*, *Laches*, and *Lysis* are typical dialogues of search. The question of the *Charmides* is what is meant by *sôphrosunê*, or "temperance," the virtue that is shown in self-command, in dutiful behaviour to parents and superiors, in balance, and in self-possession amid the turns of fortune. It seems that this virtue can be identified with the self-knowledge that Socrates had valued so highly. The *Laches* is concerned with courage, the soldier's virtue; and the *Lysis* examines in the same tentative way friendship, the relation in which self-forgetting devotion most conspicuously displays itself.

The question of whether words have meaning by nature or by convention is considered in the *Cratylus*—whether there is some special appropriateness of the sounds or forms of words to the objects they signify, or whether meaning merely reflects the usage of the community. Plato argues that, since language is an instrument of thought, the test of its rightness is not mere social usage but its genuine capacity to express thought accurately. The dialogue *Euthydemus* satirizes the "eristics"—those who try to entangle a person in fallacies because of the ambiguity of language. Its more serious purpose, however, is to contrast this futile logic chopping with the "protreptic," or hortatory, efforts of Socrates, who urges that happiness is guaranteed not by the possession of things but by the right use of them—and particularly of the gifts of mind, body, and fortune.

Ethical and political dialogues. The *Gorgias*, the *Protagoras*, and the *Meno*, like several of the lesser dialogues, give prominence to ethical and political themes. The *Gorgias* begins ostensibly as an inquiry into the nature and worth of rhetoric, the art of advocacy professed by Gorgias, and develops into a plea of sustained eloquence and logical power for morality—as against expediency—as the sovereign rule of life, both private and public. It ends with an imaginative picture of the eternal destinies of the righteous and of the unrighteous soul.

Gorgias holds that rhetoric is the queen of all "arts." If the statesman skilled in rhetoric is clever enough, he can, though a layman, carry the day even against the specialist. Socrates, on the other hand, declares that rhetoric is not an art but a mere "knack" of humouring the prejudices of an audience. There are two arts conducive to health of soul, those of the legislator and of the judge. The Sophist counterfeits the first, the orator the second, by taking the pleasant instead of the good as his standard. The orator is thus not the wise physician of the body politic but its toady. This severe judgment is disputed by Polus, an ardent admirer of Gorgias, on the ground that the successful orator is virtually the autocrat of the community, and to be such is the summit of human happiness because he can do whatever he likes.

Socrates rejects this view. He does so by developing one of the "Socratic paradoxes": to suffer a wrong is an evil, but to inflict one is much worse. Thus if rhetoric is of real service to men, it should be most of all serviceable to an offender, who would employ it to move the authorities to inflict the penalties for which the state of his soul calls. All of this is in turn denied by Calicles, who proceeds to develop the extreme position of an amoralist. It may be a convention of the herd that unscrupulous aggression is discreditable and wrong, but "nature's convention" is that the strong are justified in using their strength as they please, while the weak "go to the wall." To Socrates, however, the creators of the imperialistic Athenian democracy were no true statesmen; they were the domestic servants of the democracy for whose tastes they catered; they were not its physicians. That would be a condition like that of the Danaids of mythology, who are punished in Hades

by being set to spend eternity in filling leaking pitchers. A happy life consists not in the constant gratification of boundless desires but rather in the measured satisfaction of wants that are tempered by justice and *sôphrosunê*.

The *Meno* is nominally concerned with the question of what virtue is and whether it can be taught. But it is further interesting for two reasons: it states clearly the doctrine that knowledge is "recollection"; and it introduces as a character the democratic politician Anytus, the main author of the prosecution of Socrates.

Whether virtue can be taught depends on what virtue is. But the inquiry into virtue is difficult—indeed, the very possibility of inquiry is threatened by Meno's paradox concerning the quest for knowledge. If a person is ignorant about the subject of his inquiry, he could not recognize the unknown, even if he found it. If, on the other hand, the person already knows it, inquiry is futile because it is idle to inquire into what one already knows. But this difficulty would vanish if the soul were immortal and had long ago learned all truth, so that it needs now only to be reminded of truths that it once knew and has forgotten. To advance this argument, Socrates shows that a slave boy who has never studied geometry can be brought to recognize mathematical truths. He produces the right answer "out of himself." In general, knowledge is "recollection." Socrates next produces the hypothesis that virtue is knowledge and infers that it is teachable. But if virtue is knowledge, there must be professional teachers of it. Anytus insists that the Sophists, who claim to be such professionals, are mischievous impostors; and even the "best men" have been unable to teach it to their own sons. The *Meno* ends with a distinction between knowledge and true belief, and with the suggestion that virtue comes not by teaching but by divine gift.

The *Protagoras* gives the most complete presentation of the main principles of Socratic morality. In this dialogue Socrates meets the eminent Sophist Protagoras, who explains that his profession is the "teaching of goodness"—i.e., the art of making a success of one's life and of one's city. Socrates urges, however, that both common opinion and the failure of eminent men to teach "goodness" to their sons suggest that the conduct of life is not teachable. But the problem arises as to whether the various commonly recognized virtues are really different or all one. Protagoras is ultimately ready to identify all of the virtues except courage with wisdom or sound judgment. Socrates then attempts to show that, even in the case of courage, goodness consists in the fact that, by facing pain and danger, one escapes worse pain or danger. Thus all virtues can be reduced to the prudent computation of pleasures and of pains. Here, then, is a second "Socratic paradox": no one does wrong willingly—wrongdoing is a matter of miscalculation. It is a puzzling feature of this argument that Socrates appears to embrace a form of hedonism.

Metaphysical foundation of Plato's doctrine: "Phaedo." In the works so far considered, the foundation of a Socratic moral and political doctrine is laid, which holds that the great concern of man is the development of a rational moral personality and that this development is the key to man's felicity. Success in this task, however, depends on rational insight into the true scale of good. The reason men forfeit felicity is that they mistake apparent good for real. If a man ever knew with assurance what the Good is, he would never pursue anything else; it is in this sense that "all virtue is knowledge." The philosophical moralist, who has achieved an assured insight into absolute Good, is thus the only true statesman, for he alone can tend to the national character. These moral convictions have a metaphysical foundation and justification. The principles of this metaphysics are expounded more explicitly in the following dialogues, in which a theory of knowledge and of scientific method is also discernible.

The object of the *Phaedo* is to justify belief in the immortality of the soul by showing that it follows from a fundamental metaphysical doctrine (the theory of Ideas, or the doctrine of Forms), which seems to afford a rational clue to the structure of the universe. Socrates' soul is identical with Socrates himself: the survival of his soul is the survival of Socrates—in a purified state. For his life has

Good

Arguments for immortality of the soul

been spent in trying to liberate the soul from dependence on the body. In life, the body is always interfering with the soul's activity. Its appetites and passions interrupt the pursuit of wisdom and goodness.

There are four arguments for thinking that the soul survives death.

First, there is a belief that the soul has a succession of many lives. The processes of nature in general are cyclical; and it is reasonable to suppose that this cyclicity applies to the case of dying and coming to life. If this were not so, if the process of dying were not reversible, life would ultimately vanish from the universe.

Second, the doctrine that what men call "learning" is really "recollection" shows, or at least suggests, that the soul's life is independent of the body.

Third, the soul contemplates the Forms, which are eternal, changeless, and simple. The soul is like the Forms. Hence it is immortal.

The fourth argument is the most elaborate. Socrates begins by recalling his early interest in finding the causes of being and change and his dissatisfaction with the explanations then current. He offers instead the Forms as causes. First, and safely, he says that something becomes, say, hot simply by participating in Heat. Then, a little more daringly, he is prepared to say that it becomes hot by participating in Fire, which brings Heat with it. Now if Fire brings Heat, it cannot accept Cold, which is the opposite of Heat. All this is then applied to the soul. Human beings are alive by participating in Life—and, more particularly, by having souls that bring Life with them. Since the soul brings Life, it cannot accept Death, the opposite of Life. But in that case the soul cannot perish and is immortal. (For further discussion of the theory of Forms, see *METAPHYSICS*.)

Aesthetic and mystical dialogues. Both the *Symposium* and the *Phaedrus* present the Forms in a special light, as objects of mystical contemplation and as stimuli of mystical emotion.

The immediate object of the *Symposium*, which records several banquet eulogies of *erōs* (erotic love), is to find the highest manifestation of the love that controls the world in the mystic aspiration after union with eternal and supercosmic beauty. It depicts Socrates as having reached the goal of union and puts the figure of Alcibiades, who has sold his spiritual birthright for the pleasures of the world, in sharp opposition to him.

The main argument may be summarized thus: *Erōs* is a reaching out of the soul to a hoped-for good. The object is eternal beauty. In its crudest form, love for a beautiful person is really a passion to achieve immortality through offspring by that person. A more spiritual form is the aspiration to combine with a kindred soul to give birth to sound institutions and rules of life. Still more spiritual is the endeavour to enrich philosophy and science through noble dialogue. The insistent seeker may then suddenly descry a supreme beauty that is the cause and source of all of the beauties so far discerned. The philosopher's path thus culminates in a vision of the Form of the Good, the supreme Form that stands at the head of all others.

Though the immediate subject of the *Phaedrus* is to show how a truly scientific rhetoric might be built on the double foundation of logical method and scientific study of human passions, Plato contrives to unite with this topic a discussion of the psychology of love, which leads him to speak of the Forms as the objects of transcendent emotion and, indeed, of mystical contemplation. The soul, in its antenatal, disembodied state, could enjoy the direct contemplation of the Forms. But sense experience can suggest the Form of Beauty in an unusually startling way: through falling in love. The unreason and madness of the lover mean that the wings of his soul are beginning to grow again; it is the first step in the soul's return to its high estate.

The "Republic." In the *Republic* the immediate problem is ethical. What is justice? Can it be shown that justice benefits the man who is just? Plato holds that it can. Justice consists in a harmony that emerges when the various parts of a unit perform the function proper to them and abstain from interfering with the functions of any other

part. More specifically, justice occurs with regard to the individual, when the three component parts of his soul—reason, appetite, and spirit, or will—each perform their appropriate tasks; with regard to society, justice occurs when its component members each fulfill the demands of their allotted roles. Harmony is ensured in the individual when the rational part of his soul is in command; with regard to society, when philosophers are its rulers because philosophers—Platonic philosophers—have a clear understanding of justice, based on their vision of the Form of the Good.

In the ethical scheme of the *Republic* three roles, or "three lives," are distinguished: those of the philosopher, of the votary of enjoyment, and of the man of action. The end of the first is wisdom; of the second, the gratification of appetite; and of the third, practical distinction. These reflect the three elements, or active principles, within a man: rational judgment of good; a multitude of conflicting appetites for particular gratifications; and spirit, or will, manifested as resentment against infringements both by others and by the individual's own appetites.

This tripartite scheme is then applied to determine the structure of the just society. Plato develops his plan for a just society by dividing the general population into three classes that correspond to the three parts of man's soul as well as to the three lives. Thus there are: the statesmen; the general civilian population that provides for material needs; and the executive force (army and police). These three orders correspond respectively to the rational, appetitive, and spirited elements. They have as their corresponding virtues wisdom, the excellence of the thinking part; temperance, that of the appetitive part (acquiescence of the nonrational elements to the plan of life prescribed by judgment); and courage, that of the spirited part (loyalty to the rule of life laid down by judgment). The division of the population into these three classes would not be made on the basis of birth or wealth but on the basis of education provided for by the state. By a process of examination each individual would then be assigned to his appropriate rank in correspondence with the predominant part of his soul.

The state ordered in this manner is just because each of the elements vigorously executes its own function and, in loyal contentment, confines itself within its limits. Such a society is a true aristocracy, or rule of the best. Plato describes successive deviations from this ideal as timocracy (the benign military state), oligarchy (the state dominated by merchant princes, a plutocracy), and democracy (the state subjected to an irresponsible or criminal will).

The training of the philosophical rulers would continue through a long and rigorous education because the vision of the Good requires extensive preparation and intellectual discipline. It leads through study of the exact sciences to that of their metaphysical principles. The central books of the *Republic* thus present an outline of metaphysics and a philosophy of the sciences. The Forms appear in the double character of objects of all genuine science and formal causes of events and processes. Plato expressly denied that there can be knowledge, in the proper sense, of the temporal and mutable. In his scheme for the intellectual training of the philosophical rulers, the exact sciences—arithmetic, plane and solid geometry, astronomy, and harmonics—would first be studied for 10 years to familiarize the mind with relations that can only be apprehended by thought. Five years would then be given to the still severer study of "dialectic." Dialectic is, etymologically, the art of conversation, of question and answer; and according to Plato, dialectical skill is the ability to pose and answer questions about the essences of things. The dialectician replaces hypotheses with secure knowledge, and his aim is to ground all science, all knowledge, on some "unhypothetical first principle."

This principle is the Form of the Good, which, like the Sun in relation to visible things, is the source of the reality of all things, of the light by which they are apprehended, and also of their value. As in the *Symposium*, the Good is the supreme beauty that dawns suddenly upon the pilgrim of love as he draws near to his goal.

Dialogues of critical reconstruction. The two works that

The Form of the Good

Ascent to the supreme Form of Good

probably anticipate the dialogues of Plato's old age, the *Parmenides* and *Theaetetus*, display a remarkable difference of tone, clearly the result of a period of fruitful reconstruction.

The theory expounded in the *Phaedo* and *Republic* does not allow enough reality to the sensible world. These dialogues suppose that an entity capable of being sensed is a complex that participates in a plurality of Forms: what else it may be they do not say. Clearly, however, the relation between a thing and a Form (e.g., beauty), which has been called participation, needs further elucidation. In these dialogues truths of fact, of the natural world, have not yet had their importance recognized.

Plato clearly had an external motive for the reexamination of his system as well. The *Parmenides*, the *Theaetetus*, and the *Sophist* all reveal a special interest in the Eleatic philosophy, of which Parmenides was the chief representative. The doctrine of his friend Euclides of Megara, like that of Parmenides, was that phenomena which can be apprehended by the senses are illusions with no reality at all. Continued reflection on this problem led straight to the discussion of the meaning of the copula "is" and the significance of the denial "is not," which is the subject of the *Sophist*.

Formally the *Parmenides* leads to an impasse. In its first half the youthful Socrates expounds the doctrine of the participation of things in Forms as the solution of the problem of the "one and many." ("How can this, that, and the other cat all be one thing—e.g., black?" "Each distinct cat participates in the unique Form of Blackness.") Parmenides raises what appear to be insoluble objections and hints that the helplessness of Socrates under his criticism arises from insufficient training in logic.

In the second half Parmenides gives an example of the logical training that he recommends. He takes for examination his own thesis, "The one is," and constructs upon it as basis an elaborate set of contradictions.

Objections
to the
doctrine of
Forms

The Eleatic objections to the doctrine of participation are, first, that it does not really reconcile unity with plurality since it leads to a perpetual regress. It says that the many things that have a common predicate, or characteristic, participate in, or imitate, a single Form. But the Form itself also admits of a common predicate, and therefore a second Form must exist, participated in alike by the sensible things and the first Form, and so on, endlessly. Second, a graver difficulty is that the relations between Forms must belong to the realm of Forms, and those between sensible things to the realm of things. Thus men, belonging to the second, can know nothing of the true realities, the Forms. Scholars disagree over the precise interpretation of these objections. They also disagree about how Plato should have reacted to them—and about how he did react.

The *Theaetetus* is a discussion of the question of how knowledge should be defined. It is remarkable that the dialogue treats knowledge at length without making any reference to the Forms or to the mythology of recollection. It remains to this day one of the best introductions to the problem of knowledge. The main argument is as follows:

Efforts at
defining
knowledge

It seems plausible to say that knowledge is perception, which appears to imply that "What seems to me is so to me; what seems to you is so to you" (Protagoras). This relativistic doctrine is, rather oddly, claimed by Plato to be equivalent to the view held by the late 6th-century-BC Greek philosopher Heraclitus that "everything is always and in all ways in flux." But these views imply that there is no common perceived world and therefore nothing of certainty can be said or thought at all.

As for the thesis that knowledge is perception, one must first distinguish what the soul perceives through bodily organs from what it apprehends by itself without organs—such as number, sameness, likeness, being, and good. But because all knowledge involves truth and therefore being, perception, which cannot grasp being, is not identical with knowledge.

Is knowledge, then, true belief? The reference to true belief leads Plato into a discussion of false belief, for which he can discover no satisfactory analysis. False belief is belief in what is not, and what is not cannot be believed.

But the example of verdicts in the law courts is enough to show that there can be true belief without knowledge.

Finally, is knowledge true belief together with an "account"? The concept of an account (*logos*) is not a simple one. No satisfactory definition of knowledge emerges, and the dialogue ends without a conclusion.

Because Plato's argument nowhere appeals to his favourite doctrine of Forms and because the dialogue ends so inconclusively, some scholars have suggested that Plato wanted to show that the problem of knowledge is insoluble without the Forms.

THE LATER DIALOGUES

Formally the important dialogues the *Sophist* and the *Statesman* are closely connected, both being ostensibly concerned with a problem of definition. The real purpose of the *Sophist*, however, is logical or metaphysical; it aims at explaining the true nature of negative predication, or denials that something is so. The object of the *Statesman*, on the other hand, is to consider the respective merits of two contrasting forms of government, personal rule and constitutionalism, and to recommend the second, particularly in the form of limited monarchy. The *Sophist* thus lays the foundations of all subsequent logic, the *Statesman* those of all constitutionalism. A second purpose in both dialogues is to illustrate the value of careful classification as a basis for scientific definition.

The *Sophist* purports to investigate what a Sophist really is. The definitions all lead to such notions as falsity, illusion, nonbeing. But these notions are puzzling. How can there be such a thing as a false statement or a false impression? For the false means "what is not," and what is not is nothing at all and can neither be uttered nor thought. Plato argues that what is not in some sense also is, and that what is in some sense is not; and he refutes Parmenidean monism by drawing the distinction between absolute and relative nonbeing. A significant denial, *A* is not *B*, does not mean that *A* is nothing, but that *A* is other than *B*; every one of the "greatest kinds," or most general, features of reality—being, identity, difference, motion, and rest—is other than every other feature. Motion, say, is other than rest; and thus motion is not rest—but it does not follow that motion is not. The true business of dialectic is to treat the Forms themselves as an interrelated system, with relations of compatibility and incompatibility among themselves.

Absolute
versus
relative
nonbeing

In the *Statesman* the conclusion is reached that government by a benevolent dictator is not suitable to the conditions of human life because his direction is not that of a god. The surrogate for direction by a god is the impersonal supremacy of inviolable law. Where there is such law, monarchy is the best and democracy the least satisfactory form of constitution; but where there is no law, this situation is inverted.

The *Philebus* contains Plato's ripest moral psychology. Its subject is strictly ethical—the question of whether the Good is to be identified with pleasure or with wisdom. Under the guidance of Socrates a mediating conclusion is reached: the best life contains both elements, but wisdom predominates.

Philosophically most important is a classification adopted to determine the formal character of the two claimants to recognition as the Good. Everything real belongs to one of four classes: (1) the infinite or unbounded, (2) the limit, (3) the mixture (of infinite and limit), (4) the cause of the mixture. It emerges that all of the good things of life belong to the third class, that is, are produced by imposing a definite limit upon an indeterminate continuum.

The *Timaeus* is an exposition of cosmology, physics, and biology. *Timaeus* first draws the distinction between eternal being and temporal becoming and insists that it is only of the former that one can have exact and final knowledge. The visible, mutable world had a beginning; it is the work of God, who had its Forms before him as eternal models in terms of which he molded the world as an imitation. God first formed its soul out of three constituents: identity, difference, being. The world soul was placed in the circles of the heavenly bodies, and the circles were animated with movements. Subsequently the various

The
forming of
the world

subordinate gods and the immortal and rational element in the human soul were formed. The human body and the lower components of its soul were generated through the intermediacy of the "created gods" (*i.e.*, the stars).

The *Timaeus* combines the geometry of the Pythagoreans with the biology of Empedocles by a mathematical construction of the elements, in which four of the regular solids—cube, tetrahedron, octahedron, and icosahedron—are assumed to be the shapes of the corpuscles of earth, fire, air, and water. (The fifth, the dodecahedron, comprises the model for the whole universe.)

Among the important features of the dialogue are its introduction of God as the "demiurge"—the intelligent cause of all order and structure in the world of becoming—and the emphatic recognition of the essentially tentative character of natural science. It is also noteworthy that, though Plato presents a corpuscular physics, his metaphysical substrate is not matter but *chōra* (space). The presence of space as a factor requires the recognition, over and above God or mind, of an element that he called *anankē* (necessity). The activity of the demiurge ensures that the universe is in general rational and well-ordered, but the brute force of material necessity sets limits to the scope and efficacy of reason. The details of Plato's cosmology, physiology, and psychophysics are of great importance for the history of science but metaphysically of secondary interest.

The *Laws*, Plato's longest and most intensely practical work, contains his ripest utterances on ethics, education, and jurisprudence, as well as his one entirely nonmythical exposition of theology. The immediate object is to provide a model of constitution making and legislation to assist in the actual founding of cities. The problem of the dialogue is thus not the construction of an ideal state as in the *Republic* but the framing of a constitution and code that might be successfully adopted by a society of average Greeks. Hence the demands made on average human nature, though exacting, are not pitched too high; and the communism of the *Republic* is dropped.

Purely speculative philosophy and science are excluded from the purview of the *Laws*, and the metaphysical interest is introduced only so far as to provide a basis for a moral theology. In compensation the dialogue is exceptionally rich in political and legal thought and appears, indirectly, to have left its mark on the great system of Roman jurisprudence.

In the ethics of the *Laws* Plato is rigid and rigorous—for example, homosexuality shall be completely suppressed and monogamous marriage with strict chastity shall be the rule. (In the *Republic* the guardian class enters into temporary unions or "sacred marriages," with a community of wives and children, to foster a concern for the common good.) In politics, Plato favours a mixed constitution, one with elements of democratic freedom and autocratic authoritarianism, and he suggests a system for securing both genuine popular representation and the proper degree of attention to personal qualifications. The basis of society is to be agriculture, not commerce. What amounts to a tax of 100 percent is to be levied on incomes beyond the statutory limits. Education is regarded as the most important of all the functions of government. The distinction between the sexes is to be treated as irrelevant.

Careful attention is to be paid to the right utilization of the child's instinct for play and to the demand that the young shall be taught in institutions where expert instruction in all of the various subjects is coordinated. Members of the supreme council of the state shall be thoroughly trained in the supreme science, which "sees the one in the many and the many in the one"; *i.e.*, in dialectic. In the *Laws* Plato instituted regulations which would ensure that trials for serious offenses would take place before a court of highly qualified magistrates and would proceed with due deliberation. Also, provision was made for appeals, and a foundation was laid for a distinction between civil and criminal law.

The *Laws* also creates a natural theology. There are three false beliefs, Plato holds, that are fatal to moral character: atheism, denial of the moral government of the world, and the belief that divine judgment can be bought off by

offerings. Plato claims that he can disprove them all. His refutation of atheism turns on the identification of the soul with the "movement which can move itself." Thus all motion throughout the universe is ultimately initiated by souls. It is then inferred from the regular character of the great cosmic motions and their systematic unity that the souls which originate them form a hierarchy with a best soul, God, at their head. Since some motions are disorderly, there must be one soul that is not the best, and there may be more. (There is no suggestion, however, that there is a worst soul, a devil.) The other two heresies can be similarly disposed of. Plato thus becomes the originator of the view that there are certain theological truths that can be strictly demonstrated by reason; *i.e.*, of philosophical theology. Plato goes on to enact that the denial of any of his three propositions shall be a grave crime.

The *Laws* strikes many readers as a dull and depressing work. Its prose lacks the sparkle of the early dialogues; and Socrates, the hero of those works, would not have been tolerated under a government of the repressively authoritarian style that the *Laws* recommends. (J.B./Ed.)

Platonism after Plato

The term Platonism can be applied to any philosophy that derives its ultimate inspiration from Plato. Though there was in antiquity a tradition about Plato's "unwritten doctrines" (much discussed by German scholars since 1959), Platonism then and later was based primarily on a reading of the dialogues. But these can be read in many different ways, often very selectively, and it may be that all that the various kinds of Platonism can be said to have in common is an intense concern for the quality of human life—always ethical, often religious, and sometimes political, based on a belief in unchanging and eternal realities, independent of the changing things of the world perceived by the senses. Platonism sees these realities both as the causes of the existence of everything in the universe and as giving value and meaning to its contents in general and the life of its inhabitants in particular. It is this belief in absolute values rooted in an eternal world that distinguishes Platonism from the philosophies of Plato's immediate predecessors and successors and from later philosophies inspired by them—from the immanentist naturalism of most of the pre-Socratics (who interpreted the world monistically in terms of nature as such), from the relativism of the Sophists, and from the correction of Platonism in a this-worldly direction carried out by Plato's greatest pupil, Aristotle.

GREEK PLATONISM FROM ARISTOTLE THROUGH MIDDLE PLATONISM: ITS NATURE AND HISTORY

Since Plato refused to write his own metaphysics, knowledge of its final shape has to be derived from hints in the dialogues and statements by Aristotle and, to a far lesser extent, other ancient authorities. According to these, Plato's doctrine of Forms was, in its general character, highly mathematical, the Forms being somehow identified with, or explained in terms of, numbers. Here may be seen the influence of the Pythagoreans, though, as Aristotle says, the details of Plato's views on the mathematical constituents of being were not the same as theirs. In addition Aristotle states that Plato introduced a class of "mathematicals," or "intermediates," positioned between sensible objects and Forms. These differ from sensible objects in being immaterial (*e.g.*, the geometer's triangles *ABC* and *XYZ*) and from the Forms in being plural, unlike the Triangle itself. (H.J.Bl./Ed.)

Aristotle himself had little use for this sort of mathematical metaphysics and rejected Plato's doctrine of transcendent eternal Forms altogether. Something of Platonism, nonetheless, survived in Aristotle's system in his beliefs that the reality of anything lay in a changeless (though wholly immanent) form or essence comprehensible and definable by reason and that the highest realities were eternal, immaterial, changeless self-sufficient intellects which caused the ordered movement of the universe. It was the desire to give expression to their transcendent perfection that kept the heavenly spheres rotating. Man's intellect at

its highest was akin to them. This Aristotelian doctrine of Intellect (nous) was easily recombined with Platonism in later antiquity.

Aristotle, however, was not reacting only against Plato but also against Plato's associates and immediate successors as head of the Academy, namely Plato's nephew Speusippus (c. 410–339 BC) and Xenocrates (396–314 BC). Speusippus, in particular, accented the mathematical tendencies of the late Plato and abolished Forms in favour of numbers. He also posited different principles for different sorts of entities and so was accused by Aristotle of breaking the connections in reality. Xenocrates identified Forms and numbers and began the long process of finding firm doctrines in Plato by laying down that Forms were only of those things that exist in nature. Xenocrates was also the first, as far as is known, to turn his attention to what continued to be a subject of controversy throughout the history of Platonism, namely whether the account of creation offered in the *Timaeus* was to be taken as chronological or merely expository. He took the latter view, which turned out to be the most favoured one in antiquity; Aristotle was on the other side. Whether Xenocrates' three successors as head of the Academy (Polemon, Crates, and Crantor) developed Platonism is uncertain. Crantor (c. 330–270 BC) was allegedly the first to write commentaries on Plato, particularly on the *Timaeus*. After Crantor the Academy was preoccupied for about two centuries with the serious questioning of man's claims to knowledge. This began with Arcesilaus (316/315–c. 241 BC), who is described as the founder of the Middle Academy. There was a genuine desire to recover the critical, questioning, and agnostic attitude of the Socrates of Plato's early dialogues as well as philosophical exasperation with the dogmatism of some of the contemporary Hellenistic philosophers, especially the Stoics. It is likely that Arcesilaus was influenced to some extent by Pyrrhon (c. 360–c. 272 BC), founder of the tradition to which the name Skeptic was applied in antiquity. The Skeptical Academics denied that certainty on any subject was possible and worked out a sophisticated theory of probability as a guide to practical decision making. Their critical dialectic and probability theory were best expounded by Carneades (214/213–129/128 BC). Though he wrote nothing, he was regarded as the founder of the New Academy. A return to dogmatic and positive philosophical teaching was effected by Philo of Larissa (died c. 79 BC) and his pupil Antiochus of Ascalon, who was head of the school in 79–78 BC.

Transition
to Neo-
platonism

The next important phase of Platonism, Middle Platonism or pre-Neoplatonism, was significant through the influence that it exerted in more than one direction. In the direction of Jewish culture (further described in a later section), it formed the Greek philosophical background of the efforts of Philo Judaeus (Philo of Alexandria) to create a philosophical system on the basis of the Old Testament heritage. Though the origins of Middle Platonism are obscure, its main direction became clear in the 1st century AD. It seems to have been linked from the beginning with the closely related revival of Pythagoreanism (a philosophy holding that reality is number, and sometimes showing, after the revival, a tendency to superstitious occultism). The somewhat Platonized Stoicism of Poseidonius (c. 135–c. 51 BC), whose dualism of matter and reason enhanced the roles of emotion and will, may have influenced its beginnings, as did the Stoicized Platonism of Antiochus; and Stoic influence, especially in the ethical field, remained important in its later developments. There was also a strong Aristotelian influence, though a minority of 2nd-century Platonists, notably Atticus and, to a lesser extent, Gaius Calvenus Taurus, objected to certain Aristotelian doctrines. Atticus was particularly offended by Aristotle's failure to provide for providence. The general characteristics of this revised Platonic philosophy (and the closely related Neo-Pythagoreanism) were the recognition of a hierarchy of divine principles with stress on the transcendence of the supreme principle, which was already occasionally called "the One"; the placing of the Platonic Forms in the divine mind; a strongly otherworldly attitude demanding a "flight from the body," an ascent of the mind to the divine and eternal; and a preoccupation with

the problem of evil, attributed either to an evil world soul or to matter. The best known of the Middle Platonists is the biographer and essayist Plutarch of Chaeronea (c. AD 46–120). More important philosophically were other 2nd-century figures: Gaius and two men possibly influenced by him, Albinus and Apuleius (better known as author of the prose narrative *The Golden Ass*); Atticus; and Numenius of Apamea. It was from the thought of these and other Middle Platonists, combined with his own reading of Alexander and other Peripatetic commentators on Aristotle, that the foremost Neoplatonist, Plotinus, started constructing his own interpretation of Platonism, which was both profoundly original and firmly rooted in an established school tradition.

NEOPLATONISM: ITS NATURE AND HISTORY

Neoplatonism is the modern name given to the form of Platonism developed by Plotinus in the 3rd century AD and modified by his successors. It came to dominate the Greek philosophical schools and remained predominant until the teaching of philosophy by pagans ended in the second half of the 6th century AD. It represents the final form of pagan Greek philosophy. It was not a mere syncretism (or combination of diverse beliefs) but a genuine, if one-sided, development of ideas to be found in Plato and earlier Platonism—though it incorporated important Aristotelian and Stoic elements as well. There is no real evidence for Oriental influence. A certain Gnostic (relating to intuitive knowledge acquired by privileged individuals and immune to empirical verification) tone or colouring sometimes may be discerned in the thought of Plotinus. But he was consciously a passionate opponent of Gnosticism, and in any case there was often a large element of popular Platonism in the Gnostic systems then current. Moreover, the theosophical works of the late 2nd century AD known as the *Chaldean Oracles*, which were taken as inspired authorities by the later Neoplatonists, seem to have been a hodgepodge of popular Greek religious philosophy.

Neoplatonism began as a complex (and in some ways ambiguous) philosophy and grew vigorously in a variety of forms over a long period; it is therefore not easy to generalize about it. But the leading ideas in the thought of philosophers who can properly be described as Neoplatonists seem always to have included the following:

1. There is a plurality of levels of being, arranged in hierarchical descending order, the last and lowest comprising the physical universe, which exists in time and space and is perceptible to the senses.
2. Each level of being is derived from its superior, a derivation that is not a process in time or space.
3. Each derived being is established in its own reality by turning back toward its superior in a movement of contemplative desire, which is implicit in the original creative impulse of outgoing that it receives from its superior; thus the Neoplatonic universe is characterized by a double movement of outgoing and return.
4. Each level of being is an image or expression on a lower level of the one above it. The relation of archetype and image runs through all Neoplatonic schemes.
5. Degrees of being are also degrees of unity; as one goes down the scale of being there is greater multiplicity, more separateness, and increasing limitation—until the atomic individualization of the spatiotemporal world is reached.
6. The highest level of being, and through it all of what in any sense exists, derives from the ultimate principle, which is absolutely free from determinations and limitations and utterly transcends any conceivable reality, so that it may be said to be "beyond being." Because it has no limitations, it has no division, attributes, or qualifications; it cannot really be named, or even properly described as being, but may be called "the One" to designate its complete simplicity. It may also be called "the Good" as the source of all perfections and the ultimate goal of return, for the impulse of outgoing and return that constitutes the hierarchy of derived reality comes from and leads back to the Good.
7. Since this supreme principle is absolutely simple and undetermined (or devoid of specific traits), man's knowl-

Core
concepts
of Neo-
platonism

edge of it must be radically different from any other kind of knowledge. It is not an object (a separate, determined, limited thing) and no predicates can be applied to it; hence it can be known only if it raises the mind to an immediate union with itself, which cannot be imagined or described.

Plotinus and his philosophy. As far as is known, the originator of this distinctive kind of Platonism was Plotinus (AD 205–270). He had been the pupil at Alexandria of a self-taught philosopher called Ammonius, who also taught the Christian Origen and the latter's pagan namesake, and whose influence on his pupils seems to have been deep and lasting. But Ammonius wrote nothing; there are few reports of his views, and these are unreliable so that nothing is actually known about his thought. A number of distinguished scholars have made attempts to reconstruct it, but their speculations go far beyond the evidence. Plotinus must thus be regarded as the first Neoplatonist, and his collected works, the *Enneads* (Greek *enneas*, “set of nine”—six sets of nine treatises each, arranged by his disciple Porphyry), are the first and greatest collection of Neoplatonic writings.

Plotinus, like most ancient philosophers from Socrates on, was a religious and moral teacher as well as a professional philosopher engaged in the critical interpretation of a long and complicated school tradition. He was an acute critic and arguer, with an exceptional degree of intellectual honesty for his, or any, period; philosophy for him was not only a matter of abstract speculation but also a way of life in which, through an exacting intellectual and moral self-discipline and purification, those who are capable of the ascent can return to the source from which they came. His written works explain how from the eternal creative act—at once spontaneous and necessary—of that transcendent source, the One, or Good, proceeds the world of living reality, constituted by repeated double movements of outgoing and return in contemplation; and this account, showing the way for the human self—which can experience and be active on every level of being—to return to the One, is at the same time an exhortation to follow that way.

Plotinus always insisted that the One, or Good, is beyond the reach of thought or language; what he said about this supreme principle was intended only to point the mind along the way to it, not to describe or define it. But though no adequate concept or definition of the Good is possible, it was, nonetheless, for Plotinus a positive reality of superabundant excellence. Plotinus often spoke of it in extremely negative language, but his object in doing so was to stress the inadequacy of all of man's ways of thinking and speaking to express this supreme reality or to clarify the implications of the claim that the Good is absolutely one and undetermined, the source of all defined and limited realities.

The original creative or expressive act of the One is the first great derived reality, nous (which can be only rather inadequately translated as “Intellect” or “Spirit”); from this again comes Soul, which forms, orders, and maintains in being the material universe. It must be remembered that, to Plotinus, the whole process of generation is timeless; Nous and Soul are eternal, while time is the life of Soul as active in the physical world, and there never was a time when the material universe did not exist. The “levels of being,” then, though distinct, are not separate but are all intimately present everywhere and in everyone. To ascend from Soul through Intellect to the One is not to travel in space but to awake to a new kind of awareness.

Intellect for Plotinus is at one and the same time thinker, thought, and object of thought; it is a mind that is perfectly one with its object. As object, it is the world of Forms, or Ideas, the totality of real being in the Platonic sense. These Forms, being one with Intellect and therefore with each other, are not merely objects but are living, thinking subjects, each not only itself but, in its contemplation, the whole. They are the archetypes and causes of the necessarily imperfect realities on lower levels, souls and the patterns or structures that make bodies what they are. Men at their highest are intellects, or souls perfectly conformed to Intellect; they become aware of their intellectual nature when, passing not only beyond sense perception but be-

yond the discursive reasoning characteristic of the life of Soul, they immediately grasp eternal realities.

Soul for Plotinus is very much what it was for Plato, the intermediary between the worlds of Intellect and Sense and the representative of the former in the latter. It is produced by Intellect, as Intellect is by the One, by a double movement of outgoing and return in contemplation, but the relationship between the two is more intimate and the frontier less clearly defined. For Plotinus, as for Plato, the characteristic of the life of the Soul is movement, which is the cause of all other movements. The life of the Soul in this movement is time, and on it all physical movement depends. Soul both forms and rules the material universe from above; and in its lower, immanent phase, which Plotinus often calls nature, it acts as an indwelling principle of life and growth and produces the lowest forms, those of bodies. Below these lies the darkness of matter, the final absence of being, the absolute limit at which the expansion of the universe—from the One through diminishing degrees of reality and increasing degrees of multiplicity—comes to an end. Because of its utter negativity, such matter is for Plotinus the principle of evil; and although he does not really believe it to be an independent principle forming, with the Good, a dualism, his language about it often has a strongly dualistic flavour.

He was not, however, really dualistic in his attitude toward the material universe. He strongly maintained its goodness and beauty as the best possible work of Soul. It is a living organic whole, and its wholeness is the best possible (though very imperfect) reflection on the space-time level of the living unity in diversity of the world of Forms in Intellect. It is held together in every part by a universal sympathy and harmony. In this harmony external evil and suffering take their place as necessary elements in the great pattern, the great dance of the universe. Evil and suffering can affect men's lower selves but can only exceptionally, in the thoroughly depraved, touch their true, higher selves and so cannot interfere with the real well-being of the philosopher.

As souls within bodies, men can exist on any level of the soul's experience and activity. (The descent of souls into bodies is for Plotinus—who had some difficulty in reconciling Plato's various statements on this point—both a fall and a necessary compliance with universal law.) Man can ascend through his own intellect to the level of universal Soul, become that whole that he already is potentially, and, in Soul, attain to Intellect itself; or he can isolate himself on the lower level, shutting himself up in the experiences, desires, and concerns of his lower nature. Philosophical conversion—the beginning of the ascent to the One—consists precisely in turning away, by a tremendous intellectual and moral effort, from the life of the body, dominating and rising above its desires, and “waking to another way of seeing, which everyone has but few use.” This, Plotinus insisted, is possible while one is still in an earthly body and without neglecting the duties of one's embodied state. But the body and bodily life weight a man down and hamper him in his ascent. Plotinus' language when speaking of the body and the senses in this context is strongly dualistic and otherworldly. Platonists in general think much more dualistically about their own bodies than about the material universe as a whole. The physical world is seen positively as a noble image of the intelligible; the individual, earthly, animal body, on the contrary, tends to be regarded negatively as a hindrance to the intellectual and spiritual life.

When a man's philosophical conversion is complete and he has become Intellect, he can rise to that mystical union in which the One manifests his continual presence, carried on the surging current of the impulse of return to the source (in its strongest and final flow), the pure love of Intellect for the Good from which it immediately springs. There is no consciousness of duality in that union; the individual is not aware of himself; but neither is he destroyed or dissolved into the One—because even in the union he is still Intellect, though Intellect “out of itself,” transcending its normal nature and activity. This mystical union for Plotinus was the focus of much of his effort and, for those of similar inclination, the source of the

Meta-
physics:

Soul, world

Ethics and
religion:
purifica-
tion

continuing power of his teaching. Philosophy for him was religion, the effort to actualize in oneself the great impulse of return to the Good, which constitutes reality on all its levels; and religion for him was philosophy. There was no room in his thought and practice for special revelation, grace, and repentance in the Christian sense, and little for external rites or ceremonies. For him the combination of moral purification and intellectual enlightenment, which only Platonic philosophy as he understood it could give, was the only way to union with the Good.

The later Neoplatonists. Porphyry (c. AD 234–c. 305), a devout disciple of Plotinus and a careful editor of his works, occupied a special position in the development of later Neoplatonism. In some ways his thought paralleled that of the later pagan Neoplatonists, but in others it quite opposed them. The most distinctive features of his thought seem to have been an extreme spiritualism, an insistence, even sharper than that of Plotinus, on the “flight from the body” and—more philosophically important—a greater sympathy with the less sharply defined vertical hierarchies of the Platonists who had preceded Plotinus. Porphyry did not always clearly distinguish the One from Intellect. On the other hand one may see in him the beginnings of the late Neoplatonic tendency to structure reality in both vertical and “horizontal” triads. Thus Being, Life, and Intellect are phases in the eternal self-determination of the ultimate reality. This triad became one of the most important elements in the complex metaphysical structures of the later Neoplatonists. But perhaps Porphyry’s most important and influential contribution was the incorporation into Neoplatonism of Aristotle’s logic, in particular the doctrine of the categories, with the characteristic Neoplatonic interpretation of them as terms signifying entities. Also of interest is his declaration of ideological war against the Christians, whose doctrines he attacked on both philosophical and exegetical grounds in a work of 15 books entitled *Against the Christians*.

Iamblichus (c. AD 250–c. 330) seems to have been the originator of the type of Neoplatonism that came to dominate the Platonic schools in the 5th and 6th centuries AD. This kind of Neoplatonism sharpened and multiplied the distinctions between the levels of being. The basic position underlying its elaborations is one of extreme philosophical Realism: it is assumed that the structure of reality corresponds so exactly to the way in which the mind works that there is a separate real entity corresponding to every distinction that it can make. In the fully developed late Neoplatonic system the first principle of reality, the ultimate One, was removed to an altogether ineffable transcendence, mitigated by two factors: the presence of the expressions or manifestations of its unifying power, the “henads”—identified with the gods of paganism—at every level of reality; and the possibility of return to absolute unification through the henad with which one is linked. Below the One a vast structure of triads, or trinities, reached down to the physical world; this was constructed by combining Plotinus’ vertical succession of the levels of Being, Intellect, and Soul (much complicated by internal subdivision and the interposition at every stage of mediating hypostases, or underlying orders of nonmaterial reality) with another horizontal triadic structure, giving a timeless dynamic rhythm of outgoing and return, such as that already encountered in Porphyry.

Nearly all of Iamblichus’ works have been lost, and his thought must be recovered from other sources. At present the main authority for this type of Platonism, and also for some of the later Neoplatonists, is Proclus (AD 410–485). Proclus appears to have codified later Platonism, but it is often impossible to tell which parts of his thought are original and which derive from his teachers Plutarch (see below) and Syrianus on the one hand and Porphyry and Iamblichus, from whom he quotes copiously but not always identifiably, and other earlier Platonists on the other hand. A carefully argued summary of the basic metaphysics of this kind of Neoplatonism may be found in Proclus’ *Elements of Theology*, which exhibits the causal relationships of the several hierarchies that constituted his intelligible universe.

This later Neoplatonism aspired to be not only a

complete and coherent metaphysical system but also a complete pagan theology, which is perhaps best seen in Proclus’ *Platonic Theology*. The maintenance and defense of the old religion in a world more and more intolerantly dominated by its triumphant rival, Christianity, was one of the main concerns of the Platonists after Plotinus. By the study and sometimes forced exegesis of Aristotle and then Plato, culminating in the *Timaeus* and *Parmenides*, of which they offered a variety of highly metaphysical interpretations totally unacceptable to Plato scholars, they believed it possible to arrive at a complete understanding of divine truth. This truth they held to be cryptically revealed by the gods themselves through the so-called theologians—the inspired authors of the Orphic poems and of the *Chaldean Oracles*, published in the second half of the 2nd century AD. Porphyry first gave some guarded and qualified recognition to them, but they were inspired scripture to Iamblichus, who wrote a work of at least 28 books on the subject, and his successors. Their view of the human soul was a humbler one than that of Plotinus. It was for them a spiritual being of lower rank, which had descended altogether into the material world, while for Plotinus a part remained above; they could not therefore aspire, like Plotinus, through philosophy alone, to that return to and unification with the divine that remained for them the goal of human life. Help from the gods was needed, and they believed that the gods in their love for men had provided it, giving to all things the power of return in prayer and implanting even in inanimate material things—herbs and stones and the like—sympathies and communications with the divine, which made possible the secret rites of theurgy, through which the divine gave the needed spiritual help by material means. Theurgy, though its procedures were generally those of late Greek magic, was thus not thought of merely as magic; in fact a higher and more intellectual theurgy was also practiced. The degree of attention paid to external rites varied considerably from philosopher to philosopher; there seem to have been men even in the last generation of pagan Neoplatonists who had little use for or interest in such things and followed a mystical way much like that of Plotinus.

The different schools of late Neoplatonism seem to have differed less from each other than has sometimes been supposed. The school of Pergamum, founded by Aedesius, a pupil of Iamblichus, made perhaps the least contribution to the philosophical development of Neoplatonism, but it was not entirely given over to theurgy. Its greatest convert was the emperor Julian, called by Christians the “Apostate”; in that capacity he achieved great notoriety, but philosophically he is of no importance. By the end of the 4th century AD the Platonic Academy at Athens had been reestablished and had become an institute for Neoplatonic teaching and research following the tradition of Iamblichus. It was particularly fervent and open in its paganism and attracted Christian hostility. Though maintaining itself for a surprisingly long time against this hostility, it eventually yielded to it and was probably closed by Justinian in AD 529. In the interim, however, it had produced the greatest and most influential systematic expositor of later Neoplatonism, Proclus (see above). The head of the school at the time of its closing, Damascius, was also a notable philosopher. Another centre of Neoplatonism flourished at Gaza during the 5th and early 6th centuries; it was already Christian in its inspiration, though some of its members studied with the pagan Ammonius (see below). The school of Alexandria in the 5th and 6th centuries does not seem to have differed very much from that of Athens, either in its fundamental philosophical outlook or in the main outline of its doctrines. In fact there was much interchange between the two. The Athenian Syrianus taught the Alexandrian Hermias, whose son Ammonius was taught by Proclus. Ammonius (died c. 520) was the most influential of the Alexandrian Platonists. His expositions of Aristotle were published mainly in the commentaries of the Christian heretic John Philoponus (late 5th to mid-6th century). Simplicius, the other great Aristotelian commentator, worked at Athens but, like Damascius, had studied with Ammonius. The Alexandrian concentration on Aristotle, which produced

Neoplatonism as a pagan theology

Neoplatonic schools

Porphyry
and
Iamblichus

a vast body of learned but Neoplatonically coloured commentary on his treatises, has often been attributed to Christian pressure and attempts to compromise with the church; it may equally well have been due to the quality and extent of Proclus' published work on Plato. Though Philoponus' later philosophical work contains important Christian modifications, an openly pagan (and very inferior) philosopher, Olympiodorus, was still teaching at Alexandria well into the second half of the 6th century. Finally, in the 7th century, under Heraclius, after philosophical teaching had passed peacefully into Christian hands, the last known Alexandrian philosopher, the Christian Stephanus, was called to teach in the University of Constantinople.

PLATONISM IN THE WORLD OF REVEALED RELIGIONS

Early Jewish Platonism. Well before the beginning of the Christian Era, Jews with some Greek education had begun to make casual use of popular Greek philosophy in expounding their revealed religion: there are traces of this in the wisdom literature of the Old Testament. In Paul's speech to the Areopagus in Acts 17, commonplaces of Stoic philosophy were employed for apologetic purposes. But, as far as is known, the first Jew who was really well-read in Greek philosophy and used it extensively in the exposition and defense of his traditional religion was Philo Judaeus (Philo of Alexandria [c. 15 BC–after AD 45]), an older contemporary of St. Paul. Philo expressed his philosophical religion in the form of lengthy allegorical commentaries on the Jewish Scriptures, especially on Genesis. In these he showed to his own satisfaction that the ancient revelation given to Moses accorded with the teaching of the best Greek philosophers, which, in his view, was later and derivative. The Greek philosophy that he preferred and found to be most in accordance with revelation was an early form of Middle Platonism. Philo was neither approved of nor read by later orthodox Jews, but his influence on Greek-speaking and Greek-educated Christians from the 2nd century AD was great; and in important ways he determined the tone of their religious speculation.

Ancient and medieval Christian Platonism. Like Philo, the Christian Platonists gave primacy to revelation and regarded Platonic philosophy as the best available instrument for understanding and defending the teachings of Scripture and church tradition. But, also like Philo, they did not believe that truth could conflict with truth and were confident that all that was rationally certain in Platonic speculation would prove to be in perfect accordance with the Christian revelation. Their unhistorical approach and unscholarly methods of exegesis of texts, both pagan and Christian, facilitated this confidence. The general attitude of Christian Platonists was one of relatively moderate and humane otherworldliness (the cruder sorts of Christian otherworldliness and hatred of the body seem to derive from non-Platonic and non-Greek sources). They stressed the transcendence of God though, by insisting that it is a transcendence that is also the deepest immanence, they acknowledged his intimate presence within the world as well. They took a dualistic view of soul and body (though accepting bodily resurrection) and emphasized the primacy of the spiritual, while insisting on the goodness of God's material creation.

Patristic Platonism. From the middle of the 2nd century AD Christians who had some training in Greek philosophy began to feel the need to express their faith in its terms, both for their own intellectual satisfaction and in order to convert educated pagans. The philosophy that suited them best was Platonism. Though Stoicism had exerted a considerable influence on Christian ethical thinking (which has persisted to modern times), Stoic corporealism—the belief that God and the soul are bodies of a subtle and peculiar kind—repelled most Christians, and Stoic pantheism was incompatible with Christianity. The Platonism that the first Christian thinkers knew was of course Middle Platonism, not yet Neoplatonism. Its relatively straightforward theism and high moral tone suited their purposes excellently; and the influence of this older form of Platonism persisted through the 4th century and

beyond, even after the works of Plotinus and Porphyry began to be read by Christians.

The first Christian to use Greek philosophy in the service of the Christian faith was Justin Martyr (martyred c. 165), whose passionate rejection of Greek polytheism, combined with an open and positive acceptance of the essentials of Platonic religious philosophy and an unshakable confidence in its harmony with Christian teaching, was to remain characteristic of the Christian Platonist tradition. This was carried on in the Greek-speaking world by Clement of Alexandria (c. 150–c. 215), a persuasive Christian humanist, and by the greatest of the Alexandrian Christian teachers, Origen (c. 185–254). Although Origen was consciously more hostile to and critical of Platonic philosophy than either Justin or Clement, he was, nonetheless, more deeply affected by it. He produced a synthesis of Christianity and late Middle Platonism of remarkable originality and power, which is the first great Christian philosophical theology. In spite of subsequent condemnations of some of his alleged views, his influence on Christian thought was strong and lasting. The Greek philosophical theology that developed during the Trinitarian controversies over the relationships among the persons of the Godhead, which were settled at the ecumenical councils of Nicaea (325) and Constantinople (381), owed a great deal to Origen on both sides, orthodox and heretical. Its most important representatives on the orthodox side were the three Christian Platonist theologians of Cappadocia, Basil of Caesarea (c. 329–379), Gregory of Nazianzus (c. 330–c. 389), and Basil's brother Gregory of Nyssa (c. 335–c. 394). Of these three, Gregory of Nyssa was the most powerful and original thinker (as well as the closest to Origen). He was the first great theologian of mystical experience, at once Platonic and profoundly Christian, and he exerted a strong influence on later Greek Christian thought.

At some time between the period of the Cappadocian Fathers and the early years of the 6th century, a new turn was given to Christian Platonism by the remarkable writer who chose to publish his works under the name of St. Paul's convert at Athens, Dionysius the Areopagite. The kind of Platonism that the Pseudo-Dionysius employed for his theological purposes was the 5th-century Neoplatonism that is best represented by Proclus (see above). Almost everything about this mysterious author is vigorously disputed by scholars. But there can be no doubt about the influence that his system of the hierarchic universe exerted upon later Christian thought; his vision of man's ascent through it—carried up by divine love, to pass beyond all hierarchy and all knowledge into the darkness of the mystical union with God—had its impact both in the East, where one of the greatest of Greek Christian Platonist thinkers, Maximus the Confessor (c. 580–662), was deeply influenced by the Dionysian writings and commented extensively upon them, and in the West, where they became known and were translated into Latin in the 9th century. In the Latin West there was more than one kind of Christian Platonism. An impressive and extremely difficult philosophical theology, employing ideas approximating Porphyry's version of Neoplatonism to explain and defend the orthodox doctrine of the Trinity, was produced in the second half of the 4th century by the rhetorician and grammarian Marius Victorinus. A strong and simple Platonic theism and morality, which had a great influence in the Middle Ages, was nobly expressed in the final work of the last great philosopher-statesman of the ancient world, Boethius (c. 470–524). This was the *Consolation of Philosophy*, written in prison while its author was under sentence of death. Boethius was also influential in the medieval West through his translations of Aristotle's logical works, especially the *Categories* together with Porphyry's *Isagoge* ("Introduction"), on which he in turn produced two commentaries. But the Christian Platonism that had the widest, deepest, and most lasting influence in the West was that of St. Augustine of Hippo (354–430).

Augustinian Platonism. Each of the great Christian Platonists understood Platonism and applied it to the understanding of his faith in his own individual way, and of no one of them was this truer than of Augustine with

Justin,
Origen,
the Cappa-
docians

Pseudo-
Dionysius
and others

Philo of
Alexandria

his extremely strong personality and distinctive religious history. Augustine's thought was not merely a subspecies of Christian Platonism but something unique—Augustinianism. Nonetheless, the reading of Plotinus and Porphyry (in Latin translations) had a decisive influence on his religious and intellectual development, and he was more deeply and directly affected by Neoplatonism than any of his Western contemporaries and successors.

Teachings
of
Augustine

In his anthropology Augustine was firmly Platonist, insisting on the soul's superiority to and independence of the body. For him, as for Plotinus and Porphyry, it was axiomatic that body could not act on soul, for soul was superior in the hierarchy of reality, and the inferior cannot act on the superior. This affected both his ethical doctrine and his epistemology. On the other hand, he differed from the philosophers who influenced him in his insistence that not only man but higher spiritual beings as well are mutable and peccable, liable to sin and fall, and in his consequent stress on the necessity of divine grace. His crucial doctrine that man's destiny is determined by the right direction of love, though profoundly original, was a development rather than a contradiction of Platonism. His very original theology of history and his view of human society, however, owed little to Plotinus and Porphyry, whose interests lay elsewhere.

In his epistemology Augustine was Neoplatonic, especially in the subjectivity of his doctrine of illumination—in its insistence that in spite of the fact that God is exterior to man, men's minds are aware of him because of his direct action on them (expressed in terms of the shining of his light on the mind, or sometimes of teaching) and not as the result of reasoning from sense experience. For a Platonist, as has been said, body cannot act upon soul. Sense experience, therefore, though genuinely informative on its own level, cannot be a basis for metaphysical or religious thinking. This must be the result of the presence in the soul of higher realities and their action upon it. In Plotinus the illumination of the soul by Intellect and the One was the permanent cause of man's ability to know eternal reality; and Augustine was at this point very close to Plotinus, though for him there was a much sharper distinction between Creator and creature, and the personal relationship between God and the soul was much more strongly stressed.

In his theology, insofar as Augustine's thought about God was Platonic, he conformed fairly closely to the general pattern of Christian Platonism; it was Middle Platonic rather than Neoplatonic in that God could not be the One beyond Intellect and Being but was the supreme reality in whose creative mind were the Platonic Forms, the eternal patterns or regulative principles of all creation. Perhaps the most distinctive influence of Plotinian Neoplatonism on Augustine's thinking about God was in his Trinitarian theology. He started with the unity of God and continually insisted upon it, unlike Greek Christian thinkers, who started with the Three Persons perfectly united; and because he thought that something like the Christian doctrine of the Trinity was to be found in Plotinus and Porphyry, he tended to regard it as a philosophical doctrine and tried to make philosophical sense of it to a greater extent than the Greek Fathers did. His last and most important and influential attempt to do so was in his treatise *On the Trinity*, with its discovery of analogies to the divine mystery in the self-directed, internal activities of the soul.

Medieval Platonism. With the gradual revival of philosophical thinking in the West that began in the Carolingian period (late 8th–9th centuries), the history of Platonism becomes extremely complex. Only a sketch distinguishing the main streams of a more or less Platonic tradition is given here.

Influence
of the
Timaeus

In the 4th century the Christian exegete Calcidius (Chalcidius) prepared a commentary on Plato's *Timaeus*, which exerted an important influence on the medieval interpretation of the *Timaeus*. A Christian Platonic theism of the type of which Boethius is the finest example thus arose; based on a reading of the *Timaeus* with Christian eyes, it continued to have a strong influence in the Middle Ages, especially in the earlier period. This kind of theism, issuing in a strongly positive view of God's creation and a nobly

austere but humane view of man's duty and destiny, was particularly apparent in the Christian humanism of the School of Chartres (12th century).

The widest, deepest, and most persistent Christian Platonist influence in the Latin West was that of Augustine (see above *Augustinian Platonism*). Augustinianism in a variety of forms—often stiffened, exaggerated, or distorted—persisted throughout the Middle Ages and survived the “recovery of Aristotle” (see below). In the later Middle Ages Augustine's influence was particularly strong in the Franciscan school, though not confined to it. But the greatest and most influential of medieval thinkers deeply influenced by Augustine was Anselm of Canterbury (1033/34–1109), the originator (probably on the basis of suggestions in Augustine) of the still much discussed “ontological argument” for the existence of God (see PHILOSOPHIES OF THE BRANCHES OF KNOWLEDGE: *Philosophy of religion*) and a philosopher whose humility, openness, and readiness to consider objections had a genuinely Socratic quality.

One of the boldest and most original thinkers of medieval Europe was John Scotus Erigena (810–c. 877), who introduced to the West the Greek Christian Platonist tradition (see above *Patristic Platonism*), as it had been developed by Gregory of Nyssa, the Pseudo-Dionysius, and Maximus the Confessor. His views were much disapproved of by the Western church; and his great philosophical work, the *Periphyseon* (usually known as *De divisione naturae* [*On the Division of Nature*]), was not much read and ceased to be copied after his condemnation in 1210. But a considerable part of the text circulated in the form of anonymous glosses to the Latin translations of the Pseudo-Dionysius (of which the first adequate translation was by Erigena himself); and in this way his thought influenced both the tradition of Western mysticism, which derived from the Pseudo-Dionysius, and 13th-century Scholasticism, for which St. Paul's supposed disciple was still a major authority.

John
Scotus
Erigena

There is no more superficial and misleading generalization in the history of philosophy than that which sharply opposes “Christian Platonism” and “Christian Aristotelianism.” To be sure, the recovery of the authentic thought of Aristotle through Latin translations of his works in the 12th and 13th centuries was indeed a major event in the history of philosophy. But Platonism and Aristotelianism have never been tidily separated in the history of European thought. There was already a strong Aristotelian element in Middle Platonism and Neoplatonism. Byzantine theologians (in the East) from the 6th century AD onward were as Aristotelian as anybody in western Europe in the 13th century. Thirteenth-century “Aristotelian” Scholastics, though much preoccupied with the new translations of Aristotle and their philosophical and theological implications, were still deeply influenced by Augustine, Boethius, and the Pseudo-Dionysius (with glosses derived from Erigena). And the Islāmic philosophy, to be mentioned below, with which they had to grapple, was as much Neoplatonist as it was Aristotelian. Further, they also were influenced by Latin translations of two pseudo-Aristotelian works in Arabic, based on Neoplatonic sources (see below) as well as by those of some of the shorter works of Proclus (see above). It has been said that “Aquinas is closer to Plotinus than to the real Aristotle,” and there is some truth in this judgment.

The
Platonism
in “Aristo-
telian”
Scholasti-
cism

Islāmic and medieval Jewish philosophy. After the Muslim conquest of Syria and Egypt, there began a great work of translation of the texts that had been studied in the late Greek philosophical schools—including a number of dialogues of Plato and Neoplatonic treatises, as well as the works of Aristotle and a number of the Alexandrian Neoplatonist commentaries on them. The translations—partly from Greek, partly from Syriac versions of the Greek texts—were made between about 800 and 1000. On the basis of these translated texts an impressive development of Islāmic theology and philosophy took place, strongly influenced by Neoplatonism, though Aristotelian influence also became increasingly important. An interesting feature of this Islāmic philosophy, which distinguished it from the familiar Neoplatonism, was the reappearance in al-Fārābī and Averroës of an interest in the political and social side

of Plato's thought. The tradition may be seen in four great Muslim philosophers, the Arab al-Kindi (c. 800–870), the Turk al-Fārābī (c. 878–c. 950), and two who deeply influenced the medieval West, Avicenna (Ibn Sīnā, 980–1037) from Persia and Averroës (Ibn Rushd, 1126–98) from Muslim Spain. Of these, Avicenna was perhaps the more Platonist, and Averroës, whose fame and influence rested primarily on his commentaries on Aristotle, was the more Aristotelian although the latter's commentaries were written on the basis of Greek ones, some of whose authors had used them as a vehicle for Neoplatonism. Medieval Jewish philosophy, which also developed within this Muslim intellectual tradition, reflected—at least in its earlier phases—strong Neoplatonic influence. This is especially true of the thought of the early figure Isaac Israeli (mid-9th–mid-10th century), whose Platonism was pervasive, though derivative and less than fully coherent, and the first great Jewish philosopher of Muslim Spain, Avicbron (Ibn Gabirol, c. 1022–c. 1058/70), whose Platonism may have been derived from Israeli's. Avicbron's *Fons vitae* (*Fountain of Life*) was also a major influence on scholastic philosophers.

PLATONISM FROM THE RENAISSANCE TO MODERN TIMES

From the 15th century onward the dialogues of Plato and a large number of Middle Platonist and Neoplatonist works, above all the *Enneads* of Plotinus, became available in the original Greek in western Europe. As a result of this new acquaintance with the original texts, Platonic influences on Renaissance and post-Renaissance thought became even more complex and difficult to recognize than those on medieval thought. Older Neoplatonically influenced traditions (notably Augustinianism) persisted, and new ones developed from the direct reading of the Neoplatonic texts. And, at least from the time of Leibniz (1646–1716), European thinkers realized that the Neoplatonic interpretation of Plato was in some ways a distorted and one-sided one; hence they sometimes developed their own allegedly more authentic understandings of Plato on the basis of direct readings of such of his varied works as they found to be philosophically congenial. Only a few of the more interesting Platonic influences can be indicated here.

In spite of its deep influence on Greek Christian thinkers, Platonism was regarded with profound suspicion by the Byzantine Orthodox Church. The suspicion reflected its association in the Byzantine ecclesiastical mind with the militant paganism of the Athenian Neoplatonists (see above). Nonetheless, it survived in the Byzantine world—generally underground but with an overt revival in the 11th century, in which the most notable figures were the broadly erudite Michael Psellus, who did much to enhance the prestige of philosophy, and his rival, the syncretistic Aristotelian commentator John Italus. In the following century Eustratius, metropolitan of Nicaea, and Michael of Ephesus continued the tradition of writing Neoplatonic commentary on Aristotle, plugging some of the gaps left by the Alexandrian commentators. In the 15th century the last known Byzantine philosopher, George Gemistus Plethon, a passionate pagan Platonist in the manner of Proclus, traveled to Italy (1438–39) and persuaded Cosimo de' Medici to sponsor a Platonic Academy at Florence, of which the greatest figures to emerge were its founder, Marsilio Ficino (1433–99), who translated all of Plato and Plotinus into Latin, the first complete version of either in a Western language, and the humanist Pico della Mirandola (1463–94), author of the influential *Oration on the Dignity of Man*. Ficino's *Platonic Theology: On the Immortality of Souls* contains not only Platonic and Neoplatonic philosophy but also elements drawn from medieval Aristotelianism, Cicero, Augustine, and Italian humanist writers. In spite of the paganism of Plethon, the Platonism of the Florentine Academy was a Christian one of a humane and liberal kind. This was probably at least partly due to the influence in Italy of Nicholas of Cusa (1401–64), who worked out his own very original version of Christian Platonism, influenced by the Pseudo-Dionysius, Erigena, and the German mystical tradition (as in Meister Eckhart).

The influence of the Platonism of the Florentine Academy was quite extensive; it may be seen not only in the writings of later Italian philosophers but also in the iconography of Italian Renaissance painting and in 16th-century French literature and was particularly marked in England. Perhaps the most impressive development of this post-Renaissance movement lay in the works of the Cambridge Platonists (late 17th century). Since their time a tradition of liberal Christian Platonism has persisted in England. Moreover, there have been other notable traditions of Platonically influenced Christian thought in Europe. One that deserves to be better known is that of the outstanding French philosopher of "action" Maurice Blondel (1861–1949), who found a prominent place in his system for the formation of ideas—interpreted as an important species of action that faithfully reflects the eternal order of reality. Blondel's philosophy has had a widespread influence, mainly among Catholic philosophers dissatisfied with Neoscholasticism. Another French philosopher much influenced by Platonism, in its Plotinian form, was Henri Bergson (1859–1941), whose thought attracted much attention during and just after his lifetime but has been largely neglected since.

The rediscovery of Proclus by the great German Idealist G.W.F. Hegel (1770–1831) had an important influence on his thought and so on the whole history of 19th-century Idealist philosophy. His contemporary F.W.J. von Schelling (1775–1854) was also strongly influenced by Neoplatonism, in his case that of Plotinus. Idealism, however, should not be interpreted as revived Neoplatonism, nor Neoplatonism as an anticipation of Idealism. But the historical influence of Neoplatonism on Idealist thought is indisputable. There was a strong reaction against Hegel's influence in some quarters, and this reaction led to a corresponding depreciation of Neoplatonism though the tradition of Idealism continued in the work of F.H. Bradley and John Ellis McTaggart in England and Josiah Royce in the United States. But 20th-century continental European philosophers and scholars were, until the 1960s, readier than English-speaking ones to take a serious interest in Neoplatonism. The latter, with some notable exceptions, maintained a hostile attitude toward that philosophy which they wrongly regarded not only as "decadent" but also as "mystical," and thus outside the true tradition of Greek philosophy.

The influence of the sort of Christian Platonism mentioned above on English literature, and especially on English poetry, has been wide and deep. But there has also been a strongly anti-Christian Neoplatonic influence, that of Thomas Taylor "the Platonist" (1758–1835), who published translations of Plato, Aristotle, and a large number of Neoplatonic works in the late 18th and early 19th centuries. Taylor was as militant in his pagan Platonism as was Gemistus Plethon. His ideas had a strong influence on the English Romantics. In the poetry of William Blake, who eventually succeeded in reconciling Taylor's paganism with his own very original version of Christianity, much of the symbolism is Neoplatonic. The Platonism of the English Romantic poets Coleridge and Shelley also derives from Taylor, although both were able to read the original texts. Taylor also deeply influenced Emerson and his circle in America. Later, in the early 20th century, the influence of Taylor's writings was again apparent in the Irish poet and dramatist William Butler Yeats, who in his later poems made use of Stephen MacKenna's then new translation of Plotinus.

The foremost process philosopher (an adherent of a view emphasizing the elements of becoming, change, and novelty in experienced reality), Alfred North Whitehead (1861–1947), perhaps because of his original and abiding concern with mathematical philosophy, was interested in Plato (though not, apparently, in the Neoplatonists); and his reading of the *Timaeus* in particular contributed something to the metaphysical system of his last period and especially to his concept of a God who does not timelessly transcend process but is in some way involved in it. Whitehead is an excellent example of a Platonically influenced thinker whose development of Plato's own thought proceeded along lines completely opposed to Neoplatonism.

EVALUATION OF PLATONISM

The essential point at issue between Platonists and their opponents through the centuries has been the existence (in some sense) of a spiritual or intelligible reality that is independent of the world, and is the ultimate origin of both existence and values. This is a very rough generalization that does not apply to the Skeptical Academy (see above *Greek Platonism from Aristotle through Middle Platonism*) or do full justice to the thought of the modern skeptical Platonist George Santayana. Platonists have understood this central doctrine in a great variety of ways and defended it with a great variety of arguments. But whenever it has been strongly held, it seems to have been by a faith depending on some sort of experience rather than simply on the conclusion of an argument. Its opponents have generally followed the lines of attack laid down by Aristotle (and to some extent anticipated by Plato in the first part of his *Parmenides*), that the doctrine involves the duplication of reality and the postulation of entities for the existence of which no sufficient evidence or arguments can be offered and the relationship of which to the world of sense experience cannot be intelligibly stated. The argument continues and will perhaps never finally be settled, but there can be no doubt about the central importance of Platonism in the history of European thought.

(A.H.A./H.J.B.I.)

MAJOR WORKS

WORKS: Plato's works are here listed in their traditional order, certain spurious items being omitted: *Euthyphrōn* (*Euthyphro*); *Apologia Sōkratous* (*Apology*); *Critōn* (*Crito*); *Phaedrōn* (*Phaedo*); *Cratylus* (*Cratylus*); *Theaetētos* (*Theaetetus*); *Sophistēs* (*Sophist*); *Politikos* (*Statesman*); *Parmenidēs*; *Philebos* (*Philebus*); *Symposion* (*Symposium*); *Phaedros* (*Phaedrus*); *Alkibiadēs* (*Alcibiades*); *Hipparchos* (*Hipparchus*); *Erastai* (*Lovers*); *Charmidēs*; *Lachēs*; *Lysis*; *Euthydēmos* (*Euthydemus*); *Protagoras*; *Gorgias*; *Menōn* (*Meno*); *Hippias Meizōn* (*Hippias Major*); *Hippias Elattōn* (*Hippias Minor*); *Iōn*; *Menexenos* (*Menexenus*); *Politeia* (*Republic*); *Timaios* (*Timeaus*); *Critias*; *Nomoi* (*Laws*); and *Epinomis*.

TEXTS: The standard Greek text is the edition by Ioannes (John) Burnet, *Platonis Opera*, 5 vol. (1900–07, reprinted 1973 from various printings). All of the major works were translated into English by Benjamin Jowett, and the latest revisions of the Jowett translations are still the best available English versions of Plato. The Loeb Classical Library also contains the whole of Plato (in Greek and English); and several of the dialogues are published in the Penguin Classics series, including *Philebus*, trans. by Robin A.H. Waterfield (1982); *Protagoras and Meno*, trans. by W.K.C. Guthrie (1956, reissued 1966); and *Plato's Symposium*, trans. by W. Hamilton (1956).

RECOMMENDED LATER EDITIONS: Numerous English translations are available, including David Gallop (trans.), *Phaedo* (1975, reprinted 1983); John McDowell (trans.), *Theaetetus* (1973); Francis Macdonald Cornford (trans.), *Plato's Theory of Knowledge: The Theaetetus and the Sophist of Plato* (1935, reprinted 1973); J.B. Skemp (trans.), *Statesman* (1957, reissued 1977); R.E. Allen (trans.), *Plato's Parmenides* (1983); J.C.B. Gosling (trans.), *Philebus* (1975); R. Hackforth (trans.), *Phaedo* (1955, reprinted 1972); C.C.W. Taylor (trans.), *Protagoras* (1976); Terence Irwin (trans.), *Gorgias* (1979); R.W. Sharples (ed. and trans.), *Meno* (1985); Paul Woodruff (trans.), *Hippias Major* (1982); and James Adam (ed.), *The Republic*, 2nd ed., 2 vol. (1963, reprinted 1969).

BIBLIOGRAPHY

Plato. *Life and thought:* There are several good brief introductions to Plato, including C.J. ROWE, *Plato* (1984); J.E. RAVEN, *Plato's Thought in the Making: A Study of the Development of His Metaphysics* (1965, reprinted 1985); G.M.A. GRUBE, *Plato's Thought* (1935, reprinted 1980); G.C. FIELD, *The Philosophy of Plato*, 2nd ed. (1969, reprinted 1978); and A.E. TAYLOR, *Plato, the Man and His Work*, 7th ed. (1960, reprinted 1969). On Plato's life, see also G.C. FIELD, *Plato and His Contemporaries: A Study in Fourth-Century Life and Thought* (1930, reprinted 1975); ALICE SWIFT RIGINS, *Platonica: The Anecdotes Concerning the Life and Writings of Plato* (1976); and the old but still valuable work by GEORGE GROTE, *Plato, and the Other Companions of Sokrates*, new ed., 4 vol. (1888, reprinted 1974). On the history of the Academy, see HAROLD CHERNISS, *The Riddle of the Early Academy* (1945, reprinted 1980); and JOHN GLUCKER, *Antiochus and the Late Academy* (1978).

A full and scholarly account of Plato's philosophy can be found in W.K.C. GUTHRIE, *A History of Greek Philosophy*, vol. 4, *Plato: The Man and His Dialogues: Earlier Period* (1975), and vol. 5, *The Later Plato and the Academy* (1978), while vol.

3, *The Fifth-Century Enlightenment* (1969), contains a full account of what is known about Socrates. Other general accounts include PAUL FRIEDLÄNDER, *Plato*, 3 vol. (1958–69; originally published in German, 2nd ed., 1954–60); I.M. CROMBIE, *An Examination of Plato's Doctrines*, 2 vol. (1962–63; reissued 1979); and J.C.B. GOSLING, *Plato* (1973, reissued 1983). GILBERT RYLE, *Plato's Progress* (1966), is idiosyncratic. Much contemporary scholarly work has appeared in articles. GREGORY VLASTOS, *Platonic Studies*, 2nd ed. (1981), contains several classic papers. There are two useful anthologies: GREGORY VLASTOS (ed.), *The Philosophy of Socrates* (1971, reprinted 1980), and *Plato*, 2 vol. (1970–71, reprinted 1978).

On Plato's ethics, see in particular JOHN GOULD, *The Development of Plato's Ethics* (1955, reprinted 1972); PAMELA HUBY, *Plato and Modern Morality* (1972); and TERENCE IRWIN, *Plato's Moral Theory: The Early and Middle Dialogues* (1977, reissued 1979). On his political theory, see R.H.S. CROSSMAN, *Plato Today*, rev. 2nd ed. (1959, reissued 1971); K.R. POPPER, *The Open Society and Its Enemies*, vol. 1, *The Spell of Plato*, 5th ed. (1966, reprinted 1971); RONALD B. LEVINSON, *In Defense of Plato* (1953, reissued 1970); RENFORD BAMBROUGH (ed.), *Plato, Popper and Politics: Some Contributions to a Modern Controversy* (1967); and ROBERT W. HALL, *Plato* (1981). See also MARY MARGARET MACKENZIE, *Plato on Punishment* (1981); and RICHARD KRAUT, *Socrates and the State* (1984). For Plato's views on aesthetics, see IRIS MURDOCH, *The Fire and the Sun: Why Plato Banished the Artists* (1977); and JULIUS MORAVCSIK and PHILIP TEMKO (eds.), *Plato on Beauty, Wisdom, and the Arts* (1982).

For Plato's view of the soul, see T.M. ROBINSON, *Plato's Psychology* (1970). On the physical theory of the *Timaeus*, see GREGORY VLASTOS, *Plato's Universe* (1975); and on his attitude to science, see JOHN P. ANTON (ed.), *Science and the Sciences in Plato* (1980).

On epistemology, see W.F.R. HARDIE, *A Study in Plato* (1936); NORMAN GULLEY, *Plato's Theory of Knowledge* (1962, reprinted 1973); W.G. RUNCIMAN, *Plato's Later Epistemology* (1962); NICHOLAS P. WHITE, *Plato on Knowledge and Reality* (1976); and JON MOLINE, *Plato's Theory of Understanding* (1981). The standard study of Plato's ideas on logic and dialectic is RICHARD ROBINSON, *Plato's Earlier Dialectic*, 2nd ed. (1953, reprinted 1984). See also JULIUS STENZEL, *Plato's Method of Dialectic* (1940, reprinted 1973; originally published in German, 2nd ed., 1931); and KENNETH M. SAYRE, *Plato's Analytic Method* (1969).

On metaphysics and the theory of Forms there is a comprehensive survey by W.D. ROSS, *Plato's Theory of Ideas* (1951, reissued 1976); and a useful collection of essays, R.E. ALLEN (ed.), *Studies in Plato's Metaphysics* (1965, reprinted 1968). See also FRIEDRICH SOLMSEN, *Plato's Theology* (1942, reissued 1967); ANDERS WEDBERG, *Plato's Philosophy of Mathematics* (1955, reprinted 1977); RENFORD BAMBROUGH (ed.), *New Essays on Plato and Aristotle* (1965); J.N. FINDLAY, *Plato: The Written and Unwritten Doctrines* (1974); and WILLIAM J. PRIOR, *Unity and Development in Plato's Metaphysics* (1985).

Commentaries: Among the more useful commentaries are R.E. ALLEN, *Plato's Euthyphro and the Earlier Theory of Forms* (1970), and *Socrates and Legal Obligation* (1980); A.D. WOZZLEY, *Law and Obedience: The Law of Plato's Crito* (1979); ROSAMUND KENT SPRAGUE, *Plato's Use of Fallacy: A Study of the Euthydemus and Some Other Dialogues* (1962); B.A.F. HUBBARD and E.S. KARNOFSKY, *Plato's Protagoras: A Socratic Commentary* (1982, reissued 1984); N.R. MURPHY, *The Interpretation of Plato's Republic* (1951, reprinted 1967); R.C. CROSS and A.D. WOZZLEY, *Plato's Republic: A Philosophical Commentary* (1964, reissued 1980); NICHOLAS P. WHITE, *A Companion to Plato's Republic* (1979); JULIA ANNAS, *An Introduction to Plato's Republic* (1981); and GLENN R. MORROW, *Plato's Cretan City: A Historical Interpretation of the Laws* (1960). (J.B.)

Platonism. There are few modern English translations of the basic works of Neoplatonism, though more will appear as a result of a project sponsored by the National Endowment for the Humanities. PLOTINUS, *The Enneads*, trans. by STEPHEN MACKENNA, 3rd ed. rev. by B.S. PAGE (1962), is not entirely satisfactory; it is being replaced by the Loeb Classical Library edition, A.H. ARMSTRONG (trans.), *Plotinus* (1966–), 5 vol. having appeared to 1986. Other basic works include PROCLUS, *The Elements of Theology*, trans. by E.R. DODDS, 2nd ed. (1963), *A Commentary on the First Book of Euclid's Elements*, trans. by GLENN R. MORROW (1970), and *Proclus: Alcibiades I*, trans. by WILLIAM O'NEILL, 2nd ed. (1971). French translations of Proclus' commentaries have been made by A.J. FESTUGIÈRE, *Commentaire sur le Timée*, 2 vol. (1966–68), and *Commentaire sur la République*, 3 vol. (1970). See also PROCLUS, *Théologie platonicienne*, trans. by H.D. SAFFREY and L.G. WESTERINK (1968–), 4 vol. having appeared to 1986; JULIANUS, *Oracles chaldaïques*, trans. by ÉDOUARD DES PLACES (1971); and IAMBlichus, *Les Mystères d'Égypte*, trans. by ÉDOUARD DES PLACES (1966). A good source of information on the Platonic and Neoplatonic

philosophers up to and including Anselm is *The Cambridge History of Later Greek and Early Medieval Philosophy*, ed. by A.H. ARMSTRONG (1967; reprinted with revised bibliographies, 1970). The bibliographies of this work include a list of the editions of ancient and medieval sources (complete and fragmentary), with the more important translations and modern works. PAUL SHOREY, *Platonism, Ancient and Modern* (1938), remains an excellent introduction, but much of the important work on the period between Plato and Plotinus is still confined to technical articles; this is also true of later Neoplatonism. J.N. FINDLAY, *Plato and Platonism: An Introduction* (1978), argues that Plato developed a complete metaphysical system. JOHN DILLON, *The Middle Platonists: 80 B.C. to A.D. 220* (U.K. title, *The Middle Platonists: A Study of Platonism, 80 B.C. to A.D. 220*, 1977), offers a clear and comprehensive account of its subject; it gives the background to the best general book on ancient Neoplatonism, R.T. WALLIS, *Neo-Platonism* (1972). Many of the important problems in Plotinus are discussed by J.M. RIST, *Plotinus: The Road to Reality* (1967, reprinted 1977). Certain key ideas are traced in RICHARD SORABJI, *Time, Creation, and the Continuum: Theories in Antiquity and the Early Middle Ages* (1983). JAMES A. COULTER, *The Literary Microcosm: Theories of Interpretation of the Later Neoplatonists* (1976), is a study of Neoplatonic literary theory. A collection of articles on pagan and early Christian Neoplatonism may be found in H.J. BLUMENTHAL and R.A. MARKUS (eds.), *Neoplatonism and Early Christian Thought* (1981); a similar collection, extending to modern times, is DOMINIC J. O'MEARA (ed.), *Neoplatonism and Christian Thought* (1982). For the earlier Judeo-Christian tradition, see ERWIN R. GOODENOUGH, *An Introduction to Philo Judaeus*, 2nd ed. rev. (1963); and HARRY CHADWICK, *Early Christian Thought and the Classical Tradition: Studies in Justin, Clement, and Origen* (1966, reprinted 1984). An excellent short summary of the thought of St. Augustine, with due attention to the Platonist elements, is Chadwick's *Augustine* (1986), and his *Boethius: The Consolations of Music, Logic, Theology, and Philosophy* (1981), gives an account of the further development of Western Neoplatonism and includes a study of the development of Neoplatonic logic. For medieval Platonism, see FRIEDRICH UEBERWEG, *Grundriss der Geschichte der Philosophie*, vol. 2, *Die patristische und scholastische Philosophie*, ed. by BERNHARD GEYER, 12th ed. (1951); ÉTIENNE GILSON, *History of Christian Philosophy in the Middle Ages* (1955, reissued 1980), with valuable bibliographical material; DAVID KNOWLES, *The Evolution of Mediaeval Thought* (1962); GORDON LEFF, *Mediae-*

val Thought: St. Augustine to Ockham (1958, reprinted 1983); and WERNER BEIERWALTES (ed.), *Platonismus in der Philosophie des Mittelalters* (1969), a collection of important articles. All these works to some extent cover the later medieval period. On Islamic philosophy see the brief account in W. MONTGOMERY WATT, *Islamic Philosophy and Theology: An Extended Survey*, 2nd ed. (1985). There is no satisfactory longer treatment in English, but for Avicenna, see SOHEIL M. AFNAN, *Avicenna: His Life and Works* (1953, reprinted 1980). A sample of the Platonist contribution to Islamic thought may be seen in FRANZ ROSENTHAL, *The Classical Heritage in Islam* (1975; originally published in German, 1965). The best survey of Platonism in medieval Jewish philosophy is GEORGES VAJDA, "Le Néoplatonisme dans la pensée juive du moyen âge," in G.E. WEIL (ed.), *Mélanges Georges Vajda* (1982), pp. 407-422. For Neoplatonic movements in Jewish Hellenistic and medieval philosophy, see JULIUS GUTTMANN, *Philosophies of Judaism: The History of Jewish Philosophy from Biblical Times to Franz Rosenzweig*, trans. from Hebrew (1964, reissued 1973). D.P. WALKER, *The Ancient Theology: Studies in Christian Platonism from the Fifteenth to the Eighteenth Century* (1972), reviews the Christian apologetic tradition of the Renaissance.

On Byzantine Platonism, see J.M. HUSSEY, *Church & Learning in the Byzantine Empire, 867-1185* (1937, reissued 1963); and BASILE TATAKIS, *La Philosophie byzantine*, 2nd ed. (1959). A good short general account of Renaissance Platonism in English is that by FREDERICK C. COPLESTON, *History of Philosophy*, vol. 3, ch. 12 and 15 (1953); see also the essays in PAUL OSKAR KRISTELLER, *Renaissance Thought: The Classic, Scholastic, and Humanistic Strains* (1961, reprinted 1980). A good short introduction to Renaissance Platonism in England is ERNST CASSIRER, *The Platonic Renaissance in England* (1953, reissued 1970; originally published in German, 1932). GERALD R. CRAGG (ed.), *The Cambridge Platonists* (1968, reprinted 1985), is an excellent anthology, with good introductions and notes; see also C.A. PATRIDES (ed.), *The Cambridge Platonists* (1969, reissued 1980). On English Christian Platonism, see WILLIAM RALPH INGE, *The Platonic Tradition in English Religious Thought* (1926, reprinted 1977). On the influence of Thomas Taylor, see *Thomas Taylor, the Platonist: Selected Writings*, ed. by KATHLEEN RAINE and GEORGE MILLS HARPER (1969); and F.A.C. WILSON, *W.B. Yeats and Tradition* (1958). RICHARD D. MCKIRAHAN, JR., *Plato and Socrates: A Comprehensive Bibliography, 1958-1973* (1978), contains 4,600 unannotated entries. (A.H.A./H.J.B.I.)

Poisons and Poisoning

Although poisons have been the subject of practical lore since ancient times, their systematic study is often considered to have begun during the 16th century, when the German-Swiss physician and alchemist Paracelsus first stressed the chemical nature of poisons. It was Paracelsus who introduced the concept of dose and studied the actions of poisons through experimentation. It was not until the 19th century, however, that the Spaniard Matthieu Orfila, the attending physician to Louis XVIII, correlated the chemistry of a toxin with the biological effects it produces in a poisoned individual. Both concepts continue to be fundamental to an understanding of modern toxicology.

Poisoning involves four elements: the poison, the poisoned organism, the injury to the cells, and the symptoms

and signs or death. These four elements represent the cause, subject, effect, and consequence of poisoning. To initiate the poisoning, the organism is exposed to the toxic chemical. When a toxic level of the chemical is accumulated in the cells of the target tissue or organ, the resultant injury to the cells disrupts their normal structure or function. Symptoms and toxic signs then develop, and, if the toxicity is severe enough, death may result.

This article considers humans as the primary subjects of poisoning. It first discusses the actions of poisons on the body and then examines principal types of synthetic and natural poisons.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 321, and the *Index*. The article is divided into the following sections:

Nature of a toxic substance	908	Agricultural and industrial chemicals	916
Definition of a poison		Agricultural chemicals	
Classification of a poison		Industrial chemicals	
Transport of chemicals through a cell membrane	909	General air pollutants	
Conditions of exposure	909	Drugs and health care products	919
Routes of exposure and absorption of chemicals		Painkillers	
Frequency of exposure		Tranquilizers and sleeping pills	
Dose of exposure		Antipsychotic drugs	
Distribution of toxicants in the body	911	Cold medications	
Role of the lymphatics		Antiseptics	
Role of the blood		Vitamins and iron pills	
Role of tissue blood flow		Antidepressants	
Role of protein binding		Drugs of abuse	
Role of distribution barriers		Cardiovascular drugs	
Elimination of toxicants	912	Antiasthmatics	
Therapeutic, toxic, and lethal responses	913	Poisons of biological origin	920
Morphological versus functional toxic responses		Importance to humans	
Local versus systemic toxic responses		Microbial toxins	
Immediate versus delayed toxic responses		Plant poisons (phytotoxins)	
Reversible versus irreversible toxic responses		Animal poisons (zootoxins)	
Chemically induced immune responses		Radiation	924

Types of poison	916	Bibliography	929

Nature of a toxic substance

Definition of a poison. A poison is a substance capable of producing adverse effects on an individual under appropriate conditions. The term "substance" is almost always synonymous with "chemical" and includes drugs, vitamins, pesticides, pollutants, and proteins. Even radiation is a toxic substance. Though not usually considered to be a "chemical," most radiations are generated from radioisotopes, which are chemicals. The term "adverse effects" above refers to the injury, such as structural damage to tissues. "Appropriate conditions" refers to the dosage of the substance that is sufficient to cause these adverse effects. The dose concept is important because according to it even a substance as innocuous as water is poisonous if too much is ingested. Whether a drug acts as a therapy or as a poison depends on the dose.

Classification of a poison. Poisons are of such diverse natures that they are classified by origin, physical form, chemical nature, chemical activity, target site, or use.

Classification based on origin. Poisons are of microbial, plant, animal, or synthetic origin. Microbial poisons are produced by microscopic organisms such as bacteria and fungi. Botulinus toxin, for example, is produced by the bacterium *Clostridium botulinum* and is capable of inducing weakness and paralysis when present in underprocessed, nonacidic canned foods or in other foods containing the spores. An example of a plant toxin is the belladonna alkaloid hyoscyamine, which is found in

belladonna (*Atropa belladonna*) and jimsonweed (*Datura stramonium*).

Animal poisons are usually transferred through the bites and stings of venomous terrestrial or marine animals, the former group including poisonous snakes, scorpions, spiders, and ants, and the latter group including sea snakes, stingrays, and jellyfish. Synthetic toxins are responsible for most poisonings. "Synthetic" refers to chemicals manufactured by chemists, such as drugs and pesticides, as well as chemicals purified from natural sources, such as metals from ores and solvents from petroleum. Synthetic toxins include pesticides, household cleaners, cosmetics, pharmaceuticals, and hydrocarbons.

Classification based on physical form. The physical form of a chemical—solid, liquid, gas, vapour, or aerosol—influences the exposure and absorbability.

Because solids are generally not well absorbed into the blood, they must be dissolved in the aqueous liquid lining the intestinal tract if ingested or the respiratory tract if inhaled. Solids dissolve at different rates in fluids, however. For example, compared with lead sulphate granules, granules of lead are practically nontoxic when ingested, because elemental lead is essentially insoluble in water, while lead sulphate is slightly soluble and absorbable. Even different-sized granules of the same chemical can vary in their relative toxicities because of the differences in dissolution rates. For example, arsenic trioxide is more toxic in the form of smaller granules than is the same mass of larger granules because the smaller granules dissolve faster.

Animal
toxins

A poison in a liquid form can be absorbed by ingestion or by inhalation or through the skin. Poisons that are gases at room temperature (e.g., carbon monoxide) are absorbed mainly by inhalation, as are vapours, which are the gas phase of substances that are liquids at room temperature and atmospheric pressure (e.g., benzene). Because organic liquids are more volatile than inorganic liquids, inhalation of organic vapours is more common. Although vapours are generally absorbed in the lungs, some vapours that are highly soluble in lipids (e.g., furfural) are also absorbed through the skin.

Aerosols

Aerosols are solid or liquid particles small enough to remain suspended in air for a few minutes. Fibres and dust are solid aerosols. Aerosol exposures occur when aerosols are deposited on the skin or inhaled. Aerosol toxicity is usually higher in the lungs than on the skin. An example of a toxic fibre is asbestos, which can cause a rare form of lung cancer (mesothelioma).

Many liquid poisons can exist as liquid aerosols, although highly volatile liquids, such as benzene, seldom exist as aerosols. A moderately volatile liquid poison can exist as both an aerosol and as a vapour. Airborne liquid chemicals of low volatility exist only as aerosols.

Classification based on chemical nature. Poisons can be classified according to whether the chemical is metallic versus nonmetallic, organic versus inorganic, or acidic versus alkaline. Metallic poisons are often eliminated from the body slowly and accumulate to a greater extent than nonmetallic poisons and thus are more likely to cause toxicity during chronic exposure. Organic chemicals are more soluble in lipids and therefore can usually pass through the lipid-rich cell membranes more readily than can inorganic chemicals. As a result, organic chemicals are generally absorbed more extensively than inorganic chemicals. Classification based on acidity is useful because, while both acids and alkalis are corrosive to the eyes, skin, and intestinal tract, alkalis generally penetrate the tissue more deeply than acids and tend to cause more severe tissue damage.

Classification based on chemical activity. Electrophilic (electron-loving) chemicals attack the nucleophilic (nucleus-loving) sites of the cells' macromolecules, such as deoxyribonucleic acid (DNA), producing mutations, cancers, and malformations. Poisons also may be grouped according to their ability to mimic the structure of certain important molecules in the cell. They substitute for the cells' molecules in chemical reactions, disrupting important cellular functions. Methotrexate, for example, disrupts the synthesis of DNA and ribonucleic acid (RNA).

Other classifications. Unlike the classifications described above, there is usually no predictive value in classification by target sites or by uses. Such classifications are done, however, to systematically categorize the numerous known poisons. Target sites include the nervous system, the cardiovascular system, the reproductive system, the immune system, and the lungs, liver, and kidneys. Poisons are classified by such uses as pesticides, household products, pharmaceuticals, organic solvents, drugs of abuse, or industrial chemicals.

TRANSPORT OF CHEMICALS THROUGH A CELL MEMBRANE

In order for a poison to produce toxicity, a sufficient quantity of that chemical must be absorbed into the body. Because the chemical must pass through a number of cell membranes before it can enter the blood, the ability of the chemical to cross these lipid-rich membranes determines whether it will be absorbed, and that ability depends on the chemical's lipid solubility.

Membrane structure

The cell membrane, the most external layer of all animal cells, is composed of two layers of lipid molecules (the lipid bilayer). The lipid molecules each have a hydrophilic (water-loving, or polar) end and a hydrophobic (water-hating, or nonpolar) end. Because they are surrounded by an aqueous environment, lipid molecules of the cell membrane arrange themselves so as to expose their hydrophilic ends and protect their hydrophobic ends. Suspended randomly among the lipid molecules are proteins, some of which extend from the exterior surface of the cell membrane to the interior surface.

A chemical tends to dissolve more readily in a solvent of similar polarity. Nonpolar chemicals are considered lipophilic (lipid-loving), and polar chemicals are hydrophilic (water-loving). Lipid-soluble, nonpolar molecules pass readily through the membrane because they dissolve in the hydrophobic, nonpolar portion of the lipid bilayer. Although permeable to water (a polar molecule), the nonpolar lipid bilayer of cell membranes is impermeable to many other polar molecules, such as charged ions or those that contain many polar side chains. Polar molecules pass through lipid membranes via specific transport systems.

The four types of chemical transport systems through cell membranes are diffusion, facilitated diffusion, active transport, and pinocytosis.

As mentioned above, lipophilic, nonpolar chemicals dissolve in the lipid bilayer. Simultaneously, some of the molecules are leaving the lipid bilayer. The net result is that chemicals cross the membrane until the concentrations of chemical molecules on both sides of the membrane are equal and there is no net flow of molecules across the cell membrane (diffusion). Therefore, chemicals diffuse across the membrane only when a concentration gradient exists across the cell membrane. Diffusion is considered to be passive transport because no external energy is used. Polar molecules, such as water and small water-soluble molecules (e.g., urea, chloride ions, sodium ions, and potassium ions), can diffuse across membranes through the water-filled channels created by membrane proteins. Large polar water-soluble chemicals, such as sugars, however, do not diffuse through the membrane.

Concentration gradient

Certain relatively large water-soluble molecules cross the cell membrane using carriers. Carriers are membrane proteins that complement the structural features of the molecules transported. They bind to the chemicals in order to move them across the cell membrane. Energy is consumed because the transport proceeds against the concentration gradient.

Active transport systems move chemicals essential to cellular functions through the membrane into the cell. Such essential chemicals include calcium ions, amino acids, carbohydrates, and vitamins. Because the structures of poisons usually are not similar to those of chemicals essential to cells, few poisons are absorbed by active transport. Active transport, however, is important in the elimination of organic acids, bases, and foreign compounds by the kidneys and liver.

Molecules of similar structure compete with one another in binding with the carrier molecule. Thus, the transport of one chemical can be inhibited by another chemical of similar structure, a phenomenon called competitive inhibition. The chemical being transported also competes with itself for a carrier molecule, so that only a limited amount of the chemical can be transported by the carrier protein during a specific time.

Transport systems that use carrier molecules but which do not require energy to proceed are called facilitated diffusion. A chemical first binds to the carrier protein in the cell membrane and then diffuses through the membrane. Because no energy is used, facilitated transport into the cell cannot proceed if the concentration of that chemical is greater inside the cell membrane than outside. The involvement of carriers means that the process is also subject to competitive inhibition and saturation.

Large molecules, such as proteins and solid particles, are often transported by pinocytosis. The cell membrane engulfs a particle or protein molecule outside the cell, and brings it into the cell. Although inefficient, pinocytosis operates in the slow absorption of proteins and particles in the intestine and respiratory tract.

CONDITIONS OF EXPOSURE

Figure 1 summarizes the conditions of exposure to toxicants.

Routes of exposure and absorption of chemicals. *Injection.* Although not a common route of exposure for poisons, injection is the only route in which the entire amount exposed is absorbed regardless of the chemical administered, because the chemical is introduced directly into the body. Chemicals may be injected intravenously

Types of injection

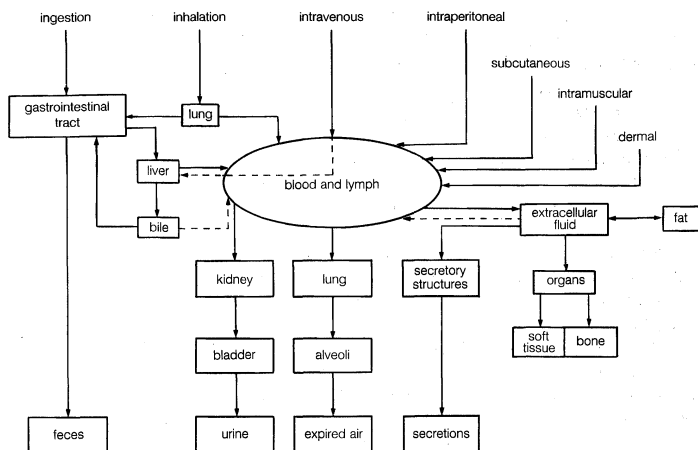

Figure 1: Routes of absorption, distribution, and excretion of toxicants in the human body.

From L.J. Casarett and J. Doull, *Toxicology: The Basic Science of Poisons* (1975); Macmillan Publishing Co., Inc.

(directly into a vein), intramuscularly (into a muscle), subcutaneously (under the skin), and intraperitoneally (within the membrane lining the organs of the abdomen).

Because the blood is the vehicle of chemical distribution in the body, intravenous injection is the most rapid method of introducing a chemical into the body. The almost instantaneous distribution, together with the irreversibility, makes intravenous injection a dangerous method of chemical exposure, with a fair chance of causing drug overdose if improperly administered.

Because there is a relatively large flow of blood to the skeletal muscles, chemicals are absorbed into the blood relatively rapidly after intramuscular injection. The slow absorption of a chemical into the blood after subcutaneous injection is probably due to the low blood flow in the subcutaneous tissues. Intraperitoneal injection is used only in biomedical research. Absorption is relatively rapid with intraperitoneal injection because of the rich blood supply to the abdomen.

Ingestion. Ingestion is the most common route of exposure to toxic chemicals. Most chemicals diffuse across the cell membrane in the nonionized form, so that the degree to which the chemical is ionized is important in determining whether a chemical is absorbed (see above *Transport of chemicals through a cell membrane*).

Organic acids and bases dissociate into their ionized forms in response to the pH conditions of the environment. Organic acids are in their nonionized form in an acidic environment (such as the stomach), and they thus tend to diffuse across a membrane, whereas organic bases are nonionized and thus diffuse across a membrane in a basic environment (such as in the intestine).

Because the pH and surface areas differ in different segments of the gastrointestinal tract, chemical absorbabilities of these segments also differ. The major sites of absorption of ingested poisons are the stomach and the small intestine, with most of the absorption taking place in the latter. The intestine has a greater blood supply and a much larger surface area. Folds in the mucosa of the small intestine house numerous projections on the luminal surface, which increases the surface area of the 280-centimetre- (110-inch-) long small intestine to up to 2,000,000 square centimetres.

The pH on the mucosal surface of the small intestine is normally about 5.4 (basic). Organic bases tend to be in the nonionized, lipid-soluble form and thus in general are absorbed there. The pH of the stomach contents is in the range of 1 to 2 (acidic), and weak organic acids tend to be in the nonionized, lipid-soluble form. It might be expected that the poisons would be absorbed there, but, because the surface area of the stomach is much smaller than that of the small intestine, often the stomach contents (along with the poisons) are passed to the intestine before the chemicals are absorbed. The acidic environment of the stomach is the main reason for the poor absorption of organic bases by the stomach.

Topical (skin). The skin is composed of three layers of tissues—the epidermis, dermis, and subcutaneous tissues—and is an effective barrier to many substances. The outer skin layer is the epidermis, containing five layers of cells. The stratum corneum, which is the outermost epidermal layer, consists of dead cells and is the major barrier to chemical transfer through the skin. Although nonpolar chemicals cross the skin by diffusion through the stratum corneum, no active transport exists in the dead cells of this layer. The second layer, the dermis, is thicker and is composed of loosely packed connective tissue cells in a watery matrix of collagen and elastin fibres, as well as sweat glands, hair follicles, capillaries, and lymphatic vessels. After crossing the epidermis, chemical molecules are absorbed into the circulatory system via the capillaries. The capillaries drain into venules in the subcutaneous tissue.

The stratum corneum is not very permeable to water-soluble molecules and ions, although lipid-soluble molecules do cross it to a certain extent. The permeability is directly proportional to the lipid solubility of the chemical (*i.e.*, highly lipid-soluble chemicals are readily absorbed) and inversely proportional to the molecular weight of the chemical (*i.e.*, the rate of absorption increases as the molecular weight of the molecule decreases).

The rate of percutaneous absorption also varies with the thickness of the stratum corneum at different sites of the body. The rate of absorption is higher for skin on the forehead, axilla, back, and abdomen than for thicker regions like the plantar surface of the foot and the palm. The condition of the skin is also important. Percutaneous absorption is faster when the skin is moist rather than dry.

Solids are not absorbed through the skin because the skin is generally not covered with liquid and because pinocytosis does not operate in dead cells. Liquid chemicals penetrate the skin largely because of their lipid solubility. Gases and certain vapours can be absorbed through the skin also, although to a much lesser extent than via inhalation.

Inhalation. The absorption of inhaled gases and vapours differs from that of aerosols and thus will be discussed separately.

Because the same principles govern the absorption of gases and vapours, the word “gases” is used here to represent both gases and vapours. Absorption of inhaled gases takes place mainly in the lungs. Before the gases reach the lung, however, they pass through the nose, where highly water-soluble, or highly reactive, gas molecules are retained by mucosa.

Unlike intestinal and percutaneous absorption of chemicals, respiratory absorption of gases does not depend on the pH of the alveoli, because gas molecules are not ionized. It also does not depend on the lipid solubility of the gas molecules for three reasons. First, the alveolar gas molecules are situated in close proximity to the capillaries. Second, the alveoli form a huge surface for gas absorption. Third, the time it takes for a unit of blood to go through the lungs is more than adequate for gas molecules to diffuse from the alveolar space to the blood.

Gas molecules move into the blood by partitioning, which is a gas-transfer process between two phases, such as between the air and the blood or the blood and the tissues. In partitioning, gas molecules move from a phase of high partial pressure to an adjacent phase of low partial pressure. When an individual first inhales the gas, the partial pressure of the gas is higher in the air than in the blood, driving gas molecules from the alveolar space to the blood. As more gas molecules are driven into the blood, the blood's partial pressure is raised. Eventually the partial pressure gradient between the air and blood dissipates and gas transfer stops; equilibrium is then reached, usually before the blood leaves the lungs.

The blood carries the gas molecules to the rest of the body, where the gas is transferred from the blood to the tissue until equilibrium is reached. The blood picks up more gas molecules in the lungs, and the process continues until the gas in each tissue of the body is in equilibrium with that of the blood entering the tissue. At this time, barring biotransformation, no further net absorption of gas takes place as long as the exposure concentration re-

Skin structure

Rate of absorption

pH influence on ionization

mains constant. A person can breathe the gas forever and not absorb more, a unique characteristic of gas exposure.

The particle size and water solubility of an aerosol chemical are the important characteristics determining absorption of aerosols. For an aerosol to be absorbed, it must be inhaled and deposited on the respiratory tract. If not deposited, the aerosol particles are exhaled. Aerosols of less than 100 micrometres (0.004 inch) can be inhaled.

The aerosol size also determines the tendency of a particle to be deposited on a certain region of the respiratory tract. The larger aerosols (greater than five micrometres) tend to be deposited in the upper respiratory tract, while the smaller ones (less than five micrometres) have a greater chance of being deposited on deeper sites of the lung. The nose acts as a "scrubber" for larger aerosols and thus protects the lung from injury.

Once deposited, aerosol particles must dissolve in the liquid lining the respiratory tract in order to be absorbed. For most aerosols of poor water solubility, the particles are cleared from the respiratory tract by mechanical or cellular means. In the nasopharyngeal region, mechanical methods of clearance include sneezing and nose blowing for particles deposited on the anterior one-fifth of the nasal cavity. Particles deposited on the remaining portion of the nasal cavity and on the pharynx are removed by tiny hairs, called cilia, on the surface of these two regions, which beat almost continuously to move a covering layer of mucous toward the throat (mucociliary apparatus). Any particles deposited on the mucous are carried along and finally swallowed.

In the tracheobronchial region, mechanical clearance includes coughing and the mucociliary apparatus. The trachea, bronchi, and bronchioles, down to the terminal bronchioles, are covered with mucous and cilia. The mucociliary apparatus moves upward toward the larynx, where the respiratory tract joins the esophagus. The particles are eventually swallowed and may be absorbed by the gastrointestinal tract.

The alveolar region has the slowest rate of particle clearance in the entire respiratory system, unless the particles are water-soluble, in which case they are cleared readily by dissolution. Water-insoluble particles in the respiratory bronchioles and alveoli are removed by cellular means, principally by macrophages—scavenger cells that engulf cellular debris in the body by a process called phagocytosis. Once phagocytosed, macrophages that contain particles are removed by the mucociliary apparatus in the terminal bronchioles. Pinocytosis by the cells lining the alveoli probably move the free particles to the interstitial space, where they either enter the lymphatic capillaries and are carried to the bloodstream, or they undergo a long process of dissolution. It can take years for water-insoluble particles to dissolve, depending on the chemical, which is why water-insoluble particles deposited in the alveolar region tend to remain in the interstitial space for a long time and can cause serious harm.

Frequency of exposure. The second important condition of exposure is frequency: acute (single exposure), subchronic (repeated exposures that in total last for no more than 10 percent of the lifetime of an individual), and chronic (repetitive exposures that last in total longer than 10 percent of the lifetime). The difference between the frequencies of exposure is the length of time a chemical is maintained in a target tissue. A single exposure of a poison at a certain dose may be sufficient to produce a toxic concentration in a target tissue, leading to the development of toxicity. Repetitive exposures at the same dose will then enhance the severity of the injury because of the presence of toxic levels of the chemical in the target tissue. The continuous presence of a toxic amount of poison may impair the ability of the damaged cells to carry out repair and thus prevent any chance of recovery. Consequently, a single dose that produces symptoms and toxic signs can lead to death if repeated over time. Repetitive exposures of some chemicals may also produce a different toxic effect than the acute exposure.

Toxic accumulation is one of the reasons repetitive exposures of a chemical produce toxicity while a single exposure may not. In a hypothetical case, as depicted in

Figure 2, a concentration of more than 100 milligrams per gram in a target tissue is required for chemical A to cause toxic injury. If chemical A is administered at a dose that does not produce toxic levels in the tissue and the elimination of the chemical is essentially complete within 24 hours, repetitive exposures at the same dose once a day will not result in toxicity. With chemical A there will be no difference in toxicity between acute and repetitive exposures. Suppose, however, that there is a similar chemical, B, with a slower elimination rate so that chemical B is not completely eliminated from the target tissue within 24 hours. If the exposure to chemical B is carried out at the same dose as chemical A, the concentration of B in the target tissue will not return to zero after 24 hours. Consequently, daily exposures of B will cause the toxin to accumulate, so that the peak target concentration of B increases daily (Figure 2). Eventually, the toxic threshold is reached and injury will develop. Therefore, repetitive exposure can produce toxicity at a dose that does not result in injury if given only once.

Figure 2: Accumulation of toxicants in the target organ during repetitive exposures.

Dose of exposure. The amount of chemical to which a person is exposed is extremely important. The chemical acts at a certain site, called the active site, triggering a biological response in a target tissue. Because the biological effect is caused by the presence of the chemical at the active site, the higher the concentration of the chemical at the site, the greater the response. This is the case with all known poisons, a phenomenon called the dose-response relationship.

The dose-response curve is sigmoid, with the linear portion between approximately 16 percent and 84 percent. To compare the potency of chemicals causing similar responses, the dose that produces a biological response in 50 percent of the subject group is chosen, because it can be calculated with the least chance of error. If the biological response is mortality, the dose that kills 50 percent of the exposed population is known as the lethal dose 50, or LD50. Toxicity ratings for chemicals are based on their LD50s. The toxicity rating indicates the amount of chemical required to produce death, but it should be remembered that all chemicals can kill. Thus, all chemicals are toxic. More important than the toxicity of a chemical is its hazard or risk of usage, a concept that incorporates exposure to dosage. For example, botulinum toxin is not especially hazardous, even though it is supertoxic, because food is well-preserved, keeping the exposure or dose very low. In contrast, ethanol (alcohol) is hazardous even though it is not very toxic, because some people have a tendency to use it to excess.

DISTRIBUTION OF TOXICANTS IN THE BODY

Role of the lymphatics. After a chemical crosses the transport barrier at the portal of entry, it remains in the interstitial spaces, the spaces between cells that are filled with water and loose connective tissue. The absorbed chemical can gain entry into the bloodstream directly via the blood capillaries or indirectly via the lymphatic capillaries.

Lymphatic capillaries are minute vessels located in the interstitial spaces, with one end closed and the other end draining into larger lymphatic vessels. Just like blood capillaries, the walls of the lymphatic capillaries are composed of a thin layer of cells, the endothelial cells. Unlike the blood capillaries, however, the junctions between the endothelial cells of the lymphatic capillaries are much looser, and as a result lymphatic capillaries are much more porous than blood capillaries. Plasma proteins and excess

Dose-response relationship

Types of exposure

fluid in the interstitial spaces from blood capillaries enter the lymphatic capillaries and eventually flow back to the heart via the lymphatic system. Insoluble aerosols that cross the alveolar wall by pinocytosis may be absorbed into the circulatory system after first entering the porous lymphatic capillaries.

Role of the blood. The chemical is distributed via the blood to the various tissues of the body, where the chemical is transported across blood capillary walls. There are four types of blood capillary walls: tight, continuous, fenestrated, and discontinuous.

Tight capillary walls are characterized by tight junctions between the endothelial cells, which prevent the diffusion of large molecules and impede that of hydrophilic molecules. The capillaries in the brain are typical of this type of capillary and form part of the blood-brain barrier.

In a continuous capillary wall, channels about five nanometres wide exist between endothelial cells, allowing most small molecules to pass through. Capillaries of this type are found in the skeletal and smooth muscles, connective tissue, lungs, and fat. Chemicals given by intramuscular or subcutaneous injection are readily absorbed into the bloodstream, as are deposited aerosols that dissolve in the fluid lining the respiratory system and cross the alveolar wall.

In a fenestrated capillary wall, holes as large as 100 nanometres are found in the endothelial cells. Capillaries in the intestine and glomeruli in the kidney have fenestrated capillary walls, which account for the high permeability of blood capillaries for absorption by the intestine and for filtration of the blood by the kidney.

The discontinuous capillary wall, the most porous of all capillaries, contains large gaps between the cells through which large molecules and even blood cells pass. This type of capillary is found in the reticuloendothelial system (including the liver, spleen, and bone marrow), which assists in the removal of aged blood cells.

The porous nature of capillaries in most tissues or organs means that a chemical in the bloodstream can be distributed almost freely to most tissues, except for organs with a barrier. The molecules diffuse from the blood to the interstitial spaces of the tissue and finally into the cells by either diffusion or active transport.

Role of tissue blood flow. The rate at which a chemical accumulates in a particular tissue is influenced by the blood flow to that tissue. The well-perfused organs—*i.e.*, organs that receive a rich blood supply relative to organ weight—include major organs like the liver, brain, and kidney. A middle group receives an intermediate blood supply and includes the skeletal muscle and skin. The poorly perfused group includes the fat and bone. As a chemical is distributed to the tissues by the bloodstream, the chemical concentrations in the well-perfused organs rapidly reach a steady state with the blood concentration while the concentrations of the chemical in the poorly perfused tissue lag behind.

Role of protein binding. The plasma contains many proteins, the most abundant being albumin. Some chemicals are known to bind to albumin. Because albumin is too large to cross the blood capillary wall, chemicals that are bound to this plasma protein are confined in the bloodstream and are not readily distributed to the tissues. Chemicals with a high affinity to bind with plasma proteins have lower concentrations in tissues than do chemicals that are not bound to plasma proteins.

Role of distribution barriers. There are barriers in certain organs that limit the distribution of some molecules. The blood-brain barrier consists of tight capillary walls with glial cells wrapped around the capillaries in the brain. Molecules must diffuse through two barriers to get from blood to the nerve cells of the brain. Despite the barrier, water, most lipid-soluble molecules, oxygen, and carbon dioxide can diffuse through it readily. It is slightly permeable to the ions of electrolytes, such as sodium, potassium, and chloride, but is poorly permeable to large molecules, such as proteins and most water-soluble chemicals. The blood-brain barrier is the reason the ions of some highly water-soluble metals, such as mercury and lead, are non-toxic to the brain of an adult. Children, however, are

more sensitive to the toxicity of lead because the blood-brain barrier is less well developed in children.

The second distribution barrier is the blood-testis barrier, which limits the passage of large molecules (like proteins and polysaccharides), medium-sized molecules (like galactose), and some water-soluble molecules from blood into the seminiferous tubules of the testis. Water and very small water-soluble molecules, like urea, however, can pass through the barrier. The lumen of the seminiferous tubules is where sperm cells of more advanced stages develop. It is thought that the barrier protects the sperm cells.

The placental barrier between mother and fetus is the “leakiest” barrier and is a very poor block to chemicals. The placenta is composed of several layers of cells acting as a barrier for the diffusion of substances between the maternal and fetal circulatory systems. Lipid-soluble molecules, however, can cross readily, while the transfer of large-molecular-weight molecules is limited.

ELIMINATION OF TOXICANTS

An organism can minimize the potential damage of absorbed toxins by excreting the chemical or by changing the chemical into a different chemical (biotransformation), or by both methods. The body can excrete exogenous chemicals in the urine, bile, sweat, or milk; the lungs can excrete gases such as carbon monoxide.

Urinary excretion, the most common excretory pathway, takes place in the kidney, where the functional units are the glomerulus (a filter) and the renal tubule. The artery entering the glomerulus divides into capillaries, with fenestrated walls encased in the Bowman’s capsule. Twenty percent of the blood is filtered through the holes in the capillary walls; molecules smaller than 60,000 molecular weight end up in the filtrate, while red blood cells, large proteins, and chemicals bound to plasma proteins are not filtered.

Chemical exchange can also take place along the renal tubule. As the filtrate flows down the renal tubule, essential molecules, such as amino acids and glucose, are reabsorbed by active transport in the first portion of the tubule (the proximal tubule). Chemicals in the filtrate are also reabsorbed by active transport if they structurally resemble these essential molecules. Unlike glomerular filtration, tubular resorption of a chemical is not influenced by whether or not it is bound to plasma proteins.

As the fluid flows down the renal tubule, water and some chemicals are reabsorbed from the tubular fluid into the blood by diffusion. The tubular fluid emerges from the kidney and is collected in the urinary bladder. Lipid-soluble chemicals are readily reabsorbed in the renal tubule, and only water-soluble chemicals are excreted in the urine to a significant extent.

The second major excretory route is the bile, which is formed in the liver and flows into the intestinal tract. The liver does not filter chemicals as does the kidney, but the liver does secrete chemicals into bile. Chemicals excreted in the bile are eventually eliminated in the feces.

Biliary excretion of a chemical does not necessarily result in the elimination of the chemical from the body. Bile is dumped into the small intestine; there is a chance that chemicals in the bile may be reabsorbed by the intestine and in turn reenter the liver via the portal vein. This cycling of a chemical, known as the enterohepatic cycle, can continue for a long time, keeping the chemical in the body.

During inhalation exposure, absorption of the gas continues until the partial pressure of the gas in the tissues is equal to that of the inspired gases in the lungs. As soon as the concentration of inspired gases decreases or the exposure terminates, respiratory excretion of the gas occurs. Because the partial pressure of the inspired gas is lower in the lungs than in blood, the blood releases some gas molecules into the alveolar space and these molecules are exhaled. The tissues lose gas molecules to the blood, which carries them to the lungs to be excreted.

The composition of sweat is similar to that of plasma except that sweat does not contain proteins. After secretion, the fluid moves through the sweat duct, where salt and water are reabsorbed. The exact mechanism of sweat

accumulation

Blood-
brain
barrier

secretion is not known. It appears that sweat is a filtrate of plasma that contains electrolytes (such as potassium, sodium, and chloride) and metabolic wastes (like urea and lactic acid). Because sweat resembles a filtrate of plasma, water-soluble chemicals, like some drugs and metal ions, are found in sweat. Sweat is not a major route of excretion of chemicals, however.

Milk is a potential, albeit minor, route of chemical excretion, but more importantly it is a potential means of chemical exposure for breast-fed infants.

Most chemicals enter milk by diffusion. Therefore, only the nonionized, lipid-soluble forms of organic chemicals are found to a significant extent in milk. Chemicals with a molecular weight less than 200 and that are present in plasma not bound to proteins are more likely to be found in milk. Because the lipid content of milk is higher than that of plasma, highly lipid-soluble chemicals can exist in a more concentrated level in milk than in plasma. Therefore, milk can be a significant route of excretion for highly lipid-soluble chemicals in lactating women.

Bio-
transfor-
mation

Biotransformation, sometimes referred to as metabolism, is the structural modification of a chemical by enzymes in the body. Chemicals are biotransformed in several organs, including the liver, kidneys, lungs, skin, intestines, and placenta, with the liver being the most important. Chemicals absorbed in the gastrointestinal tract must pass through the liver, where they can be biotransformed and thus eliminated before being distributed to other parts of the body. This phenomenon is known as the first-pass effect. As a result, smaller amounts of certain chemicals are distributed throughout the body after oral administration than after other exposure routes, such as intravenous or intramuscular injections. Biotransformation of a chemical primarily facilitates its excretion into urine or bile; however, certain chemicals are biotransformed into more toxic forms and, as a result, biotransformation of chemicals is not always beneficial.

Biotransformation of exogenous chemicals (chemicals that are not naturally found in the body) generally occurs in two phases. In phase I, an exogenous molecule is modified by the addition of a functional group such as a hydroxyl, a carboxyl, or a sulfhydryl. This modification allows phase II, the conjugation, or joining, of the exogenous molecule with an endogenous molecule (one naturally found in the body), to take place. The major end product in most cases is a more water-soluble chemical that is easily excreted.

Phase I reactions can be classified as oxidation, reduction, or hydrolysis. Oxidation is carried out by cytochrome P-450 monooxygenases, mixed-function amine oxidases, and alcohol and aldehyde dehydrogenases. The reactions mediated by cytochrome P-450 monooxygenases can make the chemical less toxic or more toxic. The cytochrome P-450 enzymes can, for example, produce epoxides of some chemicals, which are very reactive and can attack important cellular molecules, such as DNA. The remaining phase I oxidative enzymes act on a narrow range of substrates.

In addition to the oxidation of a chemical, cytochrome P-450 monooxygenases can catalyze the reduction. Another group of enzymes that can carry out reduction is the aldehyde/ketone reductases. Each of the three groups of hydrolytic enzymes (epoxide hydrolases, esterases, and amidases, respectively) creates metabolites with a hydroxyl, carboxyl, or amino functional group.

In phase II reactions an altered exogenous chemical binds with an endogenous molecule, leading to the formation of a final product (the conjugate), which is usually much more water-soluble and easily excreted than the parent chemical. There are four types of parent compounds whose excretion can be enhanced by conjugation: glucuronic acid, glutathione, amino acids, or sulfate. The first two types are the most common phase II reactions.

Conjugation of glucuronic acid with a hydroxyl, carboxyl, amino, or sulfhydryl group leads to the formation of oxygen, nitrogen, or sulfur glucuronides, which are more easily excreted than glucuronic acid because they are more water soluble and because they contain a carboxyl group. Conjugation with glutathione also enhances excretion.

Glutathione conjugation yields glutathione conjugates and mercapturic acid derivatives, which are excreted by the liver, kidney, or both.

Two types of conjugations, acetylations and methylation, do not enhance the excretion of the parent chemical. Acetylation and methylation decrease the water solubility of the parent chemical and mask the functional group of the parent chemical, preventing these functional groups from participating in conjugations that increase their excretion. Acetylation acts on chemicals with an amino group and may render them less toxic. Chemicals with an amino, hydroxyl, or sulfhydryl group can be methylated. Methylation is not as important a route of biotransformation for exogenous chemicals as it is for endogenous chemicals.

THERAPEUTIC, TOXIC, AND LETHAL RESPONSES

Because the response to a chemical varies with the dose, any substance can be a poison. Medicine can produce responses that are therapeutic (beneficial) or toxic (adverse), or even lethal. The sigmoid dose-response relationships for the therapeutic and lethal responses typically look like curves A and C, respectively, of Figure 3. If drug X has therapeutic, toxic, and lethal dose-response curves of A, B, and C, respectively, X is a very safe drug, since there is no overlap of the curves. For some medicinal agents, there is overlap of the therapeutic and lethal dose-response curves, so that a dose which causes a therapeutic response in some individuals can kill others. These agents, consequently, are not as safe.

A quantitative measurement of the relative safety of drugs is the therapeutic index, which is the ratio of the dose that elicits a lethal response in 50 percent of treated individuals (LD₅₀) divided by the dose that elicits a therapeutic response in 50 percent of the treated individuals (TD₅₀). For instance, the therapeutic index of drug X is 9,000 milligrams per kilogram divided by 30 milligrams per kilogram and is equal to 300. The larger the therapeutic index, the safer the drug. Diazepam and digoxin are examples of drugs with a large and a small therapeutic index, respectively.

Figure 3: Dose-response curves (see text).

Morphological versus functional toxic responses. Chemicals can elicit various types of toxic responses, which can be classified by the nature of the response, the site of toxic action, the time it takes for the response to develop, and the chance of resolution of the response. The nature of the toxic response can be morphological (structural) or functional or both. In most cases, the chemical produces morphological changes in an organ, which in turn affects the function of the organ. In a small number of cases, the chemical produces functional changes in an organ without changing the structure of the organ.

Inhalation exposures to silica dust at a low concentration for 10 years or more can lead to chronic silicosis, a condition characterized by the formation in the lungs of silicotic nodules, which are egg-shaped lesions composed of layers of fibroblasts (reparative cells) and inflammatory cells surrounding a central silica particle. Such lesions can be considered a morphological toxic response; unless the silica exposure is prolonged, there will be little respiratory

Nature of
response

impairment because the lungs and certain other organs have a large functional reserve. If the silica exposure is prolonged, however, the silicotic nodules coalesce (complicated silicosis), and the structure of the lungs is altered so drastically that they do not distend easily during inspiration. Oxygen exchange in the alveoli is impaired, causing such functional toxic responses as breathlessness, chest tightness, and coughing with sputum.

Malathion exposure, on the other hand, can lead to functional toxic responses without causing any morphological changes. Malathion does not alter the structure of tissues; rather, it inhibits an enzyme, acetylcholinesterase, which normally degrades acetylcholine, the neurotransmitter of the parasympathetic nervous system. Inhibition of this enzyme leads to an exaggeration of the actions of the parasympathetic nervous system, including sweating, secretion of saliva, adjustment of pupil size, and defecation. The end results are increased perspiration, increased salivation, tearing, blurred vision, abdominal cramping, diarrhea, and if severe enough, death from respiratory depression.

Local versus systemic toxic responses. Toxic responses are also classified according to the site at which the response is produced. The site of toxic response can be local (at the site of first contact or portal of entry of the chemical) or systemic (produced in a tissue other than at the point of contact or portal of entry).

An example of a local toxic effect is the tissue corrosion produced by strong acids (e.g., sulfuric acid) and bases (e.g., sodium hydroxide) in contact with tissues. If the exposure is external, skin burns result; if ingested, the acid or base causes serious local damage to the esophagus and stomach.

An example of a systemic toxicant is methanol, which is absorbed and biotransformed into formic acid. The acid is responsible for metabolic acidosis and optic nerve damage in the retina of the eye, leading to visual impairment, a systemic effect.

Immediate versus delayed toxic responses. Toxic responses may also be classified according to the time it takes for development of a toxic response. If it takes up to a few days after exposure, the response is considered immediate. There is no universal standard of minimum time for delayed toxic responses, but generally a response that takes more than a few days to develop is considered delayed. The time it takes for a systemic toxicant to act depends on many factors, such as the rates of absorption, biotransformation, distribution, and excretion, as well as the speed of action at the target site.

Reversible versus irreversible toxic responses. Toxic responses differ in their eventual outcomes; the body can recover from some toxic responses, while others are irreversible. Irritation of the upper respiratory tract by inhaled formaldehyde gas, for example, is rapidly reversible in that as soon as the inhalation exposure terminates, the irritation subsides. In contrast, the response produced by silica dust is irreversible because, once the silicotic nodules are formed, they remain in the alveolar region of the lung.

Chemically induced immune responses. The immune system protects the body against foreign substances, especially microbes and viruses. To be antigenic, a substance is usually both relatively large and foreign to the body. Large proteins are often strong antigens. Smaller chemicals can become antigenic by combining with proteins in chemicals called haptens.

The development of immunity toward an antigen is called sensitization. After exposure to an antigen, a combination of cellular and humoral immunity usually develops. Exposure routes that favour slow absorption into the bloodstream, such as percutaneous injection, often primarily elicit cellular immunity, while rapid routes of exposure, such as intravenous injection, favour the development of humoral immunity.

Cellular immunity utilizes phagocytes (such as macrophages, neutrophils, and eosinophils), which engulf antigens, and T-lymphocytes, which are thymus-derived, antigen-specific immune cells containing receptors specific for a special antigen. Cellular immunity is particularly important in defending the body against tumours and

infections. Macrophages phagocytize antigens and secrete proteins (monokines) that regulate cells involved in immune responses. One monokine is interleukin-2, which stimulates an increase in the number of T-lymphocytes. The T-lymphocytes then develop surface receptors for specific antigens. Because T-lymphocytes survive for months or years, cellular immunity toward the antigen remains with the individual for a long time. If reexposed to the same antigen, the sensitized T-lymphocytes recognize the antigen and secrete their own proteins (lymphokines), which stimulate phagocytes to destroy the antigen. If an antigen is located on foreign or tumour cells, certain T-lymphocytes are transformed into cytotoxic T-lymphocytes, which destroy the target cells.

Humoral immunity utilizes antibodies, also known as immunoglobulins (Ig), produced by B-lymphocytes. B-lymphocytes are lymphocytes derived from the spleen, tonsils, and other lymphoid tissues. They become plasma cells, which make antibodies. There are five classes of antibodies: IgG, IgM, IgA, IgD, and IgE. IgG, IgM, and IgA are involved in humoral immunity, the function of IgD is not known, and IgE takes part in immediate hypersensitivity (see below).

Humoral immunity involves the inactivation, removal, or destruction of antigens. Antibodies can inactivate viruses by binding to them. With two antigen binding sites per protein unit, an antibody can also precipitate the antigen by cross-linking in a network formed with other antibodies. Because each IgM has five protein units, and thus five potential binding sites, IgM is particularly efficient in precipitating the antigen. After the antigen is precipitated, it can be removed by phagocytes. In addition, antigen binding by IgG or IgM activates a serum protein, called a complement, which can then initiate antigen precipitation, amplifying the inflammatory response. If the antigen is on the surface of certain cells, activated complement can also facilitate the lysis of these cells. IgG or IgM can also link the antigen to phagocytes or to killer cells, resulting in lysis of the cell by an unknown mechanism.

Although the immune system generally protects the body, it can respond in certain ways that are detrimental to some individuals. Allergy, or hypersensitivity, is a condition of increased reactivity of the immune system toward an antigen that leads to adverse effects. Substances that cause allergies are known as allergens.

Confusion is sometimes caused by the terms hypersensitivity, hypersusceptibility, and idiosyncrasy. Hypersensitivity is a reaction to a chemical or substance in certain individuals and has a basis in the immune system. Hypersusceptibility is an increased predisposition of certain individuals to react to a chemical. Because of biological variability among humans, some individuals respond to a chemical at a dose too low to produce a similar effect in others. Idiosyncrasy is a genetically determined hypersusceptibility.

Allergic responses differ from the usual toxic responses in three ways. First, the allergic response does not occur during the first exposure to an allergen, but is evident only after at least one previous exposure. In rare occasions, an allergic response can occur on the first exposure to a chemical if the individual has already developed a hypersensitivity toward a closely related chemical. For example, people allergic to one kind of penicillin are usually allergic to other penicillins as well. Second, allergy is specific to both the allergen and the individual. Unlike in a toxic response, in which everyone exposed develops the response if a sufficient dose is administered, only a small fraction of the exposed population is sensitized by an allergen, regardless of the dose. Third, the amount of a chemical required to elicit an allergic response is usually much less than that required to produce a toxic response.

There are four types of hypersensitivities (allergies): immediate, cytotoxic, immune-complex, and delayed. Each differs from the others in the mechanism of induction and the responses produced. Immediate hypersensitivity is the most common form of allergy. Delayed hypersensitivity is the second most common, whereas cytotoxic and immune-complex hypersensitivities are relatively rare.

Immediate hypersensitivity, also called anaphylaxis, pro-

Immediate
hyper-
sensitivity

duces IgE in response to an allergen that binds to the surface of mast cells or basophils. When reexposed to the allergen, the antigen-binding end of IgE on mast cells and basophils binds the allergen, triggering a release of anaphylactic mediators from these cells. These mediators, such as histamine and serotonin, cause the contraction of certain smooth muscles (*e.g.*, those of the respiratory tract, leading to bronchoconstriction in asthmatic attacks), relaxation of blood vessels (*e.g.*, in the skin, resulting in redness, or in the whole body, causing a fall in blood pressure as in anaphylactic shock), and increased permeability of capillary walls (*e.g.*, in the skin, leading to local edema as seen in urticaria). The unique characteristic of immediate hypersensitivity is its rapid onset, with the response initiated within a few minutes of allergen exposure.

The anaphylactic mediators affect tissues differently. Thus, the allergic response depends on where the immune reaction takes place. In the skin, immediate hypersensitivity can result in skin eruptions or urticaria, characterized by wheals with redness. In the respiratory system, it can produce hay fever or asthma. In the gastrointestinal tract, allergic gastroenteritis, an inflammatory condition of the stomach and intestine, may result. Systemic anaphylaxis may involve the entire body, with shock as a key feature.

Other
hyper-
sensitivities

A second type of hypersensitivity is cytotoxic hypersensitivity, which has a gradual onset. After reexposure to an allergen, the allergen molecules attach to the surfaces of blood cells, forming an antigen new to the body. IgG or IgM binds to the new antigen on the blood cells, lysing blood cells via either complement fixation or antibody-dependent cell cytotoxicity. If the lysed cells are red blood cells, hemolytic anemia results. If platelets (the blood components intrinsic to blood clotting) are lysed, however, the blood clotting mechanism is impaired.

In a third type of allergy, immune-complex hypersensitivity, the allergen-IgG complex precipitates in tissues, resulting in inflammation via complement fixation. Immune-complex hypersensitivity in the kidney results in an inflammatory injury of the glomeruli (glomerulonephritis), and in the lung it leads to a pneumonia-like condition known as hypersensitivity pneumonitis.

Delayed hypersensitivity differs from other types in not involving humoral immunity. Upon reexposure to the allergen, sensitized T-lymphocytes release lymphokines, which trigger a series of inflammatory reactions. The inflammation leads to the development of allergic contact dermatitis in the skin and a chronic form of hypersensitivity pneumonitis in the lung. Symptoms of allergic contact dermatitis develop gradually, taking a day or two to reach maximum levels, which is the best way to distinguish allergic contact dermatitis from atopic dermatitis with similar symptoms. In contrast, the chronic form of hypersensitivity pneumonitis develops insidiously and not in a fixed time.

TERATOGENESIS

Teratogenesis is a prenatal toxicity characterized by structural or functional defects in the developing embryo or fetus. It also includes intrauterine growth retardation, death of the embryo or fetus, and transplacental carcinogenesis (in which chemical exposure of the mother initiates cancer development in the embryo or fetus, resulting in cancer in the progeny after birth).

Intrauterine human development has three stages: implantation, postimplantation, and fetal development. The first two stages are the embryonic stages and last through the first eight weeks after conception. The fetal stage begins in the ninth week and continues to birth.

Depending on the developmental stage, chemical exposure in the mother can result in different degrees of toxicity in the embryo or fetus. In the preimplantation period, a toxic chemical can kill some of the cells in the blastocyst, resulting in the death of the embryo. During the postimplantation period, chemical-induced cell death leads to one of two outcomes. If death is confined to those cells undergoing active cell division at the moment, the corresponding organs are affected, resulting in malformation. If the cell death is generalized without significant replication by the remaining cells to sustain life, the em-

bryo dies. During the third, fetal, period, chemical injury can retard growth or, if severe enough, kill the fetus.

The genesis of a particular organ (organogenesis) occurs at a specific time during gestation and is not repeated. Because organogenesis is a tightly programmed sequence of events, each organ system has a critical period during which it is sensitive to chemical injury. Chemical exposure in a critical period is likely to produce malformations of that organ and not others; however, because there is some overlapping of critical periods of organ development and because chemicals frequently remain in the embryo for a period of time, malformations of more than one organ usually occur. Since organogenesis occurs mostly in the embryonic stages, chemical exposure in the first trimester should be minimized, if possible.

Little is known about mechanisms of teratogenesis. It is thought that some teratogens produce malformations directly by killing the cells in the embryo. Teratogens can also produce malformations indirectly by causing maternal toxicity, resulting in oxygen or nutrient deficiency for the embryo. A few well-known examples are discussed below.

Thalidomide is a drug originally marketed to combat nausea and vomiting in pregnancy. It was discovered in the 1960s in West Germany to cause rare limb defects, among other congenital anomalies. The discoveries about thalidomide triggered legislation requiring teratogenicity testing for drugs.

Chronic alcohol ingestion during pregnancy is the most common cause of congenital problems in mental development. Ingestion of more than 30 millilitres (1 ounce) of ethyl alcohol per day during pregnancy can lead to the development of fetal alcohol syndrome, characterized by intrauterine growth retardation and subsequent learning disabilities, such as distractibility, language disorders, and low IQ. Heavier consumption of alcohol, more than 60 millilitres per day, by a pregnant woman can result in malformations of the fetal brain and in spontaneous abortions.

Diethylstilbestrol (DES) is a drug used primarily from the 1940s to the '50s to prevent miscarriage. The drug is an example of a chemical that can produce transplacental carcinogenesis. It was discovered in the early 1970s that exposures to diethylstilbestrol before the ninth week of gestation could lead to the formation of rare vaginal and cervical cancers in female progenies.

CARCINOGENESIS

Carcinogens are chemicals that can produce tumours, abnormal tissue growths caused by a loss of control in cell replication. Most tumours are solid masses (*e.g.*, lung cancer), but some do not occur as tissue swellings (*e.g.*, leukemia).

Tumours may be benign or malignant. Benign tumours are to a certain degree controlled in their growth. As a result, benign tumours maintain some form of cellular organization and grow rather slowly over a period of years. In contrast, cell growth in malignant tumours is almost totally uncontrolled. Cells in malignant tumours grow very rapidly in a disoriented fashion.

Benign tumours are encapsulated by a fibrous layer and so do not invade surrounding tissue. Malignant tumours invade surrounding tissue. Thus, while a benign tumour grows at one site, a malignant tumour sends out cancerous cells via the blood and lymphatic system to distant sites of the body, spreading by a process known as metastasis. The invasion of surrounding tissues by a malignant tumour produces various symptoms.

Carcinogenesis is a complicated process in which many factors are known to play significant roles. Certain external environmental factors are important. For instance, cigarette smoking is known to cause predisposition to the development of lung cancer. A diet low in fibre content and high in fat is correlated with a high incidence of colorectal cancer. In addition, internal factors, such as hormonal imbalances and immunosuppression, can also increase the chance of developing tumours. Sensitivity to chemical carcinogens is known to be species-dependent. A chemical carcinogen may induce tumours in one animal species but not another, and a species that is sensitive to one carcinogen may be resistant to another. Known

Critical
periodsMecha-
nismsHuman
carcino-
genesis

human carcinogens include some anticancer drugs, aromatic (containing a benzene ring in its chemical structure) amino and nitro compounds, metals, radionuclides, and miscellaneous chemicals. In humans the respiratory tract is the most common target for chemical carcinogens, followed by the liver and the blood.

Although there have been many theories on the mechanism of chemically induced tumour formation, it is now thought that DNA is the target of most chemical carcinogens. The carcinogens interact with the DNA and interfere with its normal function. Because DNA controls cellular functions, when DNA is damaged, the cell presumably loses control and divides in a chaotic fashion. A clone of the parent cell is generated, and these cells maintain the chaotic replication, which ultimately leads to the formation of a tumour. In general it takes 10 to 20 years for the initial DNA damage in one cell to develop into a recognizable tumour.

Carcinogens that are thought to produce cancer in laboratory animals by altering the DNA are referred to as genotoxic carcinogens. They are either direct-acting or indirect-acting chemicals.

Direct-acting (reactive) genotoxic chemicals can themselves interact with DNA. Indirect-acting genotoxic carcinogens do not bind to DNA until they have been biotransformed in the body to reactive chemicals. Among the indirect-acting carcinogens, polycyclic aromatic hydrocarbons, nitrosamines, and nitrosomornicotine are found in cigarette smoke. Polycyclic aromatic hydrocarbons are also formed in charcoal-broiled meat. Nitrosamines can be formed by the nitrosation of nitrite-cured, protein-rich food, such as nitrite-cured meat and fish, in the intestine.

Chemicals that produce cancer by a mechanism other than by binding to DNA are known as epigenetic carcinogens. The mechanisms by which epigenetic carcinogens produce tumours are not known with certainty, but various theories have been proposed. Cytotoxins are thought to kill cells in the target organ. The cell death increases cell replication by the remaining cells, which somehow results in tumour development, possibly by stimulating the division of cells that have previously had their DNA damaged by a genotoxic carcinogen.

It has been proposed that hormones and chemicals which modify the activities of the endocrine system create a physiological imbalance in organs dependent for their functioning on a particular hormone. With the imbalance, the organ may lose its normal physiological control and tumour growth may occur. This may be the mechanism by which estrogens in postmenopausal women lead to development of uterine cancer and the reason antithyroid agents, such as 3-amniotriazole, produce thyroid tumours.

Chemicals that depress the immune system are thought to produce tumours by impairing cell-mediated immunity, which is important in the normal elimination of tumour cells. The development of tumours involves two main steps: initiation and promotion. Initiation is the creation by genotoxic carcinogens of a cell with abnormal DNA. After initiation, promoters stimulate the replication of these neoplastic cells and facilitate the development of the tumour. Initiators include genotoxic chemicals. Although promoters do not produce tumours directly, they are still considered carcinogens because they can lead to the development of tumours in concert with an initiator. Promoters include large chlorinated hydrocarbon molecules (e.g., DDT, PCBs, TCDD, butylated hydroxy antioxidants, and saccharin) and tetradecanoyl phorbol acetate in croton oil.

MUTAGENESIS

Mutagenesis is the alteration of genes. Substances able to produce mutations are naturally genotoxic substances. Once a gene is mutated in a cell, the altered gene can be passed on to daughter cells. The body has ways to repair some of these gene alterations so that the genetic damage does not always propagate.

The effect that a mutation has depends on the cell in which the mutation occurs. In the somatic cells of most organs, mutation either has no effect, causes one cell to die, or causes a cell to divide at an uncontrolled rate so that a tumour develops. If the mutation occurs in germ

cells (egg and sperms), there may be detectable changes or birth defects, or stillbirth may result.

Types of poison

In regard to poisoning, chemicals can be divided into three broad groups: agricultural and industrial chemicals, drugs and health care products, and biological poisons—i.e., plant and animal sources. These three groups, along with a fourth category, radiation, are discussed below.

AGRICULTURAL AND INDUSTRIAL CHEMICALS

Agricultural chemicals. The majority of agricultural chemicals are pesticides, which include insecticides, herbicides, fungicides, fumigants, and rodenticides.

Insecticides. The four main classes of insecticides are organophosphates, carbamates, chlorinated hydrocar-

Table 1: Agricultural Chemicals

chemicals	toxicity, symptoms, and signs
Insecticides	
Organophosphates (e.g., malathion, parathion)	parasympathetic excess
Carbamates (e.g., carbaryl, carbofuran)	parasympathetic excess
Chlorinated hydrocarbons DDT, methoxychlor	CNS stimulation, convulsions, nausea, vomiting
Chlordecone (Kepone)	nausea, vomiting
Insecticides from plants Pyrethrins	allergic contact dermatitis, asthma, CNS stimulation
Rotenone	irritation of skin, eyes, and lung; mild CNS stimulation; breast tumours in rats
Herbicides	
Chlorophenoxyacetic acids 2,4-dichlorophenoxyacetic acid (2,4-D)	nausea, vomiting, fatigue, diarrhea, muscle ache and twitches, peripheral nerve damage, convulsion, memory loss, colour visual disorder
2,4,5-trichlorophenoxyacetic acid (2,4,5-T)	irritation to skin, eyes, and nose; teratogenic in animals
Bipyridinium compounds Paraquat	lung fibrosis; kidney and liver damage
Diquat	nosebleed, cough, fever, jaundice
Others (e.g., diuron, monuron, atrazine, simazine, chlorpropham, alachlor)	irritation to the skin, nose, and throat
Fungicides	
Pentachlorophenol	quite irritating to eyes, nose, and throat; anorexia; weakness; shortness of breath; chest pain; carcinogenic in animals
Creosote	extremely irritating to skin, eyes, nose, and throat
Ferbam, thiram	moderate irritation to eyes, nose, and throat; mild skin irritation; allergic contact dermatitis
Fumigant nematocides	
1,2-dibromo-3-chloropropane (DBCP)	mildly irritating to skin, eyes, and nose; testicular damage; carcinogenic in animals
Ethylene dibromide	severe irritation to skin, eyes, and throat; headache; anorexia; CNS depression; carcinogenic in animals
Methyl bromide	headache, nausea, vomiting, drowsiness, emotional disturbances, tremors, convulsion, coma, lung irritation, bronchial inflammation
Rodenticides	
Warfarin	internal bleeding
Strychnine	restlessness, increased audio and visual sensitivities, muscular stiffness in face and legs followed by convulsion
Thallium	hair loss; skin eruptions; intestinal bleeding; anorexia; nausea; vomiting; injuries of peripheral nerves, liver, and kidney
Plant growth regulators	
Daminozide (Alar)	carcinogenic in animals

Develop-
ment of
tumours

bons, and insecticides derived from plants (botanical). Organophosphate and carbamate insecticides act by inhibiting acetylcholinesterase, the enzyme that degrades acetylcholine (the messenger of the parasympathetic nervous system). As a result, acetylcholine levels remain high, exaggerating the normal functions of the parasympathetic system (Table 1). Effects such as salivation, lacrimation, urination, defecation, twitching of the skeletal muscles, and in severe poisoning, death from respiratory depression occur.

DDT

Chlorinated hydrocarbons used as insecticides, such as chlorophenothane (DDT), are larger molecules than the chlorinated hydrocarbons used as organic solvents, such as chloroform. The former stimulate the central nervous system; the latter depress it. The major toxic effect produced by these insecticides is convulsions (Table 1). The use of DDT is banned in many countries because of its environmental effects and because it may cause cancer in humans. DDT is a highly fat-soluble chemical that accumulates in fish, and, when birds eat such fish, the chemical also accumulates in their fat tissues. The DDT in the birds results in fragile eggs, which are prone to breakage. This will ultimately decrease the population of fish-eating birds.

In general, insecticides derived from plants are low in toxicity. Pyrethrins are widely used insecticides in the home. They have a rapid "knockdown" for insects and have a low potential for producing toxicity in humans. The major toxicity of pyrethrins is allergy. Rotenone is a mild irritant and animal carcinogen (Table 1).

Herbicides. Herbicides are chemicals used to kill plants. Their potential to produce toxicity in humans is rather low. High doses of 2,4-D, however, can produce muscular and neurological symptoms (Table 1). The systemic toxicity of 2,4,5-T is lower than that of 2,4-D, but 2,4,5-T is more irritating.

During the Vietnam War, Agent Orange, a mixture of 2,4-D and 2,4,5-T, was used as a defoliant. The 2,4,5-T used in the Agent Orange was contaminated with tetrachlorodibenzodioxin (TCDD), or dioxin. Although TCDD is extremely toxic to some animals, it is less so to others, but it does cause birth defects and cancer in laboratory animals. The major toxicity of TCDD in humans is in the production of chloracne, a condition characterized by acne that appears between the eyes and the ears. In more severe form, acne may be found on the face, trunk, and buttocks. (Significant adverse health effects in the soldiers exposed to low amounts of TCDD in Vietnam have not been clearly established.) Polychlorinated biphenyls (PCBs) also produce chloracne by damaging the sebaceous glands in skin.

Warfarin

Rodenticides. Warfarin was originally developed as a drug to treat thromboembolism, a disease caused by blood clots, since it inhibits the synthesis of a factor essential for the clotting of blood. The inhibition of blood clotting by warfarin can lead to internal bleeding (Table 1), however. Because of its ability to induce internal bleeding, warfarin is also used as a rodenticide.

Plant growth regulator. Daminozide, also known as Alar, is a plant growth regulator used to improve the appearance and shelf life of apples. Because of its carcinogenicity in animals (Table 1), concerns have been raised that daminozide may produce tumours in children who consume apples. As a result, the use of daminozide has greatly decreased.

Industrial chemicals. The term industrial chemicals is used to refer to chemicals used neither in agriculture nor as drugs. Therefore, it includes chemicals used in industry, as well as chemicals found in or near households. Poisoning with industrial chemicals occurs most often by either percutaneous or inhalation routes.

Depression of the central nervous system is a common effect of most hydrocarbons (Table 2). Examples of common hydrocarbons include gasoline, toluene, and heptanes; *n*-hexane; and benzene. The hydrocarbons are lipid-soluble and dissolve in the membrane of nerve cells in the brain, perturbing their function. Depression, such as drowsiness, occurs as a result. In addition, many of the hydrocarbons sensitize the heart to fibrillation by

epinephrine. The hydrocarbon *n*-hexane also causes damage to peripheral nerves. Benzene is toxic to organs like the bone marrow that form blood cells and can lead to the production of leukemia.

Most alcohols produce depression of the central nervous system, but some alcohols cause certain unique toxicities. Examples of common alcohols include methanol, ethanol, isopropanol, ethylene glycol, and phenol. Methanol can produce blindness after being metabolized to formic acid, which also leads to acidosis, characterized by an acidic pH in the body (lower than the normal pH of 7.4). Ethanol produces birth defects in both laboratory animals and humans. It also produces fetal alcohol syndrome, a major cause of mental retardation, in children of mothers who drink excessively while pregnant. Ethanol is toxic to the liver in chronic alcoholism and is a major cause of cirrhosis, a condition characterized by hardening of the liver. Phenol differs from other alcohols in causing damage to multiple organs. Finally, ethylene glycol, which is widely used as an antifreeze agent in automobiles, causes renal damage when it is biotransformed to oxalic acid, which crystallizes in the renal tubule (Table 2).

Alcohols

The major toxicity produced by aldehydes, such as formaldehyde, is irritation (Table 2). Formaldehyde can also cause allergic reactions in people who have been sensitized to it. Examples of other common aldehydes include acetaldehyde, glutaraldehyde, and acrolein. The toxicities of ketones and esters are similar to those of aldehydes in causing mainly irritation of the respiratory tract if inhaled and the gastrointestinal tract if ingested. (Table 2).

Aromatic amines and nitro compounds, for example, aniline, toluidine, and nitrobenzene, produce depression of the central nervous system and methemoglobinemia (Table 2). Methemoglobinemia is a condition in which the ferrous ion in hemoglobin, which is responsible for carrying oxygen, is oxidized to the ferric form. Oxidized hemoglobin, called methemoglobin, can still carry oxygen, but it does not readily release oxygen to tissues, so that the body, in effect, has a lack of oxygen. Some aromatic amines and nitro groups are known to cause bladder cancer.

Because both anhydrides and isocyanates are highly reactive, they are extremely irritating to the upper respiratory tract (Table 2). If the airborne concentration is sufficiently high, the upper respiratory tract cannot remove all of the isocyanate or anhydride molecules, and pulmonary injury (mainly edema) results. Such a situation occurred in Bhopal, India, in the mid-1980s, when methyl isocyanate from a chemical plant was inadvertently released into the air, killing as many as 2,500 people and injuring thousands of others. Because they are chemically reactive, anhydrides and isocyanates also tend to cause hypersensitivity responses, such as asthma and allergic contact dermatitis. Common examples of anhydrides include maleic anhydride and phthalic anhydride; examples of isocyanates include methyl isocyanate and toluene diisocyanate.

Anhydrides and isocyanates

Miscellaneous organic chemicals include such compounds as phosgene, carbon disulfide, and the halogenated aromatic compounds. Phosgene gained notoriety when it was used in chemical warfare in World War I. Like anhydrides and isocyanates, phosgene is highly reactive. Instead of reacting with the mucosal linings of the upper respiratory tract, however, it tends to react with the lungs, causing edema. As a result, the lungs' defenses against bacteria are weakened, and pneumonia may occur. Halogenated aromatic compounds with more than one ring, such as polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), and 2,3,7,8-tetrachlorodibenzodioxin TCDD, can produce a number of toxic effects in laboratory animals, including cancer, birth defects, liver injury, porphyria, and immunotoxicity (Table 2). The PCBs have been extensively used as a cooling agent in electrical transformers. It appears that humans are more resistant to the toxicity of these compounds than are some species of laboratory animals, and the main toxic effect observed in humans is chloracne, similar to juvenile acne.

Examples of metal compounds toxic to humans include manganese, lead, cadmium, nickel, and arsenic compounds, beryllium oxide, and the elemental vapours, inor-

Metal compounds

Table 2: Industrial Chemicals

chemicals	toxicity, symptoms, and signs	chemicals	toxicity, symptoms, and signs
Hydrocarbons Gasoline, toluene, xylene, hexanes, <i>n</i> -hexane, heptanes	CNS depression, headache, nausea, vomiting, irritation of skin and eyes	Corrosives (acids and alkalis)	corrosion of skin, mouth, throat, stomach, and intestine on contact; irritation of eyes, nose, and throat if inhaled
Chlorinated hydrocarbons Chloroform, carbon tetrachloride, methylene chloride, and others	CNS depression, sensitization of heart muscle; many cause liver and kidney injuries; some cause liver tumours in animals	Miscellaneous inorganic compounds Hydrogen cyanide, potassium cyanide, sodium cyanide	drowsiness, dizziness, headache, rapid breathing, palpitations, weakness, muscle twitches, cyanosis, coma, convulsion
Alcohols Methanol	headache; nausea; vomiting; diarrhea; abdominal pain; restlessness; cold, clammy limbs; shortness of breath; CNS depression; blurred vision; blindness	Hydrogen sulfide, chlorine	irritating to skin, eyes, nose, throat, and lung; chest pain; lung edema; shortness of breath; pneumonia; headache; dizziness; nausea; vomiting
Ethanol	irritation of stomach, CNS depression, fetal alcohol syndrome; brain damage, amnesia, sleep disturbances, heart damage, fatty liver, liver cirrhosis	Sodium fluoride, stannous fluoride	irritations of mouth, stomach and intestine; CNS depression; tooth mottling; increased bone density
Aldehydes Formaldehyde	irritation of eyes, nose, and throat; headache; bronchitis; lung edema; asthma and allergic contact dermatitis; carcinogenic in animals	Bleaches (sodium hypochlorite, calcium hypochlorite)	irritation or corrosion of esophagus, stomach, and intestine; irritation of eyes and skin; acidic condition in the body; rapid breathing; aspiration-induced lung inflammation
Ketones	irritation of eyes, nose, and throat	Silica dust, asbestos fibres	lung fibrosis; shortness of breath; cough; chest pain; cancers of the lung, linings of the lung and abdomen, and intestine (asbestos)
Esters	irritation of eyes, nose, and throat; pulmonary edema	Air pollutants Sulfur dioxide	irritation of eyes, nose, throat, and lung; nausea and vomiting; shortness of breath; alterations in sense of smell and taste; unconsciousness
Aromatic amines and nitro compounds	CNS depression, methemoglobinemia; some are carcinogenic	Nitrogen oxides, ozone	irritation of eyes, nose, throat, and lung (dry throat with ozone); shortness of breath; bluish pale appearance; rapid breathing and pulse; pneumonia; nitrogen oxides also cause the destruction of red blood cells and cause liver and kidney damage
Anhydrides and isocyanates	irritation of skin, eyes, nose, and throat; asthma; allergic contact dermatitis	Carbon monoxide	weakness, confusion, headache, nausea and vomiting, dizziness, drowsiness, jaw stiffness, shortness of breath, seizures, coma, lung edema, pneumonia
Miscellaneous organic compounds Polychlorinated biphenyls (PCB), polybrominated biphenyls (PBB), tetrachlorodibenzodioxin (TCDD)	chloracne, liver injury; carcinogenic and teratogenic in animals		
Metals Lead compounds	Colic; abnormal red blood cells; injuries to kidney, peripheral nerves (weakness and palsy), and brain (irritability, restlessness, excitement, confusion, delirium, vomiting, visual disturbance); lead acetate is carcinogenic in rats		
Arsenic compounds	Edema, heart damage, low blood pressure, vomiting of blood, bloody stool, skin lesions, injuries of nervous systems, liver and kidney damage, cancers of skin and lung		

ganic salts, and organic compounds of mercury. Chronic manganese exposure can damage the brain, resulting in a condition with symptoms similar to Parkinson's disease, such as slurred speech, masklike face, and rigidity. Mercury can also damage the brain, leading to behavioral changes; however, mercury is also toxic to the peripheral nervous system, causing sensory and motor symptoms. In addition, mercury is toxic to the kidney. Methyl mercury is especially toxic to the developing brain of a fetus.

Lead is probably the most ubiquitous metal poison. Used for numerous purposes, before World War II it was a major constituent in paint, and it has been used in gasoline. Like mercury, lead is toxic to the nervous system and kidney (Table 2), but its toxicity is age-dependent. In children, the blood-brain barrier is not fully developed, and more lead enters the brain. The extent of damage depends on the exposure; at lower levels of exposure, small decreases in intelligence and behavioral changes may result, whereas high levels result in severe brain damage and death. In adults, lead tends to cause paralysis or weakness, indicative of peripheral nervous system damage.

In acute cadmium poisoning by ingestion, irritation of the gastrointestinal tract is the major toxicity, causing nausea, vomiting, diarrhea, and abdominal cramps. With chronic exposure by inhalation, however, kidneys and lungs are the target organs. Arsenic compounds damage many organs. They cause skin lesions, decrease in heart contractility, blood vessel damage, and injuries of the nervous system, kidney, and liver. Arsenic compounds also produce skin and lung tumours in humans. Certain nickel and hexavalent chromium compounds, as well as beryllium oxide, are toxic to the lungs and can cause lung cancer.

Acids, such as sulfuric and hydrochloric acids, and strongly alkaline compounds, such as sodium hydroxide, and potassium hydroxide are corrosive to tissues on contact and can cause severe tissue injuries (Table 2). Sulfuric acid, sodium hydroxide, and potassium hydroxide are active ingredients in drain cleaners, the ingestion of which can cause severe chemical burns of the mouth and esophagus.

Hypochlorites are often used as bleaching agents. In low concentrations, as in household bleaches, hypochlorites have little toxicity but may be irritating to tissues; they can, however, be corrosive at high concentrations (Table 2). Cyanide ions poison the oxidative metabolic machinery of cells so that insufficient energy is generated. The effect is as if there were a lack of oxygen for the cells, even though there is plenty of oxygen in the blood (Table 2). Hydrogen sulfide and chlorine are highly irritating to the respiratory tract, with pulmonary edema the major toxic effect (Table 2). Chronic fluoride poisoning is called fluorosis, which is characterized by tooth mottling and increased bone density. These changes, especially of the bone, are related to a change in body calcium caused by fluoride. Silica and asbestos remain in the lungs for long periods of time, and both produce lung fibrosis (Table 2). In addition, asbestos is a well-known human carcinogen.

General air pollutants. Sulfur dioxide, an acidic pollutant, irritates the respiratory tract. It causes violent coughing when it irritates the throat, and may result in shortness of breath, lung edema, and pneumonia when it reaches the lungs.

Both ozone and nitrogen oxides are oxidizing pollutants. Like sulfur dioxide, they cause respiratory irritation;

Hypochlorites

Carbon
monoxide

ozone and nitrogen oxides, however, tend to be more irritating to the lung than to the upper respiratory tract.

Carbon monoxide, an asphyxiating pollutant, binds to hemoglobin more strongly than oxygen does. Such binding produces a hemoglobin molecule that cannot carry its normal load of four oxygen molecules. In addition, once carbon monoxide is bound, the hemoglobin molecule does not as readily release to the tissues the oxygen molecules already bound to it. Therefore, tissues lack oxygen, resulting in many toxic effects. Because the brain is especially sensitive to the lack of oxygen, most of the symptoms are neurological. Lack of oxygen is termed asphyxiation, and thus carbon monoxide is an asphyxiant.

DRUGS AND HEALTH CARE PRODUCTS

Poisoning with drugs predominantly involves oral exposures. With drugs, therefore, irritation of the respiratory tract is rare, but anorexia, nausea, and vomiting resulting from gastrointestinal irritation are common.

Painkillers. Painkillers (analgesics) are the most commonly used drugs and account for many poisoning cases. Examples include aspirin and acetaminophen. Aspirin interferes with the oxidative burning of fuel by cells. To get energy, the cells switch to a less efficient way of burning fuel that does not use oxygen but generates a lot of heat. Increased perspiration develops to counteract a rise in body temperature, leading to dehydration and thirst. Aspirin also alters the pH in the body, affecting the central nervous system (Table 3). The major toxicity of acetaminophen is liver damage.

The major toxicity from narcotic analgesics, like morphine, is depression of the central nervous system, especially the brain centre controlling respiration. The cause of death in morphine overdoses is usually respiratory failure. Nausea is caused by morphine's stimulation of the chemoreceptor trigger zone in the brain, and constipation is caused by morphine's depression of muscular activity in the intestine (Table 3).

Benzo-
diazepines

Tranquilizers and sleeping pills. Benzodiazepines, such as diazepam, clonazepam, and chloridazepoxide, have a wide margin of safety when used at prescribed doses. Their major toxic effect is depression of the central nervous system, which results in muscular incoordination and slurred speech (Table 3). For sleeping pills containing barbiturates, chloral hydrate, paraldehyde, and meprobamate, however, the margin of safety is much narrower, and the major toxicity is severe depression of the central nervous system, leading to respiratory and cardiovascular failure (Table 3).

Antipsychotic drugs. Like benzodiazepines, antipsychotic drugs such as chlorpromazine, perphenazine, and haloperidol have a relatively large therapeutic index, rarely causing fatalities. They occasionally may block the action of the parasympathetic and sympathetic nervous systems and thus produce such undesired effects as dry mouth and blurred vision from the former and a drop in blood pressure upon standing in the latter (Table 3).

Cold medications. Nasal decongestants, antihistamines, and cough medicine, which are found in over-the-counter preparations for treating the symptoms of colds, have a low potential to produce toxicity. Nasal decongestants, such as ephedrine, mimic the action of epinephrine by stimulating the sympathetic nervous system, and consequently, an overdose of ephedrine produces symptoms related to stimulation of the sympathetic and central nervous systems (Table 3). Depression of the central nervous system and parasympathetic blockade are two common toxicities of antihistamines such as diphenhydramine (Table 3). Depression of the central nervous system is also the major toxicity of dextromethorphan and codeine, both used to suppress coughing.

Antiseptics. Most antiseptics (e.g., hydrogen peroxide, benzoyl peroxide, resorcinol, benzalkonium chloride, parabens, and cetylpyridinium chloride) produce gastrointestinal irritation if ingested (Table 3). Benzoyl peroxide and parabens applied to the skin may be toxic. Among the most toxic antiseptics are hexachlorophene, benzalkonium, and cetylpyridinium chloride, any of which can cause injuries to internal organs. Systemic toxicity (double vision, drowsiness, tremor, seizures, and death) with

hexachlorophene is more likely to occur in babies because the relatively thin stratum corneum of their skin is highly permeable.

Vitamins and iron pills. Deficiencies as well as excesses of vitamins are harmful. Excessive vitamin A (retinol, or retinoic acid), known as hypervitaminosis A, can result in

Excessive
vitamin A

Table 3: Drugs and Health Care Products

drugs	toxicity, symptoms, and signs
Painkillers	
Aspirin, sodium salicylate	increased perspiration, respiration increased initially, dehydration, acidity in the body, hypoglycemia, CNS depression, respiration decreased, nausea, vomiting, diarrhea, confusion, coma, convulsion, lung edema, death
Acetaminophen	skin rash, decreases in blood cells, liver and kidney injuries, hypoglycemia, coma
Morphine	nausea, vomiting, pinpoint pupil, depressed respiration, delusions, confusion, muscle flaccidity, constipation, coma, death
Tranquilizers and sleeping pills	
Benzodiazepines	increased salivation, muscular incoordination, slurred speech, weakness, seizures, irritability, loss of appetite
Barbiturates	slowed respiration, CNS depression, depressed heartbeat, low blood pressure, shock, kidney failure, lung edema, pneumonia, muscular incoordination, slurred speech, pinpoint pupil, coma, death
Antipsychotic drugs	sympathetic blockade reflex increase in heart rate, parasympathetic blockade, tremors, rigidity, restlessness, jaundice
Nasal decongestants	nervousness, dizziness, tremor, confusion, increased blood pressure and heart rate
Antihistamines	drowsiness, dizziness, ear ringing, blurred vision, lack of coordination, headache, nausea, vomiting, loss of appetite, heartburn, dry mouth and throat, cough, palpitations, decrease in blood pressure, chest tightness, tingling of the hands
Cough medicine	CNS depression
Antiseptics	irritation of esophagus and stomach when ingested
Vitamins and iron pills	
Vitamin A	fatigue, dizziness, severe headache, vomiting, edema, dry and peeling skin, enlarged liver and spleen, teratogenic, red skin eruptions, abnormal hair growth
Iron	nausea, upper abdominal pain, diarrhea, bloody or brown vomit, dehydration, intestinal bleeding, liver damage, drowsiness, acidic condition in the body, rapid breathing, shock
Antidepressants	
Tricyclic antidepressants	parasympathetic blockade, CNS damage, cardiovascular system damage
Lithium salts	thyroid enlargement, edema, increased urination, abnormal heart rhythm, vomiting, diarrhea, tremor, muscle flaccidity, seizures, coma
Drugs of abuse	primarily CNS effects
Cardiovascular drugs	
Digitalis (e.g., digoxin, digitoxin)	gastrointestinal irritation, abdominal discomfort, salivation, fatigue, facial pain, visual disturbances, confusion, delirium, hallucinations
Beta blockers (e.g., propranolol, metoprolol)	constriction of bronchi, nausea, vomiting, diarrhea, constipation, headache, insomnia, dizziness, abnormal heart rhythm
Verapamil	headache, dizziness, gastrointestinal symptoms, edema, rash, abnormal heart rhythm, lowered blood pressure
Procainamide, quinidine	anorexia, nausea, vomiting, confusion, delirium, psychotic behaviour, abnormal heart rhythm, lowered blood pressure
Therapeutics for asthma	CNS stimulation

skin lesions, edema, and liver damage (Table 3). Overconsumption by Alaskan natives of polar bear liver, a rich source of vitamin A, has produced acute toxicities, characterized by irresistible sleepiness and severe headaches. Chronic poisoning with vitamin A can cause neurological symptoms, including pain, anorexia, fatigue, and irritability (Table 3).

Excess vitamin C can lead to kidney stones. Apart from irritation of the skin and respiratory tract, the most severe toxicity of vitamin K excess is the increased destruction of red blood cells, which leads to anemia and the accumulation of bilirubin, one of the products of hemoglobin degradation (Table 3). Excess bilirubin can result in brain damage in newborns, a condition known as kernicterus. Because the blood-brain barrier is not well developed in newborns, bilirubin enters and damages the brain. Due to the blood-brain barrier, kernicterus is not seen in adults.

Iron, a metal that is necessary for normal health, can also cause poisoning. The toxicity of iron is a result of its corrosive action on the stomach and intestine when present in high concentrations. As a result, intestinal bleeding occurs, which can lead to the development of shock (Table 3).

Antidepressants. Among tricyclic antidepressants, amitriptyline and imipramine account for most of the fatal cases of poisoning. These drugs have a number of effects, including blockage of the parasympathetic system and damage to the central nervous system, the latter producing symptoms such as fatigue, weakness, lowered body temperature, seizures, and respiratory depression (Table 3). Death is usually caused by damage to the heart. Lithium salts, used to treat manic depression, have a relatively low therapeutic index.

Drugs of abuse. Mind-altering drugs commonly abused include amphetamines, cocaine, phencyclidine, heroin, and methaqualone. These drugs are primarily toxic to the central nervous system; amphetamine and cocaine cause stimulation of the system (hallucinations and delirium), and heroin causes the depression of the system (depressed respiration and coma). In contrast, phencyclidine and methaqualone are biphasic, producing first depression (drowsiness) and then stimulation of the central nervous system (delirium and seizures). Amphetamines also affect the gastrointestinal tract (anorexia, nausea, vomiting, diarrhea) and stimulate the cardiovascular system (increased blood pressure and heart rate, palpitations, and abnormal heart rhythm). In addition to hallucinations and delirium, cocaine causes euphoria, sexual arousal, confusion, and sympathetic stimulation. Phencyclidine is also known to cause aggression and psychotic behaviour, while methaqualone produces excessive dreaming and amnesia.

Cardiovascular drugs. Digitalis (*e.g.*, digoxin) is a class of drugs used for congestive heart failure, with a very narrow margin of safety. Digitalis overdose usually begins with gastrointestinal symptoms, such as anorexia, nausea, and vomiting, followed by sensory symptoms, such as pain and visual disturbances (Table 3). There are also effects on the central nervous system, characterized by delirium and hallucinations.

The major toxicities of beta blockers (*e.g.*, propranolol and metoprolol) result from the blockage of sympathetic effects on the tracheobronchial tree (lung) and heart. Sympathetic stimulation relaxes smooth muscles in the tracheobronchial wall and makes the heart beat faster and more forcefully. Blockage produced by propranolol or metoprolol can cause bronchoconstriction and heart failure (Table 3).

Antiasthmatics. Drugs for treating asthma, such as theophylline and aminophylline, are structurally similar to caffeine. Like caffeine, which is a stimulant, theophylline and aminophylline also stimulate the central nervous system. Therefore, excitement, delirium, rapid breathing, increased heart rate, and seizures occur with an overdose. With excessive stimulation of the heart, palpitations and irregular heart rhythm (arrhythmia) can result, leading to sudden death.

(C.D.KI./K.L.W.)

POISONS OF BIOLOGICAL ORIGIN

Biotoxins can be conveniently grouped into three major categories: (1) microbial toxins, poisons produced by bac-

teria, blue-green algae, dinoflagellates, golden-brown algae, etc., (2) phytotoxins, poisons produced by plants, and (3) zootoxins, poisons produced by animals. The geographic distribution of poisonous organisms varies greatly; poison-producing microorganisms tend to be ubiquitous in their distribution. Poisonous plants and animals are found in greatest abundance and varieties in warm-temperate and tropical regions. Relatively few toxic organisms of any kind are found in polar latitudes.

Knowledge of the evolutionary significance and development of most biotoxins is largely speculative and poorly understood. In some instances they may have developed during the evolution of certain animal species as part of the food procurement mechanism (*e.g.*, in snakes; cnidarians, jellyfishes, and their relatives; mollusks, octopuses, and others; and spiders). Biotoxins may also function as defensive mechanisms, as in some snakes, fishes, arthropods (*e.g.*, insects, millipedes), and others. The defense may be quite complex—as in the protection of territorial rights for reproductive purposes—and inhibitory or antibiotic substances may be produced that result in the exclusion of competitive animal or plant species. Certain marine organisms and terrestrial plants may release into the water, air, or soil inhibitory substances that discourage the growth of other organisms; well-known examples include the production of antibiotic substances by microorganisms. Similar chemical-warfare mechanisms are used in battles for territorial rights among the inhabitants of a coral reef, a field, or a forest. Thus biotoxins play important roles in the regulation of natural populations. Of increasing interest has been the discovery that certain substances, which may be toxic to one group of organisms, may serve a vital function in the life processes of the source organism.

Importance to humans. Venom-producing animals and stinging and dermatogenic (*i.e.*, skin-poisoning) plants capable of inflicting pain and sometimes death by means of parenteral contact (*i.e.*, by bringing poisons into the body other than through the digestive tract) constitute environmental hazards. Biotoxic agents may produce their injurious effects by becoming involved in the food supply; ingestion of a poisonous microbial organism, plant, or marine animal or one of their toxic by-products may cause intoxication. An example is that of the shore fishes of many tropical islands; otherwise valuable food fishes are frequently contaminated by a poison called ciguatera. The poison, a potent neurotoxin (nerve poison), is accidentally ingested by the fishes in their food; such fish can no longer be used for either human or animal consumption.

Some of the effects produced by biotoxins on humans are of an acute nature, and the injuries they cause are readily discernible. The effects of some of the mycotoxins (poisons produced by fungi) and poisons produced by plants, however, are long-term and chronic; they result in the development of cancerous growths and other chronic degenerative changes that are sometimes difficult to detect.

Microbial toxins. Microbial poisons are produced by the Monera (bacteria and blue-green algae) and Protista (algae, protozoa, and others), and the Fungi. Various classifications have been proposed for the microbial poisons, but none is entirely satisfactory. The problems encountered when dealing with these organisms result from a lack of precise knowledge concerning their biological nature and their phylogenetic relationships; in addition, their poisons show great diversity and chemical complexity. The following outline, however, is useful in dealing with this subject.

Moneran toxins. The prefixes "exo-" and "endo-" are retained in classifying the bacterial toxins mainly for historical reasons rather than because they are found either outside or inside the bacterial cell. The main differences in these toxins lie in their chemical structure.

Poisonous proteins from bacteria are sometimes referred to as bacterial exotoxins. The exotoxins are generally produced by gram-positive organisms (*i.e.*, bacteria that react in certain ways to the staining procedure known as Gram staining); at least two bacteria, *Shigella dysenteriae* and *Vibrio cholerae*, that produce exotoxins are gram-nega-

Evolutionary aspects of biotoxins

Table 4: Representative Toxic Microfungi

	toxin	comments
<i>Claviceps purpurea</i> (ergot)	"ergotaxine," a complex of toxic alkaloids, ergocryptine, ergocornine, ergocristine, and others	causes poisoning in animals and humans; produces vomiting, abdominal pain, numbness, nervous disorders, convulsions, gangrene, and abortion
<i>Stachybotrys alternans</i>	stachybotryotoxin	causes a toxicosis in animals and humans; produces stomatitis (inflammatory disease of the mouth), rhinitis (inflammation of the mucous membranes of the nose), conjunctivitis (inflammation of the inner surface of the eyelid), failure of blood to clot, blood abnormalities, neurological disturbances, and death
<i>Aspergillus flavus</i> and other species, <i>Penicillium</i> species	aflatoxin complex (16 or more known toxins)	causes toxicosis in animals and possibly man; toxins damage liver and kidneys; aflatoxin is one of the most potent liver-cancer-producing agents known
<i>Fusarium sporotrichioides</i> and other <i>Fusarium</i> species	fusariogenin, epiclosporin acid, fagiclosporin acid	causes alimentary toxic aleukia in animals and man; produces burning sensation of the mouth, tongue, throat, and stomach; causes nausea, vomiting, headache, cold extremities, hemorrhagic spots, convulsions, anemia, gangrene, death
<i>Cladosporium epiphyllum</i> and other species of <i>Cladosporium</i>	same as <i>Fusarium</i> species	
<i>Pithomyces chartarum</i> (<i>Sporidesmium bakeri</i>)	sporidesmin	causes facial eczema (an eruptive severe rash) in cattle; produces sensitization of the skin to sunlight, resulting in scab formation and sores; there may also be severe liver damage
<i>Fusarium</i> species, <i>Rhizopus</i> species, <i>Aspergillus</i> species, <i>Penicillium islandicum</i> , and others	luteoskyrin, "islanditoxin," citrinin, citreoviridin, and others; a large complex of poisons is involved	causes moldy or yellowed rice, which is toxic to animals and man; the effects in man have not been well defined; may cause nausea, vomiting, diarrhea, prostration, liver damage, and death; the effects vary greatly because of the various poisons involved

tive, however. The exotoxins usually do not contain any nonprotein substances, and most are antigenic; *i.e.*, they stimulate the formation of antibodies. The exotoxins may appear in the culture medium in which the bacteria are growing during the declining phases of growth; in some cases they are released at the time of normal destruction of the cells after death (autolysis). The exotoxins are less stable to heat than are the endotoxins, and they may be detoxified by agents that do not affect endotoxins. They are more toxic than endotoxins, and each exotoxin exerts specific effects which are collectively known as pharmacological properties. Exotoxins are neutralized by homologous antibodies—*i.e.*, the active agents in blood serum produced by a process involving the bacteria against which the serum is to be used.

Endotoxins are antigens composed of complexes of proteins, polysaccharides (large molecules built up of numerous sugars), and lipids (fats). The protein part determines the antigenicity, or quality of being reacted against as a foreign substance in a living organism. The polysaccharide part determines the immunological specificity, or limitations on the types of antibodies that can react with the endotoxin molecule and neutralize it (the immunological reaction). Some of the lipids possibly determine the toxicity. Endotoxins are derived from the bacterial cell wall and, when cells are grown in culture, are released only on autolysis. Endotoxins are not neutralized by homologous antibodies and are relatively stable to heat; all of them have the same pharmacological properties.

The Cyanobacteria, or blue-green algae, are among the most primitive and widely distributed of all organisms. They have extreme temperature tolerances. Some strains of a species are toxic; other strains of the same species are not. Water blooms of blue-green algae have been responsible for the death of fishes, waterfowl, cattle, horses,

swine, and other animals. Blue-green algae have also been implicated as causes of human intoxications.

Mycotoxins. Fungi are plantlike members of the kingdom Fungi (Mycota) that do not contain chlorophyll. A significant number are known to produce poisons of various types. Toxic fungi can be roughly divided into two main categories on the basis of their size: the smaller microfungi and the larger mushrooms. The toxic microfungi are members of one of two classes: Ascomycetes, or the sac fungi, and the Deuteromycetes, or the imperfect fungi (*i.e.*, fungi in which no sexual reproductive stages are known). The large toxic mushrooms, or toadstools, are mostly members of the class Basidiomycetes, although some Ascomycetes, such as the poisonous false morel (*Gyromitra esculenta*), may attain a size as large as some of the mushrooms.

The ability of certain fungi, such as ergot (*Claviceps purpurea*) and some mushrooms, to produce intoxication has long been known. During the 19th century it was recognized that molds are responsible for such diseases as yellow-rice toxicoses in Japan and alimentary toxic aleukia in Russia. The eruption of so-called turkey X disease in England in 1960 and the resulting discovery of the substance known as aflatoxin (see Table 4) stimulated study of the subject of mycotoxicology. Because mycotoxins have now been recognized as potential cancer-producing agents (carcinogens) that can become involved in man's food supply, they have become important in the study of environmental carcinogenesis.

Poisonous mushrooms, or toadstools as they are commonly called, are the widely distributed members of the class Basidiomycetes, although only a few are known to be poisonous when eaten (see Table 5); some of the poisons, however, are deadly. Most deaths attributed to mushroom poisoning result from eating members of the genus

Poisonous mushrooms

Table 5: Representative Poisonous Mushrooms

	toxin	type of poisoning
Lorchel, or false morel (<i>Gyromitra esculenta</i>)	gyromitrin	toxicity to people is variable; causes severe liver damage accompanied by nausea, vomiting, abdominal pain, jaundice, enlarged and tender liver, coma, convulsions; fatality rate about 15 percent
Fly mushroom, or fly agaric (<i>Amanita muscaria</i>)	muscarine	symptoms develop rapidly and are severe, consisting of severe gastrointestinal disturbances, delirium, hallucinations, convulsions; rarely causes death
Death cap (<i>Amanita phalloides</i>)	amanitine, phalloidine	symptoms develop slowly, about 6–15 hours after eating: extreme abdominal pain, nausea, vomiting, excessive thirst, anuria (absence or defective excretion of urine), prostration, weakness, jaundice, cyanosis, convulsion, death; fatality rate about 50 percent; no known antidote but some treatment available
<i>Boletus miniato-olivaceus</i>	muscarine(?)	causes gastrointestinal and visual disturbances
Jack-o'-lantern fungus (<i>Clitocybe illudens</i>)	muscarine	causes gastrointestinal upset, not fatal
Inky cap (<i>Coprinus atramentarius</i>)	unknown	some people experience a peculiar type of intoxication after eating this mushroom and then drinking an alcoholic beverage: giddiness, gastrointestinal upset, prostration, and tachycardia (rapid heart action); the alcohol is believed to increase the solubility and absorption of the poison
<i>Entoloma lividum</i>	unknown	causes gastrointestinal upset, usually not fatal
<i>Inocybe patouillardii</i>	muscarine	symptoms are similar to <i>A. muscaria</i> poisoning
<i>Lepiota morgani</i>	unknown	causes gastrointestinal upset; fatalities have been reported
Mexican hallucinogenic mushroom (<i>Psilocybe mexicana</i>)	psilocybin, psilocin	causes euphoria, loss of sense of distance and size, and hallucinations

Table 6: Representative Poisonous Plants

name and distribution	toxic principle	toxic effects and comments
Plants poisonous to eat		
Rosary pea, or jequirity bean (<i>Abrus precatorius</i>); tropical regions	abrin (<i>N</i> -methyltryptophan) and abric acid	onset of symptoms may be delayed several hours to two days: vomiting, diarrhea, acute gastroenteritis, chills, convulsions, death from heart failure; one seed chewed may be fatal to a child
Aconite, or monkshood (<i>Aconitum napellus</i>); North America, Europe	aconite and a complex of other alkaloids	tingling, burning sensation in tongue, throat, skin; restlessness, respiratory distress, muscular uncoordination, vomiting, diarrhea, convulsions, possible death; an extremely poisonous plant
Corn cockle (<i>Agrostemma githago</i>); North America, Europe	githagin, agrostemmic acid (saponins)	dizziness, diarrhea, respiratory distress, vomiting, headache, sharp pains in spine, coma, death; frequent ingestion of small amounts results in chronic githagism (a disease, similar to lathyrism, that results in pain, burning and prickling sensations in lower extremities, and increasing paralysis); milled seeds may be found in wheat flour
Locoweed (<i>Astragalus</i> species); Northern Hemisphere	locoine	dullness, weakness, irregular behaviour, impaired vision, edema of eyelids, loss of muscular control, loss of appetite, emaciation, starvation, death in sheep, horses, and cattle
Belladonna (<i>Atropa belladonna</i>); United States, Europe, Asia	hyoscyamine, atropine, hyoscyne, and a complex of other alkaloids	dryness of the skin, mouth, throat; difficulty in swallowing, flushing of the face, cyanosis (a bluish discoloration of skin due to insufficient oxygen), nausea, vomiting, slurred speech, coma, death; children and animals frequently poisoned by eating fruit
Akee (<i>Blighia sapida</i>) Rape (<i>Brassica napus</i>) Marijuana (<i>Cannabis sativa</i>); United States, Mexico, tropical America	hypoglycin A, B glycosides (isothiocyanates) cannabinol, canabidiol, and related compounds	sudden vomiting, drowsiness, muscular and nervous exhaustion, prostration, coma, death pulmonary emphysema, respiratory distress, anemia, constipation, irritability, blindness in cattle exaltation, inebriety, confusion, followed by central nervous system depression; prolonged, frequent use may produce dullness or mania; ingestion in large quantities or injection of the purified extract may produce death by cardiac depression
Water hemlock (<i>Cicuta maculata</i>); northern temperate regions	cicutoxin	abdominal pain, nausea, vomiting, diarrhea, respiratory distress, hypersalivation, convulsions, death; among the most poisonous plants
Poison hemlock (<i>Conium maculatum</i>); temperate United States, South America, northern Africa, Asia	coniine, conhydrine, <i>N</i> -methyleconiine, coniceine, and other alkaloids	muscular weakness, paralysis of extremities, blindness, respiratory paralysis, death; responsible for many human fatalities; leaves most toxic when plant is flowering
Purging croton (<i>Croton tiglium</i>); Asia, Pacific Islands, Africa	croton, croton resin, ricinine	vomiting, violent purging, collapse, death; croton oil is also a skin irritant, causing reddening, swelling, and pustules
Daphne (<i>Daphne mezereum</i>); temperate regions	glycoside involving aglycone dihydroxycoumarin	vomiting, burning sensation of the mouth, ulceration of the oral mucosa, diarrhea, stupor, weakness, convulsions, and death
Jimsonweed or thornapple (<i>Datura stramonium</i>); temperate and tropical regions	hyoscyne, hyoscyamine, atropine	headache, nausea, vomiting, dizziness, thirst, dry and burning sensation in skin, mental confusion, mania, loss of memory, convulsions, death; children are often poisoned by eating seeds or sucking flowers
Larkspur (<i>Delphinium</i> species); northern temperate regions	delphinine, delphinoidine, delphisine, and other alkaloids	burning and inflammation of mouth, nausea, vomiting, respiratory distress, itching, cyanosis; one of the greatest causes of death in grazing livestock
Dumbcane (<i>Dieffenbachia seguine</i>); widely cultivated in temperate regions, tropical regions	protoanemonine, calcium oxalate	irritation and burning of the mouth, tongue, and lips; hypersalivation, swelling of the tongue, difficulty in swallowing and breathing
Foxglove (<i>Digitalis purpurea</i>); Europe, North America	glycosides, digitoxigenin, and others	loss of appetite, nausea, vomiting, slow pulse and irregular heartbeat, diarrhea, abdominal pain, headache, fatigue, drowsiness, convulsions, death
Wild yam (<i>Dioscorea hispida</i>); southern Asia, Pacific Islands	dioscorine	discomfort, then burning of the throat, giddiness, vomiting of blood, respiratory distress, drowsiness, exhaustion, paralysis of the nervous system, death; raw tubers are a frequent cause of death in the Philippines
Huanuco cocaine (<i>Erythroxylon coca</i>); tropics of both hemispheres	cocaine and other alkaloids	central nervous system stimulation followed by depression, numbness of tongue, paralysis of respiratory centres, cyanosis, respiratory distress, death; leaves are commonly chewed by Indians of Peru and Bolivia as a stimulant
Manchineel (<i>Hippomane mancinella</i>); Florida, Central America, South America, West Indies	physostigmine or a similar alkaloid plus a saponin	fruit causes gastroenteritis, which may be fatal, and causes ulceration of intestinal tract; sap causes burning of skin, swelling and hemorrhage of the eyes; sap is used as an arrow poison
Black henbane (<i>Hyoscyamus niger</i>); North America, Europe, Asia, Oceania	hyoscyamine, hyoscyne, atropine, and other alkaloids	similar to belladonna poisoning caused by <i>Atropa belladonna</i> ; children are poisoned by eating seeds and pods

Amanita. Wild mushrooms should be eaten only if they have been accurately identified by an experienced person; the safest procedure is to eat only cultivated species. The problem of toxicity in mushrooms is complex; no single rule or test method exists by which the toxicity of a mushroom can be determined. The most poisonous species closely resemble some of the most prized edible species; in addition, toxicity within a given wild species may vary from one set of ecological conditions or from one geographical locality to the next. Moreover, although some mushrooms that are poisonous when fresh are edible when cooked, dried, salted, or preserved in some other way, others remain poisonous in spite of all preparation procedures. It has also been observed that some people may become poisoned by eating mushrooms that apparently do not affect others. As with microfungi, the mushroom poisons vary in their chemical and biological properties from species to species.

Protistan poisons. The dinoflagellates, important producers of the primary food supply of the sea, are microscopic one-celled organisms that are dependent upon various inorganic nutrients in the water and upon radiant energy for photosynthesis, the process by which they produce their own food supplies. Although dinoflagellates inhabit both marine waters and freshwaters, most species are marine. Dinoflagellates are most often found in cool or temperate waters. During periods of planktonic blooms (times of high concentrations of microscopic organisms in the water) dinoflagellates multiply in large numbers. These planktonic blooms, sometimes referred to as red tide because they discolour the water, are often associated

with weather disturbances that may bring about changes in water masses or upwellings. During periods of bloom large numbers of toxic dinoflagellates may be ingested by shellfish; the poisons accumulate in their digestive glands. Animals and humans may in turn be poisoned by eating poisoned shellfish. Certain species of dinoflagellates are capable of producing some of the most toxic substances known. The two species of dinoflagellates most commonly involved in human intoxications have been *Gonyaulax catenella* along the Pacific coast of North America and *G. tamarensis* along the eastern coast of North America. Intoxications from these organisms are known as paralytic shellfish poisoning. The symptoms, which begin with a tingling or burning sensation, then numbness of the lips, gums, tongue, and face, gradually spread. Gastrointestinal upset may be present. Other symptoms include weakness, joint aches, and muscular paralysis; death may result. There is no specific treatment or antidote. The poison, variously called paralytic shellfish poison, mussel poison, and saxitoxin, is a complex nonprotein nitrogen-containing compound. Paralytic shellfish poisoning is best avoided by following local public-health quarantine regulations.

Respiratory irritation may result from the inhalation of toxic products in the windblown spray from red-tide areas containing the toxic dinoflagellate *Gymnodinium breve*, which is found in the Gulf of Mexico and Florida; the nature of the poison is unknown. Deaths of large numbers of brackish-water pond fishes because of *Prymnesium parvum* have been reported in Israel; the poison is known as prymnesin.

Table 6: Representative Poisonous Plants (continued)

name and distribution	toxic principle	toxic effects and comments
Barbados nut (<i>Jatropha curcas</i>); tropics	curcin	burning of the throat, bloating, dizziness, vomiting, diarrhea, drowsiness, dysuria, leg cramps, violent purgative action; may be fatal to children
Mountain laurel (<i>Kalmia latifolia</i>); North America	andromedotoxin	hypersalivation, tears, impaired vision, tingling of skin, dizziness, vomiting, muscular paralysis, convulsions, coma, death; children are poisoned by eating leaves
Grass peavine (<i>Lathyrus sativus</i>); North America, Europe, northern Africa, Asia	β -aminopropionitrile	back pain, weakness in legs, paralysis; has caused death in children
Cassava (<i>Manihot esculenta</i>); tropics	cyanophoric glycosides	nausea, respiratory distress, twitching, staggering, convulsions, coma, death
Chinaberry (<i>Melia azedarach</i>); North America, southern Africa, Asia	azadarin	stomatitis with violent and bloody vomiting, paralysis
Opium poppy (<i>Papaver somniferum</i>); Europe, Asia, tropics	morphine, codeine, thebaine, papavarine, narcotine	central nervous system depression, pinpoint pupils, depressed respiration, cyanosis, coma, death
Pokeberry (<i>Phytolacca americana</i>); North America, Europe, southern Africa	phytolaccine	burning, bitterness in mouth, vomiting, purging, spasms, convulsions, death
Castor bean (<i>Ricinus communis</i>); United States, tropics	ricin, a toxalbumin	burning of mouth, throat, and stomach, vomiting, diarrhea, abdominal cramps, dulled vision, convulsions, respiratory distress, paralysis, death; one to three seeds may be fatal to children
Black nightshade (<i>Solanum nigrum</i>); North America, Europe	solanine, a glycoalkaloid	nausea, vomiting, abdominal pain, diarrhea, trembling, paralysis, coma, death
Plants poisonous by contact		
Euphorbia, spurge (<i>Euphorbia</i> species); worldwide	a complex of substances including alkaloids, glycosides, and others	eye irritation, blindness, blistering of the skin, swelling around the mouth, burning of the mouth, unconsciousness, death; milky sap is used as an arrow poison
Spurge nettle (<i>Jatropha stimulosus</i>); North America, Europe, Asia	toxin unknown	contact produces instant, intense stinging and itching due to an irritating substance injected into the skin by the stinging hairs; results in a skin eruption of minute red papular (small conical elevations of the skin) rash, which lasts about 30 minutes; a dull purplish discoloration of the skin may remain for several weeks
Shiny-leaf stinging tree, tree nettle (<i>Laportea photiniphylla</i>); Australia	5-hydroxytryptamine (and other toxic substances?)	contact with the stinging hairs of this plant produces intense, rapidly spreading pain, reddened rash, and later a severe skin eruption; severe stings may result in intense, unbearable pain; fatalities have been reported; dried leaves may cause intense sneezing
Poisonwood (<i>Metopium toxiferum</i>); West Indies, Florida	similar to poison ivy	contact with any part of the tree, especially sap, turns the skin black, causes a rash, blisters, etc.; smoke from a burning tree is very irritating, causing illness and temporary blindness
Strophanthus (<i>Strophanthus</i> species); Florida, tropical America, Africa	an alkaloid, trigonelline, and a large number of cardiac glycosides and aglycones	vomiting, slow and irregular pulse, blurred vision, delirium, circulatory failure, death; used as an arrow poison
Curare (<i>Strychnos toxifera</i>); Central America and northern South America	toxiferines, caracurines, and other alkaloids	haziness of vision, relaxation of facial muscles, inability to raise head, loss of muscle control of arms, legs, and respiratory muscles, death; used as a poison for arrows and for blowgun darts
Poison ivy (<i>Toxicodendron radicans</i> , also called <i>Rhus toxicodendron</i>); North America	urushiol	skin irritation, swelling, blistering, itching; may be fatal to young children; smoke from burning plant is toxic
Plants that produce photosensitization		
Buckwheat (<i>Fagopyrum sagittatum</i>); North America, Europe	fagopyrin, a naphthodianthrone derivative	ingestion of the leaves by animals causes liver dysfunction, thereby resulting in deposition of a photosensitizing pigment in the skin; sunlight then causes redness of the skin, nervousness, swelling of the eyelids, convulsions, and prostration in farm animals
St. Johnswort (<i>Hypericum perforatum</i>); North America, Europe	hypericin, a naphthodianthrone derivative	similar to buckwheat
Plants that produce airborne allergies		
Box elder (<i>Acer negundo</i>); Northern Hemisphere	oleoresin and a water-soluble antigen	hay fever (respiratory allergy), may also cause an eczematous dermatitis of the exposed parts of the body

is known as phytotoxicology. Most of the poisonous higher plants are angiosperms, or flowering plants, but only a small percentage are recognized as poisonous. Several systems have been devised for the classification of poisonous plants, none of which is completely satisfactory. Poisonous plants may be classified according to the chemical nature of their toxic constituents, their phylogenetic relationship, or their botanical characteristics. The following classification, which is based on their toxic effects, has been found to be useful: (1) plants that are poisonous to eat, (2) plants that are poisonous upon contact, (3) plants that produce photosensitization, and (4) plants that produce airborne allergies (see Table 6).

Plant poisons, or phytotoxins, comprise a vast range of biologically active chemical substances, such as alkaloids, polypeptides, amines, glycosides, oxalates, resins, toxalbumins, and a large group of miscellaneous compounds whose chemical structure has not yet been determined. Alkaloids, most of which are found in plants, are characterized by the presence of nitrogen and their ability to combine with acids to form salts. They are usually bitter in taste. It has been estimated that about 10 percent of the plant species contain some type of alkaloid. Only a few of the 5,000 alkaloids characterized thus far do not produce any biological activity; most cause a strong physiological reaction when administered to an animal. Amines are organic compounds containing nitrogen. A polypeptide is a string of three or more amino acids. A few polypeptides and amines are toxic to animals. Some glycosides, which are compounds that yield one or more sugars and one or more other compounds—aglycones (nonsugars)—when hydrolyzed (chemically degraded by the introduction of

water molecules between adjacent subunits), are extremely toxic to animals. Toxicity resides in the aglycone component or a part of it. Oxalates are salts of oxalic acid, which under natural conditions is not toxic but becomes so because of the oxalate ion. Resins, a heterogeneous assemblage of complex compounds, differ widely in chemical properties but have certain similar physical properties. Some resins are physiologically very active, causing irritation to nervous and muscle tissue. Toxalbumins are highly toxic protein molecules that are produced by only a small number of plants. Ricin, a toxalbumin from the castor bean (*Ricinus communis*), is one of the most toxic substances known.

Under certain ecological conditions plants may become poisonous as a result of the accumulation of toxic inorganic minerals such as copper, lead, cadmium, fluorine, manganese, nitrates, or selenium. Photosensitization, an unusual toxic reaction resulting from the ingestion of certain plants, may be of two types. The toxic substance may be obtained directly from the plant, which thereupon acts on the skin (primary photosensitivity), or the toxicity may result from liver damage caused by the metabolism of a toxic plant and failure of the breakdown products to be eliminated by the liver (hepatic photosensitivity). In either case the animal reacts by becoming restless; in addition, the skin reddens, and a severe sloughing of the skin develops. Death seldom occurs.

A large number of poisonous plants occur throughout the world; a few representative species and their poisons are listed in Table 6.

Animal poisons (zootoxins). Poisonous animals are widely distributed throughout the animal kingdom; the

Chemical
variability
of plant
poisons

Table 7: Representative Animals Poisonous When Eaten

name and distribution	toxic principle	toxic effects and comments
Protozoans—one-celled animals		
Dinoflagellate (<i>Gymnodinium breve</i>); Gulf of Mexico, Florida	unknown	irritation of mucous membranes of nose and throat; causes sneezing, coughing, respiratory distress due to inhalation of windblown spray from red tide areas
Dinoflagellate (<i>Gonyaulax catenella</i>); Pacific coast of North America	paralytic shellfish poison, saxitoxin ($C_{10}H_{15}N_7O_3 \cdot 2\text{HCl}$)	tingling, burning sensation and numbness of lips, tongue, face, spreading elsewhere in the body; weakness, dizziness, joint aches, hypersalivation, intense thirst, difficulty in swallowing, muscular paralysis, and death; extremely toxic; usually involved with the eating of shellfish that have been feeding on toxic dinoflagellates
Mollusks—octopus, squid, shellfish, and others		
California mussel (<i>Mytilus californianus</i>); Pacific coast of North America	paralytic shellfish poison, saxitoxin	these mollusks become poisonous to eat because of feeding on toxic dinoflagellates; symptoms same as for dinoflagellates (<i>Gonyaulax</i> species)
Butter clam (<i>Saxidomus giganteus</i>); Alaska to California	same as California mussel	
Whelk (<i>Neptunea</i> species); Europe, Pacific region	tetramine	nausea, vomiting, diarrhea, weakness, fatigue; dizziness, photophobia (intolerance to light), impaired vision, and dryness of the mouth; poison is believed to be restricted to the salivary glands of the whelk
Turban shell (<i>Turbo argyrostoma</i>); tropical Pacific Ocean	poison believed to be related to ciguatoxin	diarrhea, weakness of the legs, fatigue; cold water produces a painful stinging sensation, itching; the illness closely resembles ciguatera fish poisoning
Callista shellfish (<i>Callista brevisiphonata</i>); Japan	a histamine-like substance, choline	flushing of the face, itching, urticaria (stinging sensation of skin), sensation of constriction of the chest, abdominal pain, nausea, respiratory distress, asthmatic attacks, paralysis, hypersalivation, numbness of the tongue, throat; recovery usually within 10 days
Arthropods—joint-legged animals: crabs, spiders, and others		
Shore crab (<i>Demania toxica</i>); Philippines	unknown	nausea, vomiting, diarrhea, muscular weakness, respiratory distress, difficulty in speaking, hypersalivation, muscular paralysis, convulsions, death
Crab (<i>Zoysmus aeneus</i>); Indo-Pacific	similar to tetrodotoxin; toxicity of these crabs variable	tingling about the mouth, nausea, vomiting, muscular paralysis, coma, convulsions, death
Asiatic horseshoe crab (<i>Tachypleus tridentatus</i>); Southeast Asia	unknown	dizziness, headache, nausea, vomiting, abdominal pain, cardiac palpitation, numbness of the lips, weakness, muscular paralysis, hypersalivation, loss of consciousness, death
Sharks, eels, and other fish		
Greenland shark (<i>Somniosus microcephalus</i>); Arctic	unknown; flesh toxic; liver of tropical sharks very toxic and may also cause death	nausea, vomiting, diarrhea, abdominal pain, tingling and burning sensation of the tongue, throat, and esophagus, muscular cramps, respiratory distress, coma, death
Moray eel (<i>Gymnothorax javanicus</i>); Indo-Pacific†	ciguatoxin*	symptoms may develop rapidly or slowly; tingling about the lips, tongue, and throat, followed by numbness, nausea, vomiting, abdominal cramps, muscular weakness, paralysis, convulsions, teeth feeling loose, visual impairment, skin rash, hot objects feeling cold and vice versa ("Dry Ice" or "electric shock" sensation); loss of muscular coordination, coma, death in about 12 percent of the cases; known as ciguatera fish poisoning, this is one of the most common forms of fish poisoning
Red snapper (<i>Lutjanus bohar</i>); Indo-Pacific†	same as Moray eel	

*Fish poisoning is categorically referred to as "ichthyosarcotoxism," but there are several different forms of fish poisoning, such as ciguatera fish poisoning, clupeotoxism, scombrotoxin, and others. †More than 400 species of tropical reef fishes have been involved in ciguatera fish poisoning. These fish are normally edible but under certain conditions may become toxic.

Categories of zootoxins

only major group that seems to be exempt is the birds. Zootoxins can be divided into several categories: (1) oral poisons—those that are poisonous when eaten; (2) par-enteral poisons, or venoms—those that are produced by a specialized poison gland and administered by means of a venom apparatus; and (3) crinotoxins—those that are produced by a specialized poison gland but are merely released into the environment, usually by means of a pore.

Oral zootoxins (see Table 7) are generally thought to be small molecules; most venoms (Table 8) are believed to be large molecules, usually a protein or a substance in close association with one. Venoms, which are produced by specialized poison glands, are injected by means of a mechanical device that is able to penetrate the flesh of the victim. Little is known about the biological or chemical properties of most crinotoxins (Table 9). The term poisonous may be used in the generic sense to refer to all three categories of zootoxins.

Some of the most complex relationships in biotoxicology are found in the marine environment. Certain marine biotoxins, such as ciguatera fish poison, apparently originate in marine plants, are ingested by herbivores and then passed on to carnivores and eventually to humans. The extremely complex mechanism by which this is accomplished is not clear. With the buildup of toxic industrial chemical pollutants in the marine environment, the problems of toxicity in marine organisms are becoming increasingly more serious. There is evidence that under certain conditions chemical pollutants may trigger biotoxicity cycles in marine organisms. The outbreaks in Japan of Minamata disease were the result of such a cycle: microorganisms, algae, shellfishes, and fishes ingested or absorbed industrial wastes with highly toxic organic compounds containing mercury and were in turn consumed by humans, causing a number of deaths among the population.

The relationships of representative poisonous animals and their position in the total framework of the animal

kingdom can best be appreciated by categorizing them according to the group in which they belong. They are further grouped as to whether they are poisonous to eat, venomous, or crinotoxic in Tables 7, 8, and 9.

(B.W.H./Ed.)

RADIATION

Radiation, radioactivity, and radioisotopes. Radiation is a flow of energy through space or matter. It takes the form of particles (e.g., alpha and beta particles) or electromagnetic waves (e.g., X rays, gamma rays, and visible and ultraviolet [UV] light). Radiation can be classified as either ionizing or nonionizing depending on its ability to produce ions in the matter it interacts with. Ionizing radiation is more toxic than nonionizing radiation.

Radioactivity is the emission of radiation caused by the disintegration of unstable nuclei of radioisotopes. After disintegration, a radioisotope may become a radioisotope of another element, which will further disintegrate. The disintegration series continues until a stable isotope is formed.

Ionizing radiation. Ionizing radiation is radiation that produces ions in matter during interaction with atoms in the matter. The toxic effect of ionizing radiation is related to the ionization. It is believed that ionization of tissues, composed mainly of water, generates H_2O^+ and H_2O^- ions, which in turn form H and OH radicals. Because radicals are very reactive chemically, biological damage, such as attacks on DNA and proteins, results.

There are two classes of ionizing radiation: particulate and electromagnetic. Alpha particles, beta particles, neutrons, and positrons are examples of particulate ionizing radiation. Gamma rays and X rays are electromagnetic ionizing radiation.

Among particulate ionizing radiation, alpha and beta particles are the forms most commonly encountered in the environment and are biologically the most significant.

Table 7: Representative Animals Poisonous When Eaten (continued)

name and distribution	toxic principle	toxic effects and comments
Thread herring (<i>Clupanodon thrissa</i>); Indo-Pacific	clupeotoxin, chemical nature unknown	metallic taste, nausea, vomiting, abdominal pain, vascular collapse, hypersalivation, numbness, muscular paralysis, convulsions, coma, death; this form of poisoning develops rapidly and violently; mortality rate is about 50 percent and death may come within a few minutes; this form of fish poisoning is known as clupeotoxism; no known antidote
Castor-oil fish (<i>Ruvettus pretiosus</i>); tropical Atlantic, Indo-Pacific	oleic acid	produces a painless diarrhea; poisoning known as gempylotoxism; no treatment needed
Skipjack tuna (<i>Euthynnus pelamis</i>); tropical seas	saurine, a histamine-like substance; scombroid fishes (mackerels, tunas, swordfishes, and allies) contain a chemical constituent in their flesh called histidine; when histidine is acted upon, it forms a histamine-like substance called saurine; this occurs when the fishes are permitted to stand at room temperature for several hours; scombroid fishes are more susceptible to the development of saurine poison than most other kinds of fishes	the symptoms of acute scombroid poisoning resemble those of severe allergy: sharp, peppery taste, headache, throbbing of the large blood vessels of the neck, nausea, vomiting, massive red welts, and intense itching; recovery after 8-12 hours; this is probably the most common and cosmopolitan form of fish poisoning; antihistamines are used for treatment
Bluefin tuna (<i>Thunnus thynnus</i>); subtropical and temperate seas		
Deadly death puffer (<i>Arothron hispidus</i>); tropical Pacific, Indian Ocean, Red Sea	tetrodotoxin ($C_{11}H_{17}O_8N_3 \pm y H_2O$)	tingling of lips and tongue, loss of motor coordination, floating sensation, hypersalivation, numbness of the entire body, muscular paralysis, difficulty in swallowing, weakness, nausea, vomiting, convulsions, about 60 percent fatality in humans; no known antidote
Amphibians California newt (<i>Taricha torosa</i>); California	tarichatoxin; poison said to be identical to tetrodotoxin; the eggs of this newt are extremely toxic	effects in humans are unknown; no known antidote
Reptiles Hawksbill turtle (<i>Eretmochelys imbricata</i>); tropical seas Leatherback turtle (<i>Dermochelys coriacea</i>); temperate and tropical seas	chelonitoxin, chemistry unknown; the flesh of some species of marine turtles is extremely poisonous	nausea, vomiting, diarrhea; burning sensation of lips, tongue, mouth; tightness of the chest, difficulty in swallowing, hypersalivation, foul breath, skin rash, sloughing of the skin, enlargement of the liver, coma, death; fatality rate is high; no known antidote
Mammals Sei whale (<i>Balaenoptera borealis</i>); North Pacific and North Atlantic oceans	unknown; livers of many marine mammals are toxic	intense headache, neck pain, photophobia, desquamation (peeling in scales) around the mouth and face, flushing of the face; antihistamines are used in treatment
White whale (<i>Delphinapterus leucas</i>); Arctic seas	unknown	flesh is poisonous and has caused fatalities in humans; no known antidote
Polar bear (<i>Thalarctos maritimus</i>); Arctic	vitamin A and possibly other toxic substances	intense throbbing headaches, nausea, vomiting, diarrhea, abdominal pain, dizziness, drowsiness, irritability, muscle cramps, visual disturbances, collapse, coma, rarely death

Composed of two neutrons and two protons and thus containing a 2⁺ charge, alpha particles are the heaviest ionizing particles. Although they do not penetrate tissue very well, alpha particles turn many atoms in their short paths into ions, producing intense tissue ionization.

In contrast to alpha particles, beta particles are electrons of little mass carrying only one negative charge. They penetrate up to several millimetres in soft tissues. Their low mass and low charge mean that only moderate ionization is produced in tissues when beta particles collide with atoms in its path.

Gamma rays and X rays are electromagnetic radiation of similar properties, with gamma rays having higher energy than X rays. Gamma rays usually accompany the formation of alpha or beta particles. Neither gamma rays nor X rays carry a charge, and neither have mass; consequently, they can penetrate tissues easily, creating moderate ionization along their paths.

Biological damage is related to the degree of tissue ionization produced by radiation. Thus, a physical dose of alpha particles does not produce the same amount of damage as that produced by the same dose of beta particles, gamma rays, or X rays.

Radiation sources. Radiation is either natural or man-made. Natural radiation includes cosmic radiation, terrestrial radiation, radioisotopes inside human bodies, and radon gas. Cosmic radiation consists of charged particles from outer space, and terrestrial radiation of gamma rays from radionuclides in the Earth. Radioisotopes in human bodies come from the food, water, and air consumed. Cosmic and terrestrial radiation, together with radioisotopes inside human bodies, contribute only one-third of the total natural radiation dose. The remaining two-thirds can be attributed to radon, a radioactive gas released from soil that may reach a high level inside buildings with poor ventilation. Man-made radiation consists of radiation from medical and dental diagnostic procedures, atmospheric tests of atomic bombs, emissions from nuclear plants, certain occupational activities, and some consumer products. The largest nonoccupational radiation sources

are tobacco smoke for smokers and indoor radon gas for the nonsmoking population.

Emissions from nuclear power plants contribute only a very small portion of the total yearly radiation received. The low dose reflects the negligible amount of radionuclides released during normal operation, although the amount released can be much higher after a nuclear reactor accident. Not every reactor accident is a disaster, however. The 1979 accident at the Three Mile Island nuclear power station, near Harrisburg, Pa., released only a small amount of radiation (0.8 and 0.015 mSv within a 16- and 80-km radius, respectively), less than the background annual radiation dose. The nuclear reactor accident at Chernobyl in the Soviet Union, in 1986, however, was much more devastating, leading to more than 30 deaths and the evacuation of thousands of nearby residents.

Adverse effects of ionizing radiation. Ionizing radiation quickly kills rapidly dividing cells. In general, immature blood cells in bone marrow, cells lining the mucosa of the gastrointestinal tract, and cells in the lower layers of the epidermis and in hair follicles are the most rapidly dividing cells in the body. As a result, radiation leads to the decreased production of blood cells, nausea, vomiting, diarrhea, malabsorption by the intestine, skin burns, and hair loss. Because of its relatively selective lethal effect on rapidly dividing cells, however, ionizing radiation is used in the treatment of certain cancers. Some cells in the embryo and fetus also divide rapidly, and thus ionizing radiation can cause malformations and even fetal death. Ionizing radiation can also produce mutations by altering the DNA, and it can result in cancer.

Toxicities of whole-body ionizing radiation. X rays and gamma rays irradiate the body uniformly and acutely affect all of the tissues discussed above. At sufficiently high doses, this type of radiation can lead to a condition known as acute radiation syndrome. The most sensitive tissue is the bone marrow, where blood cells are generated. The next tissue affected is the gastrointestinal tract. If the dose is high, the central nervous system is affected and the person becomes uncoordinated and disoriented

Table 8: Representative Venomous Animals That Inflict a Sting

name and distribution	toxic principle	toxic effects and comments
Cnidarians		
Portuguese man-of-war (<i>Physalia</i> species); tropical seas	tetramine, 5-hydroxytryptamine	immediate, intense stinging, throbbing, or burning sensation, shooting sensation, inflammatory rash, blistering of the skin, shock, collapse, in very rare cases death
Sea wasp (<i>Chironex fleckeri</i>); northern and northeast Australia	cardiotoxin	immediate, extremely painful stinging sensation, seared reddened lines wherever the tentacles touch the skin, large indurated wheallike lesions, prostration, dizziness, circulatory failure, respiratory distress, rapid death in a high percentage of cases
Sea anemone (<i>Actinia equina</i>); Mediterranean, Black Sea, etc.	nature of venom unknown	burning, stinging sensation, itching, swelling, redness, ulceration, nausea, vomiting, prostration; no specific antidote available
Mollusks		
Cone shell (<i>Conus</i> species); tropical Indo-Pacific region	quaternary ammonium compounds and others	blanching at the site of injection, cyanosis of the surrounding area, numbness, stinging or burning sensation, blurring of vision, loss of speech, difficulty in swallowing, nausea, extreme weakness, coma, and death in some cases; no specific antidote
Spotted octopus (<i>Octopus maculosus</i>); Indo-Pacific, Indian Ocean	cephalotoxin, a neuromuscular poison	sharp burning pain, similar to a bee sting, numbness of the mouth and tongue, blurring of vision, loss of tactile sensation, difficulty in speech and swallowing, paralysis of legs, nausea, prostration, coma, and death in a high percentage of cases
Arthropods		
Kissing bug (<i>Triatoma</i> species); Latin America, United States	unknown	bite usually painless; later itching, edema about the bite, nausea, palpitation, redness; the bite is of relatively minor importance but spreads Chagas disease caused by a trypanosome (protozoan)
Puss caterpillar (<i>Megalopyge</i> species); United States, Latin America	unknown	stinging hairs of the caterpillar associated with poison-secreting glands; contact with the hairs produces an intense burning pain, itching, pustules, redness, nausea, fever, numbness, swelling, and paralysis; recovery usually within about six days
Honeybee (<i>Apis</i> species); worldwide	neurotoxin, hemolytic, melittin, hyaluronidase, phospholipase A, histamine, and others	sting produces acute local pain or burning sensation, blanching at the site of the sting surrounded by a zone of redness, and itching; local symptoms usually disappear after 24 hours; severe cases may develop massive swelling, redness, shock, prostration, vomiting, rapid heartbeat, respiratory distress, trembling, coma, and death; it is estimated that 500 stings delivered in a short period of time can provide a lethal dose to a human; bees kill more people in the United States than do venomous reptiles
Bumblebee (<i>Bombus</i> species); temperate regions	similar to honeybee (<i>Apis</i>) venom	stings are similar to honeybee (<i>Apis</i>) stings; bumblebees are not as vicious as honeybees
Yellow jacket, hornet (<i>Vespa</i> species); temperate regions	similar to bee venom; also acetylcholine	they can both bite and sting; the sting is similar to that of the honeybee's but more painful; yellow jackets are quite aggressive; stings may be fatal
Wasp (<i>Polistes</i> species and <i>Vespa</i> species); worldwide	similar to bee venom; also acetylcholine	wasps are less aggressive than hornets, and their sting is similar to the honeybee's but generally less painful than the hornet's; stings may be fatal
Harvester ant (<i>Pogonomyrmex</i> species); United States	bradykinin, formic acid, hyaluronidase, hemolytic, phospholipase A, and others	ant stings cause immediate intense burning, pain, blanched area at site of sting surrounded by redness, ulceration, fever, blistering, itching, hemorrhaging into the skin, eczematoid dermatitis, pustules, respiratory distress, prostration, coma, and death in some instances
Fire ant (<i>Solenopsis</i> species); United States, Latin America	similar to harvester-ant venom	similar to above; stings are very painful, burning sensation, etc.
Millipede (<i>Apheloria</i> species and others); temperate and tropical areas	hydrogen cyanide and benzaldehyde	toxic liquid or gas from lateral glands causes inflammation, swelling, and blindness in contact with eyes, and brown stain, redness, swelling, and vesicle formation in contact with skin
Centipede (<i>Scolopendra</i> species); temperate and tropical regions	hemolytic phospholipase and serotonin	local pain, swelling, and redness at bite site
Brown spider (<i>Loxosceles</i> species); United States, South America, Europe, Asia	cytotoxic, hyaluronidase, hemolytic, and others	bite causes stinging sensation or burning pain, blanching at site of bite surrounded by redness, blistering, hemorrhages into the skin and internal organs, ulceration, vomiting, fever, cardiovascular collapse, convulsions, sometimes death
Black widow (<i>Latrodectus</i> species); tropical and temperate regions	neurotoxic	bite may or may not be painful, two tiny red dots at site of bite, localized swelling after a few minutes; intense cramping pain of abdomen, legs, chest, back; rigidity of muscles lasting 12-48 hours, nausea, sweating, respiratory distress, priapism (abnormal, painful erection of the penis) in males, chills, skin rash, restlessness, fever, numbness, tingling; about 4 percent are fatal; antiserum is available
Tarantula (<i>Dugesiella</i> and <i>Lycosa</i> species); temperate and tropical regions	venom varies, usually mild	most of the large tarantulas found in the United States, Mexico, and Central America are harmless to humans; some of the large tropical species may be more poisonous, but their effects are largely localized
Scorpion (species of <i>Centruroides</i> , <i>Tityus</i> , and <i>Leiurus</i>); warm temperate and tropical regions	neurotoxin, cardiotoxin, hemolytic, lecithinase, hyaluronidase, and others	symptoms vary depending upon the species of scorpion; sting from the tail stinger causes a sharp burning sensation, swelling, sweating, restlessness, salivation, confusion, vomiting, abdominal pain, chest pain, numbness, muscular twitching, respiratory distress, convulsions, death; the mortality rate from stings from certain species of scorpions is very high; antiserum is available
Echinoderms		
Crown-of-thorns starfish (<i>Acanthaster planci</i>); Indo-Pacific	nature of poison unknown	penetration of the spines produces a painful wound, redness, swelling, vomiting, numbness, and paralysis
Long-spined sea urchin (<i>Diadema setosum</i>); Indo-Pacific	nature of poison unknown	penetration of the spines produces an immediate and intense burning sensation, redness, swelling, numbness, muscular paralysis
Sea urchin (<i>Toxopneustes pileolus</i>); Indo-Pacific	nature of poison unknown	bites from the stinging jaws or pedicellariae (small pincerlike organs) produce an immediate, intense, radiating pain, faintness, numbness, muscular paralysis, respiratory distress, and occasionally death
Sharks and rays		
Stingray (<i>Dasyatis</i> species); warm temperate and tropical seas	stingray venom, cardiotoxin, chemistry unknown	penetration of the tail spines inflicts jagged painful wounds that produce sharp, shooting, throbbing pain, fall in blood pressure, nausea, vomiting, cardiac failure, muscular paralysis, rarely death; no known antidote; stingrays are among the most common causes of envenomations in the marine environment
Bony fishes		
Weever fish (<i>Trachinus draco</i>); Mediterranean Sea	weever fish venom, chemistry unknown	opercular and dorsal fin spines can produce instant pain, burning, stabbing or crushing sensation; pain spreads and becomes progressively more intense, causing the victim to scream with anguish and suffer loss of consciousness, numbness about the wound, swelling, redness, nausea, delirium, difficulty in breathing, convulsions, and death; no known antidote
Scorpion fish (<i>Scorpaena</i> species); temperate and tropical seas	scorpion fish venom, chemistry unknown	fin spines can inflict painful stings and intense, immediate pain that may cause victim to scream followed by redness, swelling, loss of consciousness, ulceration of the wound, paralysis, cardiac failure, delirium, convulsions, nausea, prostration, and respiratory distress, but rarely death; no known antidote
Stonefish (<i>Synanceja</i> species); Indo-Pacific region	stonefish venom, chemistry unknown	produces an extremely painful sting by means of the dorsal fin spines; symptoms similar to other scorpion fish stings but more serious
Reptiles		
Gila monster (<i>Heloderma suspectum</i>); southwestern United States	heloderma venom, primarily a neurotoxin	all of the teeth are venomous; bite causes local pain, swelling, weakness, ringing of the ears, nausea, respiratory distress, cardiac failure; may cause death; no antiserum available

Table 8: Representative Venomous Animals That Inflict a Sting (continued)

name and distribution	toxic principle	toxic effects and comments
Rear-fanged snakes		
Boomslang (<i>Dispholidus typus</i>); Africa	coagulates the blood; proteolytic and other enzymes are present	local pain, swelling, hemorrhages; bleeding from nose, mouth, and skin; headache, vomiting, collapse, death; antiserum is available
Front-fixed-fanged snakes		
Death adder (<i>Acanthophis antarcticus</i>); Australia, New Guinea	coagulates blood; proteolytic and other enzymes present	effects of envenomation develop slowly (15–60 minutes); nausea, vomiting, faintness, drowsiness, staggering, slurred speech, respiratory distress, hemorrhages, death; antiserum available
Indian krait (<i>Bungarus candidus caeruleus</i>); India, Myanmar, Malaya, Indonesia	cholinesterase, protease, and other enzymes present	little pain or local reaction, latent period up to 12 hours; abdominal pain, staggering gait, difficulty in swallowing, stiffness of jaws, coma, respiratory distress, cardiac failure, death; antiserum available
Brown snake (<i>Demansia textilis</i>); Australia	cholinesterase, ophio-adenosinetriphosphatase, phospholipase, and other enzymes	latent period up to 12 hours; abdominal pain, vomiting, headache, dizziness, blood in the urine, weakness, respiratory and circulatory collapse, death; antiserum available; this snake is responsible for most of the deaths due to snake bite in Australia; very dangerous
Black mamba (<i>Dendroaspis polylepis</i>); Ethiopia, Somalia, Natal, southwest Africa	cholinesterase, L-amino-acid oxidase, ophio-adenosine, triphosphatase, and other substances	local pain, swelling, salivation, paralysis of vocal cords, sweating, vomiting, restlessness, drowsiness, collapse, coma, respiratory distress, death; one of the most dangerous of all living snakes; antiserum available; a large black mamba secretes enough venom to kill 10 men
Coral snake (<i>Micrurus corallinus</i>); subtropical South America	cholinesterase, hyaluronidase, L-amino-acid oxidase, and other enzymes	numbness without pain at bite, headache, swelling of face and lips, hyperesthesia (unusual sensitivity of skin), sore throat, drooping of eyelids, photophobia, vomiting, rapid heart rate, backache, irritability, salivation, death; there are about 40 species in the genus <i>Micrurus</i> ; all are dangerous; antiserum available for some species but not others
India cobra (<i>Naja naja</i>); southern Asia, Indonesia, Taiwan, Philippines	carboxypolypeptidase, cholinesterase, diastase, dipeptidase, polypeptidase, protease, and other enzymes; one of the most complex snake venoms	pain radiating from site of bite, edema, numbness, drooping of the eyelids and head, salivation, difficulty in speech, muscular incoordination, weakness, respiratory distress, blindness, incontinence, convulsions, death; antiserum available
Black-necked cobra (<i>Naja nigricollis</i>); Africa	cholinesterase, L-amino-acid oxidase, phospholipase, protease, and other enzymes	similar to poisonings by the Indian cobra; venom sometimes sprayed at eyes; produces an intense irritation, but permanent damage to eyes is rare; antiserum available
Tiger snake (<i>Notechis scutatus</i>); Australia	coagulates blood; cholinesterase, hyaluronidase, ophio-adenosinetriphosphatase, phosphatase, and other enzymes	latent period of 15–60 minutes; nausea, vomiting, faintness, sweating, drowsiness, staggering, slurred speech, difficulty in swallowing, drooping of eyelids, respiratory distress, death; antiserum available
King cobra (<i>Ophiophagus hannah</i>); India, Myanmar, Philippines, Thailand	cholinesterase, L-amino-acid oxidase, ophio-adenosinetriphosphatase	symptoms similar to those produced by other cobras; symptoms develop rapidly, death often occurs in 30–60 minutes; one of the largest of venomous snakes—obtains a length of 16 feet; antiserum available
Taipan (<i>Oxyuranus scutellatus</i>); Australia, New Guinea	lecithinase, phospholipase	symptoms similar to those produced by the tiger snake; its long fangs and potent venom make this one of the world's most dangerous snakes; produces flaccid paralysis, respiratory paralysis, often rapidly fatal; antiserum available
Australian black snake (<i>Pseudechis porphyriacus</i>); Australia	L-amino-acid oxidase, lecithinase, phospholipase	local pain and swelling, vomiting, hemorrhages from nose and mouth, prostration, hematuria (presence of blood in the urine), and sometimes death; usually the bites are nonfatal; antiserum available
Sea snakes		
Beaked sea snake (<i>Enhydryna schistosa</i>); Indo-Pacific	lecithinase	no local reaction; latent period minutes to hours; giddiness, muscle ache, muscular weakness, drooping of the eyelids, lockjaw, respiratory failure, acute renal (kidney) failure, death; all sea snakes are venomous, but only a few species have caused death in man
Erectile-fanged snakes		
Copperhead (<i>Ancistrodon contortrix</i>); eastern and southern United States	cholinesterase, L-amino-acid oxidase, phosphodiesterase, and other enzymes	local pain, swelling, necrosis, nausea, vomiting, shock, petechiae (minute bleeding spots), bloody stools, death; antiserum available
Eastern cottonmouth (<i>Ancistrodon piscivorus</i>); southeastern United States to central Texas	cephalinase, cholinesterase, hyaluronidase, lacithinase, and other enzymes	similar to poisoning by the copperhead but more severe; local necrosis more marked; death; antiserum available
Fer-de-lance (<i>Bothrops atrox</i>); central Mexico, south into South America	cholinesterase, deoxyribonuclease, L-amino-acid oxidase, protease, and other enzymes	local pain, bleeding from bite, gums, nose, mouth, rectum; blood fails to clot; shock, respiratory distress, hemorrhages into muscles and nervous system, death; antiserum available
Eastern diamondhead rattlesnake (<i>Crotalus adamanteus</i>); southeastern United States	cephalinase, cholinesterase, hyaluronidase, and other enzymes	local pain, edema, hemorrhaging into the tissues, dryness of the mouth, vomiting, shock, anemia, tingling sensation, blood in feces, difficulty in speech, yellow vision, loss of consciousness, death; antiserum available
Western diamondback rattlesnake (<i>Crotalus atrox</i>); southwestern United States	bradykininogen, cholinesterase, hyaluronidase, L-amino-acid oxidase, and other substances	symptoms similar to poisoning by <i>C. adamanteus</i> , but neurological symptoms less marked; antiserum available
Cascabel (<i>Crotalus durissus terrificus</i>); southern Mexico south to Argentina	cholinesterase, deoxyribonuclease, hyaluronidase, lecithinase, and other enzymes	symptoms similar to cobra bites, except that no edema occurs; antiserum available
Bushmaster (<i>Lachesis muta</i>); Costa Rica to northern South America	protease	very few bites recorded and little is known concerning the effects of the venom; severe prostration, rapid death; antiserum available
Taiwan habu (<i>Trimeresurus mucrosquamatus</i>); southeastern China, Taiwan	neurotoxin, amino-acid oxidase, hemorrhagin, and other substances	local pain, blistering, bleeding into the tissues, shock, death; antiserum available
True vipers		
Puff adder (<i>Bitis arietans</i>); Africa, Saudi Arabia	fibrinolytic, bradykininogen, cholinesterase, L-amino-acid oxidase, protease, and other substances	severe local edema, necrosis and sloughing of the tissues, restlessness, respiratory distress, gastrointestinal hemorrhages, death; antiserum available
Saw-scaled viper (<i>Echis carinatus</i>); India, Iraq, Saudi Arabia, Africa	carboxypolypeptidase, cholinesterase, dipeptidase, endopeptidase, and other enzymes	local pain and edema; hemorrhages into the skin, mucous membranes, and gastrointestinal tract; liver damage, shock, death; antiserum available
European viper (<i>Vipera berus</i>); Europe, Asia, Japan	bradykininogen, L-amino-acid oxidase	local pain and edema, hemorrhages along lymphatics, very little general reaction, vomiting, abdominal pain, shock, death; antiserum available
Russell's viper (<i>Vipera russelli</i>); Asia, Indonesia	carboxypolypeptidase, cholinesterase, dipeptidase, lipase, lecithinase, protease, and other enzymes	rapidly spreading edema with hemorrhages into the tissues, abdominal pain, vomiting; blood does not clot; loss of consciousness, circulatory failure, shock, death; antiserum available
Mammals		
Duck-billed platypus (<i>Ornithorhynchus anatinus</i>); Australia	protease and other enzymes	may inflict envenomation by means of the spurs on the hind legs of the male platypus; immediate intense pain, swelling, redness in the area of the sting, faintness, numbness about the wound, restlessness, prostration; no death recorded; recovery is uneventful after a few days
Short-tailed shrew (<i>Blarina brevicauda</i>); North America	neurotoxic, proteolytic	the lower incisor teeth are associated with submaxillary poison glands; bites produce localized pain, redness in the area of the bite, shooting pains, and general discomfort of the affected part; gradual recovery after several days; no fatalities recorded

Table 9: Representative Crinotoxic Animals*

name and distribution	toxic principle	toxic effects and comments
Sponges Red moss (<i>Microciona prolifera</i>); eastern United States coastal waters	unknown	contact with the sponge produces a chemical irritation of the skin, redness, stiffness of the finger joints, swelling, blisters, and pustules
Flatworms Flatworm (<i>Leptoplana tremellaris</i>); European coastal waters	unknown	poison is produced by epidermal skin glands; no human intoxications recorded; extracts from the skin of these worms injected into laboratory animals produces cardiac arrest
Arthropods—joint-legged animals Blister beetles (<i>Cantharis vesicatoria</i>); United States	cantharidin	toxic substance does not seem to be produced by special glands but is found throughout the body of the beetle; no discomfort at time of initial contact; after about 8–10 hours large blisters develop on the skin accompanied by slight burning or tingling sensation; swallowing of the beetles may cause kidney damage; cantharidin is used as an aphrodisiac known as Spanish fly—a very dangerous substance to use; ingestion can cause severe gastroenteritis, kidney damage, blood in the urine, priapism, profound collapse, and death
Millipedes (species of <i>Orthoporus</i> , <i>Rhinocricus</i> , <i>Julus</i> , and <i>Spirobolus</i>); temperate and tropical regions	unknown	repugnatorial (distasteful to enemies) fluid may be exuded or forcefully squirted from body pores a distance up to 30 inches or more; contact with the skin causes mild to moderately intense burning pain, redness, and pigmentation of the skin; toxic fluid squirted in the eyes may cause temporary blindness, an inflammatory reaction, and pain
Venomous ticks (species of <i>Ixodes</i> and <i>Ornithodoros</i>); temperate and tropical regions	unknown	tick bites result in swelling, redness, intense pain, headache, muscle cramps, loss of memory, etc.
Fishes Sea lamprey (<i>Petromyzon marinus</i>); Atlantic Ocean	unknown	slime of the lamprey is toxic; ingestion may cause diarrhea
Soapfish (<i>Rypticus saponaceus</i>); tropical and subtropical Atlantic	neurotoxic	slime of fish is toxic; produces an irritation of the mucous membrane
Amphibians† European earth salamander (<i>Salamandra maculosa</i>); Europe	skin glands of the salamander are poisonous; contains the alkaloids samandarine, samandenone, samandine, samanine, samandarone, samandaridine, and others	effects on humans not known; affects the heart and nervous system; causes in animals convulsions, cardiac irregularity, paralysis, and death
Toads (<i>Bufo</i> species); temperate and tropical regions	bufotoxin, bufogenins, and 5-hydroxytryptamine; poison includes a complex of many substances	produces a poisonous secretion in the parotid glands and skin; handling of some toads may cause a skin irritation; ingestion causes nausea, vomiting, numbness of the mouth and tongue, and tightness of the chest; the poison has a digitalis-like action
Frogs (some species of <i>Dendrobates</i> , <i>Physalaemus</i> , and <i>Rana</i>); northern South America and Central America	skin secretions are poisonous; histamine, bufotenine, physalaemin, serotonin, and other substances; composition varies with the species	skin secretions produce a burning sensation when handled; used by Indians as an arrow poison
Tree frogs (some species of <i>Hyla</i> and <i>Phylllobates</i>); northern South America, Central America	skin secretions are poisonous; batrachotoxin, steroidal alkaloids, serotonin, histamine, and other substances; bufotenine varies with the species	some frog species produce a burning sensation and a skin rash when handled; skin secretions in the eye may produce a severe inflammatory reaction; if ingested, poison causes vomiting and abdominal pain; batrachotoxin is extremely toxic if injected; used by Indians as an arrow poison

*Animals in which poison glands are present and poison is released into the environment through a pore. †Poisonous amphibians are sometimes referred to as "venomous," but they do not possess a true venom apparatus. They possess only poison glands.

and experiences tremors, convulsions, and coma. At even higher doses, the skin, eyes, and ovaries and testes are affected. Death may follow from 2 to 35 days after exposure. Exposure to radiation can also result in cancers of the bone marrow (leading to leukemia), lungs, kidneys, bladder, esophagus, stomach, colon, thyroid, or breasts.

Radioisotopes that are absorbed and distributed evenly throughout the body also can result in whole-body irradiation. Examples are tritium and cesium-137, both of which release beta particles that can lead to bone marrow toxicities and even, in the case of cesium-137, to death. The toxicity of tritium is less severe than that of cesium-137 because the beta particles generated by tritium are less energetic and because cesium-137 also releases gamma rays.

Local toxicities of common beta-particle emitters. Unlike tritium and cesium-137, the isotopes strontium-90, iodine-131, and cerium-144 emit beta particles that are not distributed evenly in the body. Strontium-90 releases only beta particles, while iodine-131 and cerium-144 release both beta particles and gamma rays, but their toxicities are primarily caused by the beta particles. These radioisotopes produce toxicities in the tissues where they are stored or concentrated. Strontium-90 and cerium-144 chemically resemble calcium and as a result are stored in bone. Therefore, these two radioisotopes produce bone cancer and leukemia, which is a result of the irradiation of bone marrow. Iodine-131 is concentrated in the thyroid and produces thyroid damage and tumors.

Local toxicities of common alpha-particle emitters. There are radioisotopes that emit primarily alpha particles, together with some gamma rays. Because the destructive effect on tissues of alpha particles is far greater than that of gamma rays, the toxicities of these radioisotopes are

contributed mainly by the alpha particles. Because of the limited penetrability of alpha particles, only tissues in the near vicinity of the isotopic molecules are affected. These radioisotopes typically produce tumors at the storage site.

Most of the common alpha-particle emitters belong to the uranium series, which consists of radioisotopes that form one after another, via a nuclear decay reaction, and release mainly alpha particles. The series starts with uranium-238. The nuclear disintegration of uranium-238 forms radium-226 which disintegrates to form radon gas (radon-222). Radon decays to form a series of daughter nuclides, most of which are alpha-particle-releasing isotopes, such as polonium-210. The radioisotopes in the uranium series are important because uranium is the starting fuel for many nuclear reactors and because daughter nuclides in this series are commonly found in the environment.

The toxicity of uranium-238 depends on the water solubility of the uranium compound. Water-soluble forms mainly cause kidney injury, while the insoluble forms produce fibrosis and cancer of the lung. Because of its similarity to calcium, radium-226 is stored mainly in the bone, and it produces abnormal changes in the bone marrow, including anemia and leukemia, cancers of the bone, and paranasal sinuses. The next radioisotope in the uranium series is radon, radon-222. Although radon is radioactive, its toxicity is not due to retention of the gas by the lungs but rather to the series of radioactive daughter nuclides in particulate form. These particulate daughter nuclides are deposited on the respiratory tract when inhaled, the respiratory tract is irradiated by the alpha particles released, and lung cancer can result.

Other radioisotopes do not belong to the uranium series. For example, radium-224, which is deposited mainly on

bone surfaces, has been used in Europe to treat ankylosing spondylitis. Because of its short half-life (3.6 days), it affects only the bone surface and not the bone marrow. Its major toxicity is the production of bone cancer. Like uranium-238, plutonium-239, which is used in some nuclear reactors and in nuclear bombs, primarily releases alpha particles. Although there are no human data, animal studies indicate that the toxicity of plutonium-239 is similar to that of insoluble uranium-238 in causing fibrosis and cancer of the lung.

Nonionizing radiation. Nonionizing radiation includes ultraviolet light, infrared radiation, microwaves, and radio frequencies, all of which are electromagnetic waves. The toxicity of radio frequencies is rather low. On the whole, nonionizing radiation is not as toxic as ionizing radiation, and the various forms of nonionization radiation share common target organs; particularly the skin and eyes.

Ultraviolet radiation. The toxicity of ultraviolet light depends on its wavelength. Ultraviolet-A (near UV) has a wavelength of 315–400 nanometres, ultraviolet-B (mid UV) has one of 280–315 nanometres, and ultraviolet-C (far UV) has one of 200–280 nanometres. Ultraviolet-A affects primarily the skin and causes burns at high energy levels. The toxicities of ultraviolet-B and ultraviolet-C are similar, but ultraviolet-C is less toxic because it does not penetrate tissues as deeply. Both ultraviolet-B and ultraviolet-C cause injuries to the eyes and skin. Ultraviolet-B is the major component of sunlight and accelerates the aging of skin by damaging the collagen fibres under it. Ultraviolet-B also is the cause of an occupational disease known as "welder's flash," or "arc eye," which is characterized by photophobia, tears in the eyes, spasm of the eyelids, and eye inflammation. Finally, ultraviolet-B can cause skin cancer, which may be a result of the linking of thymidines, a base in DNA, produced by ultraviolet-B radiation.

Infrared radiation and microwaves. The major mechanism of toxicity of infrared radiation and microwaves is the production of heat in tissues. Infrared-A (wavelength 0.8–1.4 micrometres) penetrates the skin, causing burns and pigmentation. Infrared-A also penetrates the liquid content of the eye to reach the retina and can therefore produce damage to all parts of the eye. In contrast, infrared-B and infrared-C (wavelength 1.4–3,000 micrometres) are almost completely absorbed by the superficial layers of the skin and eyes, and the damage is thus confined to the surface. Microwaves (wavelength 1 millimetre to 1 metre) produce heat in tissues. Because testes and eyes do not dissipate heat well, due to low blood flow through these organs, temporary sterility and cataracts can be produced by microwaves.

Lasers. Lasers are high-energy light beams, visible and nonvisible, generated by atoms at an excited state and further amplified by optics. Like most other nonionizing radiation, lasers can produce skin burns. Visible lasers, with a wavelength from 0.4 to 1.4 micrometres, will cause retinal damage if they enter the eyes and are focused by the lens onto the retina.

BIBLIOGRAPHY

Toxic substances: CURTIS D. KLAASSEN, MARY O. AMDUR, and JOHN DOULL (eds.), *Casarett and Doull's Toxicology: The Basic Science of Poisons*, 3rd ed. (1986), contains in-depth discussions of basic toxicology principles and information on toxins classified according to use and target organs. Analysis of the chemical structure of toxins influencing their effect is provided in STANLEY E. MANAHAN, *Toxicological Chemistry: A Guide to Toxic Substances in Chemistry* (1989). MICHAEL A. KAMRIN, *Toxicology: A Primer on Toxicology Principles and Applications* (1988), is a concise, nontechnical general introduction. ERNEST HODGSON, RICHARD B. MAILMAN, and JANICE E. CHAMBERS, *Dictionary of Toxicology* (1988), explains concepts and terminology and covers organizations and authorities in the field.

Exposure and response to poisons: ROBERT H. DREIBACH and WILLIAM O. ROBERTSON, *Handbook of Poisoning: Prevention, Diagnosis, & Treatment*, 12th ed. (1987), contains concise but essential information on the toxicity and treatment of poisoning by biological toxins and drugs. AVRAM GOLDSTEIN, LEWIS ARONOW, and SUMNER M. KALMAN, *Principles of Drug Action: The Basis of Pharmacology*, 2nd ed. (1973), describes the principles governing chemical absorption, distribution, and excretion of the substances. MATTHEW J. ELLENHORN and DONALD G. BARCELOUX, *Medical Toxicology: Diagnosis and Treatments of Human Poisoning* (1988), focuses on the poisons derived from biological sources. SIDNEY KAYE, *Handbook of Emergency Toxicology: A Guide for the Identification, Diagnosis, and Treatment of Poisoning*, 5th ed. (1988), surveys almost 200 toxic substances.

Sources of poisoning: GEORGE D. CLAYTON and FLORENCE E. CLAYTON (eds.), *Patty's Industrial Hygiene and Toxicology*, 3rd. rev. ed., vol. 2, *Toxicology*, parts A, B, and C (1981–82), is an extensive compendium of information on the toxicology of industrial chemicals. For concise reference on the subject, see ALICE HAMILTON, *Hamilton and Hardy's Industrial Toxicology*, 4th ed., rev. by ASHER J. FINKEL (1983). The toxicology of chemicals found in commercial products is examined in ROBERT E. GOSSELIN, ROGER P. SMITH, and HAROLD C. HODGE, *Clinical Toxicology of Commercial Products*, 5th ed. (1984), where information on chemical ingredients of many commercial products is detailed. ALFRED GOODMAN GILMAN *et al.* (eds.), *Goodman and Gilman's The Pharmacological Basis of Therapeutics*, 7th ed. (1985), is an authoritative source of information on the toxicology of drugs and includes a section on the toxicity of industrial chemicals.

The toxicology of food is the subject of JOINT FAO/WHO COMMITTEE ON FOOD ADDITIVES, *Toxicological Evaluation of Certain Food Additives* (1988), including lists of acceptable consumption of flavourings, preservatives, and colours; JOSE M. CONCON, *Food Toxicology*, 2 vol. (1988), a comprehensive survey of food contamination and poisoning; PALLE KROGH (ed.), *Mycotoxins in Food* (1987); and W.F.O. MARASAS and PAUL E. NELSON, *Mycotoxicology: Introduction to the Mycology, Plant Pathology, Chemistry, Toxicology, and Pathology of Naturally Occurring Mycotoxicoses in Animals and Man* (1987). BRUCE W. HALSTEAD, *Poisonous and Venomous Marine Animals of the World*, 2nd rev. ed. (1988), is an exhaustive and profusely illustrated compendium on the toxic marine animals of the world, from protozoans to polar bears, including their historical background, names, geographic distribution, biology, mechanism of intoxication, and medical, toxicological, pharmacological, and chemical aspects.

Poland

Poland is situated on the North European Plain between the Baltic Sea and the Carpathian Mountains. Over the past 1,000 years, political frontiers have expanded and contracted dramatically, and the name Poland (in Polish, Polska) has been applied to a shifting territorial base, which has repeatedly changed its boundaries. At one time, in the mid-16th century, Poland was the largest state in Europe. At other times there was no Polish state at all. In December 1989 the official name of the Polish state was changed from the Polish People's Republic to the Republic of Poland (Polska Rzeczpospolita).

Poland lies at the physical centre of the European continent, approximately between latitudes 49° and 55° N and longitudes 14° and 24° E. Its area is 120,727 square miles

(312,683 square kilometres). Among the eastern European countries, Poland ranks second after the Soviet Union in both area and population.

The frontiers of the Republic of Poland stretch for 2,198 miles (3,538 kilometres). In the west they run along the Oder (Odra) and Lusatian Neisse (Nysa Łużycka) rivers, which border Germany. In the north they run along the Baltic shore facing Sweden, from the estuary of the Oder to the Gulf of Gdańsk (Zatoka Gdańska). In the south they mainly follow the watershed of the Sudeten (Sudety), Beskid, and Carpathian mountain ranges, separating Poland from Czechoslovakia. In the northeast and east they run along the border of the Soviet Union.

Physical and human geography

THE LAND

Relief. Poland has a largely lowland character. The average elevation of the whole country is only 568 feet (173 metres); more than 75 percent of the land lies below 650 feet (200 metres). Poland's relief was formed by the actions of Ice Age glaciers, which advanced and receded over the northern part of the country a number of times during the

Pleistocene Epoch (2,500,000 to 10,000 years ago). The great and often monotonous expanses of the Polish lowlands, part of the North European Plain, are composed of geologically recent deposits that lie over a vast structural basin. In the southern portion of the country, by contrast, older and more diverse geological formations are exposed, and the topography is dominated by the mountainous arc of the Carpathians, dating from the Tertiary mountain-building period of about 25,000,000 years ago. northern rim of the Carpathians lies a series of structural basins, separating the mountain belt proper from a much older structural mass, or foreland, that appears in the relief patterns of the region as the Bohemian Massif, the Sudeten, and the Little Poland Uplands (Wyżyna Małopolska).

This structure helps to explain the division of the country into a series of east-west zones. To the north lie the swamps and dunes of the Baltic coast; south of these is a belt of morainic terrain with thousands of lakes, the southern boundary of which marks the limit of the last ice sheet. The third zone consists of the central lowlands, whose minimal relief was created by streams issuing from the retreating glaciers. This zone is the Polish heartland, the site of agriculture in places where loess has been deposited over the relatively infertile fluvioglacial deposits. The fourth zone is made up of the older mountains and highlands to the south; though limited in extent, it offers spectacular scenery. The Little Poland Uplands protect the Little Poland Lowlands (Nizina Małopolska), in which Kraków lies, from the colder air of the north. In the extreme south are the Carpathians and their foothills.

Climate. Varying types of air masses collide over Poland, a process that strongly influences the character of both weather and climate. The major elements involved are oceanic air masses from the west, cold polar air from Scandinavia or from Russia, and warmer, subtropical air from the south. A series of barometric depressions moves eastward along the polar front year-round, dividing the subtropical from the colder air, bringing to Poland, as to other parts of northern Europe, cloudy, wet days. In winter, polar-continental air often becomes dominant, bringing crisp, frosty weather, with still colder Arctic air following in its wake. Warm, dry, subtropical-continental air often brings pleasant days in late summer and autumn.

These elements combine to give the overall climate of Poland a transitional—and highly variable—character, between oceanic and continental types. Six seasons may be clearly distinguished: a snowy winter of one to three months; an early spring of one or two months, characterized by alternating wintry and springlike conditions; a predominantly sunny spring; a warm summer with plenty of rain and sunshine; a sunny, warm autumn; and a foggy, humid period signifying the approach of winter. Sunshine reaches its maximum over the Baltic in summer and the Carpathians in winter, and mean annual temperatures range from 46° F (8° C) in the southwestern lowlands to 43° F (6° C) in the colder northeast. The climate of the mountains is determined by altitude.

The annual average precipitation is about 24 inches (600 millimetres), but in the mountains the figure approaches 31 to 47 inches, dropping to about 18 inches in the central lowlands. In winter, snow makes up about half the total in the plains and almost all of it in the mountains.

Drainage and soils. No less than 99.7 percent of Poland drains to the Baltic, more than half via the Vistula (Wisła) River and a third via the Oder. Polish rivers experience

two periods of high water each year: in spring, the lowland rivers are swollen by melted snow, the effect intensified both by ice dams (which block the rivers for one to three months) and by the fact that the thaw first strikes the upper reaches of the northward-flowing rivers; the summer rains bring a second maximum around the beginning of July.

There are some 9,300 Polish lakes with areas of more than 2½ acres (one hectare), and their total area is about 1,200 square miles (3,200 square kilometres), or 1 percent of the national territory. The majority, however, are found in the northern glaciated belt, where they occupy more than a 10th of the surface area.

Polish soils are varied and without clearly marked regional types. The greatest area is covered by podzol and pseudopodzol types, followed by the less widely distributed brown-earth soils, which are richer in nutrients. In the south are patches of the fertile loess-based soils, especially in the Little Poland Lowlands. The rendzinas, formed on limestone rocks, are a unique type. Alluvial soils filling the river valleys and peaty swamp soils found in the lake area and in poorly drained valleys are also of importance.

Plant and animal life. The vegetation of Poland has developed over the 10,000 years that have elapsed since the last Ice Age and consists of some 2,250 species of seed plants, 630 mosses, 200 liverworts, 1,200 lichens, and 1,500 fungi. Holarctic elements (*i.e.*, those appertaining to the temperate belt of the Northern Hemisphere) are dominant among the seed plants.

The northeastern limits of certain trees—notably beech, fir, and the variety of oak known as pedunculata—run through Polish territory. There are few endemic species: the Polish larch (*Larix polonica*) and the Ojców birch (*Betula oycoviensis*) are two examples. Some relics of tundra vegetation have been preserved in the peat bogs and mountains. About 28 percent of the country is wooded. Poland lies in the zone of mixed forests, but in the southeast a fragment of the forest-steppe vegetation zone intrudes, while in the northeast there are portions of the east European subtaiga, with spruce as a characteristic component. In the mountains, the vegetation, like the climate, is determined by altitude. Fir and beech woods give way to the spruce of the upper woods, which in turn fade into subalpine, alpine, and snowline vegetation.

Poland's animal life belongs to the European-West Siberian zoogeographic province, itself part of the Palearctic subregion, and is closely linked with the vegetation cover. The vertebrate fauna includes nearly 400 species, including many types of mammals and more than 200 native birds. Deer and wild pig roam the woods; the elk is found in the coniferous forests of the northeast; and steppe rodents, such as the brindled gopher, are found in the south. Brown bear and wildcat live in the mountain woods, and the chamois and marmot are found at the highest levels. The great Białowieża Forest (Puszcza Białowieńska), a national park contiguous with the Belovezhskaya Pushcha in Belorussian S.S.R., provides shelter for

Trees

Six seasons

a small herd of wisent, or European bison, all that remain of the vast numbers that once roamed the continent.

Settlement patterns. The natural landscape of Poland can be divided broadly into three groups: the lowlands, the highlands, and the mountains. The eastern extremes of Poland display characteristics common to eastern Europe, but the rest of the country is linked to western Europe by structure, climate, and the character of its vegetation.

The coastal plain. The Baltic Coastal Plain stretches across northern Poland from Germany to the Soviet border, forming a low-lying region built of various sediments. It is largely occupied by the ancient province of Pomerania (Pomorze), the name of which means "Along the Sea." The scarcely indented Baltic coastline was formed by wave action after the retreat of the ice sheet and the raising of sea levels. The Pomeranian Bay (Zatoka Pomorska) in the west and the Gulf of Gdańsk in the east are the two major inlets. In the southern portion of the former, two islands block off the Szczecin Lagoon (Zalew Szczeciński), into which the Oder discharges its waters. In the Gulf of Gdańsk, the Vistula forms a large delta. Sandbars, on which the winds have created large dunes, line much of the coast, separating the coastal lakes and lagoons from the sea. The main urban centres are the ports of Szczecin (German Stettin) on the lower Oder and Gdańsk (Danzig) and Gdynia in the east. The central portion of the Baltic Coastal Plain is scantily populated—there are only small fishing ports, of which Kołobrzeg is the most important—and the landscape has a desolate beauty.

The lake region. The belt immediately to the south of the coastal plain presents, with its many lakes, a varied, hilly landscape of glacial origin. Wide river valleys divide the region into three parts: the Pomeranian Lakeland (Pojezierze Pomorskie); the Masurian Lakeland (Pojezierze Mazurskie), east of the lower Vistula; and the Great Poland Lakeland (Pojezierze Wielkopolskie). The larger settlements and the main communications routes of this zone lie in and along the river valleys; the remainder of the area is mostly wooded and thinly populated. Only the eastern portion of the Great Poland Lakeland has a developed agriculture.

The central lowlands. The extensive central lowlands contain isolated relief features shaped by the oldest glaciations, but their character is generally flat and monotonous. The postglacial lakes have long since been filled in, and glacial outwash masks the weakly developed meltwater valley channels. The basins of the main rivers divide the area into the Silesian Lowlands (Nizina Śląska), which lie in the upper Oder; the southern Great Poland Lowlands (Nizina Wielkopolska), which lie in the middle Warta basin; and the Mazovian and Podlaskan lowlands, which lie in the middle Vistula basin. Lower Silesia and Great Poland are important agricultural areas, but large industrial centres are found in many parts of the central lowlands. Warsaw (Warszawa), the capital, situated on the middle Vistula, is most prominent.

The Little Poland Uplands. These uplands, south of the central lowlands, extend from east to west, but they are folded transversely. In the west is the Silesian-Cracovian upthrust, with rich deposits of coal. A second upthrust is formed by the ancient rocks of the Góry Świętokrzyskie ("Holy Cross Mountains"), which reach a maximum height of 2,008 feet (612 metres). Between these two regions lies the Nida Basin, with an average height of 650 to 1,000 feet. East of the Góry Świętokrzyskie, the uplands are cut by the valley of the Vistula, beyond which lie the Lublin Uplands (Wyżyna Lubelska). In the south occur patches of loess on which fertile brown- and black-earth soils have developed. The older geological regions contain valuable minerals: in the Silesian-Cracovian uplands there are coal, iron, zinc, and lead deposits. These mineral resources have made possible the rise of Poland's most important industrial region, and the landscape of Upper Silesia is highly urbanized. Katowice is the largest centre, and the region is closely linked with that around Kraków. To the north the Staropolski (Old Polish) Basin, situated in the foothills of the Góry Świętokrzyskie, has a long history of industrial production. Kielce is the area's urban centre.

The Sudeten. The Sudeten and its foreland, part of the

larger Bohemian Massif, have a long and complex geological history. They owe their present rugged form, however, to earth movements that accompanied the Carpathian uplift, and the highest portion, the Karkonosze ("Giant Mountains"; German Riesengebirge, Czech Krkonoše), reach 5,256 feet (1,602 metres) above sea level. The region contains rich mineral deposits, notably coking coal, which has occasioned the growth of an industrial centre around Wałbrzych. The region has many small towns; resorts and spas are found in more secluded areas. The foreland of the Sudeten is separated by a large fault from the larger mass. The foreland contains many granite quarries.

The Carpathians. The southernmost and also most scenic portion of Poland embraces the Carpathian Mountains and their associated chains and basins, created in the geologically recent mountain-building Tertiary Period (about 65,000,000 to 2,500,000 years ago). Within the Polish frontiers lie the Oświęcim and Sandomierz basins, a portion of the Beskid Mountains, the Orawka-Podhale Basin, and the Tatry (Tatra Mountains). The sub-Carpathian basins contain deposits of salt, sulfur, and natural gas and some petroleum. There are a large rural population and many towns of medium size. The highest peak of the Beskidy, Babia Góra, reaches 5,659 feet (1,725 metres); the high Tatry, the highest portion of the Polish Carpathians, with a maximum elevation of 8,199 feet (2,499 metres), have a unique character. Zakopane, the largest tourist and resort centre in Poland, lies at their feet. The Bieszczady Mountains, rolling, carpeted in beech woods, and sparsely inhabited, lie in the extreme southeast.

Environment. Rapid industrialization has threatened the natural environment in Poland, and pollution is severe in many areas. Upper Silesia and Kraków, in particular, are severely afflicted.

THE PEOPLE

Ethnic composition. Before World War II the Polish lands were noted for the richness and variety of their ethnic communities. In the western and northern provinces of Silesia, Pomerania, and Masuria (then in Germany) there was a preponderance of Germans. In the southeast, Ukrainian settlements predominated in the regions east of Chełm and in the Carpathians east of Nowy Sącz. In all the towns and cities there were large concentrations of Yiddish-speaking Jews. The Polish ethnographic area stretched eastward: in Lithuania, Belorussia, and the western Ukraine, all of which had a mixed population, Poles were predominant not only in the great cities but also in numerous rural districts. There were significant Polish minorities in Daugavpils (in Latvia), Minsk, and Kiev.

The war resulted, however, in severe loss of lives, in massive migrations of peoples, and in radically altered borders, and as a consequence the population of Poland became one of the most ethnically homogeneous in the world. More than 98 percent declare themselves to be of Polish nationality, with Polish as their mother tongue. Ukrainians, the largest minority group, are scattered in various northern districts. Lesser numbers of Belorussians and Lithuanians live in areas adjoining the Soviet frontier. The Jewish community, almost entirely Polonized, has been significantly reduced. In Silesia (southwestern Poland) a significant segment of the population, of mixed Polish and German ancestry, tends to declare itself as Polish or German according to political circumstances.

Language. The Polish language, together with Czech, Slovak, and Sorbian (Wendish or Lusatian), belongs to the West Slavic group of languages, as distinct from the East Slav Group (Russian and Ruthenian) and the South Slav Group. It has numerous dialects that correspond in the main to the old tribal divisions of Great Poland, Little Poland, Pomerania, and Mazovia. In some instances—among the Kashubs of Pomerania and the Górale, or "Highlanders," of Podhale, for example—the distinctive features of the regional dialects are so strong as to suggest separate linguistic classification. Elsewhere, Polish has been influenced by contact with foreign languages. In Silesia the inimitable regional patois contains a mixture of Polish and German elements. Since 1945, as the result of mass education and mass migrations, standard Polish has

Coastal
settlements

The
industrial
region

West Slavic
language
group

become far more homogeneous, although regional dialects persist. In the western and northern territories, resettled in large measure by Poles from the Soviet Union, the older generation often speaks a language characteristic of the former eastern provinces.

Literary Polish developed from the medieval period onward, on the basis of the dialects of Great Poland and Little Poland. By the 19th century, Polish was well established both as a literary vehicle and as the dominant language of common speech in Poland, despite attempts of the partitioning powers to Germanize or Russify the population. Indeed, quite the opposite happened, and the Polish language became the main touchstone of national identity.

Religion. The overwhelming majority of the Polish population is Roman Catholic, and a large number are practicing Catholics. Poland is among the most uniformly Catholic nations in the world, and the Roman Catholic Church in Poland enjoys immense social prestige and political influence.

After World War II all religious institutions became subject to the control of the state office for religious denominations. In practice the Roman Catholic Church wielded a full measure of independence, partly through the sheer force of the faithful and partly because in all important matters it answered to the Pope in Rome and not to the government in Warsaw. The religious minorities, though encouraged by the anti-Roman Catholic policies of the Communist state, were barely visible except in local areas.

There are two Protestant strongholds—that of the Polish Lutherans in Masuria (Mazury; formerly East Prussia) and the Polish Calvinists (Augsburg Confession) in Cieszyn, Silesia. There is an autocephalous Polish Orthodox Church, partly linked with the small Belorussian minority, and a Ukrainian Uniate community, which survives in southeastern districts. Poland has residual communities of Polish Jews, whose synagogues and religious activities were officially sanctioned by the Communist government. The Polish National Catholic Church, a schismatic offshoot of Roman Catholicism, was strongly patronized by the government in the early years after the war but never won popular support. Small groups representing fundamentalist sects such as the Seventh-day Adventists and the Jehovah's Witnesses operate in a few cities.

Demographic trends. The population of Poland was transformed during and immediately after World War II. Of the 34,800,000 people who had been living within the Polish frontiers in 1939, only 23,600,000 were to be found within the new frontiers by 1946. The decrease of more than 11,000,000 can be accounted for mainly by war losses but also in part by changes in frontiers and by the migration of former Polish citizens whose homelands were incorporated into the Soviet Union.

War
losses and
postwar
migrations

Polish war losses are the subject of some controversy. The official figure, issued in 1947, was 6,028,000, although this referred exclusively to losses within the postwar frontiers. As a result of the changes in frontiers, millions of Germans were forcibly expelled in 1946–47, and millions of Poles were transferred from the Soviet Union in the same period. An estimated 500,000 Ukrainians and Belorussians also were transferred into the Soviet Union. At the same time, there were vast internal movements into the new northern and western territories annexed from Germany.

Population losses and movements on this scale introduced permanent distortions into demographic structures and trends. At the end of the war there were huge deficiencies in certain categories, especially males, urban dwellers, and the educated classes as a whole. Although the immediate postwar generation had an unprecedented birth rate, the gaps created by the war could never be filled.

Emigration has been a permanent feature of Polish life for most of the last 200 years, and roughly one Pole in three lives abroad. Wave after wave of political émigrés has left Poland since the mid-18th century. By far the greatest numbers of people have left, however, for economic reasons. Starting in the mid-19th century, Polish emigrants moved into the new industrial areas of Europe and later to America.

(E.I.U./A.H.D./N.D.)

Social structures. Although in the official view of the

Communist government the principal means of production were said to be under state control and Polish society was held to be classless, some private ownership of the means of production and remnants of the former class-based society did, in fact, persist. The presence of a large, private land-owning sector among the peasantry is a case in point. Another example was the rise of a distinct group of party elite, who in the official view were the best representatives of the working class. In the eyes of their critics the elite constituted instead a new privileged ruling class.

Polish society since the war has been transformed by two great movements—by the growth of a dominant, urban, industrialized working class and by the continuing drift of peasants from the rural areas into towns and cities. One group that has contrived to benefit from both movements is that of the so-called peasant workers, who tend to live on the fringes of industrial regions, with one part of the family maintaining the farm while other family members earn wages in the local factory.

THE ECONOMY

Management of the economy. After 1948, when the Communist government was initiated, Poland developed a command economy based on the Soviet model. All economic activity was subordinated to the dictates of the state's plans, which aimed to regulate the details of production, labour, trade, prices, and social priorities. Party planners and the state planning commission were responsible for the successive five-year plans. Managers of state enterprises had very little freedom to deviate from the dictates of the plans. Most sectors of the economy were state-owned and party-controlled, but even in the relatively extensive private sector the farmers, artisans, and retailers were required to operate within a rigidly fixed economic framework. The Council for Mutual Economic Assistance (Comecon), an organization of Eastern-bloc and other socialist countries, laid down the general framework within which Poland's own national plan was to operate. In 1989 the government began reforms to move Poland toward prohibition and a market economy.

Planning
the
economy

Employment. In Poland, as in other eastern European countries, state enterprises acted as the main employer after World War II. The principal branches of industry, services, and trade were directly owned by the state. As a result, the average worker had to accept the work, pay, and conditions offered. The legal self-employed sector, however, was surprisingly large, and small-scale private workshops, services, restaurants, and businesses proliferated.

Under the Communist government, unemployment did not officially exist, and no unemployment benefits were payable. In reality, there was considerable hidden unemployment or nominal employment of people on the state payroll who did not actually have any work to do.

Wages and cost of living. For 30 years prior to the economic crisis that came to a head in 1980, wages in Poland were stable, inflation was low, and extravagant food subsidies ensured minimum costs of subsistence. In 1980 both wages and prices began to inflate wildly, after which shortages of food supplies and consumer goods alternated with shortages of wage flows. By Western standards, the percentage of income spent in the 1980s on housing, heating, and services was minimal, while the relative cost of food, clothing, furniture, domestic appliances, and automobiles was colossal.

Trade unions. Under the Communist government, unions were registered with the Central Council of Trade Unions and approved by state and party organs. Inasmuch as the government was a monopoly employer in all important branches of industry and inasmuch as the trade union organization was run by the party, it can be argued that the trade unions were employer unions. Each union was organized on the basis of an individual industry, and links between employees in different trades or different enterprises were not possible. There was no free bargaining over wages or conditions.

The Independent Self-Governing Trade Union (Niezależny Samorząd Związków Zawodowych), known as Solidarity (Solidarność), was founded in September 1980, shortly after widespread strikes organized by the Inter-

factory Strike Committee had forced the government to sanction free and independent unions with the right to organize and to strike. Solidarity broke the monopoly of the official party unions, causing them to collapse. Solidarity quickly gained mass support, even among many party members, and extended its activities far beyond narrow syndicalist concerns.

Suppression of Solidarity

After December 1981, Solidarity and its dependent organizations, such as Rural Solidarity (Wiejska Solidarność), were officially suppressed, and the leaders of the independent labour movement were denounced as "criminals." The party ordered its managers and ministers to create new trade unions along the old lines of party control. Much of the membership of the re-created unions consisted of former Solidarity sympathizers, however, and the new unions were not entirely uncritical of party policy. In 1988, renewed labour unrest and nationwide strikes forced negotiations between the government and Solidarity, held in early 1989. The talks resulted in the legalization of Solidarity in April, as well as the scheduling for June of Poland's first free elections since World War II.

Resources. *Mineral resources.* Poland is relatively well endowed with natural resources. Its principal mineral asset is bituminous coal. Almost all the output is derived from the rich Upper Silesian coalfield. Brown coal (lignite) is mined as well. Other fuel resources include small amounts of petroleum and moderately large deposits of natural gas.

Sulfur is Poland's second most important mineral, and reserves are among the largest in the world. Other important nonmetallic minerals include barite, salt, kaolin, limestone, chalk, gypsum, and marble.

Among metallic minerals, copper and zinc are the most important. Reserves of zinc and lead ores are believed to be among the world's largest. Iron ore is mined in small quantities, although most of Poland's steelworks import ore directly from the Soviet Union. Nickel and other metals such as vanadium, cobalt, and silver are also produced.

Other resources. The quality of the soil varies, but there are large fertile areas, including Lower Silesia and the Little Poland Lowlands, the Kujawy, the Vistula delta, and the Lublin area. The soil is somewhat poorer in large parts of central and northern Poland. Some four-fifths of the country's wooded lands is occupied by coniferous timbers, with pine, larch, and spruce the most important as resources. The bulk of the country's hydroelectricity comes from the Carpathians, the Sudeten region, and the Brda and Vistula rivers.

Agriculture. Polish agriculture is unique in eastern Europe in that private farms still account for the greater part of total output. Following the abandonment of the collectivization campaign in 1949–55, more than three-fourths of Poland's farmland returned to private ownership. State farms on the Soviet model remained only on large-scale former German estates in the west and north. Cooperatives account for less than 4 percent of the land.

The Communist government did not promote modern private farming. Controls on land transfers, on prices and deliveries, and on the supply of fertilizers and machinery undermined incentives. Mechanization began in the 1970s, but efforts proved inadequate. Poland's peasants, still working in 19th-century conditions, often with horse and cart on a tiny plot, were unable or unwilling to produce surplus food for the state market. As a result, food shortages, bread queues, and rationing were a regular feature in the 1980s.

The aging agricultural population has experienced great distress. The drift from the countryside has left the villages without young people to work the farms, while the demands on agricultural production have steadily risen.

Industry. Impressive quantitative advances in industrial production have been overshadowed to some extent by shortcomings in quality and by problems of organization. Following the first six-year and five-year plans of the Stalinist era, industrial production surged dramatically until the mid-1970s. Growth was most marked in heavy industry: iron and steel, mining, chemicals, and machinery. In 1972 a new industrial strategy was launched with the aims of improving the consumer sector—especially by producing more automobiles and domestic appliances—and, on

Shocking wheat in Poznań province, in the Great Poland Lakeland region.

A. Tessore/Superstock

the basis of foreign loans, of greatly expanding modern technology and export production. Only six years later, with a hard currency debt of about \$30,000,000,000 and no signs of expanded trade or success in introducing high technology, Polish industry sank into a crisis, and from 1979 to 1983 industrial production declined sharply.

All but a small portion of the total electrical power output is derived from bituminous coal and lignite. Natural gas has largely replaced manufactured gas. Power shortages have been a constant feature of the economic crisis that began in the late 1970s. Domestic crude oil production contributes less than 5 percent to the annual consumption of petroleum, most of which has to be imported.

Finance. All financial institutions were owned by the state after 1944–45 and formed an integral part of centralized economic planning after 1949. The National Bank of Poland (Narodowy Bank Polski) has acted as the main agent of the government's financial policy, managing everything from the currency and money supply to wages and prices, credit, investment, and the detailed business of all state enterprises. Other important banks include the Commercial Bank of Warsaw (Bank Handlowy w Warszawie), the Investment Bank (Bank Inwestycyjny), the Agrarian Bank (Bank Rolny), and the General Savings Bank (Bank Polska Kasa Opieki).

Until 1990, internal monetary operations were conducted in inconvertible local currency, while external operations were conducted either in foreign currency, especially U.S. dollars, or, for the Soviet bloc, in special units of account such as convertible rubles. Exchange rates against foreign hard currency were flexible according to the needs of the state bank. In 1990, as part of a government program to move the Polish economy toward a free-market system, the exchange rate of the zloty, Poland's currency, was allowed to be set freely on the international currency markets. The establishment of stock exchanges was also part of the government's plan.

Trade. Although Poland has about one-fourth of eastern Europe's population, it accounts for only slightly more than one-tenth of its foreign trade. Imports exceeded exports by a considerable margin for several decades until 1982, when a nominal trade surplus was achieved by a radical reduction in imports.

A large measure of Poland's exports consists of machinery and transport equipment, with complete plants, power and electrical machinery, and vessels the most important items. Throughout the 1980s, many of these went to Communist and developing countries. Fuels and raw materials such as coal, coke, iron, and steel also figure prominently as exports.

(E.I.U./A.H.D./N.D./Ed.)

Private farms

Balance of payments

Transportation. Railways. The communications system in Poland developed in the 19th and early 20th centuries, in a period when the country was divided between Russia, Germany, and Austria. The three areas thus developed in different economic and political conditions, and the main railway lines were centred on the capital cities of the three empires. The density of the railway networks in the three sectors was uneven. In 1918 independent Poland took over the system and began to redesign and rebuild it according to the standard European gauge. Among the most important railway lines built after that date were those linking Warsaw with Poznań and Kraków and a coal trunk line linking Upper Silesia with the newly built seaport of Gdynia.

After the devastation of World War II the railway system was reconstructed once again, and the most used lines were converted to electric power. Because of the location of the country, Polish railway lines became important in the carriage of transit freight between eastern European countries, notably between the Soviet Union and East Germany and between Czechoslovakia and the Polish ports. The railways are administered by the Polish State Railways (Polskie Koleje Państwowe).

Highways. The highway system originally showed proportions similar to those of the railways; that is, the densest network was on lands belonging to Germany and the least dense on lands belonging to Russia. An attempt to remedy this situation was made between 1918 and 1938 and again, but more intensively, after 1945. Modern multilane highways adapted to mass traffic requirements have been built in Warsaw, and projects have been undertaken to link Warsaw to provincial centres.

Inland waterways and merchant shipping. The middle course of the main Polish river, the Vistula, is not regulated, and thus the Vistula is of less importance as a waterway than the smaller Oder. The Oder is linked by the modern Gliwice Canal (Kanał Gliwicki) to the Upper Silesian industrial region and carries coal to the port of Szczecin. The Oder basin is also linked to the lower Vistula by the Bydgoszcz Canal (Kanał Bydgoski). Inland navigation is of little importance in Poland, however, less than 1 percent of Polish freight being carried on rivers and canals. Shipping is well developed, and there are three large seaports—Szczecin (the leader), Gdynia, and Gdańsk—as well as smaller fishing and coastal navigation ports.

Air transport. Domestic and international air transport is provided by a state enterprise, LOT (from Polskie Linie Lotnicze). There are numerous international routes, centred on the airport at Warsaw.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. From 1948 to 1989 Poland was governed by the Polish United Workers' Party (PUWP; Polska Zjednoczona Partia Robotnicza), the country's Communist party, which was modeled on the Communist Party of the Soviet Union. In 1989, however, Communist party dominance ended, and Poland began a reform of its political structure.

The party-state. The postwar government was run as a dual system in which state organs outlined in the 1952 constitution were controlled by parallel organs of the PUWP. The executive branch of government, therefore, was in effect the PUWP, and various state organs functioned as the party's administrative branch. Although the constitution designated the chairman of the Council of State, which acted as a collective presidency, and the chairman of the Council of Ministers, which directed the work of the state ministries, as the highest officials, the party's first secretary was in fact head of state and the most powerful authority.

Communist party structure. The structure of the ruling party was highly centralized. The central organs—the Political Bureau, the Party Secretariat, and the Central Committee—oversaw the work of the province, city, and local committees. The Political Bureau, or Politburo, which was chaired by the first secretary, maintained effective control over everything else. Members of the Central Committee met periodically to approve the work of both the Politburo and the secretariat. In addition, they prepared the

program of the unicameral state legislature, known as the Sejm. Though the fact was not generally acknowledged by official sources, the party ensured its control over all offices and appointments by use of the *nomenklatura*, a list of politically reliable people that was managed by the Party Secretariat.

Other political parties. The Patriotic Movement of National Rebirth (PRON), founded in 1982 to replace the National Unity Front, was an organization run by the PUWP for managing all other political organizations, including the PUWP's two allied parties, the United Peasants' Party (Zjednoczone Stronnictwo Ludowe; ZSL) and the Democratic Party (Stronnictwo Demokratyczne; SD). No political bodies were permitted to exist unless they acceded in advance to PRON's socialist statute. This status changed in early 1989, when the government, after conducting talks with Solidarity on the country's political and economic problems, legalized the independent trade union. As agreed to by the government, the union fielded opposition candidates in the June 1989 national elections for a new bicameral National Assembly, in which the PUWP and its allies were guaranteed 65 percent of the lower house seats. Solidarity won the remaining seats in the Sejm and all but one in the Senate and was able to form a national government with the support of the SD and ZSL, which broke their alliance with the PUWP. PRON dissolved itself in November 1989, and in January 1990 the Polish Communist party congress voted to disband the PUWP, which was replaced by two rival social democratic parties, the Social Democracy of the Polish Republic and the Social Democratic Union.

State constitution and institutions. The constitution of Poland's postwar socialist state, the Polish People's Republic, took effect in 1952. In early 1989, fundamental reforms worked out between the government and Solidarity were passed by the Sejm, among which were the replacement of the Council of State by the office of president, which had been eliminated in 1952, and the reinstatement of the Senate, which had been abolished in 1946 in an allegedly rigged national referendum. The existing Sejm became the lower house of the new National Assembly. Additional forms passed later in 1989 by the National Assembly included the guarantee of free formation of political parties and the return of the government's official name to the Republic of Poland.

The 460 members of the Sejm and the 100 members of the Senate are elected every four years. The Sejm elects the prime minister, who is nominated by the president, and the two houses together elect the president.

The president, who is restricted to two six-year terms, has the power to dissolve the National Assembly and to veto legislation. A two-thirds majority in the Sejm is required to overturn the president's veto. Members of the Council of Ministers, who direct the various government ministries, are chosen by the prime minister but must be approved by the Sejm.

Judicial system. Judges, state prosecutors, and other court officials formerly were appointed by the party *nomenklatura*. Despite constant political pressure, the Polish bar maintained a lack of subservience unique in the Soviet bloc. As a result of constitutional amendments passed in 1989, judges are nominated by the National Council of the Judiciary and appointed by the president.

Regional administration. The regional administrative system is on two levels. The largest units are the *województwa* (provinces), of which there are 49. In the lower level, the *gminy* (rural communes) are responsible for the provision of some cultural and social services and for local land-use planning. The four largest cities are also divided into districts, called *dzielnice*, which have similar responsibilities.

The armed forces. Poland's armed forces consist of four services—the army, the air force, the navy, and air defense. Under the Communist government, the armed forces were highly politicized. The military command was controlled by the party's Main Political Administration, which also oversaw the political indoctrination and supervision of all units. Officers were trained in the party's Academy of Political and Military Sciences, and most

Polish
United
Workers'
Party

National
Assembly

were party members. Senior officers normally graduated from Soviet academies.

Poland became a founding member of the Warsaw Pact in 1955 and provided the second largest contingent after the Soviet Union. Poland's national defense is the responsibility of the 10 divisions of a separate structure called the National Territory Defense.

Security services. The regular defense of the frontiers is provided by the Frontier Defense Force (known by its Polish initials, WOP). The Office of the Protection of the Constitution (UOP), established in 1989, is charged with the country's intelligence services.

Normal civilian police services are under the authority of the Ministry of Internal Affairs. Under the Communist government, police services were undertaken by the Citizens' Militia, of which the Motorized Detachments of the Citizens' Militia (ZOMO) acted as a mobile, paramilitary riot squad, and the Security Service (SB), a secret political police force. In the early 1980s, ZOMO was extensively used to enforce martial law and to control demonstrations.

Education. Schools of all types and on all levels are free, the system of schooling is standard, and attendance throughout the eight-year primary school course and at supplementary study until the age of 18 is obligatory. The system contains nursery schools, primary schools, and secondary schools. There are several types of secondary schools offering basic vocational training, vocational and technical training, and general college-preparatory education. Basically, all schools are subject to the Ministry of National Education, but medical schools and colleges are subject to the Ministry of Health and Social Welfare, army colleges to the Ministry of National Defense, and higher schools of art to the Ministry of Culture and Arts.

Prominent universities include the University of Warsaw (founded 1818), the Jagiellonian University (1364) in Kraków, and the Catholic University of Lublin (1918). The highest academic institution is the Polish Academy of Sciences (Polska Akademia Nauk), which has numerous research institutes and represents Polish learning abroad.

Health and welfare. Health care in Poland is handled largely by the Ministry of Health and Social Welfare, which has authority over the health departments of the regional governments. Health service facilities include clinics; hospitals; sanatoriums, rest homes, and spas; ambulance services; and the national sanitary inspection. Private medical and dental practices have operated with varying degrees of official approval. The pharmaceutical industry is state-owned, but many medicines are available only with a special prescription or from abroad. Medical services have been seriously strained during periods of general economic crisis, and medical aid from foreign countries has played a valuable supportive role.

Social insurance for the health service covers free treatment for all workers and the members of their families, as well as for pensioners, invalids, students, and certain others. In addition, there is a social service whose purpose is to ensure a suitable means of support for the elderly and invalids. There are homes for social care, catering to pensioners, the chronically sick, and the mentally retarded.

As a result of the program of urbanization that began in the 1940s, Polish cities became overwhelmed by migrant workers from the countryside, and the demand for housing vastly exceeded supply. In urban areas, various cooperative housing schemes were put into operation by the local government authorities, but the standard family apartment was inadequate for many families. In the 1980s, waiting lists for a newly married couple could stretch for 10 or even 20 years. As a result, there was a great deal of private building, especially on the urban periphery.

CULTURAL LIFE

The culture of Poland has been nurtured on a great variety of traditions. Until World War II, because Poland was an area of multinational settlement, it could draw not only on the dominant Polish culture but also on that of the minorities, especially the Germans, Jews, and Ruthenians. The common Slavic element is weak, although aspects of it can be identified in language, literature, and folklore. The formative experience, undoubtedly, was the adoption

of Roman Catholic Christianity in the 10th century and the resultant millennium of involvement in "Western" civilization. German, French, and Italian influences have been particularly strong. Unlike Russia, Poland was deeply immersed in all the great movements of Western culture—such as humanism, the Renaissance, the Reformation, the Baroque, the Enlightenment, and Romanticism—and its cultural identity was already very strong before the series of partitions of Polish territory began in 1773. With the loss of political independence, the 19th and 20th centuries have seen an unrelenting struggle to preserve the national culture and its values from foreign impositions and government policy.

The Roman Catholic Church in Poland has played a social and cultural role far beyond the religious sphere. After World War II, catechism lessons, conducted with great zeal in the parishes, exposed children to a nonofficial view of the world. Church-sponsored societies, such as the Catholic Intellectual Clubs, provided adults with a unique forum for free public discussion. Parish halls provided shelter for a wide variety of uncensored exhibitions, plays, films, and meetings.

Folk culture. Because of rapid industrialization and urbanization, Poland's traditional folk culture has been seriously undermined since World War II. Regional dress, regional forms of speech, peasant arts and crafts, and religious and folk festivals have all been swamped by mass culture from the new cities and the media. In an effort to compensate, the Roman Catholic Church has tried to preserve the religious elements of folk culture, notably in the large annual pilgrimages to shrines such as Częstochowa, Kalwaria, Łanckorona, or Piekary Śląskie. The Communist authorities supported folk music and folk dancing. The colourful and stylized repertoire of the State Folk Ensemble, Mazowsze, for example, has won international acclaim. Several regional communities, including the Górale ("Highlanders") of Podhale, the Kurpie in the northeast, and the inhabitants of Łowicz, near Warsaw, have created an authentic blend of the old and the new.

Literature. Polish literature developed long ago into the main vehicle of national expression. For many Poles, their literature stands beside their religion as one of the twin pillars of their heritage. It provides one of their most cherished links with Western civilization and one of the main safeguards of their national identity. The close relationship between local political events and literary trends, however, together with a necessary resort to elaborate allegories, allusions, and symbols, has rendered many excellent Polish works inaccessible to the foreign public. (For detailed discussion, see POLISH LITERATURE.)

The first half of the 19th century witnessed the flowering of the three greatest Polish poets (Adam Mickiewicz, Juliusz Słowacki, and Zygmunt Krasiński), while in the second half, and at the beginning of the 20th century, the great Polish prose writers—including the Nobel prizewinners Henryk Sienkiewicz and Władysław Reymont—were active. Among the postwar Polish poets are Zbigniew Herbert and the Nobel prizewinner Czesław Miłosz.

Music. Polish music, like Polish literature, has a continuous tradition reaching back into the Middle Ages. As the least political of the arts, it has suffered less from official constraints. Founded on the inimitable rhythms and melodies of folk music—the *krakowiak*, *mazur*, and *polonez*—its native characteristics developed early, and a distinctive school of Polish church music already flourished during the Renaissance. The first major Polish opera, *Cud mniemany czyli Krakowiacy i Górale* ("The Pretended Miracle or the Krakovians and the Highlanders"), by Jan Stefani and Wojciech Bogusławski, was staged in 1794. In the 19th century Stanisław Moniuszko wrote a series of popular operas, including *Halka*, *Straszny dwór*, and *Hrabina*. Frédéric Chopin is usually considered to have created the quintessence of Polishness in music. In addition to his renown as one of the supreme master composers, he was the first of a constant stream of instrumentalists from Polish lands, among them many prominent Jewish performers who have conquered the international scene. Pianists such as Ignacy Paderewski and Artur Schnabel and violinists such as Henryk Szeryng and Isaac Stern

Secondary
schools

Religious
elements of
folk culture

attest to the vitality of Polish musical life. Contemporary Polish composition has been dominated by the names of Karol Szymanowski, Witold Lutosławski, and Krzysztof Penderecki. All branches of classical music—opera, symphony, chamber, and choral—are well represented in Poland, and several orchestras and choirs appear regularly on the international circuit. Popular music in Poland is derived largely from Western styles, although Polish jazz has earned a reputation for experiment and excellence.

Visual arts. From the Middle Ages many fine examples of Romanesque and Gothic architecture, both secular and religious, have been preserved, together with outstanding sculptures, among which the wooden altar triptych of Wit Stosz (Veit Stoss), in the Church of the Virgin Mary in Kraków, is the most famous. The vast red-brick castle of Malbork (Marienburg), once the headquarters of the Teutonic Knights, is among the most impressive in Europe. The architecture and sculpture of the Renaissance and Baroque periods were formed under Italian influence but nevertheless developed individual Polish forms, as in the town hall of Poznań or the decorated granaries at Kazimierz Dolny. Zamość, a model Renaissance city built in the 1580s, has survived virtually intact. The best preserved urban architecture of the late Middle Ages and Renaissance is that of the old town and Wawel Castle in Kraków. The classicism of the end of the 18th century and the beginning of the 19th left its most valuable monuments in some of the great palaces, like that of the Radziwiłłs at Nieborów or at Łazienki in Warsaw. There are many examples of imperial German and Russian architecture from the 19th century, among them Lublin Castle.

Painting attained its greatest development in the second half of the 19th century, representing styles developing at that time in western Europe, but again with specific national characteristics. The greatest fame was achieved by Jan Matejko, creator of monumental, romantic historical canvases, by Henryk Siemiradzki, and by a number of landscape and genre painters. The greatest sensitivity was shown in portraits by Stanisław Wyspiański, an artist active also in drama and design.

Theatre and motion pictures. The Polish national theatre, as distinct from earlier religious, court, and foreign plays that had circulated since the Middle Ages, dates from the end of the 18th century. The great pioneer was Wojciech Bogusławski, an actor, director, and author. Political conditions during the period of partition (1772–1914) inhibited theatrical development, however, and most of the Romantic masterworks of Adam Mickiewicz or Juliusz Słowacki were never staged during their lifetime. The comedian and satirist Aleksander Fredro earned a less exalted but no less lasting reputation. Kraków in Austrian Galicia became a centre of lively theatre at the turn of the century. Between World Wars I and II, Juliusz Osterwa in Warsaw and Leon Schiller in Łódź launched the experimental tradition. After 1956, once the era of socialist realism had passed, the avant-garde came into its own. The Theatre of the Absurd was explored alongside the revival of the classical repertoire. During the 1960s the Laboratory Theatre of Jerzy Grotowski gained international acclaim. Grotowski's theories and methods, which emphasized the nonverbal aspects of theatre, had a broad impact, especially in the United States. Henryk Tomaszewski's Mime Theatre saw parallel success. Tadeusz Kantor, a painter and designer, has been an important influence.

The origins of Polish cinema go back to 1909, but it was only in the late 1950s that its products began to attract worldwide attention. Just as the State Film School at Łódź earned high standing in the filmmaking profession, so the work of individual directors who broke free of official preferences achieved great success both at home and abroad. Undoubtedly, the leading name is that of Andrzej Wajda, whose films and theatre productions have set precedents for independence and excellence in exploring the conflicts in Polish society. Among other distinguished directors are Andrzej Munk, Roman Polanski, Aleksander Ford, Tadeusz Konwicki, Krzysztof Zanussi, and Agnieszka Holland. Historical epics have enjoyed great popularity. The Communist government supported war films and themes connected with the Nazi occupation.

Museums. In part because of colossal wartime destruction and in part also because historiography in Poland has long been subject to official controls, the need to preserve and cherish the records and artifacts of the past is felt with special urgency. Archives and museums of art, ethnography, archaeology, and natural history can be found in many Polish cities. The Czartoryski Museum in Kraków dates to 1805, the Melżyński Museum in Poznań to 1857, and the National Museum in Warsaw to 1862. After World War II, official policy concentrated on the creation of new regional museums in cities recovered from German occupation, on museums connected with the history of the Communist movement, on former private palaces and collections acquired by the state, and on sites connected with Nazi war crimes, such as Oświęcim (Auschwitz) or Majdanek. The Roman Catholic Church is active in preserving and exhibiting the art treasures and records connected with Poland's religious heritage.

Sport and recreation. Group sports and spectator sports are encouraged in Poland. Professional football teams attract large crowds in the towns, while local authorities provide facilities for athletics and swimming. Skiing and mountaineering in the Tatry and sailing on the Baltic or the Masurian Lakes are well developed. Individual or small-team sports such as tennis or golf are less available.

The media. With very few exceptions, during the period of Communist rule, the mass media, including all television and radio stations, were either owned or controlled by the state or the party. The Polish press included the official organs of the party and state, such as *Trybuna ludu* ("People's Tribune"), the organ of the PZPR; a wide band of less closely controlled semi-party newspapers and journals, such as *Życie Warszawy* ("Warsaw Life"), *Polityka* ("Politics"), a lively weekly, or *Twórczość* ("Creativity"), an intellectual monthly; the independent sector, headed by the respected Kraków *Tygodnik powszechny* ("Universal Weekly") and by the Roman Catholic journals *Znak* ("The Sign") and *Więź* ("The Link"); and the underground "free sector," in which local newssheets circulated. Restrictions on the media were eased in 1989, and Solidarity supporters began publishing numerous journals and newspapers, including the daily newspaper. *Gazeta Wyborcza* ("Voters Daily"; Eng. ed. *Gazeta International*).

Censorship. Under the Communist government the Main Office for the Control of Presentations and Public Performances (GUKPIW), with its headquarters in Warsaw, controlled the media, publishing, films, theatres, exhibitions, advertising, and related activities. The bureau maintained an office in all television and radio stations, press and publishing houses, film and theatre studios, and printing works throughout the country. Plans as well as prepared material required authorization, even for such printed items as wedding invitations, obituary notices, or stationery. All photocopiers and printing machines had to be registered, and access to them was closely controlled. All purchases of paper in bulk required a permit. Censorship of the foreign mail was routine. No sphere of information was immune, however distant from immediate political concerns; censors attempted not only to suppress material but also to mold all information at its source.

Despite the official controls, the spoken word was not generally suppressed in Poland, and the highly literate Poles became masters at writing and reading "between the lines." Also, unofficial information was available from the foreign media, from within the Roman Catholic Church, and in the vast realm of underground publishing.

(J.A.K./A.H.D./N.D./Ed.)

The
Polanie
tribe

occupied by the "Poles" lying in the basins of the Oder and Vistula rivers. The Polish nation originated from a union of such West Slavic tribes as the Polanians (Polanie), Vistulans (Wiślanie), Silesians (Ślęzanie), East Pomeranians (Pomorzanie), and Mazovians (Mazowianie). These "Polish" tribes shared a basically common culture and language and were much more closely related to each other than, for example, the Germanic tribes who founded the Franconian or German kingdom about 800–1024. Chronicles and geographical descriptions of Carolingian, Saxonian, Arabian, and Byzantine origin have described in some detail these Polish tribes, their names, and the regions where they lived. The Polanie tribe (open-country dwellers) lived in the fertile Polish heartland crossed by the Warta River, and this was the group after which the later Polish nation was named. Besides the Polanie tribe, there were approximately 20 Polish tribes that formed small states between the years 800 and 960. The individual tribes owed allegiance to regional leaders, chosen from an assembly of all free Polish males as commanders in case of war. Each tribe commanded several well-fortified castles or fortresses, the larger castles developing into principalities or "castle districts." There were usually fortified city-settlements (*suburbia*) near all the larger castles even in very early times. As early as 900–1025, along the Baltic Sea coast, there were large trading centres with between 6,000 and 10,000 inhabitants; these included Wolin (Wollin) and Szczecin (Stettin), on the mouth of the Oder River, and Truso (later Elbląg) and Gdańsk (Danzig), founded before 990 on the mouth of the Vistula River. The ancient foreign trade routes linking this area with distant regions stimulated the founding and development of small states. The most significant trade route from East to West connected Ratisbon (now Regensburg)—Vienna and Kraków with Kiev and Byzantium (now Istanbul). A well-developed monetary exchange system made it possible for the individual dukes to raise tariffs and tributes, in this manner exerting their sovereign rights on the monetary economy. Mining of precious metals and iron ores probably took place in Upper Silesia and in the Polish Central Highlands at that time.

The region grew into a larger state under the dynasty of the Wiślanie (or Vistulans), as early as 875, extending over the Łędzianie (who lived either on the upper Vistula or the upper Warta River) and perhaps even over some of the East Slavonic tribes on the Bug and San rivers. Around 875 to 880 the state and Silesia came under the sovereign rule of Great Moravia, led by Prince Svatopluk (ruled 870–894). Under his reign, Christianity was introduced in both its Latin and Greek forms through the disciples of "the apostles of the Slavs," Cyril and Methodius. Destroying Great Moravia, the Magyars conquered and settled the Hungarian lands from about 896 to 907. This restored the independence of southern Poland for a short time until it came under the control of the Bohemian dukes Boleslav I (died 967) and Boleslav II (ruled from about 973 to 999).

Both the Latin and Eastern Orthodox faiths were already well established in the area by this time, and the first bishopric of Kraków was established in 969. A territorial association was formed a few decades later, consisting of the tribes of southern Poland, commonly known as Little Poland (Małopolska). Little Poland, with the exception of a few border regions, covered the same area as the bishopric of Kraków.

The Piast dynasty. The second and politically more important founding of a state took place under the Polanie dynasty. The descendants of "Piast," the legendary founder of the dynasty—Siemowit (Ziemowit), Leszek (Lestko), and Siemomysł (Ziemomysł)—united the lands around Poznań, Kruszwica, Gniezno, and Kalisz, and this region later became known as Great Poland (Wielkopolska).

Mieszko I, c. 963–992. Siemomysł's son, Mieszko I, was the first of the Piast dukes to have his biography recorded in detail in the chronicles of that time. Through his desire to conquer Western Pomerania along the Oder River to the trading cities of Szczecin and Wolin, Mieszko I came into contact with the German kingdom, whose ruler Otto I the Great (the Holy Roman emperor) had conquered and subjugated Bohemia in 950 and all the

Polabic tribes (between the Elbe and the Oder rivers) between 936 and 955. This extended the sovereignty of the German king to the Oder River, and, for the time being, Mieszko acknowledged Otto's supremacy and entered into a close trade and cultural relationship with the Duchy of Saxony, Otto's homeland. To counter the German threat, Mieszko I entered into an alliance with the Bohemian duke Boleslav II, marrying his sister, Dubravka (Dąbrówka), in 965. Baptized in 966, he promoted the general spread of Christianity in his lands. In consequence, the year 966 is considered to be the year that marks the founding of Poland. The bishopric of Poznań was established in 968 and placed under the sovereignty of the archbishopric of Magdeburg. During the Great Slav Rebellion in 983, Germany lost its territory east of the Elbe and Saale rivers. In tacit agreement with Germany, Mieszko I conquered the entire coastal region of the Baltic Sea, including Szczecin, during 967 to 990. After dissolving his treaty with Bohemia, he further added Silesia and Little Poland to his other conquests. This established Mieszko as the ruler of an empire covering about 96,500 square miles (250,000 square kilometres) and populated by 1,250,000 people. Of decisive importance for the later development of internal unity was the fact that Mieszko submitted to the formal supremacy of the Holy See in Rome around 990. He took this step in order to avoid being subjected to the authority of the German Church.

Bolesław I the Brave, 992–1025. The eldest son of Mieszko I, Bolesław, further enlarged his empire, going beyond the ethnic boundaries of the Polish tribes. With Bolesław's help, the Holy Roman emperor Otto III set up his own Polish metropolitanate (church province), with the bishoprics of Kraków, Wrocław, and Kołobrzeg and the archbishopric of Gniezno, at the Congress of Gniezno (1000). The first bishop of Prague, Adalbert (Vojtěch), became the national patron saint of Poland in that year, following his martyrdom in 997 during his missionary work with the pagan Prussians in Samland in east Prussia. When Otto III died, Bolesław I conquered Bohemia, Moravia, the German borderlands in Lusatia (Lausitz), west of the Oder River, and probably also Slovakia between 1003 and 1004. But the new king of Germany, Henry II (ruled 1002–24), reconquered Bohemia and also led three campaigns against Bolesław I, without success. In 1018 Bolesław turned east, occupying Kiev for a short period and regaining the borderland at the Bug and San rivers, which had belonged to Poland before 981. Bolesław I was crowned king (presumably with the consent of the Holy See in Rome) on Dec. 25, 1024, and the new kingdom gradually became known under the name of Poland (Polonia) even during his reign. After his death the Polish monarchy came to be the secular symbol of the country's unity, in spite of all the partitions and divisions that the future held in store.

Attempts to expand Polish domination. *Mieszko II Lambert, 1025–34.* One of the younger sons of Bolesław I, Mieszko II Lambert was well educated but did not possess the strategic and statesmanlike talents of his father. After victorious campaigns against the barbarian Polabs in 1030, he attacked the German king Conrad II, who, in alliance with the grand duke Yaroslav of Kiev, attacked Poland (1031), further supported by rebellions within the country. Eventually, about 1033, Mieszko was forced to recognize German supremacy. His death in 1034 thus came at the height of a crisis. The boom in foreign trade that had been a factor in the establishment of the Piast empire had come to a close; the regional overlords were in a state of rebellion, and the barbarian insurrections deeply affected the barely established organization of the church. Chaos followed for the next few years (1034–39), the Bohemian duke Bretislav I occupying Silesia, totally devastating Great Poland, and resettling many of its inhabitants in Bohemia. The coastal regions from Szczecin to Gdańsk seceded from the Polish crown for about a century. The bishopric of Kołobrzeg—and with it the entire Christian movement in Western Pomerania—foundered again.

Casimir I the Restorer, 1039–58. A former monk, Casimir (Kazimierz) I slowly restored Poland with the help of the German king Henry III. Both Great Poland and

tion of
Christian-
ity

Little Poland recognized Casimir I as their duke in 1039–40. Mazovia followed in 1047 and Silesia recognized him in 1050, but Casimir had to pay tribute to Bohemia for Silesia.

Bolesław II the Bold, 1058–79. Casimir's successor, Bolesław II, continued the power politics of Bolesław I, leading many successful campaigns into Hungary (1060–77) and Kiev (1068–77). He also maintained the independence of Poland from Germany by skillfully taking advantage of a controversy between the German king Henry IV and Pope Gregory VII. With the help of the Pope he also renewed the crown of Poland. But after Henry IV had regained power (1077), a party of Polish nobles rebelled in his favour against Bolesław. For reasons unknown, Bolesław had decreed the execution of Bishop Stanisław of Kraków in 1079, and this led to open rebellion. Bolesław was forced to flee to Hungary, where he died in exile in 1081. His younger brother Władysław I Herman (1079–1102) sided with the imperial party and in 1088/89 married Judith, Henry's sister, and relinquished all claims to the Polish crown.

Exile of
Bolesław II

Bolesław III the Wry-Mouthed, 1102–38. Władysław's younger son, Bolesław III, again strengthened the position of the Polish monarchy, expelling his elder brothers and his half brother Zbigniew (1107). Two years later he drove back a campaign of the German king Henry V into Silesia. He reconquered all of the Western Pomeranian lands during 1113–22 and incorporated Eastern Pomerania and Gdańsk into Poland. Bolesław then ordered the final and complete Christianization of Western Pomerania and forced Polish rule on the land of Lubusz (Lebus), on the Oder, thus restoring the previous boundaries of the empire of Mieszko I. But the German emperor Lothair finally pushed the German frontier to the banks of the Oder and the western shores of the Neisse (Nysa) River. Bolesław was forced to swear allegiance to Lothair in return for Western Pomerania and the island of Rügen in 1135.

The period of division. Endeavouring to reconcile the separatist demands of the provinces with the needs of national unity, Bolesław III divided Poland among his sons, with the result that Poland ceased to be a united state for two centuries. The eldest son, who was already prince of Silesia and also owned Pomorze (Pomerania), was to have seniority over his brothers and rule over "the land of the senior," with its capital in Kraków; this territory stretched from western Little Poland to central Poland and on to the Baltic shore (eastern Pomerania and Gdańsk). His brothers ruled over Great Poland with Poznań and western Kujavia, Mazovia (in the basin of the middle Vistula) and eastern Kujavia (within the Vistula bend), and Sandomierz (east of Little Poland).

The seniority system. A "seniority constitution" was also introduced with this arrangement, but the plan immediately led to strife. The first "senior," Władysław II the Exile (1138–46), was forced into exile and fled to Germany. His brother Bolesław IV the Curly, hereditary duke of Mazovia, asserted himself as senior between 1146 and 1173, but this led to conflict with the German emperor Frederick I Barbarossa, who intervened twice (1163 and 1172) to secure Silesia for the sons of Władysław II. Władysław's sons divided it among themselves and founded the lineage of the Silesian Piasts; yet another son became the third senior. Of these sons, Mieszko III the Old (1173–77) was exiled from Kraków during a rebellion in 1177 but succeeded in retaining his hereditary land, Great Poland. His youngest brother, Casimir II the Just (1177–94), succeeded as senior after him and, in 1186, also acquired Mazovia, thus becoming the ancestor of the Mazovian line of the Piasts. After the Congress of Łęczyca in 1180, the land of the senior—Little Poland with its capital, the city of Kraków—became a hereditary land like the other lands. Both Pope Alexander III and the emperor Frederick I recognized this decision, but one of its great disadvantages was that the internal unity of Poland would be constantly exposed to foreign hereditary claims as a result. Leszek the White was the last duke who claimed the honour of senior with some success, but he was assassinated together with other Piast dukes in 1227.

The reign
of Mieszko
the Old

Territorial losses. The internal disintegration of Poland

led to the secession of the lands along the Baltic Sea and other border regions. Bogusław I (who ruled about 1156–87), the son of Warcisław I, was forced to yield Western Pomerania to the Danish crown. Even the reigning governor of Eastern Pomerania and Gdańsk, Świętopełk I (died 1266), took advantage of the weakness of the Piasts. Instrumental in the assassination of Leszek the White, he asserted his country's independence and styled himself sovereign duke of Eastern Pomerania, though regarded as a usurper by the Piasts.

The Teutonic Order. The establishment of the Order of the Teutonic Knights, a German crusading organization that had lost a sphere for its activities in Palestine, was of dangerous consequence for Poland. His lands harried by pagan Lithuanians, Jatvingians, and Prussians, Duke Konrad I of Mazovia (died 1247) called for help from the Teutonic Order in 1225–26, leaving them the lands of Chełmno (Kulm) east of the lower Vistula River as a territorial base for combat and control of the Prussians in 1228–30. The grand master of the Teutonic Knights, Hermann von Salza, received sovereign rights over the "masterless heathen country" of the Prussians in the Golden Bull of Rimini (1226) from the emperor Frederick II and in the Privilegium of Rieti (1234) from Pope Gregory IX. In spite of Konrad I's claim to sovereignty over the land, the Order established a system of local government in Chełmno and in Prussia. The subjugation and Christianization of Prussia was completed by 1283. The Teutonic Order soon became the principal military power in Europe.

Supremacy
of the
Teutonic
Order

Internal developments. In the era of knighthood, from about 1025 to 1241, the Polish aristocracy owned large landed estates and also occupied the most important administrative positions at court and in the provinces. With the continuous partition of the country from 1138 on, similar posts were also established within each individual duchy. The internal unity of the Polish nation remained intact, and, in accordance with Polish law, the dukes exercised no personal power but a collective sovereignty. From about 1058 Kraków was considered the common capital for about five centuries. A Latin church organization emerged, and the most important protector of the unity of Poland was the metropolitanate of Gniezno. The archbishopric of Gniezno held the largest estates in Poland (1136), controlling 149 cities and villages. The oldest monastery of Poland was established about 1044 in Tyniec (near Kraków) by the Benedictines, and the order of the Cistercians led the second wave. When Bishop Stanisław was canonized in 1253, Poland acquired a new national patron saint whose cult spread rapidly in the church province of Gniezno. As part of the community of the Holy See, Polish church members contributed the special levy, Peter's Penny, to Rome. The Synod of Łęczyca (1285) further promoted unity by demanding the advancement of the Polish language.

The Mongol invasions and attempts at reunification. The Mongol invasion (1241–42), in Poland's period of division, turned the tide of Poland's history. The Mongol leader Batu Khan first conquered Kiev and most of the Russian principalities before defeating the Polish army at Chmielnik and the Silesian knights of the Teutonic Order at Legnica (Liegnitz; 1241). This frustrated the attempt of the two Silesian dukes Henry I and Henry II to unite all the Polish lands. The Mongols retired in 1242 to elect a new great khan in Mongolia but still remained masters, for another 50 years, of Red Ruthenia, east of Little Poland; from this base their repeated raids devastated Poland. Meanwhile, Great Poland and especially Mazovia suffered from raids by the pagan Lithuanians (1246–1307) and Jatvingians (1248–82). The Mazovian border region around Drohiczyn on the Bug River was lost to Mongol Red Ruthenia around 1241–52, and the land of Lubus with its river passage across the Oder River to the Ascanians of Brandenburg, in about 1249–52. The Bohemian king Wenceslas II (1278–1305) attempted a new dynastic reunification of Poland. Establishing his sovereignty over most of the Silesian duchies around 1289–91, he also gained supremacy over the Duchy of Kraków in 1291–92.

The
Mongol
raids

Przemysł II. His opponent was Przemysł II (1279–96),

Reestablishment of the kingdom

who had reunited Great Poland (including Gniezno) in 1279 and Eastern Pomerania in 1294. His coronation by the archbishop in 1295 in Gniezno reestablished the kingdom of Poland. He was assassinated in 1296, presumably at the instigation of the Margrave of Brandenburg.

Wenceslas II. Wenceslas (Wacław) II of Bohemia, who succeeded him as king (1300–05), ruled over about two-thirds of all Polish territory. He considered these lands as an extension of Bohemia and, consequently, as part of the Holy Roman Empire. His death in 1305 and the assassination of his son Wenceslas III the following year left both the Polish and the Bohemian thrones vacant.

Władysław I the Short, 1314–33. The minor Piast prince Władysław the Short availed himself of the support of Hungary and the traditional protection of the Holy See. He occupied Little Poland in 1305 and sought the help of the Teutonic Order to regain Eastern Pomerania in 1308. The Teutonic Knights, however, bought the interests to these lands from the Brandenburg rulers and established themselves as the legal authority, incorporating Eastern Pomerania into Prussia. By 1314 Władysław had secured Great Poland, and in 1320 he was crowned king of Poland as Władysław I with the consent of the Roman Curia. This act restored the Polish Crown through a national dynasty, and for the next 475 years the crown was to remain the symbol of unity for Poland. The Piast dukes welcomed immigrant Germans and Flemings into Polish territories, and resettlement took place according to the municipal law of Magdeburg, based on German law.

Władysław I faced the opposition of a coalition between Bohemia and the Teutonic Order. The new Bohemian king, John of Luxemburg, laid claim to the Polish crown, and almost all of the Piast dukes in Silesia had recognized him as their feudal lord by 1327–29. Only the little principality of Wieluń (1321–29) was loyal to Władysław I. He instituted lawsuits against the Teutonic Order for the sovereignty of Eastern Pomerania but without success. The Teutonic Knights and the Bohemians terribly devastated Great Poland, especially in the war of 1328–32. At the Battle of Płowce (1331), however, Władysław drove them back and, in alliance with Hungary and Lithuania, secured Poland. Ties with Hungary were strengthened by the marriage of Władysław's daughter Elizabeth (Elżbieta) to the new Angevin king of Hungary, Charles I, in 1320, and the Polish crown prince Casimir (Kazimierz) was married to the Lithuanian princess Anna (Aldona) in 1325, thus creating a pact with Lithuania.

Casimir III the Great, 1333–70. Władysław's son Casimir was a talented statesman and administrator. During the congresses of Trenčín and Vyšehrad in Upper Hungary (Slovakia), he persuaded John I of Luxemburg to relinquish his claims to the Polish crown. In return, after an unsuccessful campaign in 1348 and in face of the Silesian Piast dukes' support of the Bohemian crown, Casimir was forced to renounce finally all demands on Silesia, the country's most densely populated and wealthiest region. In the Treaty of Kalisz in 1343, Casimir relinquished all claims to Eastern Pomerania in favour of the Teutonic Order—for the time being. Instead, he coerced the Piast dukes of Mazovia to recognize him as their overlord and seized parts of Mazovia. He also regained some of the lands in the west that had been annexed by Brandenburg. Between 1340 and 1352 Casimir won Red Ruthenia with the cities of Przemyśl, Lwów (Lvov), and Halicz; and in 1366 he extended his rule over the Ruthenian principalities of Chełm, Bełz, Włodzimierz, and Podolia. Casimir died in 1370 without a male heir, but in his will he appointed his grandson Casimir to be prince of Pomerania and awarded him parts of the Polish territory to tie Western Pomerania to Poland.

Louis I of Hungary, 1370–82. Poland nevertheless remained a unified kingdom under Casimir's successor, his nephew Louis I of Hungary. Louis, however, regarded Poland as his secondary kingdom, and a governor took over the administration of Halicz Ruthenia. The Polish aristocracy, a deciding factor in the succession to the throne of Poland in 1370 and 1382, obtained from Louis the grant of special privileges at Košice (Kaschau; 1374), which formed the basis of a Polish "Magna Carta."

Treaty of Kalisz

Internal developments and reform. The years from 1320 to 1382 marked the founding of many new cities, especially during the reign of Casimir the Great. Castles and fortifications, town halls, and merchant houses also were erected. Casimir also established local courts of justice for the cities of Little Poland (1356) and Great Poland (1365), in order to separate his country from the jurisdiction of Magdeburg and the need for its appellate court.

Even though a new social class of burghers and merchants evolved in the cities of Poland, the aristocracy remained the most influential group in politics. The first confederation of nobles in Polish history was founded in Great Poland in 1352–56. Since the previous official positions in the separate palatinates of Poland had long before become the benefices of the aristocracy, Casimir and Louis appointed a governor (*starosta capitaneus*) for each section of the country, after the example set by Wenceslas II (1291). The office of *starosta* remained the most important branch of executive power during the next 470 years. In the Statute of Wiślica (about 1346) Casimir codified the law that was in force in Little Poland. This *jus Polonicum*—the law of the nobility (as opposed to the *jus Teutonicum*, which was the law for the burgher-peasant population of Poland)—was later extended and applied throughout Poland.

The Roman Catholic Church influenced the character of public life in Poland. Poland had lost Silesia in 1348, but the Silesian bishopric of Wrocław remained under the church authority of Gniezno for another 400 years. The Dominican, Franciscan, and Augustine mendicant preaching orders had already built 80 monasteries in the metropolitanate of Gniezno by 1382. Yet, in spite of the power of the Roman Catholic Church, the ideal of religious tolerance became entrenched in the consciousness of the Polish people. In addition to Gniezno, the metropolitanate of Halicz–Lwów was established; and a separate Eastern Orthodox metropolitanate in Halicz (later Lwów), and an Armenian bishopric (later archbishopric) of Lwów were founded. Casimir's kingdom was the only continental European country where several Christian creeds were able to live side by side for any length of time two centuries before the Reformation.

Casimir the Great also provided, with the Statute of Wiślica (1346), protection for the Jews from pogroms and ritual murders at the hands of the Christians. When the Black Death raged through the German lands between 1348 and 1352, more than 300 Jewish communities were either destroyed or expelled from their homelands. The survivors migrated to Poland. Ever since, the majority of Polish Jews has consisted of Ashkenazim (from Germany). Retaining their own Middle High German language—later evolved into Yiddish—most of the Jews rejected any language assimilation until their near extermination by the Nazis during World War II. The Poland of Casimir thus developed into a cosmopolitan empire: Poles, Germans, Ruthenians, Flemings, Walachians, Jews, Armenians, and even Tatars and Karaites living together. Religious and political tolerance was reflected in the founding in 1364 of the University of Kraków, after Prague the second oldest university in Central or Eastern Europe, whose brilliant faculty of law prepared for the later juridical thinking during the Renaissance in Europe.

Religious tolerance

Founding of the University of Kraków

THE JAGIELLON DYNASTY, 1382–1572

Jadwiga and Władysław II Jagiełło. The union between Poland and Hungary was broken with the death of Louis because the Hungarian aristocracy chose his eldest daughter, Maria, to be their queen, whereas the Polish aristocracy gave preference to his 10-year-old daughter Jadwiga (1384). This was the first step in the direction of developing an elected Polish monarch. The Polish aristocracy favoured a dynastic alliance with Lithuania, especially in order to regain Red Ruthenia and Podolia, which had become estranged from Poland under Louis' regime.

Union of Poland and Lithuania. The grand duke of Lithuania (from 1377 to 1401), Jagiełło (Jogaila), was still a heathen; but after adoption by the widow queen Elizabeth in the Union of Krewo (1385), he was married to the crown princess Jadwiga. Jagiełło thus accepted the

Catholic faith and became the recognized "Master and King of Poland" under the assumed name of Władysław II Jagiełło in 1386. This procedure created a Polish-Lithuanian union that continued under the Jagiełło dynasty during the following 183 years. But the effect was that Poland was able to incorporate, during 1385–86, a state about four times as large as the original Polish realm. The bishopric of Wilno was established in 1387 to convert the Lithuanian people to the Catholic faith. Another area belonged to the Eastern Orthodox Church. The polyethnic, multireligious, and legal-constitutional structure of the Jagiełło empire was more complicated than ever before. The authority of Władysław II also included the old Russian capital Kiev, which had come under Lithuanian suzerainty in 1366 and was now reduced to the status of a residential border town. To the southeast of these lands stretched more than 58,000 square miles of almost uninhabited steppe country, which belonged to Lithuania in name only. The annexation of Lithuania secured the eastern boundaries of Poland against the attacks of the Mongol and Tatar tribes as well as against those from the great principality of Moscow, then under Mongol and Tatar control. It meant also, however, that Poland had to defend Lithuania against the incursions of the Teutonic Order. With the help of the Lithuanians (1387), Poland was able to renew the incorporation of Red Ruthenia and Podolia and to assert its authority over the principality of Moldavia (1387–1497), until then a minor country under Hungarian rule. This gave Poland access to the rich Oriental commerce that flowed via the cities of Caffa (Feodosia, in the Crimea) and Akkerman (now Belgorod-Dnestrovsky).

Władysław II and Vytautas. Władysław II and Jadwiga reigned together until Jadwiga's death in 1399. Władysław then ruled as the sole king of Poland until 1434. In Lithuania, Władysław found it expedient to acknowledge his cousin Vytautas (Witold; 1392–1430), first as governor, then as duke (1401), and finally as grand duke of Lithuania (1413). But he himself kept supreme command. To free his hands to attack the Tatars and annex Moscow, Vytautas surrendered the Duchy of Samogitia (Žmudź), which linked the Teutonic Order lands of Prussia and of Courland, to the Teutonic Order in 1398 in return for the cessation of all hostilities between them. He suffered a grave defeat in 1399, however, on the Vorskla River against the Mongols of the Golden Horde, which ended Lithuania's eastward expansion. Vytautas also supported rebellions in the still pagan Samogitia (1401 and 1409), which prompted the Teutonic grand master Ulrich von Jungingen to declare war against Władysław II in 1409. The Teutonic Knights suffered a decisive defeat in the Battle of Grunwald (Tannenberg) in 1410. The first Treaty of Toruń (1411) returned Samogitia to Lithuania; the return of Eastern Pomerania to Poland was discussed at the Council of Constance (1414–18) and was a factor in two later wars (1421–22 and 1431–35), but the Order remained in possession of the territory. When the Protestant Hussite rebellion broke out in 1419, Władysław II favoured the Hussites, even promoting his relative Sigismund (Zygmunt) as the Hussite candidate for the Bohemian throne in 1422. Because this brought him under suspicion of being a heretic and friend of the heathens, Władysław felt obliged to issue the strong Edict of Wieluń in 1424, against Hussite trends among the Polish nobility, and he crushed a pro-Hussite confederation of the lower Polish nobility in 1438–39. Władysław had obtained 16 mainly German mountain cities in the Spisz (south of the High Tatra Mountains) in 1412, thus giving Poland a share in the rich mining activities of upper Hungary.

Władysław III, 1434–44. Władysław II was succeeded on his death by his 10-year-old son, Władysław III, the chief position in the realm being held by the most eminent of the Kraków magnates, Zbigniew Oleśnicki, bishop of Kraków and one of the previous king's chief advisers. Władysław III renewed the Polish-Hungarian union with the help of the Hungarian commander in chief János Hunyadi. Under the influence of the strongly Roman Catholic Oleśnicki, he organized a crusade to save Byzantium, which was threatened by the Ottoman Empire.

Władysław died when only 20 in the catastrophic defeat of Varna (1444) on the Black Sea coast. The Ottoman troops conquered Byzantium in 1453 and marched immediately against Hungary. The threat was delayed for some decades, however, when Hunyadi defeated the Ottomans in 1456. But the Hungarian imperial administration of Hunyadi terminated the Polish-Hungarian union.

Casimir IV, 1447–92. The younger brother of Władysław III, Casimir, had been ruling as the grand duke of Lithuania since 1440, but it was only after a long interregnum in Poland that he was finally recognized as the king. He signed a treaty with Moscow that established the Lithuanian boundary about 90 miles west of Moscow. This secured the eastern boundary for 37 years. The peace in the east became important when, in 1454, uprising against the rule of the Teutonic Knights broke into the open, led by the cities of Gdańsk, Toruń, and Elbląg, which requested Casimir IV to integrate the Prussian-Eastern Pomeranian lands of the Teutonic Knights with Poland (1454). This marked the start of the Thirteen Years' War against the Teutonic Order. The second Treaty of Toruń (1466) recovered for Poland the former Eastern Pomerania (which received the new name of Royal Prussia), along with the bishopric of Warmia (Ermland). The rest of the territory of the Teutonic Knights acknowledged the king of Poland, and Königsberg became the new residence of the Order's grand master. Poland won back the access to the Baltic Sea that it had lost in 1308–09, and Polish rule stretched from the Baltic Sea to the Black Sea for a period of 32 years.

The King's main interest still lay with the so-often-attempted union with Bohemia and Hungary. Casimir IV succeeded in temporarily acquiring the Kingdom of Bohemia in 1471 (finally acquired 1478–79), for his oldest son Władysław (Vladislas). The smaller Bohemian lands, Moravia and Silesia, remained under the rule of Matthias I Corvinus, the son of János Hunyadi. But after the death of Matthias, even Moravia, Silesia, and Hungary recognized Władysław as their king (1491–92). The result of this dynastic union was the creation of one of the largest empires in Europe. By 1491–92 Casimir IV controlled an area of at least 336,000 square miles, while his son Władysław ruled the Bohemian lands of the crown of Wenceslas and the Hungarian lands of the crown of Stephen, an area of at least 174,000 square miles. This agglomeration of states was, however, as much torn by internal strife as it was exposed to external danger—the greatest external threat coming from the Ottoman Empire and its ally, the tsar of Moscow.

Political changes. Political authority in Poland was gradually taken over by the aristocracy. Aided by the mechanism of the election of kings, the many wars, and the tax exemptions, they were able to slowly reorganize the kingdom into a monarchy of the estates. The main organ of aristocratic authority was the Privy Council (1385–1493), which became the Senate after 1493. The rights and privileges of the nobility were successively established between 1422 and 1433, securing for them the right to a voice in political matters, their factual exemption from taxation, and finally the political and judicial maxim of habeas corpus, or no imprisonment without trial. After the Union of Horodło (1413), the regional assemblies slowly grew into provincial diets (*sejmiki*), becoming recognized as standing establishments in all parts of the country with the Privilegium of Nieszawa (1454). In addition to the Polish diet (Sejm), the Prussian diet held a special position with its own particular law. The lower nobility represented its own interests (usually directed against the hegemony of the aristocracy) through elected delegates.

These delegates marked the beginning of parliamentarism in Poland when they assembled for the first time in a House of Legates at Piotrków (1493). After this, the Polish Senate became the upper house and the House of Legates became the lower house of the Polish parliament, again called the Sejm. Lithuania also absorbed the culture and the system of government of Poland through the German municipal laws, introduced by the Polish burghers. According to the statutes of 1386–87, at first only the newly converted Roman Catholic nobles were equal to

the nobility of Poland, excluding the Eastern Orthodox Boyars, many of whom seceded to the Tsar of Russia. But the Lithuanian and Ruthenian nobles were gradually assimilated into the Polish sphere of interests, and in 1447–93 the first diets of the great principality were formed.

After the death of Casimir IV, his second son, John I Albert (1492–1501), ascended the throne of Poland, and the two countries were temporarily separated, his third son, Alexander, becoming grand prince of Lithuania. Alexander succeeded John Albert as king of Poland (1501–06) through the Union of Mielnik (1501), and Poland and Lithuania were thus united again. A statute of 1499 called the combined kingdoms a “republic” for the first time, terming the Union of Mielnik an indivisible body. The union became even further consolidated under the reign of the fourth of the Jagiellon brothers (Casimir IV’s sons), King Sigismund I the Old (1506–48). Ruled by the eldest of the Jagiellons, Władysław (1491–1516) and his son Louis II (1516–26), the combined Kingdom of Bohemia and Hungary remained only loosely connected with the unified Kingdom of Poland-Lithuania.

The Ottoman and Russian incursions. The Ottoman Empire directed its attacks mainly against the unified states of the Jagiellons, conquering the commercial trading cities of Kaffa (1475), Kilia, and Akkerman (1484). Poland was cut off entirely from the trade with the Orient. In addition, Poland found yet another enemy in the Tatars in the Crimea. These had come under Ottoman rule in 1475, and from 1492 they undertook pillaging and slave raids into Red Ruthenia and Little Poland. The Tatars of the Crimea pushed into Polish territory with the aid of the Ottomans, reaching Kraków in 1498–99. Moldavia had also come under the influence of the Ottomans and Tatars. John Albert, the brilliant Polish commander in chief, had always been victorious against the Tatars, but he suffered a heavy defeat at the hands of the Moldavians in the forests of Suceava in 1497.

Tsar Ivan III the Great took advantage of the situation, and, allying himself with the Tatars of the Crimea, he attacked Lithuania twice (1486–94 and 1500–03), capturing all the principalities on the Oka and Desna rivers as far as the middle of the Dnepr River. Another ally of Russia, the German emperor Maximilian I, laid claim to Bohemia and Hungary and prompted the states of the Teutonic Order to rebel against Poland. The result was that the grand master Frederick of Saxony (1498–1510) refused to swear his oath of allegiance, and his successor, Albert (Albrecht) of Hohenzollern, a cousin of the Elector of Brandenburg, went so far as to enter into an alliance with Russia (1517). Poland supplied armed help to Lithuania, but in spite of this Russia took the city of Smoleńsk (1514) in the course of two wars (1507–08 and 1512–22). After this, at the First Congress of Vienna (1515), Maximilian changed sides, renouncing the help of both Russia and the Teutonic Order. Instead, he entered into a mutual hereditary agreement with the Jagiellon kings with respect to the succession in Bohemia and Hungary.

The Ottoman troops advanced through Little Poland (1524), under the leadership of their sultan Süleyman I the Magnificent, and at the first Battle of Mohács (1526) they conquered the greater part of Hungary, killing King Louis II, the last Hungarian Jagiellon. The Ottomans next threatened Vienna (1529), and Poland found it wise to conclude a perpetual peace agreement with them in 1533. This did not, however, prevent the Muslims from threatening Poland’s southern boundaries from bases in Hungary—a threat that was to last for about 140 years.

Renewed Moldavian and Russian attacks were repelled by the Polish troops under the brilliant leadership of Jan Tarnowski. Sigismund I the Old was able to incorporate the Duchy of Mazovia into his empire after the death of the last of the Piasts in Mazovia (1524–29). His campaign from 1519 to 1522 also secured Polish sovereignty over Prussia. Albert of Hohenzollern became the first secular duke of Prussia to swear an oath of allegiance to Sigismund (1525), and the land came to be known as Ducal Prussia.

Sigismund II Augustus, 1548–72. The son of Sigismund the Old, Sigismund Augustus, was the last Polish Jagiellon. Trying to secure his country against the Ottoman and

Russian empires, he sought alliances with the emperor Charles V and the Roman king Ferdinand I (1549). This at least brought him Charles’s final renunciation of any intervention in settling the question of the constitutional position of both Royal and Ducal Prussia. For 24 years Tsar Ivan IV the Terrible had led a war of conquest to obtain the remains of the lands of the Teutonic Order in Livonia (1558–82), and he succeeded in occupying part of the territory. This prompted Sigismund Augustus to enter into an agreement (the Union of Wilno [1561]), with the last grand master of the Order, Wilhelm Ketteler, integrating Livonia directly with Poland while Courland (now a secular duchy) had to recognize the authority of Poland. This antagonized Russia, which invaded Poland and conquered the lands of Połock on the Dvina River in the first Nordic War (1563–70). Under pressure of the Russian threat and the lack of an heir to the throne, the Sejm combined the former crown lands, Lithuania, Royal Prussia, and Livonia in the Union of Lublin, creating a unified and indivisible republic (1569).

Political changes. The Polish population now began to integrate the nobility, the burghers, and a large part of the peasantry in the Lithuanian–Ruthenian regions in the east. From about 1420, but in particular between 1540 and 1580, the people of densely populated Mazovia began to migrate. Resettling, they colonized the enormous virgin forests in the west of Lithuania—particularly Podlasie. Moving south, they also settled in the Duchy of Prussia. As early as 1582, there were more than 150,000 Jews among the many nationalities of the Polish Commonwealth, more than in all the rest of Europe. The two main parts of the country that composed the Polish Republic—the crown lands and Lithuania—each retained its own ministers, treasury, and army. Unification was finally accomplished by the consolidation of a common elective kingdom with a diet consisting of two houses. The upper house seated about 100 senators, and the lower house about 150 delegates. This arrangement created a Royal Republic in 1569, with a constitution that was similar to the constitutions of England and Hungary, and it remained basically unchanged for the next 226 years.

Between 1493 and 1569 the Polish Estate Kingdom slowly evolved into a parliamentary monarchy, which was governed almost entirely by the nobility. The Sejm of Piotrków, in 1493, was the first of about 200 diets that would be convened in the course of the next 300 years. From the assembly of the Sejm of Mielnik in 1501, the king was regarded as the president of the Senate, and in 1505 the constitutional act *Nihil Novi* (“No innovations”) decreed the making of laws to be the sole right of the parliament. The supreme authority of the aristocracy led to a growing opposition from the ranks of the lower nobility, who were incensed at the aristocracy’s virtual escape from the burdens of taxation. The lower nobility at last secured their own appointment to the supervision of the highest courts of appeal and secured the formal recognition of their equality with the aristocracy, together with the prohibition of titles (*e.g.*, duke, prince, margrave, count). The superiority of the aristocracy over the lower nobility continued, however, since the aristocracy remained in possession of the wealthiest estates, while the lower nobility were very often poor and propertyless.

Economic changes. The “Golden Age” of Poland expressed itself in the wealth of the country and a favourable boom in its foreign trade. The autonomous free republic of Gdańsk (Danzig) controlled about 80 percent of Poland’s foreign trade and became the most important trading city of central and eastern Europe by 1576. The production of raw materials was in the hands of the propertied Polish nobles, now turned into farming entrepreneurs.

The nobles extended their previous manorial domination over the peasant class with statutes passed in 1496, 1518–20, 1532, and 1543 that reduced the peasants to virtually the same status as property; they came under the jurisdiction of the nobles and, as a result, lived under conditions of virtual slavery as cheap labour for the nobles’ farmstead economy. The discovery of the Americas paved the way to the second feudal system in Poland, made possible by the imports of gold and silver from the American conti-

ment. In contrast, the same era led to the establishment of modern manufacturing plants and industrial enterprises in western Europe, ushering in the period of early capitalism.

Cultural developments. The Renaissance and the Age of Humanism set their stamp for ever after on the spiritual and intellectual life in Poland. The first Polish books were printed between 1514 and 1524; the art of book printing spread, as did general school education. Young Poles studied at major foreign universities, particularly at Padua, at Bologna, and at the Sorbonne, as well as at the Protestant universities of Wittenberg, Leipzig, Königsberg, Tübingen, and Basel. The department of astronomy at the University of Kraków achieved renown through Nicolaus Copernicus (Mikołaj Kopernik; 1473–1543) and his work on the motions of the planets. Polish literary language came into its own, supplanting the use of Latin alone by scholars.

The Reformation. The Reformation came to Poland from Germany, Italy, France, and Bohemia between 1523 and 1526. Lutheran and Calvinist denominations were established alongside the originally Hussite Bohemian Brethren and the Anti-Trinitarians, or Arians (from about 1562–65). Under the leadership of Laelius Socinus (1525–62) and Faustus Socinus (1539–1604) the Arians strove for both a rational secularization of religious life and a radical change in society, including the liberation of the peasantry. In spite of the first suppressive edicts of 1520–26, the Reformation gained strength, particularly after the Sejm suspended the secular execution of ecclesiastical sentences (1552). After this, Poland was the only country in Europe without religious persecutions for about the next 130 years. The Lutheran, Calvinist, and Hussite denominations consolidated in 1570 at the Concord of Sandomierz, but this soon disintegrated because of dogmatic differences. The Compact of Warsaw in 1573 removed the Catholic Church from its dominant position, introducing the constitutional equality of all religions—the first enactment in Europe of complete religious tolerance.

THE ROYAL REPUBLIC AND THE VASA DYNASTY, 1572–1697

The Interregnum and reform of the monarchy. The Interregnum, or period without a ruler, lasted from 1572 to 1575. During this time the republican constitution was further improved and extended. The election of Henry III of Valois (1573–74)—King Henry III of France from 1574—established the basic rule that not only the council of the aristocracy but also all nobles and squires should elect the king. This meant a formal victory for the lower nobility and the founding of the Polish rule by the nobility. The fundamental basis of the constitution, the “Henrician Articles” of 1573, required the king to swear an oath reducing his authority to no more than that of a contract partner in a sovereign nation of nobles. The king was also obliged to convoke the Sejm every two years; and between the sessions he was to be advised by a group of senators. Should the king fail to observe any of these articles, the nation was *ipso facto* absolved from its allegiance.

The next elected king was Stephen Báthory (Stefan Batory; 1576–86), who had defeated the emperor Maximilian II. During his reign Jan Zamoyski, who had helped to gain the victory for the lower nobility during the Interregnum, rose to the positions of grand chancellor (1578) and grand hetman (commander in chief; 1580). Stephen Báthory and Zamoyski defeated Tsar Ivan IV with three brilliant campaigns (1578–81), forcing the Russians to return the occupied territories of Livonia and Polock by 1582.

Sigismund III Vasa, 1587–1632. Báthory was succeeded by Sigismund III Vasa, who defeated Maximilian of Austria. Since he was also the legitimate king of Sweden—as the son of John III Vasa of Sweden and of Catherine, daughter of Sigismund I—Sigismund established a brief Polish-Swedish union, but this soon fell apart as the result of Swedish-Lutheran opposition to the Catholic faith of their king.

Revolting against Sigismund III in 1599–1600, Sweden pursued the Swedish-Polish war for 35 years, but Sigismund never relinquished his demands for the Swedish crown. The Polish grand hetmans Zamoyski and Jan Chodkiewicz were at first able to repel the attacks of the

Swedes against Livonia (1600–09). They won a famous victory in the Battle of Kirkholm (1605), although outnumbered four to one by the Swedes. In the meantime, a Polish volunteer corps helped the False Dmitry to gain the tsar's throne in 1605–06. Sigismund found it necessary to openly intervene in Russia (1609–13) when a coup d'état took place there. Under the leadership of Stanisław Żółkiewski, the Polish army won a brilliant victory at Klusyn (1610) against a sixfold Russian-Swedish majority. Polish troops occupied Moscow (1610–12), but they were driven out by the new tsar, Michael Romanov. The important fort of Smoleńsk remained with Poland.

At the outbreak of the Thirty Years' War (1618), Sigismund remained officially neutral but favoured the Austrian side. The Prince of Transylvania had advanced and besieged Vienna, but a decisive victory by the Polish army in 1619 prepared the way for the Austrian victory at the Bila Hora (Weisser Berg, or White Mountain) in 1620. Although the Poles won a decisive victory against the Turks also at the Battle of Chocim on the Dnestr River in 1621, the Turkish attacks did not cease for another decade. Taking advantage of this Polish predicament, Sigismund's cousin, Gustav II Adolf of Sweden, occupied Livonia and its important Baltic seaport Riga (1621). At the Peace of Altmärk, the Swedes temporarily gained possession of Livonia as well as of some Royal Prussian port cities (1629–35).

Władysław IV Vasa, 1632–48. A highly talented field marshal, Sigismund's son Władysław IV (1632–48) assured the existence of Poland when he repelled the renewed attacks of the Turks, Russians, and Swedes (1633–34). He also reconquered, in 1635, the Prussian ports on the Baltic Sea that Sweden had occupied. But his plans to establish a Polish navy that would hold its own against the Swedish domination of the Baltic, to regain sovereign rights over Livonia (1639), and to prepare for an extensive war against the Ottoman Empire (1646–47) were all frustrated by the disinclination of the Polish nobles to wage wars. They wanted peace at any price in order to take advantage of the splendid opportunities opening up on the European market in the wake of the Thirty Years' War.

The prominent powers in northern, eastern, and south-eastern Europe had attacked Poland constantly and had forced the republic into repeated compromises on the question of sovereign rights over the Ukraine and the Duchy of Prussia. Meanwhile, the nomadic Ruthenian-Eastern Orthodox farmers—the Cossacks—had established themselves in the Ukraine, and their number was steadily growing with the addition of escaping peasants from Poland and Russia. The Polish landed estate owners could hardly keep them under control over the vastness of the barely populated steppe that the Cossacks inhabited. The Cossacks eventually rebelled against the constant attempts of the Polish estate owners to reduce them to the state of bonded peasants, and their leaders demanded a position of equality with the Polish nobility. The Cossacks remained the foremost social danger in the republic, allying themselves with the Tatars in 1648.

In 1618 John Sigismund, elector of Brandenburg (1608–20), also became duke in Prussia, and thus the two crowns were in personal union, though the sovereignty over Ducal Prussia remained with the Polish crown. His grandson, however, the Great Elector Frederick William (1640–88), by clever maneuvering between Sweden and Poland, succeeded in removing Ducal Prussia from Polish sovereignty by the Treaty of Welawa (Wehlau) in 1657. From then on, the Brandenburg state of Prussia became the most dangerous of Poland's neighbours, not least because Frederick William intended to establish a territorial connection between Western Pomerania and the Duchy of Prussia, henceforth a leading aim of Brandenburg-Prussian politics until the First Partition of Poland about 115 years later. It threatened to cut off Poland from its connections with the Baltic Sea.

Economic and political changes. The booming years between 1577 and 1654 became the high point in the history of Polish economics. At that time, Poland was considered, appropriately, the “granary of Europe.” Polish grain was exported to France, England, Spain, and sometimes even

campaigns
against
Tsar
Ivan IV

to Italy and the Middle East via Amsterdam, the most important grain stock exchange. Gdańsk soared in importance to the rank of a trade city of world renown. As a result of this foreign-trade boom, the landowners pushed the farmstead economy to its very limits, developing estates into tremendous areas. In many cases the servitude of the peasantry became actual slavery. This caused a number of small rebellions by the peasants, many of whom escaped into the Ukraine.

The economic power of the magnates encouraged the forming of groups of supporters among propertyless voters who would keep their votes at the disposal of one particular aristocrat, thus enabling the magnate to command entire districts of the provincial Sejm and, if necessary, even to paralyze it. In this way the original, formal "democracy of nobles" based on about 150,000 voters had evolved into an oligarchy of about 300 families. This was to prove a decisive factor in the later disintegration of the Polish republic. The undermining of the power of the Sejm culminated in a procedure that made it possible for just one delegate to disrupt it through the liberum veto. The liberum veto was based on the assumption of the political equality of every Polish gentleman, with the corollary that every measure introduced into the Sejm must be adopted unanimously. Consequently, if any single deputy believed that a measure already approved of by the rest of the house might be injurious to his constituency, he had the right to exclaim "Nie pozwalam" ("I disapprove"), the measure in question falling at once to the ground. All efforts toward increasing the power of the central government were held to be against traditional freedom and were opposed. This principle was extended still further until a deputy, by interposing his individual veto, could at any time dissolve the Sejm, and all measures previously passed had to be resubmitted for the consideration of the following Sejm. The liberum veto was used for the first time during the Sejm of 1652, but before the end of the 17th century it was used so recklessly that all business was frequently brought to a standstill. It thus became the chief instrument of foreign ambassadors or native magnates for dissolving inconvenient sessions, as a deputy could always be bribed to exercise his veto.

The Counter-Reformation. Poland experienced the effects of the Counter-Reformation after the Council of Trent (1545–63). Led by prominent scholars such as Cardinal Stanislaus Hosius (Stanisław Hozjusz), who introduced the Society of Jesus, or Jesuits, in Poland in 1564, a total of approximately 50 Jesuit establishments were founded in the republic between 1564 and 1654. The Jesuit colleges in Połock, Smoleńsk, and Černigov and the Jesuit Academy of Wilno (founded in 1578–80) were mainly intended for the conversion of Eastern Orthodox Russia to Catholicism. Through their colleges and schools, the Jesuits established a dominant influence on the education of the Polish people that would last for about two centuries. Piotr Skarga was the most prominent theologian and politician among the Jesuits. The Order of the Camaldolese also supported the Counter-Reformation. The Counter-Reformation led to religious disorders; many of the Protestant churches were closed, especially in the large royal cities (particularly between 1574 and 1612); and the number of Protestant parishes diminished as many of the aristocratic dynasties reverted to Catholicism. By 1650 there were not more than 270 non-Catholic parishes left in the country. Only the established German-Lutheran Church in the city republics of Prussia and the Calvinist Church in Lithuania (approximately 140 churches) remained important. The most significant result of the Counter-Reformation was the Synod of Brześć in 1596, whereby six of the 10 Eastern Orthodox eparchies acknowledged the authority of the Holy See in Rome. Declared illegal and schismatic in 1595, the Eastern Orthodox faith was again recognized in 1635. Its spiritual centre became the Academy of Kiev, modeled after the colleges of the Jesuit order. The Protestant academies of Gdańsk and Leszno retained their European distinction, however, and John Amos Comenius, the philosopher and pedagogue, taught in Leszno.

John II Casimir Vasa, 1648–68. The reign of the last of

the Vasa kings in Poland, John II Casimir, is remembered in history as a period of bloody wars and disasters.

The era began with a rebellion of the Ukrainian Cossacks, led by Bohdan Khmelnytsky, who heavily defeated the Polish troops in 1648 and 1651 and established their own military state (1651–54) with the armed assistance of the Tatars of the Crimea and the Ottomans. In the Union of Pereyaslav, in 1654, the Cossacks acknowledged the authority of the Russian tsar Alexis Mikhailovich. On the strength of Cossack aid, Alexis attacked Poland, conquering almost the entire eastern part of the country, as far as Lwów, in 1654–55.

Charles X Gustav of Sweden took advantage of the Polish predicament and occupied the Polish and Lithuanian lands of the republic in 1655, receiving some support from the native aristocrats and from Frederick William of Brandenburg. John Casimir fled to Silesia, and the majority of the nobles (among them the future king John III Sobieski) recognized Charles as their king, particularly after he had promised to reconquer the eastern part of Poland from the Russians and Cossacks. The extraordinary brutality of the Swedish army, however, gave rise to a general revolt against Charles, and the Swedes were not able to take the two largest cities of Poland (Gdańsk and Lwów). The brilliant grand hetman Stefan Czarniecki eventually destroyed the Swedish and defeated Frederick William's Brandenburg army between 1655 and 1657. In the treaties of Welawa (Wehlau), Bromberg (Bydgoszcz), and Oliwa (Oliva, 1660), Poland recognized the "superior power of government" of Frederick William over the Duchy of Prussia but reserved the right to reversion with regard to the duchy and did not relinquish this right until 1773.

The Ukraine again entered into a union with Poland in 1658, and Russia was decisively defeated in 1660–62. Nevertheless, Russia obtained Smoleńsk and the eastern half of the Ukraine in the truce of Andruszów (Andrusovo; 1667), after the rebellion of Jerzy Lubomirski against the King of Poland. Having been instrumental in bringing about the greatest catastrophe in the history of Poland, John II Casimir finally abdicated in 1668. The war, the bubonic plague, slave raids, and mass murders had reduced the total population to approximately 4,000,000 people, or 45 percent of the former total population. The cities suffered worst of all, losing all manufacturing establishments and industrial enterprises along with three-quarters of all their inhabitants. The tremendous costs of the war caused the greatest inflation in the history of Poland. Religious feeling was fanatically inflamed since the war had been conducted in the spirit of a religious struggle, and the Protestant parishes almost totally disappeared. The constitutional maxim of religious tolerance was finally abandoned in 1648–58.

Michael (Korybut) Wiśniowiecki, 1669–73. The short reign of Michael (Korybut) Wiśniowiecki was dominated by internal fighting between the Habsburgs, led by the King, and the French-oriented faction that had gathered around John Sobieski, a military commander of rising fame. The Cossacks seceded again in 1667, allying themselves with the Ottoman Empire (1668), and in the succeeding Turkish attack in 1672–73, the Poles lost Podolia and two-thirds of the Ukraine.

John III Sobieski, 1674–96. A brilliant victory in 1673 established John Sobieski as the "vanquisher of the Turks" and brought him the crown of Poland in 1674. In spite of his many successes in the fight against the Ottomans (1675–76) and despite his liberation of Vienna in 1683—a crucial factor in the development of European history—John III Sobieski was not able to regain the regions in the southeast of the republic held by the Ottomans. He also failed in his attempts to secure the return of the Duchy of Prussia to Poland through treaties with France (1675) and Sweden (1677). Poland's participation in the Holy Alliance against the Ottoman Empire (1684) and the many Turkish campaigns of John III Sobieski (1684–92) eventually aided the development of Austria and Russia as new great European powers. With the Peace of Carlowitz (Karlöwice, 1699), Poland again received Podolia and the Ukraine west of the Dnepr River. Given to Russia for two years in 1667 but never returned to Poland, the city of

THE SAXONIAN ERA AND THE RUSSIAN PROTECTORATE, 1697–1763

Augustus II the Strong, 1697–1733. On the death of John III, no fewer than 18 candidates for the vacant Polish throne presented themselves. The successful competitor was Frederick Augustus I, elector of Saxony, who renounced Lutheranism for the crown. Under his reign as Augustus II the Strong, Poland experienced a new wave of wars and catastrophes. The planned union between the industrially developed Saxony and raw material-producing Poland would have been advantageous for the economy of both countries, but that did not materialize because the King, as ambitious as he was lacking in talent, became involved in a war with Sweden through his alliances with Peter I the Great of Russia and King Frederick IV of Denmark.

The Northern War. These allies attacked Sweden and began the Northern War (1700–21). The Swedish king Charles XII repelled Denmark and Russia in 1700 and marched from Livonia into Poland (1701–02), the latter serving him as the base for his future military operations. Appointing Stanisław Leszczyński (Stanisław I) as puppet king (1704), Charles XII invaded Saxony in 1706 and forced Augustus to abdicate. During the civil war of 1704–10, Swedish troops totally devastated Poland, and the Saxonian and Russian armies fared little better. Cultural losses were enormous, and one-third of all Polish cities lay in ruins. Although by 1702 the population had recovered again, reaching about 8,000,000, war and then the bubonic plague of 1709 took their toll, and other disasters reduced the population to about 6,400,000. Poland was spared any further Swedish occupation when the Swedish troops advanced into the Ukraine, where they suffered a decisive defeat at the Battle of Poltava (1709). Stanisław Leszczyński escaped from Poland in 1710, and Augustus II again assumed the crown with the particular support of Peter the Great of Russia. Breaking all agreements with Poland, the Tsar annexed Swedish-held Livonia (1710), the very land that had given Augustus II the pretext to start the war. Then the Tsar turned east and put down the last Cossack rebellion in the Polish Ukraine (1702–04), which the Polish Sejm had provoked by despotically deciding to disband the Cossacks in 1699.

The Prussian situation. The Hohenzollern prince Frederick III had assumed the title of king of Prussia in 1701, with consent of Augustus but without the approval of the republic, which alone had the power to grant this title. In 1715 King Frederick William I tried to acquire the Polish Prussian territory, again with the approval of Augustus. The intervention of Peter the Great, who resided in Gdańsk at the time, frustrated this attempt in 1716, and the Russian troops remained in control of the southern coast of the Baltic Sea. Peter thus assumed the role of protector of the territorial integrity of the Polish republic. From then on, Poland was to all intents and purposes a protectorate of Russia, and this relationship lasted until the dissolution of the republic in 1795.

Augustus III, 1733–63. The French-supported candidate, Stanisław Leszczyński, was elected king for the second time after the death of Augustus II in 1733. The Russian and Saxonian armies interfered, however, forcing the election of his opponent, Augustus III, the son of Augustus II. It was in his reign that Prussia conclusively achieved the position of a European power under its king, Frederick II the Great (1740–86). He annexed Silesia between 1740 and 1745, securing control of the western boundaries of Poland as well as of Polish foreign trade at the points where it was shipped overland to central and western Europe. Inhabited mainly by Poles, the southeastern half of Silesia retained political and cultural ties with Poland, but the Prussian annexation ended the church sovereignty of the metropolitanate of Gniezno over Silesia.

The Seven Years' War. During the Seven Years' War (1756–63), the Russian army used the territories of Gdańsk, Toruń, and Poznań as operational bases in their war against Prussia. Frederick II ordered the counterfeiting

of Polish money, a measure that severely damaged and inflated the monetary system of the republic.

Social, religious, and political change. During the peaceful era between 1716 and 1768, the population grew rapidly, due to both the steady immigration of Germans and the mass exodus of an enslaved peasantry from Russia. By 1772 Poland's population numbered approximately 11,420,000. Comprising more than one-half of all the Jews in the world, the Jewish population of Poland lived in all parts of the country. The Counter-Reformation reached its zenith under the Jesuits, who trained students of noble birth in their greater colleges and other educational institutions. In 1717 and 1733 laws were passed that restricted the spiritual and secular rights of the non-Catholic population. Popular education fell to its lowest level. Spreading through all the other parts of Europe, the Age of Reason affected Poland only by virtue of some individual achievements. Parliamentary life came to an almost complete standstill. Under the reign of Augustus II only four of a total of 13 diets came to an orderly conclusion; under Augustus III only one out of 13 did so, as the result of the use of the liberum veto.

REFORM AND PARTITION

Stanisław II August Poniatowski, a former diplomat, gained the crown of Poland with the help of Russian troops in 1764. Aided by his relatives, the Czartoryski, he tried to introduce political reforms, among other things the temporary abolition of the liberum veto in 1764–66, but his plans failed because of the objections of Catherine II the Great, the Russian empress. Taking advantage of the religious quarrels in Poland, the Empress sent Prince Nikolai V. Repnin as Russian minister to Warsaw with instructions that led to further discord in Polish affairs. Of Poland's population of 11,500,000, about 1,000,000 were dissidents, one-half Protestant and one-half Orthodox. For these people, who had been largely deprived of their rights by the laws of 1717 and 1733, Repnin, in the name of the Russian empress, demanded absolute religious and political equality with the Catholic population of Poland. He was well aware that an aristocratic and Catholic assembly like the Sejm would never concede such a demand.

Early in 1767 a confederation was formed at Repnin's instigation to send a deputation to Catherine, petitioning her to guarantee the liberties of the republic. Subsequently, but not without a stubborn resistance, the Sejm accepted Catherine's authority, and the so-called fundamental laws were enacted, guaranteeing the liberum veto and all the other ancient abuses as unalterable parts of a Polish constitution ensured by Russia. All the restrictions against the dissidents were repealed at the same time.

These events led to a Catholic uprising known as the Confederation of Bar, aided by the Turks. After four years of fighting (1768–72), the Russian troops were able to gain the upper hand. Frederick II of Prussia tried to use this civil war to achieve a partition of Poland, but he met with the resistance of Catherine II. Only the threat of Austrian troops advancing against Russia and the Austrian annexation of some Polish territory in the Carpathian Mountains forced Catherine to seek help from the Prussian king on his terms—namely, the partition of Poland.

The First Partition and reform efforts. With the First Partition of Poland in 1772, the republic lost about 28 percent of its territory, the Livonian and White Ruthenian regions north of the Dvina River and east of the Druć River falling to Russia. Austria received Little Poland south of the Vistula River and almost all of the Red Ruthenian territory under the name of the Kingdom of Galicia. Prussia obtained the smallest but most valuable property, namely, Royal Prussia, comprising Warmia (Ermland) and a part of Great Poland on both sides of the Noteć River, though without the cities of Gdańsk and Toruń. Through this annexation Prussia had not only acquired the desired land connection between Western Pomerania and East Prussia that it had tried to secure for almost 120 years, but it had also gained control over approximately four-fifths of the total foreign trade of Poland. By levying enormous custom duties on the Polish foreign trade going via this route, Prussia made this its most important source of income.

Civil war of 1704–10

Intervention by Catherine the Great of Russia

Prussian control of foreign trade

Prussia was now able to shake off the last vestiges of the old Polish sovereign rights; the treaty of 1773 established the full and complete sovereignty of Prussia over its lands.

The shock of the First Partition caused political and economic reforms in Poland—as far as Russia would permit. The taxation system and the army were thoroughly reorganized, and with the Permanent Council, in 1775, Poland installed its first real central government. Many landed estate owners carried out individual peasant emancipations, and almost 200,000 Germans and at least 300,000 Russians emigrated to Poland, a land that was considered free. Slowly, the cities began to flourish again, and the beginnings of an industrial revolution could be observed with the rise in mining activities, the advances of the textile industry, the founding of the first joint-stock companies, and the employment of the first machine equipment. Polish intellectual pursuit and reasoning received fresh impetus when the Age of Reason was finally accepted. The King promoted the political theories of such men as Edmund Burke and George Washington, while the educated Poles advanced the political theories of Montesquieu and Rousseau. But whatever the theory, the concept of modern democracy, including all ranks and classes of society, quickly became established in Poland. The first governmental department for public education in Europe was established in conjunction with the appointment of an education commission in Poland in 1773. Its task was the reorganization of the universities of Kraków and Wilno, as well as the supervision of approximately 80 gymnasiums. The printing of books and the publication of magazines and journals also flourished.

The first codified constitution in Europe since antiquity and the second in the world after the United States, the new Polish constitution passed by the “Four Years Sejm” embodied the following ideas: first, the precept of a “people’s sovereignty,” which included the nobility as well as the metropolitan bourgeoisie; second, the constitutional separation of powers between the executive, legislature, and judiciary; and third, the responsibility of the cabinet to parliament. The liberum veto and all the obstructive machinery of the anomalous old system were abolished. According to its own rules, this constitution had to be revised after 25 years at the latest. But Catherine II considered such a constitution dangerous to the existence and continuation of her own autocratic governmental system; she therefore ordered her troops to invade Poland in 1792, and the reforms were destroyed by force.

The Second and Third Partitions. The Russo-Prussian treaty of 1793 (the Second Partition) placed almost all the Red Ruthenian and White Ruthenian lands under Russian rule, while Prussia received Gdańsk, Toruń, Great Poland, and part of Mazovia. In 1794 a general popular insurrection broke out under the leadership of Tadeusz Kościuszko against this latest Russo-Prussian humiliation. Kościuszko achieved a partial liberation of the peasant class and began a general armament of the people, mobilizing more than 150,000 men. At first the Polish forces were almost universally successful; but ultimately Kościuszko was defeated by the Russian troops under Aleksandr Suvorov at the Battle of Maciejowice, and Warsaw capitulated at the end of 1794. Russia and Austria—joined later also by Prussia—agreed to the Third Partition of Poland in 1795. Russia annexed the territory east of the Niemen and Bug rivers, Austria took almost all of Little Poland, including Kraków, and Prussia received the remaining lands, including Warsaw. Stanisław II abdicated officially in 1795. For all official purposes, at least, this was the end of the Republic of Poland, which was eradicated from the map of Europe for the next 123 years.

POLAND UNDER PARTITION, 1795–1914

The Russian, Prussian, and Austrian sectors. With the Third Partition of Poland in 1795, the largest part of the territory fell to Russia. Officially, Catherine II called these partitions a return of Russian territory, even though such a claim dated back 450 years. Proclaiming the unity of all Russians, the largest part of the Uniate Church returned to the fold of the Eastern Orthodox faith. In spite of this, the Polish constitution and culture remained fairly unaf-

fected at first in these “Russian” parts, where Poles still held positions of influence.

Because Russia’s level of civilization was still extremely low under the reign of the tsars Paul I (1796–1801) and Alexander I (1801–25), the government was unable to administer the area without Polish help. The land had been divided into eight governmental units in 1801; and since the Poles retained basic administrative control, the municipal rights, control of the Polish county courts and of the Polish diets remained in force for a number of years (1796–1831). This region had the highest standard of civilization, culture, and education within the realm of the Russian Empire—with the exception of the Baltic Sea provinces—and the fundamental principles of the Russian educational system were based on the essential features of the Polish educational institutions of this region.

The Prussian area consisted of the three provinces of West Prussia, South Prussia, and New East Prussia. Together with the province of East Prussia, which had not been under Polish rule since 1657, the country came to be known officially as the Kingdom of Prussia, a part of the Prussian monarchy. Of its population of almost 4,000,000, however, about three-quarters were ethnic Poles.

The Kingdom of Galicia, as the Austrian section was known, was repeatedly reorganized administratively. Most of the native intellectuals in both the Prussian and the Austrian sections were replaced by German administrators who governed in autocratic fashion. In these areas numerous nationalist secret societies were established.

The struggle of the patriots. As early as 1768, Polish emigrant groups were formed in Hamburg, Dresden, Constantinople, and particularly in Paris. The group of Polish Jacobins organized in Warsaw and Wilno (1792–94) had established connections with the French Revolution, especially through Józef Sułkowski, who had politically supervised Napoleon Bonaparte in his capacity as secret police inspector (1796) of the French Directoire. Branching out from their Jacobin origins, the conspiratorial Society of Polish Republicans, formed in Warsaw around 1798–1800, and the Warsaw Society of the Friends of Science, founded in Warsaw in 1800, served partially as a cover organization for Jacobin activities. The centre of the conspiratorial network was in Paris, but it gained a particularly strong hold in Galicia after the French-Austrian War of 1792–1801. Gen. Jan Henryk Dąbrowski, who had gained his fame from the defense of Warsaw in 1794, established Polish legions in northern Italy in 1797, recruiting men from Austrian prisoners of war of Polish nationality. The legions fought without any political success against Austria between 1797 and 1801.

Prince Adam Jerzy Czartoryski, the Russian foreign minister, tried to reestablish the Polish Republic from the sector occupied by Russia. He was aided in this by the tsar Alexander I. The plan was designed to create a buffer zone against Prussia, then allied with France. The idea lost its rationale, however, when Napoleon I of France attacked Prussia in 1806 and Russia came to the aid of Prussia. The French advance against Poznań and Warsaw paved the way for a general Polish insurrection against Prussia, led mainly by Jan Dąbrowski and Józef Wybicki.

Napoleon’s Duchy of Warsaw. Taking some purely Polish areas of the Kingdom of Prussia, Napoleon I created the Duchy of Warsaw, placing it under the rule of the king of Saxony, Frederick Augustus (1807). The constitution dictated by Napoleon I and the introduction of the Code Napoléon called for the personal liberation of the peasants. But the soil remained fundamentally with the landed nobility, and therefore this liberation promoted rather than alleviated the agrarian population surplus in Central Poland. Józef Poniatowski (1763–1813), the nephew of the last king, distinguished himself as field marshal during the war of 1809, when the Duchy of Warsaw acquired the Austrian part of the Second Partition, including Kraków, as well as Zamość, annexed with Galicia in 1772. Thus, the Duchy of Warsaw had by this time grown to almost the same size as the Prussian monarchy. The failure of Napoleon’s war against Russia in 1812, however, meant that by 1813 the Duchy of Warsaw had come under Russian administration.

Repartition and repression. The Congress of Vienna (1814–15) established the territorial division of Poland (within the boundaries of 1772) until 1918. In accordance with the Prussian demands, the Grand Duchy of Poznań was detached from the authority of the Duchy of Warsaw and incorporated into the Prussian monarchy. Cut off from the Duchy of Warsaw as well, the “Free City of Kraków” was designated to be the “symbolic capital of the divided Poland,” though these intentions came to an end when Austria annexed the city in 1846. Galicia remained an Austrian hereditary land.

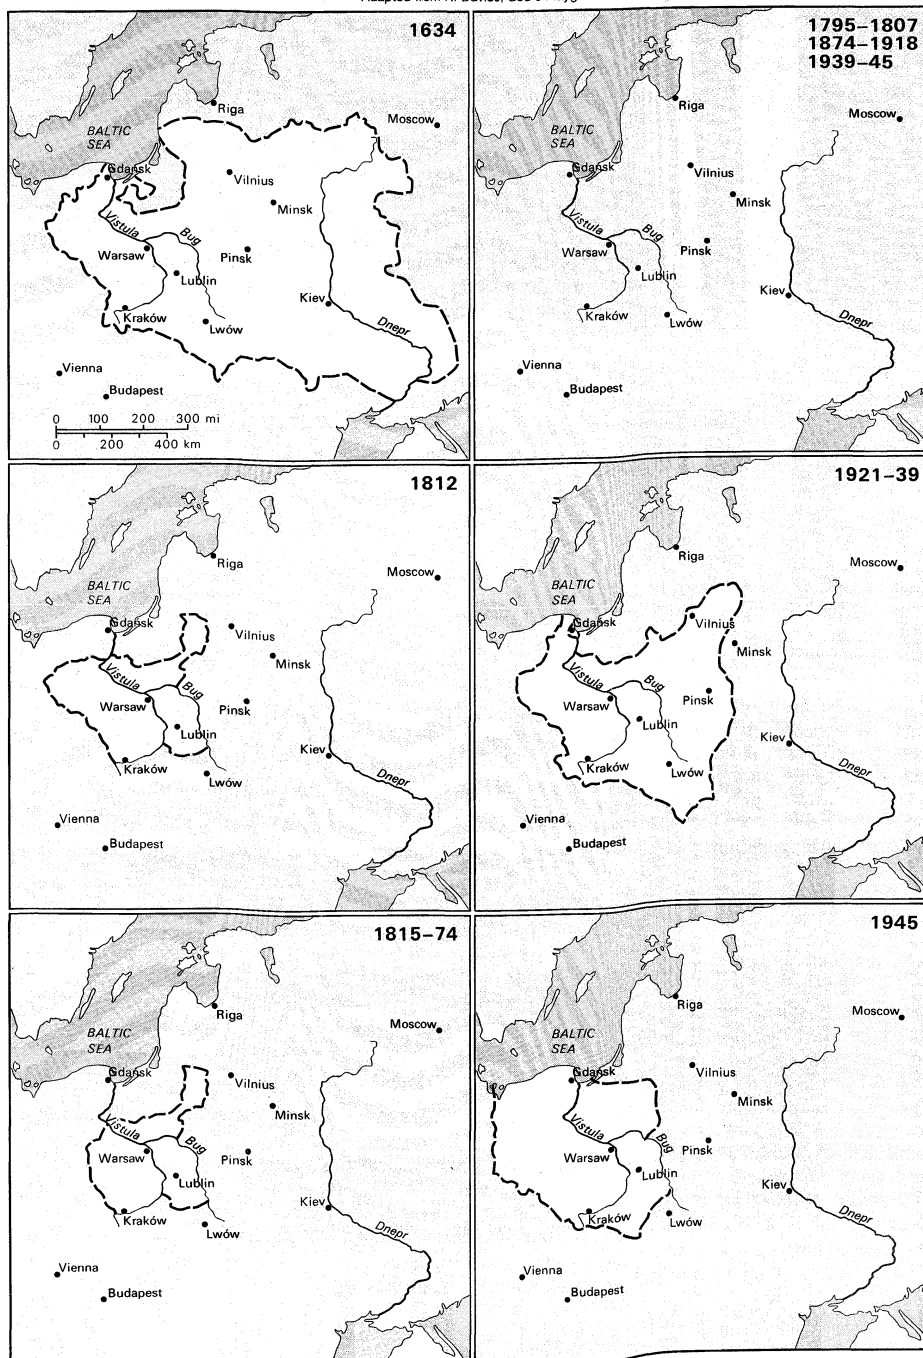

The Kingdom of Poland. The main part of the Duchy of Warsaw was given the title of Kingdom of Poland in 1815. Approximately four-fifths of its population (more than 4,000,000 in 1827) were ethnic Poles, of whom as many as 325,000 were nobles. This area thus came to be considered as the Polish nucleus. After the Congress of Vienna, in 1815, this Congress Kingdom of Poland, or Congress Poland, as it often came to be called, was united

with the Russian Empire, though it retained its own governmental system, its own Sejm, and its own army. Tsar Alexander I was now in command of about three-quarters of all the historically Polish territories and, being not only the tsar of Russia but also the king of Poland, he was well advised to try to win the loyalty of the Polish people.

The constitution of the Kingdom of Poland, passed between 1815 and 1831, was considered the most liberal in all of Europe. The population of the Congress Kingdom of Poland included more voters than France, whose population was six times greater. A severe impediment, however, was the fact that Alexander I reigned with the harshness of an absolute monarch from 1819 on, breaking the constitution several times. This again promoted the creation of secret societies, the most consequential of which was the National Freemasonry (1819–25) under the leadership of Walerian Łukasiński. Similar secret societies were founded in Kraków, Poznań, and especially in the University of Wilno, where the Society of the Philomats functioned

Changes in Poland's territory from 1634 to 1945.

as a front for several conspiratorial groups. Even Adam Mickiewicz, the greatest Polish Romantic poet, became involved in the affairs of the Philomats and was sent into exile for some time. The secret societies continued and flourished, despite repression at the hands of the Russians.

The Rising of 1830 and the aftermath. Alexander's successor, the autocratic tsar Nicholas I (1825–55), planned a military campaign against France and Belgium after the revolution in France in July 1830. He was going to send a Polish army to accomplish this, but most of the Polish ensigns banded together to create the November Insurrection on Nov. 29, 1830, under their leader Piotr Wysocki. Almost the entire army and the majority of all Polish politicians joined in the insurrection, and the Sejm proclaimed the ousting of Tsar Nicholas I on Jan. 25, 1831, an act that led to a formal war between Russia and Congress Poland. The war lasted from January to September 1831, the superior Russian forces finally defeating the Poles, who received no response to their appeal for western European protection. About 6,000 leaders of the rising were forced into exile during 1831–32, most of them emigrating to France in what has become known as the Great Emigration.

The suppression of the November Insurrection meant heavy reprisals in the Russian as well as in the Prussian Polish areas, even though the latter had no actual part in it. Extensive confiscations of estates, deportations, and enforced recruiting were designed to break the national patriotism of the Poles. The universities of Warsaw and Wilno were suppressed, and Polish students were compelled to go to St. Petersburg (now Leningrad) and Kiev in Russian Poland. The remainder of the Uniate Church was abolished and converted to Eastern Orthodox between 1831 and 1839, though continuing to exist in Congress Poland until 1875 and in Galicia until 1945. The Organic Statute of 1832 replaced the constitution, the Sejm, and the army in the Kingdom of Poland; and the land was united with the Russian Empire in a true union, although officially the kingdom retained a few autonomous rights.

The conservative group of emigrants led by Adam J. Czartoryski, the "king in exile," tried to solve the Polish question through legal and diplomatic means. His minimum goal was the restoration of the legal status of 1815, which had been violated from the very beginning. The radicals had splintered into many factions, but the Polish Democratic Society founded in 1832 soon emerged as the leading organization. Its Manifesto of Poitiers of 1836 was less realistic than the program set up by the conservative side, because its revolutionary agenda demanded an independent Poland within the borders of 1772. But the Manifesto proclaimed the idea of a land reform without compensation to the present owners, and this drew many supporters. In the years between 1833 and 1846, emissaries and leaders of the partisans of the "left" established secret revolutionary cells in all parts of Poland. These cells were persistently traced down by the authorities, and thousands of their members were deported or imprisoned.

The 1846 insurrection. The Polish Democratic Society gained a certain influence in the country with the installation of a committee in Poznań between 1839 and 1846. This committee drew up a plan for a general revolution, but the Prussian police discovered it in 1846. In spite of this, a central government in Kraków, under the revolutionary leaders Jan Tyssowski and Edward Dembowski, tried to get an insurrection started. The uprising spread to Galicia, where Austrian troops soon put it down, at the same time inciting the local population so that many Galician peasants turned against the revolutionaries. The failure of the 1846 revolt severely weakened Polish participation when a general revolutionary wave swept through Europe during the early spring of 1848–49. Originally, Prussia and Austria had nominally supported Polish demands for independence, but now attempts by the Poles to establish a real independence were resisted by armed force in both countries. The course of this revolutionary struggle showed clearly that the fight was no longer only about the ideal of a unified republic based on the boundaries of 1772 but also about the Romantic Idealism of the time, which favoured individualistic, linguistically and cultur-

ally separated nationalities. On the other hand, nationalist ambitions now extended beyond the borders of 1772 for the first time. The Polish question also gained more impetus on the international scene. Adam Mickiewicz founded a new Polish legion in Italy and a little later published the moderate socialist newspaper *La Tribune des Peuples* in Paris (1848–49). The landed gentry of Poznań financed the *Neue Rheinische Zeitung* ("The Newspaper of the Rhineland"), the journal through which Karl Marx and Friedrich Engels in 1849 proclaimed the national liberation of Poland to be one of the most important tasks of the workers' movement of Europe.

Alexander II and the rising of 1863. The Eastern Question and the Crimean War (1853–56) caused violent upheavals within the Russian Empire, which motivated Alexander II (1855–81) to take a more conciliatory stand toward the Kingdom of Poland. A series of reforms were implemented, in their later stages by the autocratic count Aleksander Wielopolski, who was installed in high office and stood for a national policy of loyal union with Russia. His methods and character lost him the support of the moderate gentry, however, and aroused the outright enmity of the young patriotic radicals, who were influenced by ideas expressed by Napoleon III of France and by the national reunification of Italy (1859–60). (The left wing of these radicals became linked with the Russian liberal movement and the international emigrants in London centred around Karl Marx and Aleksandr Herzen.) Religious ceremonies became occasions of political demonstrations, rioting broke out in Warsaw, and the situation culminated in the widespread insurrection of Jan. 22, 1863, sparked off by Wielopolski's plans to press the revolutionary youth of the cities into the Russian army. The revolutionaries had relied on French and Austrian support, but these hopes proved to be in vain; and to make matters worse, Prussia again cooperated with Russia. As before, the ethnic groups in the Russian sectors—Poles, Lithuanians, and the Catholic White Ruthenians—united in a common war against the Tsar that lasted for 15 months, though the insurrection was finally crushed when the rebel "National Government" was detected by the Russian administrative authorities on April 10–11, 1864. The defeat was followed by executions, confiscations, and deportations, and all hopes for the Polish people to establish an autonomous national state were ended for the next half century. The Russian government did proclaim, however, the liberation of its peasants on March 13, 1861, and it extended this to the Kingdom of Poland on March 2, 1864. By so doing, it took the most important traditional premise for the revolution out of the hands of the revolutionaries. The agrarian policy, however, was expressly calculated to stir up ill feeling between the peasants and the country gentry, whom Russia was determined to punish in every way for their leading part in the insurrection. Yet the agrarian reforms accelerated the growth of towns and industry and the new social structure produced both financiers who exploited the great possibilities of the Russian market and a new working class, among whom the first socialist organizations began their secret activity.

The founding of modern Poland, 1864–1914. After the failure of the January Insurrection, a policy of harsh repression fell upon the Poles remaining in the Russian and Prussian sectors. The Russian sector was now officially named the Western Region of the Russian Empire, and its governor general, Mikhail Nikolayevich Muravyov (who became known as the "hangman of Wilno"), made every effort to stamp out Polish culture altogether.

Russification. The Kingdom of Poland was reorganized as the Land of the Vistula under a purely Russian administration. The University of Warsaw became a Russian university in 1869. Russification of all secondary schools was implemented from 1869 to 1874 and of all other public schools after 1885: the Russians accomplished their aim of keeping illiteracy among the common people at as high a level as possible. Consequently, by 1905 there were relatively fewer schools and students in the Land of the Vistula than there had been in 1815. Nearly all private schools and all social and political activities were prohibited.

Galicia

Prussian and Austrian Poland. Following the Russian example Otto von Bismarck, the German chancellor, instituted a similar policy, and the Prussian sector was incorporated into the newly founded German Reich. In 1872 the entire school system was Germanized. The Colonization Law of 1886 tried to integrate German peasants into the native Polish population. Polish autonomy was able to achieve some success only in the Austrian sector, where its most important agency was the Galician provincial Sejm. The Poles in Austria became the country's second nationality, and they were allowed to participate in the government at Vienna and retained sovereignty over the Ruthenians in Galicia. Galicia itself became the haven of Polish culture, with the University of Kraków, the University of Lwów, and the Academy of Sciences attracting many Polish intellectuals.

Mass emigration to Germany

Industrial growth and social change. The development of modern industry, notably the textile and metal manufacturing industries, as well as mining, made Congress Poland after the abolition of the customs barrier with Russia the most dynamic, industrialized part of the Russian Empire until about 1890. In Congress Poland alone there were more than 400,000 industrial workers by 1910. It was mainly Polish intellectuals who stimulated industrialization in the Russian and Austrian sections, whereas German intellectuals led the industrialization program of the Prussian part—particularly in Upper Silesia, with its 200,000 Polish miners. Due to the many agrarian crises between 1846 and 1892, most of the 3,200,000 descendants of the former nobility moved to the cities in the Russian sector, where they formed the majority of the liberal professions. In the Polish regions of eastern Germany, Congress Poland, and West Galicia, the intellectual classes were mostly without property and therefore dependent on wages, whereas the Poles in the Western Region of the Russian Empire and in East Galicia were mainly wealthy landowners or belonged to the city bourgeoisie. One of the main features of the period was the mass emigration of Poles from their native lands into the more industrialized parts of Germany, a movement that was to continue for decades to come. Thus, by 1910 more than 100,000 miners of Polish descent were working in the industrial Ruhr district. The rural population of Congress Poland and Galicia was mostly illiterate, and poverty increased there to such an extent that at least 3,500,000 people emigrated between 1890 and 1914, mainly to the United States.

Development of political parties. The first permanent political parties were established in Congress Poland and in exile between 1891 and 1893. The Polish League (LP), founded in 1886–87, was reorganized as the National League (LN) by Roman Dmowski in 1892–93 and later became the nucleus of National Democracy (ND), which was the strongest bourgeois party between 1905 and 1939. The Polish Socialist Party (PPS) was founded in 1892–93 under the patronage of Bolesław Limanowski and subsequently, under the leadership of Józef Piłsudski, became the strongest socialist party in the entire Russian Empire during the Russian Revolution of 1905. The left-wing socialist party (SDKP; from 1900 SDKPiL, Social Democracy of the Kingdom of Poland and Lithuania), founded in 1893 and led by Rosa Luxemburg and Junian Marchlewski, remained a minor party in comparison. The 1905 revolution, which swept over Russia, changed political life in all the Polish regions. The National Democracy, led by Roman Dmowski and supported by the majority of the landed gentry and the bourgeoisie, restricted its national platform to the demand for Polish autonomy. For this reason it was allowed to operate legally not only in Congress Poland but in Russian Poland, too, after 1905. The same party also controlled the Polish faction in the Russian Duma, or parliament (1905–17). The PPS split in 1905–06: the patriotic wing under Józef Piłsudski and Tomasz Arciszewski retained its “radical program for independence,” in accordance with the teachings of Friedrich Engels, and took part in the abortive revolution of 1905 against the Russian government; the left wing adjusted its program to an internationalist standpoint and so found it easy later on to merge with the SDKPiL, on the extreme left. The introduction of universal suffrage in Austria,

including the Austrian sector of Poland (Galicia), for the parliament in Vienna in 1907 promoted the founding of the agrarian Polish Peasant Party (PSL). This party soon spread its influence to southern Congress Poland, but it split in 1913 into a moderate majority and a radical left. Only in Prussia was the repression of Polish cultural and political life continued, and after 1905 this policy was pursued in an even severer form. For this reason the Polish National Democrats regarded the German Reich rightfully as their main opponent from 1905 on.

THE FOUNDING OF THE SECOND REPUBLIC, 1914–21

Events during World War I. At the outbreak of World War I the governments of Austria and Russia tried to use the Polish question as a political weapon. On Aug. 16, 1914, the Austrian government allowed the formation of a Supreme National Committee (NKN) in Galicia and the organization of a Polish legion recruited mainly from the membership of the followers of Józef Piłsudski. The ultimate goal of Austrian policy was the incorporation of Congress Poland into Galicia. On Aug. 14, 1914, the Russian government recognized the basic right of the Poles to autonomy, particularly in the lands that the Russian troops hoped to conquer. The Polish National Committee (KNP) was formed in Warsaw in November 1914—its chief members coming from the National Democrats, led by Roman Dmowski. The KNP supported the Russian war effort, and Russian forces conquered almost all of Galicia in 1914.

Piłsudski and Dmowski

Division of Congress Poland. The troops of the Central Powers—Germany and Austria-Hungary—were able subsequently not only to retake Galicia but to advance deep into Congress Poland. The Central Powers divided it into two military occupation zones, with a German governor general in Warsaw and an Austro-Hungarian one in Lublin. The political groups in both of these zones separated into those who believed in adopting a passive stance and the activists. With the majority of the PPS and the left-wing intellectuals on their side, the activists established the Central National Committee (CKN) in December 1915, their goal being to reestablish a Polish republic with the help of the Central Powers.

Creation of a Kingdom of Poland. At the request of the German commander, Gen. Erich Ludendorff, and the German governor general, Hans Hartwig von Beseler, the German and Austrian emperors proclaimed a new Kingdom of Poland on Nov. 5, 1916. The kingdom consisted of both occupied zones but constituted only about one-sixth of the territory established in 1772. The hopes of both monarchs for more support among the Polish volunteer troops in the Austro-German fight against Russia were in vain, for German aspirations did not match the expectations of the Poles, who had envisioned an eastward expansion of the Kingdom of Poland. Ludendorff, in turn, tried to establish what he himself termed “a national kingdom of Lithuania” in the eastern regions. All these elements now gave the first incentive to an internationalization of the Polish question.

The Russian Revolution. The Russian Revolution in March 1917 brought about the two Poland proclamations of the Soviet of Petrograd and the provisional government of Russia. These recognized Poland's right to independence, while the latter insisted on a military alliance with Russia. After this, three Polish army corps were formed from the ranks of the Russian army between May 1917 and May 1918, and France also recruited a Polish volunteer army. The Polish National Committee, reestablished by Dmowski in Lausanne on Aug. 15, 1917, worked closely with the governments of the Western Allies. In the Kingdom of Poland, Piłsudski and the Polish Legion, now reorganized as the Polish Auxiliary Corps, with about 20,000 men, clashed with the Central Powers. Piłsudski and the majority of his corps were interned in July 1917. The grant of a limited Polish self-government in the Kingdom of Poland and the installation of a Regency Council on Sept. 12, 1917, came too late to overcome the distrust that now divided the Central Powers and the Poles.

The fight for self-determination. The October Revolution in Russia, as well as the proclaimed principle of

the "right for self-determination of all nations" as stated by both Lenin and the U.S. president Woodrow Wilson (though both with very different interpretations), gave the Polish question international significance. Wilson demanded the creation of an "independent Polish state" with a free and secured access to the sea in his well-known "14-points speech" of Jan. 8, 1918. This program was ratified as an integral part of the future peace settlement by the governments of France, Great Britain, and Italy on June 3, 1918. The Central Powers used the "right for self-determination of all nations" in the peace negotiations of Brest-Litovsk (now Brest, Belorussian S.S.R.) in February–March 1918 as a pretext for the separation of the Kingdom of Poland from the Russian Empire, but they apportioned the Chełm province, with its predominantly Polish population, to the Ukraine on Feb. 9, 1918. This infuriated Polish opinion.

Reestablishment of the state. The military collapse of Austria in October 1918 led to the formation of a Polish Liquidation Commission in Kraków on Oct. 28, 1918, which assumed power in Western Galicia. On November 7 a Provisional Government of the Polish Republic was established in Lublin. With the collapse of the German Reich in November 1918, Piłsudski was freed from his internment in Germany. Returning to Warsaw, he took control of the whole of Poland on Nov. 11, 1918. The administrations for the regions of Kraków and Lublin also put themselves under his command. Nov. 11, 1918, has thus been generally recognized as the day of the founding of the Second Polish Republic.

The Second Polish Republic. To begin with, the Second Polish Republic consisted of the Kingdom of Poland as it existed in 1916, the Duchy of Cieszyn, and West Galicia. Poland's losses during World War I numbered about 800,000 dead as well as the destruction of the majority of industrial plants and communications and the serious disruption of the Polish monetary system and economy.

Internal developments. Piłsudski secured his position of power in the country by reaching an agreement, in January 1919, with the KNP in Paris, headed by Roman Dmowski. The KNP was the recognized official Polish delegation at the Paris Peace Conference. Ignacy Jan Paderewski, a close associate of Dmowski, formed a government in Warsaw in 1919, but the executive power remained in the hands of Piłsudski, as the Polish "chief of state," from Nov. 22, 1918, until Dec. 14, 1922. The succeeding democratic elections led to the formation of a constitutional Sejm, which operated as both the constituent and legislative assembly (1919–22) after the passing of the "Little Constitution" on Feb. 20, 1919. The strongest parties in the country were the National Democrats and the Peasants (PSL), the latter for the most part cooperating with the National Democrats. The left-wing parties commanded only about one-quarter of the votes. The Communist Workers' Party of Poland was founded on Dec. 16, 1918, and Workers' Councils were set up in November 1918. The Councils were broken up by the government in June 1919, and this established and secured a "bourgeois democracy" in Poland as opposed to the "Soviet democracy" in Russia.

The Treaty of Versailles. At the Paris Peace Conference the Polish delegation demanded the surrender of the formerly Prussian sector, Upper Silesia, and southern East Prussia (Mazuria) from Germany. The largest part of the province of Poznań was already under Polish authority because the December 1918 Polish uprising against the Germans in Poznań had engulfed almost the entire province. The Treaty of Versailles, signed on June 28, 1919, awarded Poland the main part of the Prussian sector, providing the desired direct access to the Baltic Sea, even though the port of Gdańsk (Danzig), to which the Poles had laid claim, became a "Free City." The plebiscite in Mazuria, held on July 11, 1920, resulted in a heavy defeat for Poland, partly because of the Polish-Soviet war, and it brought only a few border regions under Polish authority. The Polish population in Upper Silesia rebelled three times against the German administration. In the plebiscite of March 20, 1921, 682 communes voted for Poland and 792 for Germany, but the Poles secured preponderance in the southeastern plebiscite area, which was industrially

the most important. The new frontier of Oct. 20, 1921, divided this area: Poland was awarded 76 percent of the coal production, 22 out of 37 blast furnaces, and nine out of 14 steelworks, with about 990,000 people. Populated by Poles, Czechs, and Germans, the former Duchy of Cieszyn was the subject of controversy between Poland and Czechoslovakia. On July 28, 1920, it was divided, but in a manner that left a considerable Polish minority in the Czechoslovakian sector.

Territorial disputes. Poland owed its rapid eastward expansion to its quickly recruited and effective army. Evacuation of the territories occupied in the east by the German troops had to be completed by the beginning of February 1919, but every strip of land left by the Germans was promptly taken over by the Red Army. Thus, between November 1918 and February 1919, that army moved westward from the Dnepr to the Bug River line. Piłsudski decided that it was imperative to throw back eastward the forces aiming at imposing a foreign form of government on restored Poland. The central part of historic Lithuania was occupied by the Poles in April 1919. On July 27 the Supreme Council approved a demarcation line between Poland and Lithuania, leaving Wilno (Lithuanian Vilnius) on the Polish side. In eastern Galicia the West Ukrainian People's Republic had been established in November 1918, but Polish troops occupied it in June–July 1919. In addition, the Polish Army extended its sphere of influence over the largest part of White Ruthenia and over the western Ukraine—far beyond the boundary lines of the Second Partition of 1793—without meeting any serious resistance from the Red Army until December 1919, because the Russians were still embroiled in civil war. The Soviets launched a military offensive against Poland between February and May 1920. The militarily and politically ill-advised Polish advance against Kiev in June 1920 led to the Polish-Soviet war that had been brewing for the past one and a half years. The Red Army, under the command of Mikhail Tukhachevsky, advanced, reaching the vicinity of Toruń, Warsaw, and Lwów by July and August 1920. The Polish forces led by Piłsudski defeated the Red Army decisively, however, in a battle on the Vistula between August 16 and 28. This victory crushed the Bolsheviks' last chance of a widespread revolution in central and western Europe. The Polish Army reconquered Central Lithuania with Vilnius (ceded to the Lithuanians by the Red Army), western White Ruthenia, western Wolhynia, and East Galicia before the armistice of Oct. 12, 1920. The Soviet government finally recognized this boundary unconditionally in the Peace of Riga on March 18, 1921.

POLAND FROM 1921 TO 1945

The constitution of March 17, 1921, established a parliament consisting of two houses, the Senate and the Sejm. The political forces in the country had splintered up into numerous parties and groups, and this proved a hindrance to the development of a stable, unified parliamentary government.

Domestic policy. Between 1922 and 1926 Poland was governed by frequently changing cabinets that were based mainly on a coalition between the National Democrats, the Christian Democrats, and the moderate Peasant Party. The primary task of these governments was to attempt to eliminate the inflation that the destruction of World War I and the subsequent conflicts had caused. The government stabilized the situation through the introduction of a new currency, the zloty, on Feb. 1, 1924. But the new currency was in danger again by 1925, mainly as the result of a tariff war instigated by the Germans. The financial crisis that followed led to high unemployment and severe unrest among the working people. This, in turn, gave the Communist Party a steadily rising influence, even though it had been declared illegal in 1923. Piłsudski had not been active on the political scene since 1923, but these new developments compelled him to organize a military coup on May 12–15, 1926, in order to take power. Supporting their former leader with a general strike, the PPS played a decisive role in Piłsudski's victory.

Piłsudski headed the government from 1926 to 1930.

Piłsudski's
return to
Poland

Defeat of
the Red
Army

The
Piłsudski
coup

His rule was a moral dictatorship with only a formal preservation of parliamentary authority. His administration aimed at the "moral cleansing" of society in Poland and at eliminating corruption. Piłsudski relied mainly on the army and the conservative nobility of eastern Poland for his support. Between 1926 and 1927 a right-wing opposition emerged, led by Dmowski. Piłsudski confronted them with his Non-Party Block for Cooperation with the Government (BBWR), which was a loose organization held together only by Piłsudski's personality. At any rate, in the elections to the Sejm held on March 4, 1928, the BBWR obtained one-quarter of all the parliamentary seats, though a contributing factor for this political success was the increasing economic prosperity of 1926–29.

The Great
Depression

The crisis in the world economy began to affect Poland in October 1929. Unemployment hit about 893,000 workers, excluding agricultural workers—or approximately one-third of those employed in 1931. Production sank between 1931 and 1933 to only 46 percent of the 1913 level. Under the pressure of the general misery and need, the PPS, the Polish Peasant Party (PSL), and some others united on Nov. 1, 1929, to form a left-wing opposing coalition (Centrolew, or Centre-Left). Piłsudski used harsh measures against his opponents, ordering the arrest of about 70 politicians. The Sejm elections of November 1930 gave the BBWR its desired majority, but the genuine political parties now practically disappeared from the political scene. Piłsudski governed from 1930 to 1935 without holding an official public political office. His authority was based on the support of the civil service and of his officers' corps and, in particular, the support of the colonels trained in the legions. Piłsudski tried to master the economic crisis through a program of nonintervention and thrift, but he was largely unsuccessful.

A constitutional reform was introduced on April 23, 1935, strengthening the executive branch of government and giving the head of state the power to enact important laws without the approval of Parliament.

Piłsudski's successors. Piłsudski died on May 12, 1935, and the resulting struggle for power, complicated by strikes and demonstrations, soon reduced all parliamentary activity to a complete farce.

Opposition groups. The elections held in September 1935 and November 1938 showed this only too well, and a large part of the population and most of the opposition parties boycotted them. There were violent demonstrations and strikes in 1936 and 1938, and the beginnings of a popular front, bringing left and left-centre parties together, could be noted. The established radical workers' parties, the PPS and the KPP, found a new ally in the Peasant Party, which had now also become radical under its new leader Stanisław Mikołajczyk. Joseph Stalin's reaction to these signs of national unity was to have the Comintern dissolve the Communist Party of Poland in 1938, branding its leaders as provocateurs and capitalist agents. On the right wing, the National Radical Camp (ONR) generated some Fascist groups, but they were dissolved in 1934 and received hardly any support. Founded by the government on March 1, 1937, the Camp of National Unity (OZN) remained an authoritarian association that—like the BBWR—had no real social or political platform.

Dissolution of the
Communist Party
of Poland

Social problems. The important social questions of Poland remained unsolved in the time between World Wars I and II. Any permanent solution was beyond the reach of the country's economic resources. The surplus in the agrarian population could only have been eliminated by a comprehensive program of industrialization, but there was no capital to do this. Nevertheless, the agrarian reform based on the laws of July 15, 1920, started the distribution of approximately one-tenth of all arable land. Industrialization made some progress with, for example, the energetic promotion of the chemical industry and the building of the "coal-railroads" from Upper Silesia to the Baltic Sea coast, but the funds necessary for investment in these enterprises stretched Poland's national economy to its limits. The entire 1938 production barely reached the 1913 level. Poland remained an agrarian country, and about two-thirds of its total population depended either directly or indirectly on its agricultural produce. Only one-

quarter of the country's inhabitants received their income from industry.

Foreign policy. In its foreign policy, Poland attempted to strengthen its position through alliances with France and Romania (1921). Endangered by political and military cooperation between Germany and the Soviet Union, as well as by their concerted policy aiming at the revision of existing frontiers, Poland found itself in a hazardous position after the treaties of Locarno (1925) and the April 1926 treaty negotiated by Gustav Stresemann and Georgy Vasilyevich Chicherin of the Soviet Union stating that German-Soviet relations should continue to be based on the 1922 Treaty of Rapallo. Acting under Piłsudski's instruction, Józef Beck, Poland's foreign minister, concluded a nonaggression pact with the Soviet Union in 1932 and a similar one with Germany in 1934—the latter preserving both Poland's alliance with France and its freedom of action as a member of the League of Nations. This safeguarded Poland's position, at least for a short time. But the German Reich had by now annexed Austria and the largest part of Czechoslovakia, and it established control over the Slovakian republic and seized Lithuanian Memeland. This placed it in such a strategically favourable position toward Poland that Adolf Hitler dispensed with all caution. His proposals for a global solution were aimed at making Poland completely dependent on Germany so that he would be able to use it as a base for his planned attack on the Soviet Union. Observing the guarantee of March 31, 1939, the British government under Neville Chamberlain gave Poland diplomatic, but no military or financial, assistance. This did nothing to prevent the Germans from attacking Poland or to stop the outbreak of World War II. Hitler, on Aug. 23, 1939, concluded with Stalin a nonaggression pact containing a secret protocol dividing Poland into German and Soviet spheres of interest, circumscribed by the Narew, Vistula, and San rivers. This "Fourth Partition of Poland" proved to be the decisive factor leading to the outbreak of World War II.

Beck's
nonaggression
pacts

World War II. The fall of Poland came unexpectedly fast during the September campaign of 1939. Warsaw capitulated on Sept. 27, 1939, after the defeat of the Polish Army. The last organized Polish resistance ended on Oct. 5, 1939. Following German demands, the Soviet Union ordered two army corps to invade eastern Poland on Sept. 17, 1939, breaking its earlier agreements of 1921 and 1932. On Sept. 28, 1939, Hitler and Stalin again agreed on a new partition of Poland along the Narew, Bug, and San rivers. Hitler's plans for the creation of a Polish puppet state did not materialize because no collaborator could be found. On Oct. 12, 1939, Hitler gave the order to annex outright the former Prussian section, parts of Mazovia, eastern Great Poland with Łódź, and a border strip in Little Poland.

The
division
of Poland

Soviet annexations. The regions in the Soviet sphere of interest were incorporated into the Soviet Union with the help of supervised plebiscites held between Oct. 22 and Nov. 2, 1939. The Soviet Union based its decisions, at least formally, on the "right for self-determination of the nationalities," hoping in this way to get its demands internationally legalized. The annexation put the British government into an embarrassing situation. On the one hand, it had guaranteed the security of Poland, while, on the other hand, it did not want to risk a conflict with the Soviet Union. For this reason, on Oct. 26, 1939, the British foreign minister Lord Halifax pointed to the fact that the westward extension of the Soviet boundary approximated the Curzon line of Dec. 8, 1919, and of July 11, 1920. He was the first European statesman to do so, but this explanation became the basis for the later establishment of the boundary between Poland and the Soviet Union at the end of World War II.

Polish government-in-exile. The forming of a Polish government-in-exile in France, based on the 1935 constitution, assured the survival of the Polish Republic. Its leading statesman and supreme commander was Władysław Sikorski. The Polish government-in-exile moved to the United Kingdom after the defeat of France in June 1940. A civil and military resistance movement was also formed in occupied Poland in September 1939.

German repression. From the very beginning, in October 1939, the occupational policy of the Germans was designed to completely eradicate Polish culture. Almost the entire Polish school system was suppressed. Mass executions of Polish intellectuals were carried out, and the infamous concentration camp of Oświęcim (Auschwitz) was set up. The intention was to Germanize the territory, and mass deportations of Poles and mass settlings of Germans in their place were supposed to accomplish this. Germans from the Baltic states and eastern Poland were transferred to the western Polish lands incorporated into the German Reich. The Soviet government also participated in mass deportations of the Polish inhabitants from the eastern parts of their country incorporated into the Soviet Union.

Alliance with the Soviet Union. The German attack on the Soviet Union on June 22, 1941, changed the situation drastically for Poland. Stalin agreed to the annulment of the "Fifth Polish Partition" agreement between the German and the Soviet governments of 1939, but he declined the restitution of the Polish-Soviet border of 1921. In his debate with the British foreign minister, Anthony Eden, on Dec. 16, 1941, he proposed the Curzon Line as the basis for the future Polish-Soviet boundary.

German policy of extermination. The extermination of the Polish intellectuals and the mass deportation of Poles from western Poland continued to be vigorously pursued. Polish citizens of Jewish descent were deported to extermination camps, such as Auschwitz and Treblinka, where they were killed, along with the Jewish population of the greater part of Europe. Neither the belated ghetto risings of Warsaw, Białystok, and Wilno (April–September 1943) nor the special actions taken by the Polish underground were effective enough to halt this extermination.

(Ha.Ro./Ed.)

Stalin's Polish policy. In September 1939 both Hitler and Stalin hoped that a Polish national state would never rise again. When the Germans invaded the Soviet Union, however, Stalin had to reverse his Polish policy. On July 30, 1941, he reestablished diplomatic relations with the Polish government-in-exile in London. A military convention was signed in Moscow on August 14 on organizing a Polish army in Russia.

There were at that time hundreds of thousands of Polish deportees on Soviet territory; in addition, in September and October 1939 the Red Army had captured about 230,670 Polish soldiers, from privates to generals. To command the new Polish army, Stalin freed from imprisonment a Polish officer, Gen. Władysław Anders. Both Sikorski and Anders knew that some 15,000 Polish prisoners, including 8,400 officers, were interned at the Soviet prison camps at Kozelsk, Starobelsk, and Ostashkov. Great, however, was Anders' surprise and anxiety when he was told that he could count on only 448 officers picked from the three camps and grouped in April 1940 at Gryazovets.

By December 1941 Anders had put together two divisions. Finding that he could not organize a truly national Polish army, Anders suggested to Sikorski that his units be transferred to the West. During 1942, as a result of an agreement between Stalin and Churchill, 75,000 Polish soldiers were evacuated from the Soviet Union to the Middle East.

As early as November 1941 a small group of Polish Communists was parachuted into German-occupied Poland, where they contacted a few members of the old KPP (dissolved in March 1938); Władysław Gomułka was one of them. In January 1942 the Communist Party of Poland was revived in Warsaw under the name Polish Workers' Party (Polska Partia Robotnicza, or PPR), which in May 1942 formed a nucleus of the People's Army (AL).

On April 13, 1943, the Germans announced the discovery in the Katyn Forest, on the upper Dnepr River, of mass graves of Polish officers with their personal papers in their pockets. The officers' names published by the Germans were those of inmates of the Kozelsk prison camp, and the Germans accused the Soviets of having executed the prisoners in May 1940. Two days later the Soviet government alleged instead that the Polish prisoners had been engaged in construction work west of Smolensk in 1941 and had been executed by the Germans. On April

17, 1943, the Polish government asked the International Committee of the Red Cross to examine the situation on the spot. Eight days later the Soviet government, accusing the Poles of "contact and accord with Hitler," severed diplomatic relations with the Polish government in London for the second time.

During these fateful weeks Sikorski was in the Middle East inspecting the 2nd Polish Army Corps under Anders. Returning to London, Sikorski was killed on July 4 in an aircraft crash at Gibraltar. Stanisław Mikołajczyk, leader of the PSL, succeeded him as premier. Ignoring the Polish government's views concerning the territorial problems, Franklin D. Roosevelt and Winston Churchill agreed at the Tehrān Conference (Nov. 28–Dec. 1, 1943) to Stalin's demand that the Curzon Line be the new Soviet-Polish frontier.

To consolidate his diplomatic victory at the Tehrān Conference, Stalin instructed the PPR (of which Gomułka became secretary general in November 1943) to form the National Home Council (Krajowa Rada Narodowa, or KRN), which would become the government of the Polish People's Republic with Bolesław Bierut, an old Comintern hand, as president. That was done during the night of December 31.

Even before the severing of diplomatic relations with the legal Polish government, Stalin ordered the organization of a new Polish army, and by March 1944 the 1st Army came into existence. Its first commander was Gen. Zygmunt Berling, a Polish officer who refused to follow Anders, but the majority of officers in command of divisions, regiments, and battalions were detailed from the Red Army. On July 21, 1944, a Polish Committee of National Liberation (PKWN), commonly referred to as the Lublin Committee, was established as an executive branch of the KRN. On July 21 the 1st Belorussian Army Group under Marshal Konstantin Rokossovsky, into which the 1st Polish Army was incorporated, crossed the Curzon Line. Two days later it liberated Lublin, where the Lublin Committee launched a manifesto in which it declared itself to be "the sole legal Polish executive power." A week later Rokossovsky approached the Vistula River near Warsaw. At the same time Radio Moscow was broadcasting in Polish to the population of Warsaw and calling for a general uprising against the Germans. Foreseeing such an eventuality, Gen. Kazimierz Sosnkowski, who had succeeded Sikorski as commander in chief of the Polish armed forces, on July 7 warned Gen. Tadeusz Komorowski (called General Bór), commander of the 300,000-strong Home Army (Armia Krajowa, or AK), that considering its poor armament he should not order a general anti-German insurrection but that it was imperative that the Poles gain control of an important city before the entry of Soviet troops. On July 25, however, Mikołajczyk informed Jan Stanisław Jankowski, delegate general of the Polish government in German-occupied Poland, that he had full powers to order an uprising in Warsaw. Under this decision, General Komorowski ordered his Warsaw units (40,000 men in all) to start fighting on August 1. As soon as Stalin learned of the uprising, he ordered Rokossovsky to stop the offensive and let the Poles feel their dependence on the actions of the Soviet army. After 63 days of struggle, Komorowski had to surrender on October 2. The AK lost 10,200 men in combat and 13,900 were missing. Of the 950,000 civilian population of Warsaw, about 700,000 were evacuated by the Germans and some 200,000 perished in the fighting. Immediately after surrender Hitler ordered the total destruction of the Polish capital. On Jan. 17, 1945, the Red Army "liberated" Warsaw's empty ruins.

The winter offensive of three Soviet army groups, including two Polish armies of five divisions each, liberated by March 1945 almost all of the lands east of the Oder-Neisse Line. In the meantime, at the Yalta Conference (February 4–11), Roosevelt and Churchill sacrificed the legitimacy of the Polish government-in-exile in London to Stalin by consenting to the formation of a Provisional Polish Government of National Unity, which should include the members of the Lublin administration as well as "other Polish democratic leaders from within Poland and from abroad."

The ghetto risings

The Warsaw uprising

The Katyn Massacre

COMMUNIST POLAND

Formation of the People's Republic. On Dec. 31, 1944, the Lublin Committee was reorganized as a provisional government. On April 21 its chairman, Edward Osóbka-Morawski, a left-wing Socialist, signed a Polish-Soviet alliance treaty. The Polish Government of National Unity was finally constituted in Moscow on June 28, 1945. Among its 21 members there were only five newcomers, the most important being Mikołajczyk, who became vice premier. The acting president of the republic was Bierut. This government was transferred to Warsaw, and on July 5 the British and U.S. governments recognized it and withdrew recognition from the government in London.

Poland's
new
frontiers

On Aug. 2, 1945, at Potsdam, U.S. Pres. Harry S. Truman, the new British prime minister, Clement (later Lord) Attlee, and Stalin issued a declaration establishing a de facto western frontier of Poland along the Oder-Neisse Line. Poland took over the administration of lands held by Germans to the east of that line, with the exception of the northern part of East Prussia, which was incorporated in the Soviet Union. Gdańsk was again a part of Poland. The Potsdam agreement authorized Poland to transfer to the zones of Allied occupation about 3,300,000 Germans (about 4,000,000 had fled westward earlier, dreading the advancing Soviet armies). On Aug. 16, 1945, in Moscow, a Polish-Soviet treaty confirmed Poland's eastern frontier along the Curzon Line. In the east Poland lost 69,290 square miles (179,460 square kilometres) to the Soviet Union. In the west it gained at Germany's expense 39,596 square miles (102,555 square kilometres).

The Bierut era. The Sovietization of Poland was Stalin's constant aim, and Bierut was his obedient servant. First, he postponed the general elections while the secret police, supervised by the Soviet general Ivan V. Serov, made mass arrests of prominent political and military leaders. Farms of more than 124 acres (50 hectares) were expropriated, and all industrial establishments employing more than 50 workers were nationalized.

The PPR, PPS, and the Democratic Party were combined in the Democratic Bloc. As Mikołajczyk's PSL refused to join the bloc, Bierut started a ruthless intimidation campaign against its supporters. Nevertheless, at the general elections of Jan. 19, 1947, the PSL received about 84 percent of all votes; the "official" results, however, gave the Communist-controlled bloc 382 seats out of a total of 444. The new Sejm elected Bierut president of the republic, and Józef Cyrankiewicz, a pragmatic Socialist, became premier. Mikołajczyk, accused of being "an ally of foreign imperialists," fled to England. In December 1948 the PPS was eliminated by its compulsory merger with the PPR, and the Polish United Workers' Party (PUWP; Polska Zjednoczona Partia Robotnicza, or PZPR) was born.

During 1948 Gomułka opposed the collectivization of agriculture in Poland, and in consequence he was dismissed from the party and the government and later (1951) arrested. Bierut, now both president and party leader, asked Marshal Michał Żymierski, a prewar Polish officer, to resign as minister of defense and commander in chief because Stalin wanted this post for Rokossovsky (who held it from November 1949 until 1956).

On July 22, 1952, the Sejm approved a Soviet-type constitution. The president of the republic was replaced by a Council of State, and Bierut became premier. In September 1953 he ordered the internment of Stefan Cardinal Wyszyński, Roman Catholic primate of Poland, who opposed the government's interference in church affairs. Bierut abandoned the premiership in March 1954, and Cyrankiewicz returned to that post. In February 1956 Bierut attended the 20th congress of the Communist Party of the Soviet Union in Moscow, at which Nikita Khrushchev denounced Stalin's crimes. This speech devastated Bierut. He died on March 12 in Moscow.

The Gomułka era. On March 20, 1956, the PUWP Central Committee elected as its first secretary Edward Ochab, who, apparently immediately, and in conjunction with Cyrankiewicz, began to plan for the return of Gomułka. While they were still in the planning stage, an event of historic significance overtook them on June 28: industrial workers in Poznań started a general strike, and

The
Poznań
general
strike

a procession of 50,000 persons demanded bread, freedom, free elections, and the departure of the Russians. On Rokossovsky's order the revolt was crushed by tanks, and more than 70 people were killed.

When the Central Committee met on October 19 to elect a new Politburo, Khrushchev arrived in Warsaw uninvited. At the same time, Soviet divisions were marching on Warsaw. Having elected Gomułka a member, the Central Committee decided that the old Politburo—but with Gomułka—would discuss Polish-Soviet relations with Khrushchev. The meeting took place during the night of October 19–20. Gomułka succeeded in convincing Khrushchev that the PUWP Politburo wished to keep Poland within the Communist camp but as an equal member, and Khrushchev returned to Moscow. On October 21 a new Politburo was elected and Gomułka became first secretary again. He promised to end the compulsory collectivization of agriculture and to reduce the rigour of press censorship. He also released Cardinal Wyszyński from confinement. In November Rokossovsky returned to Moscow with 12 other Soviet officers.

During his 14-year reign Gomułka abandoned the principle of collective leadership, becoming an authoritarian martinet. He picked fresh quarrels with the Roman Catholic Church and imposed economic measures that the workers resented as exploitative. On Dec. 12, 1970, he announced considerable price increases on 46 items of basic foodstuffs, fuel, and clothing. Two days later workers from Gdańsk, Gdynia, and Szczecin shipyards went on strike, and riots occurred. Gomułka used force against the "counterrevolution": about 100 workers were killed by militia, and more than 1,100 workers and militia-men were injured.

Baltic riots

Ironically, this bloody tragedy occurred shortly after a great success in the field of foreign policy. On Dec. 7, 1970, Chancellor Willy Brandt of West Germany signed in Warsaw a treaty declaring that the existing German-Polish border along the Oder-Neisse Line "forms the western state frontier of Poland" (East Germany had recognized this reality in June 1950).

The Gierek era. On Dec. 20, 1970, at a session of the Central Committee, Gomułka and his supporters were ejected from the Politburo. Edward Gierek, the party first secretary in the highly industrialized province of Katowice, assumed the party's leadership as first secretary of the Central Committee. Three days later Piotr Jaroszewicz, a deputy premier from 1952, succeeded Cyrankiewicz as chairman of the Council of Ministers.

The new government started well. Gierek's decision to rebuild the Warsaw Royal Castle, destroyed in 1944 on Hitler's order, roused the patriotic feelings of the nation. The West German Bundestag on May 17, 1972, ratified the Oder-Neisse treaty, and the Holy See soon afterward adjusted the external borders of the new western and northern Polish bishoprics with the internationally recognized frontier. The years 1971–73 were the years of Gierek's "specific economic maneuver." Assuming that prosperity in the West would continue, he sought foreign credits to finance the long overdue modernization of Polish industry. Because wages in Poland were lower than in the West, and energy and raw materials were abundant and cheaper, it seemed reasonable to expect a competitive edge for Polish exports in Western markets and repayment of the debts from hard currency profits. Unfortunately a severe recession that affected the developed market economy in 1974 interfered with Gierek's imaginative plan.

Higher prices had become an economic necessity, but, when on June 24, 1976, Jaroszewicz announced in the Sejm increases averaging 60 percent on many staples, industrial workers went on strike. The protest movement was so strong that the following day Jaroszewicz told the nation on television that the bill was being withdrawn. There was no bloodbath similar to that of December 1970, but the regime was shaken. Hundreds of protesters were summarily tried and sentenced to prison. A group of Polish intellectuals appealed to the Sejm for clemency and for a free flow of information to avert further such disasters.

Protest
strike

In 1978 Karol Cardinal Wojtyła, archbishop of Kraków, was elected pope and took the name John Paul II. His

first papal visit to his native country, in June 1979, was a triumph for him and for the Catholic faithful of Poland, while the Communist government garnered some praise for civility and restraint. During the nine days of his visit, the Pope spoke on 32 separate occasions, sometimes to gatherings of more than 1,000,000 enthusiastic people.

Revolt, repression, and reform. By 1980 the Polish people were facing food shortages, rationing of electric power, and insufficient housing. At the eighth congress of the PUWP, held in February, Jaroszewicz was dropped from the Politburo and replaced as premier by Edward Babiuch. On August 14 the entire work force of 17,000 stopped production at Gdańsk's Lenin Shipyard. The strike, led by Lech Wałęsa, an electrician by trade, spread to other industrial plants on the Baltic coast and to the coal mines of Silesia. On August 24 Gierek dismissed Babiuch, and Jozef Pinkowski was nominated as premier. Having sought guidance from the Soviets, who advised him to reach a compromise with the strikers, Gierek appointed Mieczysław Jagielski, a Politburo member and first deputy premier, to begin negotiations with Wałęsa, the charismatic leader and cofounder of the independent trade union Solidarity (*Solidarność*). On August 31 in Gdańsk, Jagielski and Wałęsa signed an agreement stating that the new self-governing trade unions would "adhere" to the constitution and recognize the central role of the PUWP. All of Solidarity's major demands were granted.

The Soviets warned the Polish party that elements in the country were attempting to overthrow the Communist system. It was reported on Sept. 5, 1980, that Gierek was suffering from ill health, and on the following day the Central Committee elected Stanisław Kania first secretary. On October 24 the government formally recognized Solidarity, by then numbering 10,000,000 members. Rural Solidarity, with about 3,000,000 small farmers, was legalized by the parliament in May 1981. Solidarity held its first national congress in the fall, and on October 2 Wałęsa was elected president of its governing commission.

Pinkowski resigned as premier in February 1981, and Gen. Wojciech Jaruzelski, minister of defense, became the head of the radically revamped government. Under the term *odnowa* ("renewal"), the ninth congress of the PUWP met in mid-July and, for the first time in a Soviet-bloc country, elected the Central Committee in a free vote. Kania was confirmed as first secretary, and a new Politburo was elected by the Central Committee. Of the new membership, only Kania and Jaruzelski had belonged to that body before February 1980. Gierek, Jaroszewicz, and 10 of their associates were stripped of their party memberships and state medals and decorations. On October 19, after criticism by the Soviets for irresolution in dealing with Solidarity, Kania resigned from his post as first secretary. He was succeeded by Jaruzelski.

Poland's archbishop Jozef Glemp and Solidarity leader Wałęsa had an unprecedented two-hour meeting with Jaruzelski on November 4 concerning creation of a Council of National Understanding. In mid-November, talks were held between the leaders of the government and Solidarity. The government appealed for cooperation, but instead the conflict intensified. Meeting in Gdańsk on December 12, Solidarity leaders proposed a nationwide referendum for establishing a non-Communist government and defining Poland's military relationship with the Soviet Union, unless the government agreed to meet a series of union demands by the end of the year. These demands included access to the mass media and free and democratic elections to local councils in the provinces.

On Dec. 13, 1981, the government struck back. In a nationwide radio address, General Jaruzelski imposed martial law on the nation. Censorship and restrictions of personal freedoms were imposed throughout Poland. Wałęsa and other leaders and supporters of Solidarity became the targets of periodic arrests and detentions, and in October 1982 the government outlawed Solidarity.

The economy continually worsened, causing greater hardships among the people. The situation was only partially relaxed by the lifting of martial law in July 1983. In an effort to improve Poland's sagging economy and to calm

the increasing labour unrest, the government began negotiations with Solidarity in late 1988. As a result of these talks, Solidarity was restored to legal status in April 1989, and a partially free election was held in June 1989. In the election, Solidarity-supported candidates won all but one seat that they contested in the Sejm and the reinstituted Senate (the Communists and their allies, the Democratic Party [SD] and the United Peasants Party [ZSL], were guaranteed 65 percent of the seats in the Sejm). In July a joint session of the Sejm and Senate elected Jaruzelski as Poland's first president since 1952. The Communists, however, failed to form a government in the Sejm. Jaruzelski, with little choice but to nominate a Solidarity member for prime minister, selected leader Tadeusz Mazowiecki, a close aide to Lech Wałęsa. With the support of the SD and the ZSL, which broke their alliance with the PUWP, Mazowiecki formed Poland's first non-Communist government in more than 40 years. (K.M.S./Ed.)

Police

The term police is now used primarily to denote a body of people organized to maintain civil order and public safety, to enforce the law, and to investigate breaches of the law.

All societies need some way to maintain order. In the smallest societies, informal sanctions discourage deviation. In the simplest forms of state organization, informal sanctions are supplemented by agents of the ruler who enforce his decisions. Although the police function is universal in society, it is only in the larger and more complex states that full-time officials are appointed with special

police responsibilities regulated by politics, tradition, and law. Most police in such societies are enrolled in state, provincial, or municipal forces concerned with criminal investigation, traffic regulation, and preventive patrol. A central government generally has personnel responsible for the collection of political information, counterespionage, and so forth, not all of which is considered policing.

Police and society

THE DIVERSITY OF POLICE ACTIVITIES

There is a remarkable historical, geographical, and organizational diversity in the activities of persons who are, or have been, counted as police. Within any one country the work of police today is very different from what it was 200 years ago. There are also major differences between countries—policing New York City is bound to have little in common with policing the Solomon Islands. The diversity is so great that the onlooker may wonder if the different kinds of activity and organization have sufficient in common to be classified together.

The principle of police accountability is helpful in explaining the diversity. The problem is summarized in a Latin question: *Quis custodiet ipsos custodes?* ("Who guards the guardians?"). From one point of view, it is desirable that a police force be as efficient as possible. This consideration favours the establishment of national police forces, which can take advantage of the economies of scale in training, promotion, organization, and so on. But it often has been felt that the existence of a national force places too much power in the hands of those who direct it; that there is a danger that the government will use its control of the police to keep itself in office; and that the police will not be accountable to the public. Therefore, some countries favour a local basis for police organization.

A second principle that helps explain the diversity of police activities in different societies is that of police adaptation to cultural traditions. If the society is agricultural, as in rural India, the police will be concerned with the state of the crops, the irrigation of fields, the conditions of roads and paths, private feuds and quarrels, the registration of births and deaths, feasts, fairs, and all manner

of private and public events. If local landowners are influential, as they were in 19th-century England, much police effort will be expended in the enforcement of laws against poaching and much less in the investigation of ways in which the behaviour of employers infringes the rights of employees. If some offenses are committed by criminals using vehicles, the police must be partially motorized. If criminals use firearms, the police are likely to be armed. Police activity must be adapted to the society that is being policed.

Social control in small communities. Most people obey most laws willingly, whether or not there is a police officer looking on. They comply with the laws because they believe them right and perceive that in the long run it is in everybody's interest to observe them. In small communities in which everyone knows everyone else, people who live up to the shared ideals are rewarded by the esteem of their fellows. If they fall short of other people's expectations, life is made more difficult because others are no longer so ready to help them in times of trouble. This pattern of informal rewards and punishments is, in all kinds of society, the most potent force in law enforcement, but it is stronger in the small community. The forces that order the life of the small community make the task of the police much easier. Instead of imposing requirements, they have only to lubricate the mechanisms inherent in social relations, and police action is needed only when the informal controls have proved insufficient.

Social control in large societies. The bigger a society becomes, the weaker its self-policing elements are likely to be and the stronger the legal means of social control becomes. In the first place, when people are involved with those whom they are unlikely ever to meet again, there may seem to be less reward for honest dealing. In the second place, with technological progress there comes a

Police
account-
ability and
adaptation

need for new laws. With the growth of automobile traffic, for example, many new laws governing vehicle construction, licensing, and manner of driving become necessary. Because many such laws do not have the same moral significance as laws penalizing personal violence or dishonesty, the reporting of offenses cannot be left to members of the public. Controls are needed in the form of trained inspectors, officials, and traffic police. When the legislature declares that certain actions are in the future to count as offenses, it increases the amount of crime. There is a danger that people who are convicted of one offense—say, a motoring offense—may feel aggrieved and in the future be less willing to cooperate with the police or to obey the law when they are not being observed. In the third place, as societies grow it becomes more difficult to relate public and private interests. If an employer catches a group of employees committing an offense within the workplace, he may not wish to call in the police. He may believe that, if he deals with it in his own way, production and profit may suffer less; the public interest, however, may not be served thereby.

CENTRALIZATION VERSUS DECENTRALIZATION

For these and other reasons, a tension exists between the forces of society that tend to centralize the public police and those that tend to decentralize it. On the one hand, it would appear that communities cannot wholly be left to police themselves, and that a central government should impose its standards upon local communities. On the other hand, if the central government itself is corrupt or self-seeking, the outcome will be worse than if communities were left to enforce law and order according to their own rights. Moreover, good intentions on the part of the central government are in themselves obviously not sufficient. Much depends upon whether it can induce its agents to use their powers in desired ways.

Although the belief still persists that decentralization favours police accountability, some centralization is required for economic and operational efficiency. As the period of training needed for effective police work has grown longer and work hours have been reduced, police manpower has become more expensive; and it has become important to see that police are not employed on tasks for which less highly trained employees could be used. Consequently, police in most industrial countries are now assisted by a host of auxiliaries: photographers, mechanics, fingerprinting technicians, forensic scientists, and so on. It has become advantageous to have national schemes for fixing the pay scales of both police and auxiliaries; for recruiting; for seeing that similar standards are employed throughout the nation; for establishing a common system of criminal records; for developing national facilities for higher training and the selection of top administrators; for forming specialist squads to investigate particular kinds of crime; for research; and, generally, for seeing that the police service keeps abreast of the changing pattern of criminal activity. Such tendencies make for increased centralization, and they operate in a similar fashion in all industrialized countries. As a result, regardless of the way in which police services have started out—whether, like the French, they have been highly centralized or, like the British, have taken community policing as their model—all have tended to develop some common features.

The classification of police as centralized or decentralized organizations is a relative concept. The English police, for example, are generally considered to be a decentralized force; however, when they are compared to police forces in the United States, they appear quite centralized. The organization of police forces around the world forms a wide spectrum, in which the police of the United States represent the decentralized end and the secret police of totalitarian states the centralized extreme.

(M.P.B./Ed.)

The history of policing

Forms of policing have existed for several thousand years, with religious, political, or military police wielding power as early as the time of Babylon. Early police were usually

either military or semi-military organizations that developed from the personal bodyguards of rulers and warlords or from community organizations in which citizens banded together for mutual protection.

The duties of the military type of police usually consisted of keeping the public order and enforcing the religious or political mandates of those in power. Rome, under the emperor Augustus, had one of the earliest forms of organized policing. In 7 BC Augustus divided Rome into 14 *regiones* (wards), each divided into *vici* (precincts) overseen by *vicomagistri* responsible for fire protection, among other administrative and religious duties. In AD 6, after a particularly bad fire, Augustus expanded the city's fire brigade into a corps of *vigiles*, consisting of seven squads, or cohorts, of 1,000 freedmen each. Each cohort was responsible for fire and, especially at night, police protection in two *regiones*. To further impose order on the often violent streets of his city of nearly 1,000,000, Augustus created three cohorts of police, part of the army of the state, who were placed under the command of the urban prefect. These cohorts could, in turn, call upon the emperor's own bodyguard (the Praetorian Guard) for assistance.

Military and semi-military police forces developed independently in many countries of the world. For example, the shogun, ruler of 17th-century feudal Japan, devised an elaborate police system in which each castle town had a military samurai warrior who served as town magistrate, judge, and chief of police. He appointed other sword-carrying samurai (*yoriki* and *dōshin*) to serve as a patrolling police force.

In the early 1700s the Russian tsars also established a police system to enforce their laws. Tsar Nicholas I later expanded the powers of this police force and turned it into an early form of state political police—the dreaded Okhranka. After the Russian Revolution, this force gave rise to V.I. Lenin's powerful and highly organized Cheka, the political police that served as a model for Mussolini's OVRA and Hitler's Gestapo.

The other system of early policing, consisting of citizens banding together for mutual protection, was best evidenced by the frankpledge system of early England. This beginning in communal policing eventually led to the development of the Metropolitan Police Act and a British police system that served as the model for most modern police forces.

ANGLO-SAXON BEGINNINGS

As ubiquitous as the contemporary Western police system may seem, it has existed in its present organizational form only for the past 150 years. The earliest policing system in England predates the Norman Conquest. The Saxon frankpledge was a private system of social obligation in which all adult males were responsible for the good conduct of all others. To formalize this social obligation, all males were grouped into tithings headed by a tithingman. Each tithing, in turn, was grouped into a hundred. The hundred was headed by a hundredman, who served as both administrator and judge.

When crimes were observed, citizens were expected to raise an alarm, gather their countrymen, and pursue and capture the criminal. All citizens were obliged to pursue wrongdoers, and those who refused were subject to punishment. If a crime was committed with no witnesses, efforts to identify the criminal after the fact were the responsibility of the victim alone; no governmental agency existed for the investigation and solution of crimes.

The frankpledge method of policing continued unchanged until the Norman Conquest in 1066, when the Normans added the office of constable to the system. The office of constable was originally a post in the royal court, but by the late 13th century the position had evolved into a local office of individual manors and parishes. In addition to their frankpledge obligations, constables were responsible for overseeing the "watch-and-ward" system (the nightwatch). The primary responsibility of the watch and ward was to guard the city gates at night. Later, the duties of watchmen were expanded to include lighting lamps, calling time, watching for fires, and reporting other conditions. Despite the addition of constables, however,

Police
specialists

The
frankpledge
system

the investigation and prosecution of crimes remained a private matter to be handled by the victims.

The Statute of Winchester of 1285 codified this system of social obligation. It provided that (1) it was everyone's duty to maintain the king's peace, and any citizen could arrest an offender; (2) the unpaid, part-time constable had a special duty to do so, and in towns he would be assisted by his inferior officer, the watchman; (3) if the offender was not caught red-handed, a hue and cry must be raised; (4) everyone was obliged to keep arms and to follow the cry when required; and (5) the constable had a duty to present the offender at court tests.

In one form or another, this system remained in place in Anglo-Saxon countries until the 19th century. Essentially, it was an unpoliced system in which police functions were fulfilled by citizens who held rotating local offices. Constables and watchmen were supported by citizens, posses, and, in the case of riots, by the military or the yeomanry (a cavalry force largely composed of landowners). Victims who could not recover their property offered rewards for its return and often resorted to hiring "thieftakers." These precursors to modern bounty hunters were private citizens who, for a fee or reward, attempted to identify wrongdoers and return stolen property to its rightful owners.

The stipendiary police. The system of private rewards grew until the payment of fees to justices of the peace and constables was firmly established. When communities began paying private citizens for the capture and conviction of thieves, a standard set of fees was established and a "stipendiary" police system evolved. Sources of fees for this system included public rewards, insurance companies, commercial houses, prosecuting associations, and funds raised by subscription. Any citizen, not only constables and justices, could earn those fees and rewards by becoming a thieftaker or "common informer."

Jonathan
Wild

Jonathan Wild is a notorious example of a private citizen who abused the system and turned it into a gigantic racket. He organized the London underworld and systematically arranged to have goods stolen so that he could sell them back to the original owners. Any thief wishing to remain independent of Wild's crime ring was delivered to the authorities (and ultimately the gallows). Finally, after a seven-year reign as the "Thief-Taker General," Wild, too, ended up on the gallows.

The stipendiary system was supported by a legal system that decreed Draconian punishments for crimes that, by today's standards, would be considered petty, and capital punishment and serious mutilation were prescribed for almost every conceivable crime. Such harsh punishments were handed out for two reasons—to deter wrongdoers from committing crimes and, failing that, to provide criminals with the opportunity to repent through punishment and save their souls.

The decline of constabulary police. Although the system of social obligation remained in place for more than 800 years and was transplanted to countries like Australia, Canada, and the United States, it had serious weaknesses that were amplified by industrialization and urbanization. The system had become corrupted, specially in the cities. The status of constables deteriorated through the years, and eventually the position became one of subservience to justices of the peace. As the office was degraded, persons of high social status no longer were willing to serve as constables. As a consequence, laws were established allowing persons to hire replacements to serve their terms as constables. While this did not create serious problems in small towns and agrarian areas, only the poor, aged, and infirm were willing to be constables in cities such as London, Boston, and New York City.

Although riots were an established means of political protest in agrarian England, they were an intolerable disruption of economic life in the urbanized England of the Industrial Revolution. The military and yeomanry, therefore, were called upon to quell rioting with increasing regularity. This presented two problems. First, calling in the military was seen as an easing of the restrictions on the political authority of the crown, and it was feared that once in place, the military could extend the king's political jurisdiction. Second, use of the yeomanry to control

rioting exposed propertied classes to attack and created another threat to political stability.

The constable system ultimately failed because it was inefficient. Serious crimes and disorders in cities had reached intolerable levels, and the current system was under constant attack from political leaders and writers like Henry Mayhew and Charles Dickens.

Powerful forces opposed reform, however. Every alternative to the stipendiary system required substantial public funding, and raising taxes was not popular. Also, the idea of government becoming actively involved in policing violated the basic tenets of the dominant political philosophy of the era, which posited that the government that governed least governed best. Political opposition to the idea of a standing police force was substantial. Concerned about the threat of political centralization and aware of the political abuses of the French, or "continental," police, political leaders envisioned the political misuse of a standing police force. Finally, provincial leaders saw inefficiency and corruption as "London" problems and believed that the constable system worked satisfactorily in their areas.

THE FRENCH POLICE SYSTEM

Pre-Revolutionary French police. The pre-Revolutionary French police system was totally different from the English system. Organized, financed, and controlled by the government, the French police were actually the personal political police of the king. The system serves as a striking example of action by a central government to enforce its own standards of behaviour. One fact, however, is certain—the 18th-century citizen of Paris was far better protected from crime than the citizen of London. Police in Paris were controlled by the *lieutenant-général de police*, an appointee of the king. Officially under the control of the minister of Paris, the lieutenant general included in his authority the scrutiny of social, political, and economic activities of Paris, as well as a responsibility for controlling crime and maintaining order.

Paris' 20 districts were policed by 48 *commissaires de police*, officials holding both local administrative and judicial authority in the districts; 20 *inspecteurs de police*, investigators responsible for collecting and collating information from each of the districts; 50 *exempts de police*, officials responsible for maintaining order and who were supported by *sentinelles* (foot soldiers) dispersed throughout the city; 10 brigades of 10 archers each who patrolled throughout the city; a watch guard consisting of 220 horsemen and 400 foot soldiers who also patrolled the city; and *mouchards*, irregular spies, or secret police, who obtained information on the activities of all citizens. The police system also was supported by the military, which could be called upon at any time by the lieutenant general.

Despite its use of preventive patrols, the system was characterized (and made infamous) by its undercover intelligence-gathering activities. *Inspecteurs de police* and *mouchards* gathered enormous amounts of criminal and personal information from spies, brothel keepers, employers, and interdicted mail. Indeed, at one time it was estimated that one-quarter of all the housemaids and lackeys in Paris were receiving money from the police in return for information about their employers and acquaintances. The police chief Sartine once boasted to Louis XV, "Sire, whenever three people speak to one another in the street, one of them will be mine." Each day this information was passed on to the king through the *bulletin moral* and was further distributed to political officials through the *bulletin politique ou d'espionnage*. The king could issue a *lettre de cachet* ordering the imprisonment of persons even if there was insufficient evidence to bring them to trial. Such letters allowed police to detain people without charge and to exercise a kind of summary justice.

At the same time the ordinary police took an active part in many aspects of the city's life. The lieutenants general of police built markets, paved and constructed streets, founded the Bourse (stock exchange), moved a cemetery, provided street lighting, established a system of state pawnshops, created a hospital for children, founded a veterinary college, built schools for children of the poor, sought work for the unemployed, and organized fire and

Political
abuse of
the early
French
police

river rescue services. The police took stock of the city's food supplies and forbade wine sellers to have leaden counters and milkmen to use copper vessels. They censored posters and regulated the employment of foster mothers. They persecuted Protestants, controlled the sale of lottery tickets, and inspected drains. They had the streets cleaned. They supervised cabdrivers, made regulations about dogs, checked food prices, surveyed dangerous buildings, read people's letters in the course of post, and even stopped fishmongers from selling oysters between April 30 and September 10. The police inspected prisons, read theological works for signs of heresy, and had a financial agency for the encouragement of overseas trade.

National police (*maréchaussée*), originally created to control crimes committed by patrolling soldiers, eventually were used to deter civilian crimes as well. Immediately before the Revolution, the *maréchaussée* consisted of 3,000 men organized into 30 patrolling companies. Officers had both the privileges of soldiers and the powers of civil arrest.

Post-Revolutionary French police. After the Revolution, the Paris police was reconstructed, and its direction was entrusted to a conglomeration of Parisian committees. The clumsy committee arrangement failed, and in March 1800 control of the police was centralized in the *prefet de police*, an office with administrative but no judicial authority.

The French Ministry of Police was created in 1796 with a mandate to enforce laws and forestall challenges to the Revolution. When Joseph Fouché was appointed director in 1799, he consolidated police administrative powers into four *arrondissements*, each directed by a *conseiller d'État*. His councillors operated with his authority and had few legal restrictions on their power. Ultimately, Fouché's power in France became second only to Napoleon's.

In Paris, Fouché maintained the pre-Revolutionary orientation of the police by recruiting more than 300 spies, including many ex-convicts, into the *regulators de l'opinion à Paris*. Spying was so ubiquitous that private individuals, the military, and even the Jesuits organized their own secret police forces. Eighteenth-century Parisians believed that police agents and spies were everywhere, listening for the smallest hints of discontent. They may have been right, but the belief that nothing that happened in Paris would go unnoticed by the police was far more helpful to the authorities than a host of paid undercover agents. The potential of this system to be politically misused, to stifle dissent, was enormous. Police regularly disrupted, controlled, and even shaped political thought, until corruption and injustice had riddled every phase of the system.

Perhaps the most famous manifestation of the French detective orientation of policing, at least with crimes of robbery and theft, was the Sûreté. The Sûreté was founded by François-Eugène Vidocq in 1810. A convict and a daredevil jailbreaker, Vidocq approached the police and offered to use his knowledge of the criminal world in exchange for his freedom. The police agreed, and eventually Vidocq became chief of the criminal police. Running the Sûreté with the philosophy that to know and capture criminals one had to be a criminal oneself, Vidocq directed a network of spies and informers in a war against crime that was completely successful. His knowledge of the underworld and his reliance on criminals to catch criminals were the reasons for his success. In 1817, with only 12 full-time assistants, he was responsible for more than 800 arrests.

THE FORMATION OF THE ENGLISH POLICE

The creation of the Thames River Police was one of the most significant police reform experiments of the time. The first regular professional police force in London, the Thames River Police was organized to curb the thefts that plagued the world's largest port. The West India Trading Company created these marine police in June 1798 and installed police reformer Patrick Colquhoun as director of a permanent staff of 80 men and an on-call staff of 1,120. Two features of the marine police were unique. First, patrols were preventive; officers patrolled visibly to prevent thefts. Second, officers were not stipendiary police; they were salaried and were prohibited from taking fees.

The venture was a complete success, and reported crimes dropped appreciably. In July 1890 the House of Commons passed a bill making the marine police a publicly financed organization, which ushered in a new era of policing.

Debate about the creation of a standing police force in England raged during the early part of the 19th century. Confronted with political objections and fears of potential abuse Robert Peel (later Sir Robert Peel) sponsored the first successful bill creating a bureaucratic police force in England.

The Metropolitan Police Act was passed in 1829 as a political compromise. The jurisdiction of the bill was limited to the metropolitan London area, excluding the City of London and provinces. All police were to be uniformed; crime and disorder were to be controlled by preventive patrols; police were to be paid regular salaries; and no stipends were permitted for successful solutions of crimes or the recovery of stolen property. But crime prevention was not the only business of the new police force: they inherited many functions of the watchmen, such as lighting lamplights, calling time, watching for fires, and providing other public services. "Bobbies," named after Peel, were not immediately popular. Most citizens viewed constables as an infringement on English social and political life, and people often jeered the police.

The preventive tactics of the early metropolitan police were successful, and crime and disorder declined. Their pitched battles with (and ultimate street victory over) the Chartists in Birmingham and London proved the ability of the police to deal with major disorders and street riots.

Despite the early successes of the metropolitan police, the expansion of police forces to rural areas was gradual. The Municipal Corporations Act of 1835 ordered all incorporated boroughs to set up police forces under the control of a watch committee, but it was not until 1856 that Parliament mandated that provinces establish police forces.

The Metropolitan Police Act established the principles that shaped modern English policing. First, policing was to be preventive, and the primary means of policing was conspicuous patrolling by uniformed police officers. Second, command and control were to be maintained through a centralized, quasi-military organizational structure. Third, police were to be patient, impersonal, and professional. Finally, the authority of the English constable derived from three official sources—the crown (not the political party in power), the law, and the consent and cooperation of the citizenry.

The origin of modern English policing

EARLY POLICE IN THE UNITED STATES

The United States inherited England's Anglo-Saxon common law as well as its system of social obligation and constables. As both countries moved from rural agrarian to urban industrialized economies, urban riots, crime, and disorder followed. Yet Americans, like the English, were wary of creating standing police forces.

In the early 1800s, as the United States became more urban, patterns of ethnic diversity began to erode the social and political hegemony of the original English and Dutch settlers. Not only did rioting, crime, and disorder begin to flourish, but the basic life-styles of new German and Irish immigrants offended the moral and social sensitivities of the original settlers. Immigrant and urban behaviour was perceived as a threat to the social, economic, and political fabric of American life.

The American response to growing urban unrest was twofold. Versions of the constable and nightwatch system were tried, and voluntary citizens' groups were encouraged to try to solve urban problems. Reformers distributed religious tracts and Bibles, started Sunday schools, created organizations such as the Young Men's Christian Association, and presented themselves as moral examples to immigrants and the poor. By the mid-19th century, middle-class frustration with the deterioration of the cities led to the passage of laws regulating public behaviour and creating new public institutions of social control and coercion—penitentiaries, asylums, and police forces.

In 1844 New York City created the first police department in the United States, using the London Metropolitan Police as a model. Boston and Philadelphia followed. The

Vidocq and the Sûreté

idea of police spread quickly, and in 10 years cities as far west as Milwaukee had created police departments. The model for American police originated in England: police were organized in a quasi-military command structure; there were no detectives; their task was the prevention of crime and disorder; and they provided a wide array of public services.

Each city created its own police department. Since Americans lacked a unifying symbol like the English crown, local politics and laws became the primary bases of police authority. The decentralization of the authority for policing was extended to political wards and neighbourhoods, which developed relatively autonomous police units. The police established intimate relations with neighbourhoods and neighbourhood leaders and initially did not even wear uniforms. Middle- and upper-class reformers believed that one of the primary tasks of the police was to reestablish political and social control over a population wracked by ethnic and economic rivalries. This tension between being closely linked to communities and being perceived of as an instrument for reform of those same communities inevitably resulted in struggle for political control of the police. This struggle for political control is one of the dominant themes in the history of police in the United States.

DETECTIVE POLICING IN ENGLAND AND THE UNITED STATES

The investigation of crimes was not a central function of the newly formed preventive police departments in England and the United States. In both countries, thief-takers, stipendiary police, and constables continued their investigations of criminal activities. Despite the high hopes of reformers when they created the police, the number of preventable crimes was limited. As victimizations continued, police were pressured into accepting public responsibility for investigations and creating detective units. The London Metropolitan Police created the first criminal investigation division (CID) in 1842. Many American cities followed with detective units: Boston in 1846; New York City in 1857; and Chicago in 1861.

Investigators usually were recruited from former thief-takers or constables who had continued their stipendiary investigative activities after the creation of police departments. Although they brought investigative skills to the police, they also brought the bane of stipendiary police—corruption. In 1877, when three of the four chief inspectors of the CID were found guilty of corruption, the CID was eliminated although later reorganized. Chicago disbanded its unit in 1864 and Boston its unit in 1870, and New York City suffered major scandals in 1877—all as a consequence of corruption. All of these cities soon reconstructed their investigative units, but improvement of the status of detectives had to wait until well into the 20th century.

LATE 19TH-CENTURY ENGLISH AND AMERICAN POLICING

After the Act of 1856 mandated police in the provinces, police departments spread throughout England. Provincial police were funded by both local and central governments. After the Home Office certified the quality of a provincial police department, the central government paid half of the cost of local policing, and local taxes paid the rest. The dominant methods of provincial policing were foot patrols and criminal investigations.

Policing in the United States during the late 19th century, however, was complicated by migration and immigration, which continually reshaped the ethnic and cultural makeup of cities, and by the radical decentralization of police authority within the cities. Decentralized policing had one major strength: it gave police close contact with the public. Police knew the local citizens, and often they were recruited from the very neighbourhoods they policed. Such close communities allowed police to spot troublemakers, identify local problems, and provide an array of public services to the residents, such as manning soup lines and providing overnight lodging in police stations for immigrants.

The decentralization of police jurisdictions to individual cities also created problems. Crime did not respect jurisdictional lines, but police organizations had to. Thus, al-

though serious crimes were rife on the American frontier, no national or state police organization had jurisdiction over crimes committed there. A second problem arose from the lack of a national organization. Since no binding ideology of policing existed, each police organization was an entity unto itself. Each department formed local policy and had little or no communication or coordination with other police organizations. Unlike English policing, for which Sir Robert Peel had articulated a unifying vision, American policing was atomistic and without a coherent identity.

In response to the intra-jurisdictional crime waves of the latter half of the 19th century, states enacted laws giving many corporations the authority to create their own private police forces or to contract with established police agencies. The Coal and Iron Police of Pennsylvania was an example of a company police force that later became notorious for its antilabour vigilantism. The most famous independent police force was the Pinkerton National Detective Agency. Created by Allan Pinkerton, a political fugitive from Scotland, the Pinkerton agency provided a wide array of private detective services, specializing in protecting trains, apprehending train robbers, and participating in anti-labour union activities.

Attempts in the late 19th century to develop a coherent vision of an intercity police system were largely unsuccessful; the police theory that did develop, however, was formulated mainly in local political halls. As ethnic residents gradually gained political control of city wards and neighbourhoods, the link between the police and neighbourhood politics became closer. In some instances the relationship became so close that the police were actually seen as adjuncts of the local political machines. The linking of police and politics bred political and financial corruption and injustice. Police became involved in partisan political activity to ensure election of particular candidates; they received "gratuities" for not enforcing unpopular vice laws; and they excluded strangers from social and political life.

By the end of the 19th century, middle- and upper-class citizens attempted to centralize political power to end the ward-level political control of ethnic minorities. Reformers attempted to centralize services on a citywide basis, create a civil service to end political patronage, and transfer control of police to cities-at-large, or, if all else failed, transfer control of the police to the state government.

DEVELOPMENTS IN AUSTRALIA AND CANADA

Australia. Settled as a penal colony in 1788, Australia first used the British constabulary and watch-and-ward systems. Problems plagued these systems, however, because both constables and watchmen were often recruited from the ranks of convicts. Modeled after England's Metropolitan Police Act, the Sydney Police Act of 1833 led to the establishment of urban police forces. Police coverage was extended to rural areas in 1838 when each of the country's six states created its own state police agency.

Although the state police encountered a lack of public acceptance and many of the same problems of police in England and the United States, their task was complicated by additional responsibilities. Not only were they mandated to capture villains, but they also were responsible for inflicting corporal punishment on convicted criminals. Moreover, from their inception, Australian police duties included the enforcement of health and welfare provisions of the law.

Canada. Canada's earliest legal traditions can be traced to both French and English origins. Quebec City followed French traditions and created a watchman system in 1651. Upper Canada, later renamed Ontario, adopted English traditions and established both a constabulary and a watch-and-ward system. The English system was imposed on French areas after 1759. Using England's Metropolitan Police Act as a model, Toronto created a police department in 1835, Quebec City in 1838, and Montreal in 1840. Provincial police forces were established in 1867 to provide police coverage for the vast rural areas in eastern Canada.

The North West Mounted Police (renamed the Royal

The North
West
Mounted
Police

Strengths
and
weaknesses
of decentral-
ized
policing

Canadian Mounted Police in 1920) were created in 1873 to police the vast western plains. The original 300 officers initially were assigned the task of eliminating incursions of whiskey-trading Americans who were inciting Canadian Indians to acts of violence; later the force spearheaded attempts to mold the Canadian frontier into an integral part of Canada.

The North West Mounted Police represented a significant departure from Anglo-Saxon policing traditions. Reminiscent of continental policing in organization, style, and method, they operated more like a military organization than the traditional police force. Strong leadership ensured that they operated with restraint and within Canadian political traditions. The Royal Canadian Mounted Police, along with city and provincial police forces, constitute the three-tier police system now in place in Canada.

20TH-CENTURY POLICING

The struggle for political control of police in the United States gave rise to a distinctive strategy of policing that was to influence policing throughout the Western democracies. This new style of policing integrated managerial techniques, sources of authority, innovative tactics, and a narrowed definition of police work.

The first two decades of the 20th century were tumultuous times for American police: progressives battled entrenched ward and "machine" leaders for political control; labour unrest and concerns about Communist influences preoccupied many politicians and local police organizations; political and economic corruption were widespread at all levels of government; and, the Prohibition movement was becoming a political force. Riots, mass demonstrations, and bombings were not unusual. Arrayed against these vast social problems were scattered local police forces and private detective agencies. So limited was their ability to handle such diverse national and local problems that federal and state governments were forced to create additional police agencies.

Federal and state police. The United States Secret Service was created in 1865 to prevent counterfeiting. Never numbering more than 30 or 40 agents during the 19th century, the agency was operated in the traditions of the previous century. During the 1890s the Secret Service occasionally was called upon to guard the president, but that was not made a permanent duty until 1901.

The Bureau of Investigation—later the Federal Bureau of Investigation (FBI)—was created in 1908. In debates reminiscent of those in the British Parliament a century earlier, the U.S. Congress opposed the creation of a secret investigatory agency. In this case the concern was more than ideological—the Secret Service had been investigating corruption in Congress as well as in governmental agencies, and many congressmen were wary of increasing the president's investigatory powers. At Pres. Theodore Roosevelt's direction, Charles J. Bonaparte bypassed the reluctant politicians and created the bureau by executive order after Congress had adjourned. The Bureau of Investigation began with a modest mandate to investigate antitrust cases, several types of fraud, and certain crimes committed on government property or by government officials.

In 1920 the Treasury Department created the first sizable federal police agency. Charged with enforcing Prohibition, T-Men, as they came to be known, grew to a force of approximately 4,000 during the peak of the crusade against alcohol.

During the early 1900s states also began creating police forces. Although some states, such as Texas and Massachusetts, had small police forces earlier, in 1905 Pennsylvania established the first modern state police department. Formed with the professed purpose of fighting rural crime, state police in Pennsylvania (and later other states) were used primarily to circumvent corrupt or inefficient local police forces and to control strikes where city police were considered to be sympathetic to the unionists. Other states followed Pennsylvania's lead: New York in 1917; Michigan, Colorado, and West Virginia in 1919; and Massachusetts in 1920. Regarded as models of efficiency and honesty, state police were the prototypes of

what came to be known as professional police organizations: highly disciplined, narrow in focus, and organized along rigid military lines of command and control.

Municipal police reform in the United States. Most efforts to reform the police system during the late 1800s originated from reformers who were outside the occupation of policing. During the early 1900s, pressures for reform started within the police system itself. The most notable and representative police reformer was August Vollmer. Beginning his career in 1905 as the head of a six-person police department in Berkeley, Calif., Vollmer ultimately offered a vision of policing around which the nation's police rallied.

Prohibition was the worst of times for police: corruption flared, fueled by vast amounts of bootlegging profits; public confidence declined; and the profession came to be symbolized by Hollywood's Keystone Kops, who portrayed police as inept and venal. Vollmer and his colleagues were concerned about the broad social issues of policing. Changes in morals, increases in crime and corruption, and, later, the Great Depression, all were seen by reform-minded police as symptoms of the erosion of the authority of basic social institutions like the family, church, schools, and neighbourhoods.

Vollmer saw the police as the vanguard for socializing America's youth. In his view police should continue their traditional law enforcement role, and when necessary they should arrest and process delinquent youths through juvenile and adult courts. Arrest, however, was an undesirable outcome. Special juvenile bureaus should be created to handle problems of children and families; police should take a more active role in casework for social agencies; police should exploit their intimate knowledge of the community and place themselves at the hub of community activities with youth and families.

In addition to giving police an ideal to strive for, Vollmer also helped consolidate the International Association of Chiefs of Police (IACP) into a truly national police organization. Under its auspices he created the Uniform Crime Reports, which became an important indicator of the health of society and of the performance of police departments. Finally, through his work on the Wickersham Commission, Vollmer exposed many unconstitutional police practices to public scrutiny, especially the practice of detectives using the "third degree" in questioning suspects.

New models of policing. When J. Edgar Hoover took over the Bureau of Investigation in 1924, he laid the groundwork for a strategy that was to make the FBI one of the most prestigious police organizations in the world. The public's opinion of detectives was ready for change. Inspired by detective-heroes in the novels and short stories of Charles Dickens, Edgar Allan Poe, and Sir Arthur Conan Doyle, readers developed a new interest in real-life accounts of detectives' exploits. Hoover set out to make the fictional image of the detective into reality. He eliminated corruption by suspending bureau investigations requiring considerable undercover or investigative work (e.g., vice and, later, organized crime) and by creating a strong bureaucratic organization that emphasized accountability. Educational requirements were established for new agents, and to ensure that they were well trained in police procedures, Hoover created the FBI Academy. He concentrated his resources on crimes that received great publicity and were relatively easy to solve, such as bank robberies and kidnappings. But most of all, Hoover assiduously cultivated publicity to create an image of the "G-Man" as the nation's incorruptible crime fighter.

Vollmer's idealistic vision of police work, with its strong elements of social work, was soon replaced by Hoover's strategy. Ironically, Vollmer's protégé, O.W. Wilson, became the architect of the new police model. Instead of broadening police responsibilities as Vollmer had proposed, the new reformers narrowed them to concentrate on fighting serious street crimes. They also moved to sever the close ties between police and neighbourhoods: assignments were changed often; police no longer patrolled areas in which they lived; and, most importantly, police began to use automobiles to patrol. To insulate police from political influences, reformers created a civil service to hire and

The police reforms of August Vollmer

O.W. Wilson's new police model

promote officers and modified the basic police authority from law and politics to law only (especially criminal law). Finally, administrative decentralization within cities was abandoned, and police departments developed centralized citywide bureaucracies that restricted discretion at all levels of the organization. Since its introduction this model has dominated American policing. As the political influence of the United States grew after World Wars I and II, American policing methods spread to other nations.

Until the 1930s and '40s, police tactics were based on crime prevention by conspicuous foot patrol. As automobiles became a more important part of American life, and as reform-minded chiefs broke police officers' ties to neighbourhoods, more officers were assigned to automobile duty. The full motorization of American police was largely accomplished after the end of World War II.

The rationale for using automobiles in anticrime patrols was manifold. Police cars moving randomly and quickly through city streets would create a feeling of police omnipresence to deter criminals and reassure citizens of their safety. Rapidly patrolling police also would be able to spot and intercept crimes in progress. The use of radios in police cars increased the value of automobile patrols. The rapid response to calls for assistance would either deter criminals or help in their immediate apprehension. Police throughout the United States set an optimum goal to arrive at the scene of a crime within three minutes of its first being reported.

Contemporary policing. Wilson's strategy of policing came into fruition during the 1960s. Indeed, in 1967 the President's Commission on Law Enforcement and Crime, which was critical of the strategies of other criminal justice agencies, endorsed both preventive patrol and rapid response to calls. They agreed that improvement of policing would come as a result of fine-tuning police organizations, equipment, and personnel and that the basic strategy of policing was satisfactory. The commission noted that preventive patrol elicited hostility from some, especially minority, communities, but that its anticrime potential was so great that it had to be maintained. Police community-relations programs were proposed to offset the negative results of preventive patrol.

In Britain the police strategy of Sir Robert Peel was successful during the 20th century. Although influenced to some extent by the tactics of American police, the British approach appealed to the public and remained effective. Foot patrols continued in most cities, which lacked the suburban "sprawl" of American cities. Although "fire brigade" policing, as many British characterized the rapid-response orientation of American police, had some influence in Britain, it was counterbalanced by the continued emphasis on the neighbourhood bobby.

Aside from terrorism, which confronts police in all countries, the most serious contemporary problem facing British police surfaced during the 1980s—urban rioting by youths, often minorities, who believed that police tactics were brutal and unjust. The Scarman Report, which resulted from an official inquiry, suggested that police had become too remote from their communities, that local citizens should have more input into police policy-making, and that police tactics should be more sensitive to the growing cultural pluralism of Britain's major cities.

Research and new developments in policing. American policing strategy underwent a crisis during the 1960s. Crime continued to rise despite massive financial outlays for increased numbers of police. The depth of hostility that minority communities felt toward police surfaced during the riots and civil disturbances of the decade. Minority leaders not only resented the police tactics used to suppress civil disturbances, but many also believed that police actions actually caused the riots. With the fear of crime escalating more rapidly than crime itself, citizens refrained from using public and private facilities, took self-defensive measures, and abandoned city streets and parks; many fled the cities completely. Research studies were initiated to find a means of reversing these trends.

In the 1950s and '60s, both civilian and police groups assumed that the primary activity of police officers was dealing with crime and doing so with little discretion. Re-

search on police functions conducted during this period, however, showed that when police activities, calls, and dispatches were analyzed, anticrime activities constituted less than 20 percent of patrol activities. The remaining patrol functions included resolving conflicts, providing emergency services, maintaining order, and providing other public services. Moreover, it was discovered that police officers regularly used discretion in handling events, criminal or otherwise, and that the use of discretion was an essential ingredient of police functions.

One of the earliest and most sophisticated research efforts concerning the effectiveness of police patrol was the Bright Foot Patrol Experiment in Britain in 1970. Although this experiment indicated that crime declined in areas covered by officers on foot patrol, efforts to further decrease crime by using additional foot patrols in the same neighbourhoods did not have a measurable impact.

American studies on the efficacy of preventive automobile patrols found that, despite the commitment of substantial amounts of police time to patrol, relatively little crime-related activity resulted from police initiatives. The vast majority of arrests (93 percent) resulted from citizens' requests for police action. Later studies suggested that preventive patrol by automobile did not effectively attain its goals to reduce crime, increase the public's satisfaction with police, or decrease citizens' fear of crime. Moreover, research studies on the efficacy of rapid response to calls for service suggest that it has little impact on crime prevention or criminal apprehension and that alternative approaches might produce greater levels of citizen satisfaction.

Introduced in the New York City Police Department by Patrick V. Murphy, team policing emphasizes decentralized patrol decisions by teams of officers policing a limited geographical area. Patrol decisions are made on the basis of relatively close communication with local leaders and residents.

Another promising area of police activity focuses on eliminating the opportunities for crime. Certain conditions, such as leaving one's keys in a car, invite crime. By identifying conditions that increase the likelihood of criminal activity, police can help develop policies and procedures to alter conditions and thereby make crimes more difficult to commit. Automobile thefts can be reduced, for example, by making automobiles more difficult to steal.

In the 1970s and '80s strong community anticrime efforts also were developed in many countries, including the United States, Canada, and Britain. In a sense, these groups represented a return to the ancient tradition of social obligation, with each citizen obliged to come to the aid of others. Although police were instrumental in developing such groups, in cities such as Boston, Philadelphia, and Chicago, which had traditions of strong neighbourhoods, many groups developed on their own. Research suggests they are relatively effective in reducing crime and fear in neighbourhoods. Police experience and research suggests that police action, in itself, is limited in its ability to prevent and investigate crime. Police can be successful only to the extent that they work closely with citizens.

Indeed, the most promising development in American policing during the 1980s was community policing. Incorporating many of the ideas of team policing with research on foot patrols, community policing is an attempt to reintegrate the police officer into the community. Community policing has since proved so effective that most major U.S. cities, including New York City, Los Angeles, Chicago, Houston, and others, have either implemented the procedure or experimented with it. (G.L.Ke.)

CENTRALIZED POLICE ORGANIZATIONS

The United States and Britain typify countries that have developed decentralized police organizations. France and Italy, on the other hand, are examples of countries with highly centralized police forces.

France. The centralized police force of France's Revolutionary period gradually developed into two national police organizations: the Police Nationale and the Gendarmerie Nationale. The Police Nationale was formed in July 1966 by the amalgamation of the Prefecture of Po-

Eliminating opportunities for crime

British police strategy

lice of Paris and the Sûreté Nationale, which had been responsible for policing the provincial towns and for certain specialized work. The director general's headquarters includes divisions covering general intelligence, judicial police, public safety, security, regulations, training, and personnel.

The Gendarmerie Nationale is composed of soldiers formed in strictly disciplined units and quartered in barracks. In the larger towns there are Gardiens de la Paix who serve as municipal police, responsible for preventive patrol and the control of traffic.

The mayors of certain communes have communal or rural policemen at their disposal; but, as a rule, police work in country districts and in towns with less than 10,000 inhabitants is undertaken by gendarmes.

These divisions within the French police service, and the separate ties that units have with local administrators, suggest that, though centralized, the French police is far from monolithic. There are many opportunities for one police body to check upon the activities of another to prevent corruption.

Italy. Italy, too, has several national police forces. The Public Security Guards (Guardia di Pubblica Sicurezza), which is part of the armed forces, is charged with the maintenance of internal public security and order, with the protection of life and property, and with preventing and checking crime and gathering evidence in criminal matters. Although the force is of a semi-military character, it performs all normal police functions and is responsible to the minister of the interior. The Corps of Carabinieri is a military-like body housed in barracks; it is responsible to the minister of defense in certain matters but to the minister of the interior in regard to police duties. As an executive organization for the detection of crime, the corps carries out duties assigned to it by law, under the direction of judicial authorities to whom it reports on investigated crimes. At every level, commanders of the corps must maintain liaison with the army and with political, judicial, and police authorities. A Guardia di Finanza is charged principally with protecting the national frontiers from activities connected with smuggling, counterfeiting, illegal entry, and tax evasion. In addition to the national forces, municipalities maintain their own police, the Vigili Urbani, which undertake certain kinds of municipal administration but are increasingly concerned with traffic control. Frequent attempts have been made to amalgamate the Vigili with the Public Security police, but the municipalities have resisted such proposals.

DECENTRALIZED POLICE ORGANIZATIONS

United States. The United States provides a picture of what may be the most decentralized police system in the world, accompanied by an extraordinary degree of duplication and conflicting jurisdiction. Since there is no federal government control to ensure uniform standards, every community is entitled to run its own police department but cannot exclude federal or state officials from investigating offenses over which they have jurisdiction. There are five major types of police agency: (1) the federal system, consisting of police officers attached to the Department of Justice (the Federal Bureau of Investigation, together with 700 U.S. marshals), the Bureau of Internal Revenue (investigating tax evasion), the U.S. Secret Service, the Drug Enforcement Administration, the Postal Inspection Service, and many others; (2) police forces and criminal investigation agencies established by each of the 50 states of the union; (3) sheriffs and deputy sheriffs in more than 3,000 counties, plus a few county police forces that either duplicate their police jurisdictions or displace them; (4) the police forces of about 1,000 cities and more than 20,000 townships and New England towns; and (5) the police of some 15,000 villages, boroughs, and incorporated towns. To this list must be added special categories, such as the police of the District of Columbia; various forces attached to authorities governing bridges, tunnels, parks, and parkways; university, or "campus," police forces; and some units for policing special districts formed for fire protection, soil conservation, and other diverse purposes. The usual estimate is that there are about 20,000 separate

public police agencies in the United States and that the majority of them consist of one, two, or three men who are not employed full-time. Many are not paid wages but are compensated by the payment of fees for duties undertaken.

These police forces are controlled in different ways. The federal bodies are responsible to the federal authorities, and the state forces to the governors of their states. At local levels there are variations. States are divided into counties, and every county has its sheriff, usually elected and with responsibilities for the investigation of crime and the supervision of the custody of prisoners. He may have deputies performing duties as uniformed policemen. In some states there are county police forces under the control of county boards, whereas elsewhere, appointments are made by state governors on the recommendation of the county authorities. In some places county police forces are completely independent of the sheriff's office.

The existing American police structure to some extent reflects public opposition to any concentration of police power. It has been argued that the nation would suffer should all offenses become federal offenses and should power be transferred to Washington, D.C., and local government be enfeebled. Local problems require local remedies, and the weaknesses of big government are all too apparent. On the other hand, it is argued that the integration and consolidation of police forces could result in an improved service that would reduce costs, increase efficiency, and eliminate the problems of overlapping jurisdictions. The first steps in this direction have been taken in respect to training. Since 1960 no police officer in the state of New York has been able to assume his duties until he has received a certificate for successfully completing basic training. California has introduced grants-in-aid for training that are so attractive that most municipalities are taking advantage of them. Other states have adopted similar schemes. The federal government has made available to the police, through the Law Enforcement Assistance Administration, substantial funds for improving police resources and their management.

Australia. Certain other countries with a federal political structure have federal police forces complementing state forces, but the principles involved are no different from those exemplified by the United States. In Australia, for example, each of the six states has its own laws but does not legislate in matters pertaining to federal organizations and cannot pass laws at variance with those of the commonwealth. Each state has its police force. The minister of administrative services oversees the Australian Federal Police who are responsible for the enforcement of federal legislation. Other police forces under federal control are responsible for overseas territories, the Northern Territory of the subcontinent, and the capital territory.

The U.S.S.R. In many countries, changes in the structure of police administration have been in the direction of greater centralization; and it is of interest to consider a country where the change has been in the reverse direction. After the death of Joseph Stalin the police force of the Ministry of State Security of the Soviet Union was absorbed into the force of the Ministry of Internal Affairs (MVD) under Laventry Beria, who was arrested less than a year later. This force was then divided. The organization dealing with state security was transferred to the Committee of State Security under the Council of Ministers of the U.S.S.R.; known by the initials KGB, it is understood to be primarily a counterintelligence agency. The body that carries out duties performed elsewhere by the normal uniformed police is the militia. Prior to 1956 it was centralized under the Ministry of the Interior, but in December of that year the administration was decentralized. Units are now subject to control by the higher organizations of the militia, by the soviet of the local administrative area, by the local representative of the procurator general of the U.S.S.R., and by the courts. In 1960 the MVD was abolished, and in some areas the militia was itself replaced by Public Order Detachments made up of workers, builders, farmers, teachers, and students. Two and a half million citizens were enrolled into these detachments as voluntary militia. Two years later these new detachments were being

Carabinieri

Major
types of
U.S. police
agencies

criticized in the Soviet press for using their powers in too high-handed a way. To the outsider it would seem as if the Soviet Union found that a highly centralized police service was not accountable to the public and that better responsiveness required drastic decentralization, even to the extent of occasionally relying upon citizen volunteers.

(M.P.B./Ed.)

SECRET POLICE

Secret police are a special category of police. Established by national governments to maintain political and social orthodoxy, they are generally clandestine organizations that operate independently of regular civil police.

Abuses
of secret
police

Two notorious 20th-century secret police forces, the Nazi Gestapo and the Russian NKVD, were formed during the early days of unstable regimes. The Nazis, a minority party elected to power, quickly moved to cement their political control by taking control of the civil police and the military with their secret police organization. Their tactics included the arrest, imprisonment, torture, or assassination of political foes, as well as subversive activities aimed at discrediting political enemies and contenders for power.

Russian Communists, after a surprisingly successful political revolution, used secret police (then known as the Vecheka or Cheka) to intimidate and eliminate political enemies. Later Stalin used the force to eradicate all competing political forces and contenders for authority both inside and outside the Communist party.

Secret police not only have the traditional police authority to arrest and detain, but in some cases they are given unsupervised control of the length of detention, assigned to mete out punishments independent of the judiciary, and allowed to administer those punishments without external review. Civil police or militia may continue their traditional common policing roles and may even, at times, restrain secret police, but the tactics of investigation and intimidation permit secret police to accrue so much power that they usually operate with little practical restraint.

In the Soviet Union, Nikita Khrushchev's public revelations of the horrors of Stalin's NKVD is thought to have greatly reduced the organization's powers. However, even though the Soviet secret police have come to operate with more restraint, the potential for serious abuses still exist.

On occasion some police agencies in liberal democracies, like the CIA in the United States or the DGSE in France, also take on characteristics of secret police when they move to discredit political or social deviants. However, since most democracies establish governmental agencies to scrutinize and control secret police organizations, there is little comparison between their excesses and those of genuinely secret police like the Gestapo.

Police work and law enforcement

ROUTINE POLICE ACTIVITIES

Watchman,
legalistic,
and service
styles of
law en-
forcement

Earlier reference was made to the way in which police activity is adapted to the kind of society that is to be policed. There are features common to the work of police in differing societies that are founded upon similar technology. Yet within the same society, at times within the same police force, there are variations in the policies of police chiefs. One police administrator, because of his personal beliefs or because of his perception of public opinion, may allocate more officers for the investigation of vice than of fraud, may allocate more or fewer officers for traffic control or crime prevention. A police chief may instruct officers not to bother about prostitution, provided it is confined to a given locality. Thus, the police in different neighbourhoods may follow different patterns of policing.

Within the framework of enforcement policy, police work is divided into various branches. The largest number of officers is usually allocated to uniformed patrol, either on foot or with motor transport. Studies of the activities of police on patrol indicate that only a small portion of their time goes to the making of arrests or to initiating formal actions under the criminal law. Moreover, whether one examines the types of calls for service that police receive, the calls to which police are dispatched, or the activities that police initiate on their own, it is clear that the ma-

jority of police activities consist of providing emergency services, maintaining order, resolving disputes, and providing other services.

POLICE AND COURTS

One of the most important ways in which police are held accountable for the manner in which they perform their duties is through the courts. In France (and in countries with similar juridical procedures) the police making inquiries are under the direction of the investigating magistrate, whose task it is to decide whether there is a case for trial and, if so, what it is. The French think it improper that police should inquire into a citizen's activities without his knowledge that they are doing so and without these investigations being under judicial control. The British and American procedure is very different. Anyone may prosecute. The judge listens to the prosecution's argument and evidence that the accused has broken a particular law, and he listens to the defense. Then he decides between them. If he finds the case proved, he then inquires into the accused's previous record and determines the sentence. Should it transpire that the defendant has broken a law but not the one he is accused of having broken, the case must be dismissed.

If the accusatorial system is to function justly, the police must bring all cases of lawbreaking before the courts. It is for the court to decide whether they merit punishment. But, in practice, the police exercise considerable discretion as to whom they will prosecute.

There are three chief arguments in favour of police discretion. First, it has not been possible to draft and keep up-to-date a criminal code that unambiguously encompasses all conduct intended to be made criminal and none other; there are technical offenses or offenses that public opinion no longer regards as culpable. Second, those charged with enforcing the law do not have sufficient resources to enforce all the laws all the time, so that enforcement must be selective. Third, to bring a technical offender to court may, in practice, unduly damage that person's reputation.

The courts control police activities in other ways. In Britain a set of publicized "Judges' Rules" outlines safeguards for accused persons while under investigation. If in court it can be proved, for example, that the police failed at the proper points to warn a person that he was under suspicion of having committed a particular offense and that any statement he might make could be given in evidence, then the prosecution might fail. In the United States the Supreme Court has held that an accused need not answer police questions and that he has a right to consult a lawyer before questioning; if he cannot afford to hire a lawyer, one must be provided. In other decisions, police have been prevented from submitting at a trial any evidence that was obtained by unreasonable search and seizure.

tion

CROWDS AND RIOTS

The London police have developed skillful methods of crowd control but have had little experience of urban rioting on the scale with which American police were confronted in the 1960s. Both crowds and riots require patrol officers to adopt a very different approach from that to which they are accustomed. Normally, police are free to handle members of the public in an individual manner. But the control of civil disturbances requires large numbers of disciplined personnel working as a team under unified command.

From their beginnings in 1829, the English metropolitan police were careful not to overreact when handling crowds. In Britain, if the police fail to control a riot, recompense for the damage has to be paid by the police authority for the district. Were the police to use, say, water cannon, an injured onlooker could sue the police for assault. The London police use no riot squads, no protective clothing, no arms, no riot gas, and no barriers for crowd control. The police line has always to be in close contact with the crowd, preventing the stone throwing and violence that occurs when there is a gap between them and the citizenry. The advantages of the passive police stance encouraged by their legal accountability were exemplified by four

British
methods
of crowd
control

London demonstrations in 1967–68 against U.S. policy in Vietnam. At the fourth of these, in an atmosphere made tense by press apprehensions of revolution, some 50,000 people marched through the city. In February 1971 a demonstration of some 140,000 individual workers passed without an arrest.

Disturbances that erupted in more than 50 American cities in 1967 posed serious problems for the police. Most of these disturbances began during the evening watch, when a police department normally has about 13 percent of its uniformed force on duty. At this time, a city with a population of about 500,000, for example, would have had about 95 uniformed police officers on duty. The National Advisory Commission on Civil Disorders found that many of the disturbances began when allegedly abusive or discriminatory police actions set sparks among the grievances of blacks. In some cases the police were unable to control the resulting situation, and the National Guard, composed of private citizens who undertake part-time military duty, was summoned. The commission concluded that the National Guardsmen were inadequately trained for riot duties and that their performance in 1967 raised doubts about their capabilities for such assignments. Whereas in some cities National Guardsmen and police fired thousands of rounds of ammunition, in others regular troops restored order by calm discipline and little use of firearms. The experience of the 1967 disorders suggests that giving the police more destructive weapons is not sufficient to maintain order when a substantial section of the population is disaffected.

POLICE WORK AS AN OCCUPATION

As has been seen, some police bodies are constituted as part of the armed services. In some European countries it has been normal to recruit as police those who have served as regular soldiers or sailors. It has been even more common to appoint retired army, navy, or air force officers to command police forces. Since World War II the trend has been in the opposite direction.

Police work is seen as a specialist career, and it is argued that the senior positions should go to those who have learned the work by experience. This poses certain problems of recruitment. It is argued that the police should be able to offer appointments as cadets to young persons who want to become policemen. If they have to wait until they are 21 years or so before they are eligible for appointment, they may be lost to the police. On the other hand, it is said that a youth who has come straight into the police from secondary school has had too little experience of life and is likely to be too narrow in his outlook. Cadet training schemes therefore seek to give such entrants a wider experience by sending them to social-service agencies and other bodies.

A similar problem is that of officer entry. The French recruit graduates to the Police Judiciaire by examination, and in Norway only those with legal qualifications are eligible for appointment as police chiefs. In the United States many universities offer courses in police science, and those who obtain qualifications in this field have a certain but limited career advantage. In Britain, graduates are welcomed but have to compete with other entrants for promotion. The most able among the younger officers are selected for a 12-month course at the national Police College at Bramshill; they divide their time so that half is devoted to professional and half to general studies, by contrast with the rather shorter courses at the Federal Bureau of Investigation Academy at Quantico, Va., where all the teaching concentrates on police subjects.

INTERNATIONAL ORGANIZATION

The International Criminal Police Organization (Interpol) has a history going back to 1914, though its present constitution dates from 1956. Each member nation has established a bureau that maintains relations with the General Secretariat in Paris. The bureaus transmit criminal information that may be of interest to other countries; they undertake, within their own countries, inquiries, searches, and arrests requested by other countries; and they take steps to implement resolutions voted by the annual as-

sembly. Interpol can act only within the framework of national laws; criminals can be returned only if an extradition treaty is in force and the offender is a national of the country requesting return. The International Association of Chiefs of Police, with headquarters near Washington, D.C., draws its members largely from the United States and is the leading voice in the United States for professional police standards. It is active in training, research, and public relations. The International Police Association was founded in Britain in 1950 as a social organization. Although it is most active in Europe, its members come from dozens of nations worldwide. The association grants scholarships for study travel and arranges annual conferences. (M.P.B./Ed.)

Police technology

Police technology covers the methods and techniques of, and the equipment available to, police agencies. Throughout the 20th century, improvements and innovations have been made in police transportation, communications, weaponry, laboratory facilities, and other areas, but these have scarcely more than kept pace with the pressures generated by denser urban populations, greater sophistication on the part of criminals, social disturbances, and new types of crime made possible by economic and technological developments—*e.g.*, aircraft hijacking and computer fraud.

Police technology increasingly involves borrowings from the physical and social sciences, as well as from the fields of jurisprudence and education. Although it was only in the 1960s that police technology became recognized as a distinct academic and scientific discipline, the proliferation of professional publications, educational programs, workshops, and international conferences of police reveals the growing importance attached to the technical aspects of police work.

Two influences serve to restrict the application of technology to police work. First, technical problems themselves may arise when the technology of one discipline is transferred to a different application in police science. Second, in the United States and other democracies, constitutional and legal issues may limit or prevent the use of feasible technologies in police work.

Many examples of an incipient police technology can be found in the ancient and medieval world. Long before the beginning of the Christian Era, Egyptians used detailed word descriptions of individuals, a concept known in modern times as "portrait parle." The Babylonians pressed fingerprints into clay to identify the author of cuneiform writings and to protect against forgery. Fingerprints were also used by the Chinese at an early date for purposes of identification. The concept of comparison and identification of handwriting was established in Roman times, as is evidenced by the Code of Justinian of the Eastern Roman Empire, first enacted in AD 529. Branding and mutilation were used from time immemorial to identify convicted criminals. Trial by ordeal and trial by combat were medieval methods of interrogation of suspects, with the survivors judged innocent. A more humane medieval method, and a step toward modern concepts, was compurgation, in which the friends and families of the disputant took oaths not on the facts but on the disputant's character.

An Asian interrogation method involved scientific principles based on the lessening of salivation under nervous tension. The mouths of several suspects were filled with dry rice; the suspect exhibiting the greatest difficulty in spitting out the rice was judged guilty. Another precursor of the modern lie detector was employed in India. Suspects were sent into a dark room where a sacred ass was stabled and directed to pull the animal's tail. They were warned that if the ass brayed it was a sign of guilt. The ass's tail had been dusted with black powder; those with a clear conscience pulled the tail, whereas the guilty person did not, and an examination of the suspects' hands revealed the person with the guilty conscience.

Modern police methods were beginning to develop in Europe by the 18th century and in the 19th century were reinforced by a great number of technological advances.

detector

Officer
entry

When the British Parliament enacted the reforms of Robert Peel in 1829, the importance of keeping comprehensive police records was recognized. In principle, Peel stated that police records were indispensable for the proper distribution of police strength. His reforms laid the foundation for the development of the modern police communications system and provided for a coherent police organization.

Until the mid-19th century, however, police signal systems consisted of whistles, raps on the pavement with a nightstick or baton, and flashing of lights. In 1849 the central police station at Scotland Yard and the district police stations of London were connected by a telegraph line. Other cities followed, and telegraph boxes placed at points on patrolmen's beats permitted swift calls to headquarters when assistance was needed. The telephone was first installed in a police station in Washington, D.C., in 1878. Two years later Chicago took the important step of installing telephone boxes on patrolmen's beats.

Important advances in identification occurred in the late 19th century. In 1882, Alphonse Bertillon of France introduced a means of identifying suspects by using measurements of the body, head, and limbs. This system was largely supplanted by modern fingerprinting, which dates from about the same period. The Henry system of classifying fingerprints (by patterns and shapes) was adopted by Scotland Yard in 1901, and this system, or variants of it, soon became standard throughout the world.

The idea of tracing and identifying an individual writer by means of the peculiarities of its type characters probably first appeared in Arthur Conan Doyle's story "A Case of Identity," written in 1891, three years before the first mention of the subject in technical literature.

First use of
the auto-
mobile

The automobile, first used in police work in Akron, Ohio, in 1899, became the basis of police transportation in the 20th century. Closely linked with it was the adoption of radio communication. Other innovations in communications were the teletypewriter and facsimile. The teletypewriter evolved from printing telegraphs and developed rapidly during World War I; by the 1920s it was used in police communications in most countries. Facsimile transmission (telephotography) dates from the early 1900s, and in 1908 a criminal was captured as a result of his photo being transmitted by facsimile from Paris to London. After World War I the use of this technique became widespread.

Perhaps the single most important invention in the development of police communications was the transistor, which, in the 1950s, led to the development of small, lightweight, reliable radio transmitter-receivers.

In the 1920s the technique of identifying firearms by the striated markings on bullet jackets was introduced. As these and other new techniques became available, the first police crime laboratories were instituted in Europe and the United States. One of the earliest was established in Lyon, Fr.

There have been few innovations in weaponry. The nightstick (club) and firearm, invariably adaptations of military weapons, remained virtually unchallenged in the police arsenal until the 1960s, when chemicals, tranquilizing darts, light- and sound-energy techniques, and other devices began appearing.

MODERN SURVEILLANCE SYSTEMS

Police use a number of surveillance techniques, but their chief reliance is almost universally placed on patrolling.

Patrol systems. Patrols vary in methodology, assignments, structure, and mobility. Their flexibility has been significantly enhanced by improved methods of communication, especially the two-way radio, and by the availability of numerous types of vehicles such as the automobile, the motorcycle, and, in many countries, the bicycle. The mobility provided by modern communication and transportation techniques is particularly useful in dealing with civil disorders.

The areas covered by metropolitan police patrols vary enormously in population density, character of commerce and industry, terrain, and roads. The initial enthusiasm for using helicopters in routine patrol work lessened when cost analyses showed that the true cost of helicopters was

much higher than expected. High maintenance costs and excessive downtime because of a lack of pilots, aircraft disrepair, and poor flying weather resulted in helicopters being rarely used in routine patrols. Helicopters have come to be used primarily for rescue work and special tactical situations requiring surprise or high mobility. In some countries short takeoff and landing aircraft have been adopted for patrol and rescue work.

Police dogs. The training of dogs for police work was originally developed in Ghent, Belg., about 1900 and was soon copied elsewhere. Though certain breeds with especially keen senses are used for special purposes, such as detecting caches of illegal drugs or for tracking fugitives and missing persons, the most widely trained dog for regular patrol work is the German shepherd, or Alsatian. Other breeds that are sometimes used include boxers, Doberman pinschers, Airedale terriers, rottweilers, schnauzers, and bloodhounds. Selection involves the use of standard criteria related to breeding and physical measurements, and training is rigorous.

Electrical protection systems. Electrical protection (alarm) systems substantially reduce burglaries and contribute to the capture of many criminals. The development of alarm equipment and the evolution of operating procedures in the United States, Canada, and western Europe have been significantly influenced by the published standards of Underwriters Laboratories (UL). Central-station systems and local-alarm systems are the two basic categories of UL-regulated burglar-alarm systems.

Central stations are commercially operated control centres serving metropolitan and surrounding areas. Burglar-alarm protective circuits and devices automatically transmit signals to these centres. Armed guards are on duty at all times and are dispatched to conduct immediate investigations of unauthorized entry of protected properties. Central stations generally have direct communication channels to police control centres. Some centralized operations in large European cities control several completely automatic satellite stations in nearby cities; the local police are dispatched by the central station.

Central
stations

Local burglar-alarm systems consist of sensitive warning mechanisms that are connected to loud alarms and, often, to a signal system in local police stations. Originally local burglar-alarm systems were used primarily in small towns where central station services were not available, but technological improvements and lower prices have led to their use in homes and small businesses in all types of cities. Many police departments discourage the use of these systems, however, because up to 95 percent of the alarms given by them are false.

Technical surveillance. The application of technology to surveillance operations has greatly expanded the capabilities of law-enforcement agencies and has led to the creation of a special field of police technology known as technical surveillance.

Audial surveillance. Audial surveillance, or electronic eavesdropping, became practical for obtaining evidence and investigative leads as a result of the intensive development of the magnetic tape recorder and solid-state electronic components during World War II and subsequent years. The field has two technically and legally distinct areas: the surreptitious interception of oral communications, commonly known as "bugging," and the surreptitious interception of wire communications, commonly known as "wiretapping." Typical devices used include miniature microphones, miniature radio transmitters, and a variety of radio-receiving and voice-recording equipment.

Microphones, of course, are always required for the interception of oral communications and may be connected by cables directly to recorders located at remote locations or may be connected to transmitters. Excellent quality microphones of very small size are available throughout the world. Some microphones located in the handsets of telephones can be modified to intercept nearby conversations.

Radio transmitters the size of a cigarette package, equipped with integral batteries and microphones, are commonly known as "wireless mikes." Most radio transmitters used for audio surveillance operate within the very high frequency (VHF) range.

The most common type of interception of wire communications consists of monitoring telephone conversations. Equipment used for telephone tapping ranges from the telephone repairman's handset to automatic voice recorders connected to target telephone lines.

Optical surveillance. Optical surveillance makes use of such devices as binoculars and telescopes; cameras with long-focal-length, or telephoto, lenses; closed-circuit television; and video tape recorders. Closed-circuit television is a versatile surveillance method that has become widely used both by police and by private security systems. From a central location, a supervisor can monitor events at one or several remote locations. Cameras may be fixed or they may oscillate to sweep a large area.

Optical surveillance is sometimes used as an evidence-gathering technique. In arrests involving driving and the use of alcohol, the physical condition of the driver is filmed or videotaped and later used as evidence. In an effort to reduce lawsuits concerning interrogation methods, some police agencies also film or videotape interrogation.

Devices for
low light
levels

Low-light-level devices have greatly extended passive optical-surveillance capabilities. Practical low-light-level television systems are manufactured for optical surveillance operations under light intensities as low as 10^{-8} lumens per square metre, or virtual darkness. Night-vision telescopes using two and three light-amplification stages are also used.

Tagging and tracking. Object tagging and signal tracking are a third category of police technical-surveillance operations. Devices emitting a unique signal are attached to vehicles or implanted in targeted objects. Compatible receiving or activating equipment is used to track the tagged objects. A typical device used in tracking is a miniature radio transmitter using distinctive tone modulation, commonly known as a "bumper beeper," which is surreptitiously attached to a vehicle. The target is discreetly tracked with one or more surveillance vehicles equipped with appropriate receiving equipment.

CRIME REPORTING AND RECORDS

The efficiency and effectiveness of a police department depend in large degree on complete, readily available, and up-to-date record keeping.

Information must be reported, collected, classified, analyzed, processed, and stored. Numerous files must be kept, of which the most important include fingerprints, modus operandi of criminals, and various investigation and reference files. There should be as much cross-filing as possible.

Fingerprint classification. Fingerprint records are among the most significant files that are maintained. Inked fingerprints from all 10 fingers of an individual person can be classified; *i.e.*, be put into narrow categories for file purposes and ultimate retrieval. Most countries use the Henry extension system, a modification of the Henry system, which was developed prior to 1900 in England. In the Henry extension system, each of the 10 individual fingerprints of a person is classified as to arches, loops, whorls, or composite style prints. The type of design, plus subclassification based on locating certain fixed points and counting the ridges lying between the points, is used to make the classification.

Fingerprints obtained from individuals are classified and compared with the fingerprints of other individuals having the same classification. With this system, personnel in a police centre need not compare a set of fingerprints with the millions of cards on file but only with the few in the same classification. (For the technique of fingerprint identification, see below *Laboratory procedures*.)

Modus operandi. If a criminal has been successful using certain methods and techniques, he tends to repeat the same procedure. Thus, evidence of characteristic behaviour and procedure at the crime scene can serve to identify the offender if the pattern is recognized by the police. Although classification of criminals according to operational methods and manners has lost a good deal of its effectiveness in the investigation of burglaries, large law-enforcement agencies still maintain modus operandi files to recognize patterns of behaviour, to associate a group of crimes with a single perpetrator, and to enable

them to predict the next target of the criminal. The modus operandi file is most effective in crimes involving personal contact, such as felonies against persons, confidence games, and forgery. Enhanced computer storage and search capabilities have rekindled interest in modus operandi methods of investigation, even in such cases as burglaries and robberies.

Investigation and reference files. Informational files are maintained by law-enforcement agencies. The primary purpose of these records is to identify the source of evidence discovered in connection with a crime. For example, a file of automotive paint samples can assist in identifying the make and model of a vehicle involved in a hit-and-run case. Automotive registrations and records of firearms assist in establishing ownership. In addition to their own files, the police have access to the records of many governmental agencies that record titles, contracts, vital statistics, significant events, and official acts in general. Among other files maintained by the police the following prove exceptionally useful.

Missing persons. Each year many thousands of persons are reported missing to the police. In addition, the police must investigate cases of unidentified persons, living and dead. Descriptive files are maintained of missing persons under the age of approximately 19, unidentified dead, and unidentified persons who are physically and mentally afflicted.

Laundry and dry cleaners' marks. A valuable clue to the identity of an unknown person can be found in the mark or marked tag placed in his clothing by a laundry, dry cleaner, or tailor. The mark usually consists of a set of numbers or letters identifying the retail store or the wholesale processor. Samples of these marks are filed systematically by larger police departments for the purpose of tracing a lost, dead, or wanted person.

Lost or stolen property. Many cases of burglary and larceny are solved simply by tracing stolen property to the possession of the criminal. For this purpose, police maintain a central cross-indexed file of property lost or stolen and of articles pledged at pawnbrokers or sold to second-hand dealers. The common objects of larceny—automobiles, watches, jewelry, furs, and cameras—are identified by means of an accurate physical description, including serial marks and personal inscriptions.

Computerized records. The record-keeping tasks of police work were long handled by using a diversity of manual systems. Quick nationwide or international utilization of records and files was impossible. Now, however, electronic data processing has revolutionized information-handling techniques. Manual filing systems have been superseded by computers that operate from central geographic points, storing data and making it instantaneously and accurately available to many police constituents. Advances in computer networking permit the linking of many police and investigative data bases and make possible the development of national criminal investigation systems. Interpol is an example of an international computer network that coordinates the exchange of criminal intelligence to aid police agencies in searching for fugitives or missing persons or property.

Electronic
data
processing

In addition to serving as a depository and dispenser of information, the computer can provide statistical analysis for research and management, develop intelligence data bases and analysis systems, assist in the analysis of physical evidence, facilitate swift document retrieval, and help in such areas as identification of fingerprints. Using traditional manual methods, fingerprint examiners, for example, have to make visual comparisons of thousands of individual 10-digit fingerprint cards in order to make a positive identification. The development of a computerized fingerprint search system took more than 20 years of industry-wide research. Although the Federal Bureau of Investigation was a pioneer in the development of automated fingerprint files, the vast size of its collection of fingerprint cards and the high cost of converting its files delayed the completion of a high-speed fingerprint search system. The Japanese National Police Agency established the first practical system in Tokyo in the early 1980s.

A second generation of the Japanese system focused on

individual images instead of 10-digit cards. Since its introduction, this system has been used as a prototype for several computerized systems in the United States, including those in police agencies in Alaska, Massachusetts, San Francisco, and Suffolk County, N.Y. An interactive system established by the California Bureau of Criminal Identification is one of the largest, linking several major police departments and covering more than 90 percent of the population of the state. New Scotland Yard in London also has a computerized fingerprint system that makes some 1,000,000 comparisons a day.

COMMUNICATIONS

A total police communications system can be extremely complex, but its complexity varies with the needs associated with particular police organizations and their operational environmental situations. Each police function or situation calls for its own subsystem of communication.

In a large city the sources of information that must be fed into the central system are remarkably varied. Police may be on foot or motorcycles, in patrol cars, in patrol boats, or in aircraft. In addition, the system must encompass links to fire stations, ambulance services, traffic-control systems, rescue teams, alarm systems, emergency utility services, crime-information systems, and crime laboratories. A variety of fixed and mobile systems are used, including radios, television (including closed-circuit), telephone, teletypewriters, and facsimile transmission.

Police radio-communications systems, which profited considerably from the advances in electronics during and after World War II and from developments in the U.S. space program, also benefited from the development of computers, which made possible the quick retrieval of information on stolen property, wanted persons, and other police intelligence. Many urban centres now use police cars that have direct access to departmental computers and contain equipment capable of receiving printouts of orders and lists of wanted persons or missing property. The augmented flow of information has placed an added burden on existing communications systems, which have consequently grown more complex. Among numerous technological innovations, the development of the modern police communications centre merits particular mention.

Functions
of a police
communi-
cations
centre

A communications centre performs several functions: (1) receives and processes police calls from the public; (2) audits and dispatches police resources in response to police calls; (3) receives and responds to information inquiries as well as to calls for assistance from police patrols; (4) maintains moment-to-moment information on police resources for command and control purposes.

The geographic distribution of police communications centres has been broadened to include locations in many countries of the world. These centres facilitate police work needed to deal with the international mobility of modern criminals. The extensive radio network maintained through Interpol serves to promote international cooperation among world police organizations.

INTERROGATION METHODS AND EQUIPMENT

Police and other investigators depend on interrogation as a principal means of determining facts and resolving issues. Reliance on interrogation, however, involves certain problems: ascertaining when a suspect or witness is telling the truth, evaluating memory, allowing for the physical and mental condition of a witness or suspect, and understanding the problems created by an individual's perspective.

Interrogation methods and equipment have evolved in response to these problem areas. The psychological, psychophysical, and physical sciences have played vital roles in police interrogation techniques.

The most dramatic gains in interrogation technology have come through the polygraph, or so-called lie detector. The polygraph monitors and records selected body changes that are affected by a person's emotional condition. The recorded changes are then studied, analyzed, and correlated in respect to specific questions or other stimuli.

The first modern polygraph was constructed in 1921 by John A. Larson, a medical student at the University of California, working with a member of the local police

department. Larson's instrument was capable of continuously recording blood pressure, pulse, and respiration; since it recorded these conditions simultaneously, it was called a polygraph. A later development provided for the recording of the psychogalvanic skin reflex (electrodermal response), the flow of current between two different parts of the body. Research has continued on both the instrumentation and the psychological techniques necessary for its effective use by the police.

Even though the polygraph has been formally and successfully used in police intelligence and security investigation since 1924, there is still no complete agreement by psychologists on its validity. Furthermore, the results of a polygraph test are not always judicially acceptable. Despite these qualifications, the polygraph has proved an invaluable aid to police interrogation and the development of investigative leads.

WEAPONS AND RELATED DEVICES

To contend with the wide diversity of criminal situations, police require a variety of weapons and restraining and protective devices.

Standard weapons. Standard equipment varies. London police carry only a small baton; New York City police carry a large-calibre revolver and a baton; Paris police carry a small-calibre semiautomatic pistol, a baton, and a leaded cape; and Cairo police carry a submachine gun or automatic rifle.

The most universal physical weapon and certainly the most frequently used weapon over the years has been the baton, nightstick, truncheon, or billy. The baton has been the subject of study and research, and there now exists a family of batons that include, in addition to the original wood or plastic baton, devices that contain firearms, aerosols or tear-gas cartridges, and electric-shock systems. Some batons are made to break at a certain degree of impact in order to avoid serious injury.

Pistols, including the automatic pistol and the revolver, are the second most widely used police weapons. In the United States the revolver (.38 special to .45 calibre) is the primary pistol, whereas in Europe and Asia the automatic (.25 to .38 calibre 9 mm) is extensively used. Shotguns, rifles, and automatic weapons are usually included in the police arsenal but are issued only when essential.

Chemical and other nonlethal weapons. Chemical weapons include those that deliver compounds which cause either severe weeping or tearing at the eyes (lacrimators) or extreme discomfort or sickness (nauseators). The three most commonly used chemicals are known by the initials CN and CS, both lacrimators, and DM, a nauseator. Among the systems used to dispense the chemicals are riot shotguns, fog generators, and grenades. The most commonly used modern weapon is the handheld aerosol tear-gas projector (Mace). It can be carried in a holster, and it is easily aimed and instantly effective. Its range is 15 feet, and it delivers about 40 one-second bursts.

Lacrima-
tors and
nauseators

Other nonlethal weapons include sound and light devices that cause confusion, pain, or temporary blindness, as well as stun guns. Stun guns emit a high-voltage charge that temporarily renders a person unconscious. (Because some physicians object to its use, the stun gun must undergo widespread testing and evaluation before it is added to the standard police arsenal.) The water cannon is used, especially in Europe, for crowd control. Nonlethal projectiles include plastic shot and bullets made of rubber, wood, or fabric.

Restraining and protective devices. Criminal restraining and police protective systems have been subjects of much study and research. The developments in restraining devices and systems include lighter, more effective handcuffs with improved locking systems, lightweight thumb cuffs, pressure-twisting devices that are applied to wrists, and lighter and stronger straitjackets and leg irons.

A modern restraining device is the disposable handcuff. It consists of a nylon plastic strap with a slotted head at one end and a tapered tail at the other. A stainless steel barb in the head allows the tail to be pulled through the head in one direction and locks the strap so that it cannot be withdrawn. To remove plastic cuffs, the police officer

merely cuts them off. This device is particularly useful in mass arrests, as in riots.

Significant developments in the technology of protective devices include heavy plastic shields to ward off rocks and other missiles, lightweight nylon clothing resistant to pistol bullets, bulletproof shields, and bulletproof armour made of nylon and ceramic materials, which can withstand high-powered rifle bullets. Studies show that in their first five years of use in the United States, bulletproof vests saved the lives of more than 700 police personnel. Of all the police killed by guns during that period, only 10 percent were wearing vests, and virtually all of that number suffered head wounds.

LABORATORY PROCEDURES

Crime laboratories may be either specialized, such as those that handle principally documentary evidence, or broad in coverage, as is the case with most national police laboratories. The fundamental purposes include the collection and preservation of physical evidence, its examination, and the preparation and presentation of accurate, objective testimony regarding it.

Personnel include specialists such as document examiners, generalists such as criminologists, and technicians and other supporting personnel. They are usually employed by a government unit and must pass rigid examinations.

Facilities and equipment. Crime laboratories usually are equipped with an array of scientific instruments and facilities. Instruments are constantly being developed, and the resources of individual laboratories vary. Some are equipped with expensive and sophisticated analytical instruments, such as the mass spectrograph, the electron microprobe, and the scanning electron microscope. Close cooperation among laboratories makes possible the sharing of specialized equipment when needed.

The largest category of laboratory equipment is related to photography. The usefulness of the medium extends from straightforward photography of, for example, automobile accidents and sites of crimes to specialized work of various kinds. Colour photography is commonly used to obtain more realistic and informative representations of the crime scene. Ultraviolet and infrared photography aid in detecting stains, invisible writing, and alterations on documents. Radiography is also used to provide details that would otherwise be invisible. Photography through a microscope (photomicrography) is a common technique, a special case being the examination of bullets. Fingerprint photography is an area of specialization that may involve conventional methods or any of a number of special techniques to recover useful prints from different types of surfaces.

Among the more common facilities are chemical laboratories, with a range of reagents and analytical instruments, including spectrographs and chromatographs. Optical equipment includes a full range of magnifying devices, from magnifying glasses to specialized microscopes of various kinds, including stereomicroscopes and comparison microscopes.

Evidence and its examination. An investigation at the scene of a crime, particularly in crimes of violence, is the first phase of the laboratory function. Many jurisdictions have mobile crime laboratories, in which some of the regular laboratory tests can be performed by specially trained police personnel called evidence technicians.

Crime sites must be searched to locate pertinent physical evidence, which may range from latent fingerprints to bloodstains to pieces of a broken automobile headlight. Evidence must be marked for identification, preserved, and protectively packaged for transportation to the laboratory. In addition, records (written or photographic) must be made of each piece of evidence and its exact location with respect to the crime. The law requires that the "chain of evidence" remain unbroken and makes police accountable for every item of evidence from the time of its discovery to its ultimate presentation in court.

Certain laboratory procedures and tests are carried out in the field when time is limited or when there is a possibility that the evidence might be disturbed. Among such procedures or tests are dusting for fingerprints, making

casts of footprints and automobile tracks, making blood tests, and collecting specimens of organic and inorganic materials from the environment.

Hypnosis. In the 1970s police began experimenting with hypnosis as a means of interviewing witnesses to certain crimes. Hypnosis is reported to be particularly effective in helping witnesses give descriptions of criminals, relate the details of violent sexual attacks, and recall the scenarios immediately preceding certain accidents.

Drug and alcohol testing. Portable field chemical kits have been developed to help police detect narcotics and dangerous drugs. These kits are designed to provide a practical method for initial tests in the field and are not intended to replace the more thorough laboratory examinations.

Tests for determining if a suspect has taken a narcotic or dangerous drug must be performed in a forensic laboratory. These tests require the taking of a urine or blood sample from the suspect and require close medical supervision. Many new techniques for the detection of drugs, including specially trained police dogs, are used.

For many years the basic test for legally determining a driver's blood-alcohol content involved taking a blood sample and sending it to a laboratory for analysis. This method, although accurate, is not practical for law-enforcement purposes because many people object to having a blood sample taken and because test results are not immediately available. The development of the breath analyzer for the determination of blood-alcohol content has given the police a more practical tool. This instrument permits a precise amount of the suspect's breath to pass through a chemical solution (potassium dichromate and sulfuric acid), resulting in a colour density change that is proportional to the amount of alcohol in the air sample. The percentage of alcohol in a given air sample is determined, and from this the percentage of blood-alcohol content can be derived. In cases where the suspect is not conscious or requires serious medical attention, a blood test may be the only recourse.

Classes of evidence. Evidence can be categorized according to its potential value as proof. Certain types of evidence can be individualized, or associated with a unique source, whereas other types cannot be pinpointed but can aid in identification because they fall into particular classes. Types of evidence that can be individualized are handwriting, typewriting, fingerprints, footprints, tire marks, impressions or casts of nonstandard items, striated markings on bullets, tool marks, objects with random fractures or tears, and substances that have undergone an alteration that makes them unique among others of the same class. Among evidence that only identifies a certain class are blood and other body fluids, narcotics, toxicological materials, fibres, soils, inks, and many kinds of materials produced in batches.

Examinations can be either "unilateral" or comparative in nature. Blood-typing and establishing the distance from which a weapon was fired are unilateral examinations, whereas studies of handwriting or spent bullets involve comparisons with other examples.

Pathological examinations. Although pathological examinations are not ordinarily conducted by a crime laboratory, they are part of forensic science. Definitive statements relating to the cause of death and time of death are made by the coroner or medical examiner of the jurisdiction in which the death took place. Observations by crime laboratory personnel of the conditions at a crime scene, plus toxicological analysis by a crime laboratory, are used in concluding whether a death was by accident, suicide, or murder. In most jurisdictions an autopsy is conducted if a physician was not in attendance or if the cause of death is not obvious, as in cases involving poisoning, electrocution, asphyxiation, heart attack, or stroke. In cases involving identification of a decedent, crime laboratory personnel may work with a coroner or medical examiner to establish identity by comparison of fingerprints or other methods.

Fingerprints, palm prints, and footprints. Fingerprints found at the scene of a crime can be evidence connecting an individual with a crime. Fingerprints can be either visible or latent. Visible prints—formed by dirt or blood, for

The breath analyzer

Value of photography

example—or three-dimensional prints formed in soft matrices, can be photographed directly. Latent fingerprints, which are not ordinarily visible, can be brought out by dusting techniques when the surface is hard and by chemical techniques when the surface is porous. In dusting for fingerprints, a fine powder of contrasting colour is applied with a fine brush. The powder clings to the residual oils and fats in the print and the excess powder is removed with the brush. On porous surfaces such as paper, fuming iodine, silver nitrate, or ninhydrin solutions are used to develop the latent fingerprints. The most effective developer of latent fingerprints is ninhydrin, which can reveal prints that are several years old.

Finger-
print
“points”

Fingerprints are identified on the basis of agreements in a significant number of individualities, commonly known as “points.” These are the bifurcations, ending ridges, and dots in the fingerprint pattern. If sufficient points are found with spatial relationship to other points, a basis exists for identifying a fingerprint. It was formerly considered necessary to have 12 points to identify a fingerprint, but in current practice, a lesser number is often used. Palm prints and footprints are identified in the same manner as fingerprints.

Document examination. The work of the “questioned document examiner” encompasses the examination of handwriting, typewriting, ink, paper, and typography and covers such problems as the identification of handwriting and typewriting, the sequence of events involved in the preparation and handling of a document, the alteration of a document, and the age of a document.

Handwriting, like all other evidence, is identified on the basis of individuality. Children are taught specific ways of forming letters, but they rapidly begin to inject their own individuality into letter forms and writing execution. By the time a person reaches maturity, his writing has acquired peculiarities that serve to identify him.

A forged signature presents other problems. Simulated signatures based upon recollection contain a combination of the forger’s own writing habits and his recollection of the victim’s habits. In many cases, such simulations can be identified. On the other hand, when the perpetrator makes a careful drawing of the victim’s signature or traces an authentic signature, the forgery can be exposed but cannot be identified with the handwriting of the perpetrator. Two individuals making careful tracings of the same signature can produce virtually identical drawings.

Typewriter
identification

The make and model of typewriter used to prepare a document can be determined by examining typeface designs and comparing them with information contained in reference files and differentiation charts. The work of a specific typewriter can be identified if it contains sufficient identifying individuality, based on broken or tilting characters, badly aligned characters, characters that print more heavily on one side than on another, and rebounding characters. Mechanical conditions affecting the type basket or the escapement may also have identifying value. Since it is impossible to reinsert a document into a typewriter in its exact former position, it is possible, using a ruled screen, to determine if a document has been prepared at one sitting or has been reinserted.

Ink comparisons provide class evidence that is frequently of value, but it is not possible to individualize ink; *i.e.*, identify it as coming from a unique source. Chemical tests of various kinds are used for ink comparisons.

Papers can be differentiated on the basis of fibre, filler, and sizing constituents. Fibres can be identified by differential staining and microscopic examination. Fillers can be identified by X-ray diffraction because they are crystalline substances. Chemical tests are used for the identification of sizing constituents. Research with neutron activation analysis, a technique involving chemical analysis by radioactivity, indicates that it may even be possible to identify paper by batches.

Questions concerning the sequence of writing—*e.g.*, whether the ink signature is over or under the typewritten portion of a document—can be important in proving the authenticity of a document. In this and related problems, such as deciphering and restoration of eradicated or erased writing, examinations are carried out using stereomicro-

scopes, ultraviolet and infrared techniques, or chemical tests, depending on the specific problem.

Ballistics techniques. Firearms examinations involve such problems as ascertaining the type of weapon and the specific weapon used to fire a bullet, determining the distance between the weapon and the target, and establishing whether or not a particular individual fired a weapon.

The identification of a particular weapon is based upon the comparison of minute striations, or striae, left on bullets as they pass through the rifled barrel. Each barrel leaves a different combination of striae on the side of bullets. A bullet recovered from the scene of a crime can be compared with a test bullet fired from a suspect weapon. The striated markings on both bullets are brought into juxtaposition under a comparison microscope. If there is agreement in the width, depth, and spacing of a significant number of striae in both bullets, an identification can be made. (The same principle is used in the identification of tool marks.) The extractor and ejector markings on rifle and automatic-pistol cartridges can be identified in the same manner. In some cases the firing pins and breech-blocks leave individual markings on the face of a cartridge.

The distance from which a weapon was fired can be determined, up to several feet, by examination of the form and size of the hole in a target, the extent of the burned area around the hole, the amount of embedded powder grains, and the presence of mercury or lead from primers. The effects vary with the weapon and the type of ammunition. Such information can be vital in determining whether or not a gunshot wound was self-inflicted. Infrared, X-ray, and chemical tests are used in determining the extent of powder residues.

The best means of determining whether or not an individual has recently fired a gun has been the subject of much controversy. In the dermal nitrate test, melted paraffin is used to pick up traces of nitrates and nitrites on the hand, after which a chemical test is made for such compounds. This method has been discredited because it can give incorrectly positive test results. Use of the neutron-activation technique to detect the presence on the hand of antimony and barium from cartridge primers is much more definitive.

Paint. Under certain circumstances, paint evidence can be individualized. If a jagged edge of a paint fleck found on a suspect can be matched with the edges of the matrix from which it came, a basis exists to connect a suspect with a crime scene. Multilayered paint chips can sometimes be individualized if the discrete layers possess sufficient individuality. Under other circumstances, paint must be considered class evidence. Examination of paint for class characteristics involves the use of chemical tests to determine constituency, as well as examination with instruments such as the infrared spectrophotometer, emission spectrograph, or electron microprobe.

Individ-
ualization
of paint

Inorganic materials. Soil, safe insulation, and other inorganic evidence can also be compared to determine common origin. It is not possible to individualize the evidence, but the fact that the same type of mineral matter was found on a suspect and at a crime scene is usually considered significant. Inorganic materials can be compared in terms of metallic element constituents, density of constituents, and microscopic structure.

Blood, blood spots, and semen. Bloodstains are a natural consequence of many crimes of violence; examinations usually concern the position, extent, and nature of suspected bloodstains. In most cases, the blood is dry. The Teichmann and Takayama tests, both of which rely on a reaction with hemoglobin, are confirmatory tests for blood. Human blood can be differentiated from the blood of other species by the precipitin test, which involves the reaction between blood and antihuman rabbit serum.

Forensic scientists have worked to individualize blood samples. For many years blood analysis was limited to simple groupings (A, B, O, or AB) and a few traits like Rh, Lewis, and Kell factors. Advances in serology now permit the isolation and identification of additional blood factors, including histocompatibility antigens, blood enzymes, and serum proteins. These advances also point to the possibility of individualizing other body fluids.

The shape, position, and extent of bloodstains often give valuable information about the circumstances surrounding the commission of a crime. Blood falling from different heights forms stains of different shapes, which are further modified by the angle at which the blood drop hits the surface. Rough estimates can be made as to the age of bloodstains.

Ultraviolet light and the acid phosphatase test are used for the presumptive identification of semen. Positive identification for semen relies on identifying spermatozoa in the suspected sample.

Hairs and fibres. Hairs and fibres found at the scene of a crime can also be important evidence. It is not possible to trace hair to a specific individual, but narrow classes having probative value can be established. Human hair can be distinguished microscopically from other animal hairs. Hairs from different portions of the body vary in structure. Microscopic examination can reveal if hair has been recently cut, burned, or split. Chemical tests can demonstrate the presence of bleached or tinted hair. Neutron activation analysis has come to be used to identify specific trace elements in hair and to measure the quantities of such trace elements.

The various fibres used in clothing, rope, and furniture are of vegetable, animal, or synthetic origin. They can be differentiated by microscopic study and by simple chemical tests for solubility and other properties. Colour comparisons can be conducted using a comparison microscope or by spectrophotometric evaluation. Because they are mass-produced, fibres cannot be individualized.

Toxicology. Toxicological examinations concern the identification of drugs and poisons, either in the form of pills and powders or as materials recovered from body organs. Among the drugs and narcotics of interest to crime laboratories are marijuana, morphine, heroin, and other narcotic alkaloids, cocaine, amphetamines, barbiturates, tranquilizers, and LSD. These substances must be differentiated from nonprescription drugs. In the case of pills, the exact shape, colour, and external marking may serve as aids in identification. Laboratory test methods for specific chemical substances include colour reaction tests, crystal tests, chromatography, and infrared spectrophotometry. Normally, several tests are performed for the sake of confirmation.

Examination of body organs for the presence of poisonous material requires an involved extraction procedure with a series of tests to confirm or eliminate the presence of toxic materials. In addition to the drugs previously mentioned, other poisonous substances include gaseous and liquid poisons, metallic and inorganic poisons, organic poisons, vegetable and animal poisons, and bacterial poisons.

Voice identification. The use of the sound spectrograph for voice identification is a relatively new development. The sound spectrograph is an instrument that graphically presents the time, frequency, and intensity of speech sound waves. The graphic forms for a sound, as spoken by one person, can be compared with those produced by the speech of a second person and thus differentiated. The accuracy of the technique in identifying individuals remains in doubt among speech scientists, even though voicegraphs, or voiceprints, have been used in court.

Polish Literature

Poland acquired a literary language in Latin when it became a Christian land in the 10th century, and thereafter literature in the Polish language was slow to emerge. Its development as a national literature was restrained in part by Poland's remoteness from cultural centres and the difficulties that assailed the young state, frequently attacked by plundering invaders and weakened by division into small principalities, and in part by the domination of foreign priests (when Mieszko I, prince of Poland, accepted Christianity in 966, in effect he placed his lands in the hands of the pope). This article reviews the literary history of Poland from its origins to the present day.

The article is divided into the following sections:

The Middle Ages	973
Religious writings	
Early secular literature	
The Renaissance period	973
Kochanowski and his disciples	
Achievements in prose writing	
The Baroque period	974
Poetry	
Other literary forms	
The Enlightenment	974
Rise of the Polish drama	
Didactic element in prose writing	
Continued development of lyric poetry	
The 19th century	975
Romanticism	
Positivism	
The 20th century	976
The "Young Poland" movement	
Literature in restored Poland	
Literature after 1945	
Bibliography	978

THE MIDDLE AGES

Religious writings. As in other European countries, Latin was at first the only literary language of Poland, and early writings included saints' lives and annals and chronicles written by monks and priests. Two among these works are most important: the *Chronicon*, compiled in about 1115 by a Benedictine known only as Gallus Anonymus, and the *Annales seu cronicae inclity Regni Poloniae*, written in about 1480 by Bishop Jan Długosz. The two works introduced Polish history and literature into the culture of Europe. Use of the vernacular was allowed by the church where Latin could not meet particular needs—in prayers, sermons, and songs; and the oldest surviving text of poetry in Polish is a song in honour of the Virgin Mary, "Bogurodzica," in which language and rhythm are used with high artistic craftsmanship. The earliest extant copy of the text dates from 1407, but its origins are much earlier. Preaching in Polish became established toward the end of the 13th century; the earliest known example of Polish prose, the *Kazania świętokrzyskie* ("Sermons of the Holy Cross"), dating from the end of the 13th or the beginning of the 14th century, was discovered in 1890. Part of a translation of the Bible, made in about 1455 for Queen Sofia, widow of Władysław II Jagiełło, has also survived.

Early secular literature. Secular works began to appear toward the second part of the 15th century. There was a poem criticizing the papacy (c. 1449) by Jędrzej Gałka, a follower of reformers John Wycliffe and Jan Hus, and a high literary standard was achieved in a morality verse dialogue, *Rozmowa mistrza Polikarpa ze Śmiercią* ("Dialogue Between Master Polycarp and Death"). The style of the medieval period lasted late in Poland. Marcin Bielski represented this late medievalism in his *Kronika wszyst-*

kiego świata (1551; "Chronicle of the Whole World"), the first general history in Polish.

The best examples of Polish literature imply a continuous literary tradition. Although its themes were those of the common European heritage, Polish writing of this period could be intensely personal within its anonymous framework. The groundwork for a leap into the ranks of major literatures was laid during the reign of Casimir III the Great, who in 1364 founded the University of Kraków.

THE RENAISSANCE PERIOD

Although the Renaissance reached Poland comparatively late, it was the golden age of Polish literature. External security, constitutional consolidation, and the Reformation contributed to this flowering.

The first generation of writers that were influenced by the Italian humanists wrote in Latin. Included among this group were Jan Dantyszek (Johannes Dantiscus), author of incidental verse, love poetry, and panegyric; Andrzej Krzycki (Cricius), an archbishop who wrote witty epigrams, political verse, and religious poems; and Klemens Janicki (Janicius), a peasant who studied in Italy, won there the title of poet laureate, and was the most original Polish poet of the age.

Mikołaj Rej of Nagłowice was notable for combining medieval and Renaissance aspects. Self-educated, he was the first idiomatically Polish talent and widely read writer of his time, being known as "the father of Polish literature." He wrote satirical epigrams, but of more importance were his prose works, especially *Świętych słów a spraw Pańskich kronika albo Postilla* (1557; "Chronicle or Comments on the Holy Words and Matters of the Lord"), a collection of Calvinist sermons, and the *Żywot człowieka poczciwego* (1568; "Life of an Honest Man"), a description of an ideal nobleman.

Kochanowski and his disciples. The second generation of humanist poets, and indeed the whole Renaissance period, was dominated by Jan Kochanowski. The son of a country squire, he wrote in the vernacular and was the first Polish writer to attempt both satirical poetry and classical tragedy, but his lyrical works surpassed these experiments. His crowning achievement, the first Polish work to equal the great poems of western Europe, was *Treny* (1580; *Laments*), inspired by despair after the death in 1579 of his young daughter, to be succeeded by a final recovery of his spiritual harmony. In Kochanowski's poetry the archaisms still apparent in Rej's work had almost disappeared; language and idiom were modern. The flexibility and assurance of his poetic genius were immediately recognized as a sign that the literary language had attained its maturity.

The most notable of Kochanowski's followers was Szymon Szymonowicz (Simonides). He introduced in his *Sielanki* (1614; "Idylls") a poetic genre that was to retain its vitality until the end of the 19th century. These pastoral poems exemplified the processes of imitation, adaptation, and assimilation by means of which writers of the Renaissance period brought foreign models into the native tradition.

The numerous poems, in Latin and Polish, of Sebastian Klonowicz were of interest for their description of contemporary life. *Worek Judaszów* (1600; "Judas' Sack") was a satirical poem on the plebeian life of Lublin, of which he was mayor.

Achievements in prose writing. The prose of the 16th century ranked with its poetry in vitality and range. The most eminent writer in Latin was Andrzej Frycz-Modrzewski. In *Commentariorum de republica emendanda libri quinque* (1554; "Commentary on Reforming the Republic in Five Books"), he evolved a bold social and political system, based on the principle of equality before God and the

The humanist poet Jan Kochanowski

law. Another notable writer in Latin was Marcin Kromer, scholar, humanist, historian, and Catholic apologist. Of his controversial works, most interesting is the Polish *Rozmowy dworzanina z mnichen* (1551–54; “Dialogues of a Courtier and a Monk”), a defense of Catholicism. Many historical and polemical writings and translations of the Bible were also published during this period; the Catholic translation by Jakub Wujek is an outstanding literary work.

Polish literature had become a national literature, reflecting the country's position as a great power with far-flung boundaries, the evolution of the nobility as a ruling class, and the nation's economic prosperity. Its influence spread east, above all to Moscow, while to the west its culture was represented by men of such high repute as the scientist and astronomer Nicolaus Copernicus (Mikołaj Kopernik).

THE BAROQUE PERIOD

The Baroque period began very early in Poland. In 1564 Poland invited the Jesuits to settle in the country, and from about 1570 Protestant influence began to wane. The Baroque style and outlook were congenial to the Polish spirit; the period was one of considerable literary output, in spite of almost incessant wars. Indeed, perhaps it mirrored, in its stylistic tension, the external strife characteristic of the 17th century.

Poetry. A forerunner of Baroque poetry was Mikołaj Sęp Szarzyński, who wrote predominantly religious poetry akin to that of the English Metaphysical poets. In this period satire and pastoral were the most popular forms. Foremost among satirists was Krzysztof Opaliński. His *Satyry albo przestrogi do naprawy rządu i obyczajów w Polsce należące* (1650; “Satires or Warnings on the Reform of the Government and Customs in Poland”) is bitter, pessimistic, and wide-ranging. The pastoral was represented by Samuel Twardowski, author of *Daphnis drzewem bobkowym* (1638; “Daphne into Laurel Tree”) and a romance *Nadobna Pasqualina* (1655; “Fair Pasqualina”), a tale of sacred and profane love, in which Polish Baroque achieves its most finely wrought splendour. The *Roxolanki* (1654), a collection of love songs by Szymon Zimorowic, and the *Sielanki nowe ruskie* (1663; “New Ruthenian Idylls”), written by his brother Józef Bartłomiej Zimorowic, introduced topical dramatic elements into the traditional pastoral lyric; images of war and death are superimposed upon the pastoral background, with macabre effect and typical Baroque incongruity.

A parallel but less formalized rustic genre produced much verse celebrating rural life. One of the more successful examples is the *Votum* by Zbigniew Morsztyn, whose finest achievement, however, was in religious poetry. In contrast was the work of his cousin, Jan Andrzej Morsztyn, whose language was marked by the extravagant style of 16th-century Italian. The formal complexity and skill of his verse were unsurpassed; and his translation of the French dramatist Pierre Corneille's *Le Cid* has remained the standard Polish version.

The age was characterized by ambition to write heroic epics—a preoccupation to be explained perhaps by historical events: wars with Sweden, Russia, and Turkey, internal revolts, and attempts to introduce constitutional reforms. The Italian poet Torquato Tasso's *Gerusalemme liberata* (1581; “Jerusalem Liberated”), brilliantly translated by Piotr Kochanowski, inspired attempts at epics on national themes, notably the vigorous *Wojna chocimska* (written 1670, published 1850; “The War of Chocim”) by Wacław Potocki. Another epic, the *Psalmodya polska* (1695; “Polish Psalmody”), by Wespazjan Kochowski, was written under the impact of John III Sobieski's victory over the Turks at Vienna in 1683, at which Kochowski was present. The work was the first example of a theme developed by writers of the Romantic movement—the messianic interpretation of Poland's destiny.

Other literary forms. The prose of the period did not rise to the level of its poetry, though there was a wealth of diaries and memoirs. Outstanding were the memoirs of Jan Chryzostom Pasek, a country squire and soldier. The period was also notable for the emergence of the letter as a literary form. The letters of John III Sobieski to his

wife are remarkable for their passion and tenderness and for their day-by-day account of his experiences of battles and diplomacy. Another interesting development was the rise of a popular anonymous literature, exemplified by the *komedia rybaltowska* (“ribald comedies”). These were generally popular satiric comedies and broad farces written mainly by playwrights of plebeian birth. One of the few whose names are known was Piotr Baryka, author of a carnival comedy, *Z chłopów król* (performed 1633; “From Peasant to King”), which developed the theme of the introduction to Shakespeare's *Taming of the Shrew*. Some 30 anonymous examples of this type of comedy survive, and they include realistic depictions of popular customs and grotesquely humorous situations, parodying the lofty themes of “official” literature and so expressing an indirect protest against social inequality.

The last stage of Baroque literature (c. 1675–c. 1750) displayed a long process of decline, marked only by the emergence of the first women writers and by the major figure of Stanisław Konarski, a reformer of education, literature, and the political system, who wrote poetry in Latin, a tragedy in Polish (*Tragedia Epaminondy* [1880]), and political treatises.

It was not until the mid-20th century that the literature of the Baroque period was fully appreciated. It may well be regarded as the most enduring of Polish styles, for many of its features have recurred in the Romantic period and in modern writing.

THE ENLIGHTENMENT

Close contact with western Europe, especially France and England, characterized literature of the Enlightenment period in Poland, whose writers were imbued with a desire to save the national culture from effects of partition and foreign rule. Literary developments included the rise of drama; introduction of the periodical and the novel; publication of the first Polish dictionary; and, in poetry, the introduction of *dumy* (ballads).

Rise of the Polish drama. Drama was established late in Poland. The earliest significant event was the inauguration of a national theatre in Warsaw in 1765. There were three principal dramatists: Franciszek Bohomolec, who satirized the aristocracy in adaptations of Molière; Wojciech Bogusławski, who wrote a popular national comic opera, *Cud mniemany czyli Krakowiacy i górale* (1794; “The Pretended Miracle or Krakovians and Highlanders”); and Franciszek Zabłocki, important for *Fircyk w zalotach* (1781; “The Dandy's Courtship”) and *Sarmatyzm* (1785; “Sarmatian Ways”). Aleksander Fredro's comedies appeared when the Romantic movement was under way, and in them the influences of Molière and Carlo Goldoni were assimilated, as *Zemsta* (1834; “Vengeance”) illustrated. They were remarkable for brilliant “type” characterization, ingenious construction, and metrical facility.

Didactic element in prose writing. Didacticism permeated most of the period's prose writing. Modern periodicals appeared at this time (e.g., *Monitor*, 1765–85), and a Polish dictionary was published between 1807 and 1814. Bishop Adam Naruszewicz wrote early in the Enlightenment. His poetic works, considered chronologically, reflected the transition from Baroque to Classical, and he also wrote a history of Poland in which modern methods of scholarship were used. The most important poet, Bishop Ignacy Krasicki, of European outlook and skeptical intellect, wrote two mock-heroic poems, *Myszeis* (1775; “The Idylls of the Mice”) and *Monachomachia* (1778; “War of the Monks”), as well as *Satyry* (1779; “Satires”) and *Bajki i przypowieści* (1779; “Fables and Moral Tales”), and was remarkable for concise expression, formal elegance, and wit. Krasicki also introduced the novel *Mikołaja Doświadczynskiego przypadku* (1776; “The Adventures of ‘Nicholas Try-all’”), written in diary form and showing the influence of Swift and Rousseau. Two other outstanding poets were Stanisław Trembecki, whose works had an important place in Polish classicism as models of stylistic fluency, and Kajetan Węgiński, a freethinker and admirer of Voltaire, best known for his notorious lampoons.

Continued development of lyric poetry. Lyrical poetry continued to develop. Franciszek Karpiński developed

The literary developments of the Polish Enlightenment

Polish epics

features of the Baroque style in popular pastorals and religious songs, while Franciszek Dionizy Kniaźnin, a conscious experimenter, rewrote much of his earlier work to achieve stylistic uniformity; his verse, cool and intellectual in quality, anticipated Romantic themes of folk poetry, popular superstition, and gypsy life.

Julian Ursyn Niemcewicz's writings were inspired by patriotism and concern for reform. He knew English literature thoroughly and made early translations of English Romantic ballads, his original *dumy* being the first in Poland; he introduced the historical novel to Poland with *Jan z Tęczyna* (1825; "Jan of Tęczyn"), which showed Sir Walter Scott's influence. His comedy *Powrót posła* (1790; "The Return of the Deputy") was one of the best dramatic works of the period, and *Śpiewy historyczne* (1816; "Historical Songs") was widely read.

After loss of national independence, with the third partition of the country between Russia, Austria, and Prussia in 1795–96, the tradition of patriotic poetry was continued by émigré soldier-poets in the Polish legions of Napoleon's army, among them Józef Wybicki, whose popular patriotic song "Mazurek Dąbrowskiego" (1797; "Dąbrowski's Mazurka") was adopted as the national anthem in 1918.

THE 19TH CENTURY

A second distinct period of Polish classicism, called pseudoclassicism, occurred in the early 19th century. In general, pseudoclassicist writing lacked freshness. During the Enlightenment period, literature had reestablished contact with the West and become the voice of national consciousness. Although it was the literature of a community undergoing a severe political crisis, it exercised an influence on neighbouring countries.

Romanticism. The Romantic period began later in Poland than in England or Germany, and it lasted longer. It has been regarded as the greatest period in Polish literature. The rise of Romanticism coincided with the loss of independence, and great writers found in it an expression of their own mood. A need to interpret their country's destiny gave the work of the three great Romantic poets—Adam Mickiewicz, Juliusz Słowacki, and Zygmunt Krasiński—visionary power and moral authority. Writing in exile, they kept faith in the restoration of Polish independence alive, and their concern gave the literature of the Polish Romantic movement its strength and passion. Mickiewicz was the greatest Polish poet and leader of the Romantic period. His *Poezye* (2 vol., 1822–23; "Poetry") was the first major literary event of the period. In its second volume were included parts two and four of *Dziady* (*Forefathers' Eve*), in which he combined folklore and mystic atmosphere to create a new kind of Romantic drama. Mickiewicz' greatest works were written after 1824, when he was deported to Russia for revolutionary activities as a student; they included *Sonety krymskie* (1826; *Sonnets from the Crimea*); a visionary third part of *Dziady* (1832); a messianic interpretation of Poland's past and future destiny, *Księgi narodu polskiego i pielgrzymstwa polskiego* (1832; *The Books of the Polish Nation and of the Polish Pilgrimage*), written in biblical prose; and a great epic, *Pan Tadeusz* (1834; *Master Thaddeus*).

The suppression of the insurrection of 1830–31 drove the cultural elite into exile in France; among poets whom Mickiewicz joined there were Słowacki, Krasiński, and Cyprian Kamil Norwid. Słowacki, a Romantic in the fullest sense, who in all his work showed genius, wrote verse narratives in the style of Byron and accomplished lyric poetry. He was inspired by patriotic themes: *Kordian* (1834) was a drama of conspiracy and problems of commitment. His subtle *W Szwajcarii* (1839; "In Switzerland") is probably the finest lyrical work in Polish. Much of Słowacki's work was in dramatic form, and although written for an imaginary stage rather than for an intended production, it laid the foundations of Polish tragic drama. His plays showed the influence of French Romantic drama, Shakespeare, classical tragedy, and Calderón. The last years of Słowacki's life were devoted to writing *Król-Duch* (1847; "The Spirit King"), an unfinished lyrical and symbolic epic describing the history of a people as a series of incarnations of the essential spirit of the nation.

Zygmunt Krasiński, when 23, published (anonymously, as with all his works) *Nieboska komedia* (1835; *The Undivine Comedy*), which presented, for the first time in Europe, a struggle between opposed worlds of aristocracy and disinherited masses. *Irydion* (1836; *Iridion*), his second play, was an allegory of Poland's fate. In *Przedświt* (1843; "Daybreak") he developed a messianic interpretation of Polish history, and this conception of Poland as "the Christ among the nations" was also expounded in *Psalmy przyszłości* (1845; "Psalms of the Future"). The introduction of fantastic or supernatural elements into a realistic setting was characteristic of many Polish Romantic works.

The genius of Cyprian Norwid was not fully recognized until the 20th century. During his lifetime he was misjudged and remained obscure, partly because he accepted some ideas of Romanticism while criticizing others but even more because of his ironic intellectual reserve. Among the most important works published in his lifetime was a verse dialogue on aesthetics, *Promethidion* (1851), which expounded a theory of the social and moral function of art anticipating that of John Ruskin. An authentic text of his most important lyrical collection, *Vade-mecum*, was first published in 1947. Norwid experimented with free verse and with the rhythms of speech, and, furthermore, he foreshadowed the French Symbolists in his analogical method of presenting the poetic concept.

The lesser talents of early Romanticism formed the Polish Ukrainian school, of whom Antoni Malczewski was outstanding as the author of a single poem, the Romantic verse narrative *Maria* (1825), a tale of love and treachery remarkable for original diction, dramatic tension, and unity of mood.

There were fewer prose writers than poets among the exiles. Zygmunt Miłkowski (pseudonym Teodor Tomasz Jeż) wrote on a wide range of subjects, including folklore and the history of the Balkan countries. The literary criticism of Maurycy Mochnacki, a passionate advocate of Romanticism and the first Polish critic to link literature with Poland's political progress, exercised a strong and not wholly beneficial influence on literary theory. The historical works of Joachim Lelewel, a great, many-sided scholar, were an impressive example of the prose of the period.

As a result of partition, Romantic poetry in Poland was limited to closed provincial circles. In Warsaw a group of young poets was formed, but its activities were restricted by political pressure. Its most fully developed talent was that of Teofil Lenartowicz. Ryszard Wincenty Berwiński, a poet of social radicalism, wrote *Poezje* (1844) and *Studia o literaturze ludowej* (1854; "Studies on Folk Literature"), which marked a step away from Romantic nationalist interpretations and stressed the international community of folk tradition.

Prose was more popular with writers in Poland than with those in exile. Henryk Rzewuski belonged spiritually to the 18th century: *Pamiętki J. Pana Seweryna Soplicy* (1839; "Memoirs of Mister Seweryn Soplica") evoked the atmosphere of the Baroque tradition. As the century progressed, signs of a Realistic tendency were discernible in Józef Korzeniowski's novels *Spekulant* (1846; "The Speculator") and *Kolokacja* (1847; "The Collocation"). A woman novelist, Narcyza Żmichowska (pseudonym Gabryella), produced *Poganka* (1846; "The Pagan"), a psychological allegory anticipating 20th-century sensibility in its subtle analysis of feeling. The dominant figure among prose writers was Józef Ignacy Kraszewski, whose output ran into hundreds of volumes of fiction, history, ethnography, criticism, and so on. His imaginative writings reflected a change of literary styles during his long career. Banished in 1863, he continued to influence Polish writers at home and in exile, maintaining the Polish cause by his manifold activities.

Polish Romanticism, conscious of its role as the torch of national spirit, retained its force as a mode of thinking beyond the period of the political circumstances that fostered it. It produced works of highest artistic value, which excited the interest of foreign writers. Mickiewicz influenced Slavonic literatures and was compared by George Sand with Goethe and Byron. Słowacki's poetic technique

The influence of Polish Romanticism

The poets in exile

proved of fundamental importance to writers at the end of the 19th century, whereas Norwid's influence grew steadily stronger in the 20th century. The political implications of the Romantic movement led to the insurrection of 1863, which ended in Poland's becoming a province of Russia.

Positivism. The literary trend of the period following the 1863 uprising was called positivism and reflected a practical mood and reaction against Romanticism, the rise in Russian and Austrian Poland of an urban intelligentsia acting as a leaven in this ferment. Periodicals were of particular importance in disseminating new ideas, especially the *Tygodnik Ilustrowany* ("Illustrated Weekly"), founded in 1859. The natural consequence of a positivist outlook was a predominance of prose. With other writers of the Warsaw school, Aleksander Świętochowski voiced anticlerical and anti-aristocratic views in his weekly *Prawda* ("Truth"). Bolesław Prus (Aleksander Głowacki), a journalist, ranked high among Polish novelists: *Lalka* (1890; *The Doll*) gave a complex picture of bourgeois life in Warsaw, and *Faraon* (1897; *The Pharaoh and the Priest*) was an ambitious evocation of ancient Egypt, masking political problems that could not be published in the form of a modern novel.

Eliza Orzeszkowa, a campaigner for social reform, wrote about women's emancipation, the ignorance of the peasants, and the Jewish problem. Her books showed psychological penetration and a fine sense of style.

In 1905 Henryk Sienkiewicz was a winner of the Nobel Prize for Literature; his early critical works propounded positivist aesthetic theories, and his early short stories showed an acute awareness of the contemporary situation and a stark Realism. His famous *Quo Vadis?* (1896; Eng. trans. 1898), a historical novel of Rome under Nero, has been widely translated.

A more flexible Naturalism gained ground toward the end of the period, as seen in the stories of Adolf Dygański, famous for portrayals of animal life—such as *Zajac* (1900; "The Hare")—which could be compared with those of Rudyard Kipling. Gabriela Zapolska, a critic of social hypocrisy in Naturalistic novels and lively comedies, excelled in dialogue and dramatic situations, in such plays as *Moralność Pani Dulskiej* (1906; "The Morality of Mrs. Dulski").

The period produced two important positivist poets: Adam Asnyk, a reflective lyricist of formal dexterity; and Maria Konopnicka, who wrote of the plight of the oppressed.

THE 20TH CENTURY

The "Young Poland" movement. The "Young Poland" movement describes several different groups and tendencies united by opposition to positivism, and a desire to return to imagination in literature; hence its other name, Neoromanticism. Among its pioneers were Antoni Lange, a poet, and Zenon Przesmycki (pseudonym Miriam), editor of a Symbolist review, *Chimera*. Both made translations from a number of other languages and expressed aesthetic theories in critical essays. Przesmycki's most influential contribution to a development of modern literature was his discovery of Cyprian Norwid.

Kazimierz Tetmajer achieved popularity with his nostalgic *Poezje* (1891–1924), but his prose had greater vigour and precision of observation, *Na skalnym Podhalu* (1903–10; *Tales of the Tatras*) containing some effectively stylized folk material. An interesting poet, Jan Kasprzowicz, was of peasant origin. His principal contribution to Polish literature lay in the structure of his longer lyrical poems; those in the volume *Ginącemu światu* (1901; "To a Dying World") employed a technique of association, quotation, musical repetition, and free metre that anticipated the early style of such poets as T.S. Eliot. Tadeusz Miciński, a forerunner of Expressionism and Surrealism, wrote philosophical and mystical poems and plays, notably a collection of poems, *W mroku gwiazd* (1902; "In the Twilight of the Stars"), and a play, *Kniaz Patiomkin* (1906; "Prince Potemkin"). The lyrical poet Leopold Staff, whose work shows great variety and technical dexterity, was at this period associated with the "Young Poland" movement, although some of his finest work was written later.

Stanisław Przybyszewski was a leading exponent of the movement's new aesthetic theories and edited a literary magazine, *Życie* ("Life"). Stefan Żeromski expressed passionate concern for social justice and national freedom in widely read works, but an excess of Realist documentation frequently vitiated the power of his later work. Władysław Stanisław Reymont, of peasant stock, adapted the Naturalistic technique to create a vision of peasant life in an epic novel cycle, *Chłopi* (4 vol., 1904–09; *The Peasants*), for which he received the Nobel Prize for Literature for 1924. One of the most effective novels of the period, *Żywot i myśli Zygmunta Podfilipskiego* (1898; "The Life and Thoughts of Zygmunt Podfilipski"), by Józef Weyssenhoff, presented an ironical portrait of the egoist in society. Waław Berent's *Próchno* (1903; "Rotten Wood") portrayed with biting irony the late 19th-century decadence of life and art. His *Ozimina* (1911; "Winter Corn"), a Symbolist novel, foreshadowed the associative structure and narrative technique of James Joyce's *Ulysses* (1922). His *Żywe kamienie* (1918; "The Living Stones") stressed the unity of medieval culture and Poland's place within it. A bold experiment antedating by several years the psychoanalytical novel in western Europe was *Patuba* (1903; "The Hag") by Karol Irzykowski. In it, motivation and behaviour were presented from different viewpoints, ingeniously cemented by the author's own analyses, as in a scientific study. Irzykowski was also a critic and, in *Dziesiąta muza* (1924; "The 10th Muse"), the first to give attention to the cinema as an art form.

Stanisław Brzozowski, an outstanding critic, insisted that a critic must represent the moral consciousness of his age; in *Legenda Młodej Polski* (1909; "The Legend of Young Poland") he analyzed the weakness of the period's literature and expounded his view of the unity of all work—physical, technical, intellectual, and artistic.

Stanisław Wyspiański was an artist and dramatist of genius. In his plays he reformed elements from classical tragedy and mythology, Polish Romantic drama, and national history in a complex whole. *Wesele* (1901; "The Wedding") was a visionary parable of Poland's past, present, and problematical future, cast in the form of the traditional puppet-theatre play. It was a masterpiece of evocative allusion, tragedy, and humour.

The literature of the period was characterized by close contact with western European literatures, but writers such as Wyspiański turned back to the Polish Romantics in a search for new poetic language.

Literature in restored Poland. The restoration of independence in 1918 decisively affected Polish literature. The period between 1918 and 1939 was characterized by richness and variety and increasing contact with other European literatures, especially through publication of many translations. For nearly a decade after 1918 lyrical poetry predominated. A periodical, *Zdrój* ("The Fountainhead"), showed affinities with German Expressionism. In Warsaw several poets formed a group called Skamander, from the name of their monthly publication; it was united by a desire to forge a poetic language, attuned to modern life. Julian Tuwim, a poet of emotional power and linguistic sensitivity, headed the group, and during World War II, in exile in Brazil and the United States, wrote a long, discursive, autobiographical poem, *Kwiaty polskie* (1949; "Polish Flowers"). Among Skamander members were Jan Lechoń, Kazimierz Wierzyński (both died abroad after World War II), Antoni Słonimski, and Jarosław Iwaszkiewicz, who was also a prolific prose writer; among sympathizers of the group were two eminent woman poets, Maria Pawlikowska-Jasnorzewska and Kazimiera Iłakowiczówna, and Władysław Broniewski, a poet with strong left-wing sympathies, who became a master of the revolutionary lyric, expressing involvement in current social and ideological problems.

A writer of importance was Bolesław Leśmian, whose symbolic, Expressionist poetry was remarkable for the inventiveness of its vocabulary, sensuous imagery, and philosophic content, all anticipating Existentialism. He published only three notable collections—*Ląka* (1920; "The Meadow"), *Napój cienisty* (1936; "The Shadowy Drink"), and *Dziejba leśna* (posthumous, 1938; "Wood-

The
Skaman-
der poets

land Tale")—but has been recognized by his admirers as the most outstanding 20th-century Polish lyrical poet.

Other experimental movements, such as Futurism, followed revolutionary trends in poetry—particularly in Italy and Russia. More original was a group called Awangarda Krakowska ("Vanguard of Kraków"). Led by Tadeusz Peiper, it produced few works but had widespread influence in the regeneration of poetic technique. Two of its adherents, Julian Przyboś and Adam Ważyk, who was loosely connected with the movement, ranked among the outstanding poets of the post-World War II period. Also noteworthy was Józef Czechowicz, who assimilated traditional and regional elements to the new style.

Prose writing reached its ascendancy in the second decade of independence. Early stories by Zofia Nałkowska belonged to the "Young Poland" movement and aimed to expose the feminine psyche; later she turned to other themes, striving for narrative objectivity and technical simplicity. Two other women writers of distinction were Zofia Kossak-Szczucka, noted for historical novels, and Maria Kuncewiczowa, who wrote psychological novels. Juliusz Kaden-Bandrowski used experimental Realism in *Czarne skrzydła* (1928–29; "Black Wings") and *Mateusz Bgda* (1933), which treated social and political themes. Michał Choromański's *Zazdrość i medycyna* (1933; *Jealousy and Medicine*) used experimental methods of narrative sequence and was remarkable for its clinical analysis of character. A writer skilled in reflecting subtleties of perception was Bruno Schulz, author of *Sklepy cynamonowe* (1934; *Cinnamon Shops*), whose prose was reminiscent of that of Kafka.

Tadeusz Żeleński (pseudonym Boy), witty, irreverent, and widely read, was a leading literary critic and one of Poland's best interpreters of French literature. The essay form was represented by Jan Parandowski, whose main theme was the classical culture of Greece and Rome. A subversive attack on intellectual and social conventions was launched in *Ferdynand* (1937; Eng. trans., *Ferdynand*) by Witold Gombrowicz, who displayed in it a satirical talent reminiscent of Alfred Jarry. The taste for the cyclic novel was satisfied by Maria Dąbrowska with *Noce i dnie* (4 vol., 1932–34; "Nights and Days"), an outstanding modern Polish example of a chronicle novel in epic style, about the development of the Polish intelligentsia of upper-middle-class origin.

The drama was the weakest of the literary forms during this period and returned to the Young Poland's especially symbolic form (Karol Hubert Rostworowski, Jerzy Szaniawski). The experimental dramas of Stanisław Ignacy Witkiewicz were of interest chiefly for their expression of anti-Realist aesthetic theories; he developed many ideas of the Awangarda, applied the principles of "pure form" to painting and drama, and was the main exponent of a movement in Polish literature known as "catastrophism." Obsessed with the idea of a disintegration of European culture, endangered by totalitarian ideologies, and an attempt to impose the uniformity of a "mass society," he developed his ideas in plays combining elements of Surrealism, grotesque misrepresentation, and what later became known (in the plays of Eugène Ionesco, for example, whose work Witkiewicz to some extent foreshadowed) as the Theatre of the Absurd. His novels *Pożegnanie jesieni* (1927; "Farewell to Autumn") and *Nienasyce* (1930; "Insatiability") expressed the same philosophy. After World War II his work attracted interest abroad and appeared in translation (e.g., *The Madman and the Nun and Other Plays*, 1968).

Literature after 1945. The impact of World War II, the experience of occupation, and the establishment in 1945 of the People's Republic decisively affected the character of literature in Poland and also produced a number of émigré writers who had become famous between World Wars I and II: lyrical poets of the Skamander group and former associates of the Awangarda movement. Among them was Czesław Miłosz, who emigrated to France in 1951 and moved to the United States a decade later. He was awarded the Prix Littéraire Européen for *Zdobycie władzy* (1955; first published in French, as *La prise du pouvoir*, 1953; *The Seizure of Power*), and he received

the Nobel Prize for Literature for 1980. Many émigrés wrote of experiences in enemies' prisons and forced-labour camps. The most accomplished as literature were *Inny świat* (1953; *A World Apart*) by Gustaw Herling-Grudziński and *Sprawa Józefa Mosta* (1953; "The Affair of Józef Most") by Herminia Naglerowa. Jerzy Pietrkiewicz, whose early work was published in Poland during World War II, later wrote mainly in English (the novels *The Knotted Cord*, 1953; *Isolation*, 1959). Witold Gombrowicz, who died in France after a long stay in Argentina, also published his postwar work abroad and became famous with the novels *Trans-Atlantyk* (1953), *Pornografia* (1960; Eng. trans., *Pornografia*), and *Kosmos* (1965; *Cosmos*), which won him the 1967 International Prize for Literature. He also published abroad the plays *Ślub* (1953; *The Marriage*) and *Operetka* (1966; "Operetta"); three volumes of diaries (*Dziennik*, 1953–66); and a book of recollections and reflections, *Wspomnienia polskie* (1977; "Polish Reminiscences"). In all these works, especially the novels, Gombrowicz treated philosophical and psychological themes in a satirical narrative style in which, by emphasizing the grotesque and irrational elements in human nature, he presented an exposé of the conventions of modern life and culture.

In Poland the years immediately after the war saw publication of works written during the occupation or by writers who had been in concentration camp or prison. A frequent theme was the attempt to come to terms with Fascism and war. This was exemplified in the short stories of Tadeusz Borowski, a prisoner at Auschwitz, who, in collections published in 1948, *Pożegnanie z Marią* ("Farewell to Mary") and *Kamienny świat* ("The World of Stone," published in *This Way for the Gas, Ladies and Gentlemen, and Other Stories*, 1967), explored human depravity and degradation; and in those of Adolf Rudnicki, who treated moral and philosophical themes in lyrical prose and described, in *Szekspir* (1948; "Shakespeare") and *Ucieczka z Jasnej Polany* (1949; "Flight from Jasna Polana"), the wartime fate of the Jewish community in Poland. Another theme, shown, for example, by a novel *Popiół i diament* (1948; *Ashes and Diamonds*) by Jerzy Andrzejewski, was the examination of the moral controversies that accompanied political and social changes of the postwar period, especially the tragic situation of young conspirators involved in the struggle against the new regime.

During 1949–54 the literature of Socialist Realism gained ground, and writers attempted to emulate the great 19th-century Realists. A new type of hero was created—the ordinary man or woman actively engaged in "productive" work, and those elements in the social scene that served to present an idea of revolutionary progress were accentuated. The main writer was Leon Kruczkowski, a prewar exponent of the Marxist novel whose outstanding plays *Niemcy* (1949; "The Germans") and *Pierwszy dzień wolności* (1960; "The First Day of Freedom") were successfully performed abroad. Kazimierz Brandys, whose development typified postwar tendencies in Polish literature, published an epic novel cycle, *Miedzy wojnami* (1948–52; "Between the Wars"), and a Socialist Realist novel, *Obywatele* (1954; "Citizens").

Among writers of the period who stood aside from political involvement were Konstanty Ildefons Gałczyński, who combined lyricism with grotesque fantasy, and the reflective Mieczysław Jastrun, who in later work—for example, the essay collection *Mit śródziemnomorski* (1962; "The Mediterranean Myth")—moved toward Existentialism. A group of Catholic writers opposed to Socialist Realism included Antoni Gołubiew, author of an epic novel cycle, *Bolesław Chrobry* (1947–54), the prose writer and dramatist Jerzy Zawieyski, and a historical novelist, Hanna Malewska. Teodor Parnicki used a background of conflict between cultures for an analysis of contemporary problems in experimental and semi-historical novels set mainly in the early Christian period: *Koniec "Zgody Narodów"* (1955; "End of the Covenant of Nations"), *Nowa baśń* (6 vol., 1962–70; "A New Fairytale"), and others.

The weakness of the Socialist Realist movement—its attempt to impose a political pattern on creative writing, its avoidance of themes arising from contemporary

The literature of Socialist Realism and the reaction against it

Witkiewicz and "catastrophism"

conflicts—resulted partly from the stranglehold of the Stalinist regime. In the period beginning in 1954–55, writers began to criticize these weaknesses and to oppose them. Andrzejewski, for example, presented contemporary ideas and problems in two novels combining historical and metaphorical treatment, *Ciemności kryją ziemię* (1957; *The Inquisitors*) and *Bramy raju* (1960; *The Gates of Paradise*), and Brandys criticized Stalinism in the novel *Matka królów* (1957; *Sons and Comrades*).

The political “thaw” after 1956 made it possible for writers to renew contacts with the West. As a result, a period of development and experiment began in which the essay was a vehicle for philosophical and intellectual discussion and comment, and there was an increase of satire. Tadeusz Breza analyzed contemporary life and ideas in a prose of Proustian subtlety in, for example, *Spóźniona brama* (1959; “The Bronze Gate”), a keen description of life in the Vatican. Writers continued to be concerned with World War II, as shown by such novels as *Czarny potok* (1954; *Black Torrent*) by Leopold Buczkowski, *Kolumbowie-rocznik* 20 (1957; “The Columbus-Generation of 1920”) by Roman Bratny, and *Tren* (1961; “Threnody”) by Bohdan Czeszko. Many chose as their theme consequences of wartime experience, as, for example, Tadeusz Konwicki in *Sennik współczesny* (1963; *A Dreambook for Our Time*). His later novels *Wniebowstąpienie* (1967; “Ascension”) and *Nic albo nic* (1971; “Nothing or Nothing”) project those themes on contemporary problems. In *Głosy w ciemności* (1956; “Voices in the Dark”) and *Austeria* (1966; “The Inn”), Julian Strykowski restated the feeling of the Orthodox Jewish Polish community that the world has already ended and gave it universal application.

A number of prewar Polish writers continued to publish: the poets Leopold Staff and Kazimiera Iłakowiczówna; Maria Dąbrowska, who enhanced her reputation with a collection of short stories, *Gwiazda zaranna* (1955; “Morning Star”), and a series of critical essays on Joseph Conrad; the novelist Maria Kuncewiczowa; and the novelist, poet, and dramatist Jarosław Iwaszkiewicz, who published the epic novel *Stawa i chwala* (1956–62; “Fame and Glory”).

Many writers of the 1950s and 1960s wrote prose works, ranging from the political novels of Jerzy Putrament to the psychological novels of manners of Stanisław Dygat, while the novels of Stanisław Lem, the leading Polish representative of serious science fiction, looked to the future. Young writers such as Marek Hlasko (died in his early years in Germany after some years spent abroad as an émigré writer) and Marek Nowakowski, in their search for a moral basis for life, often looked into the worlds of those on the fringes of society—outcasts and misfits. An interesting younger writer, Sławomir Mrożek, both in his plays—*Policja* (1958; “The Police”), *Na pełnym morzu* (1961; *Out at Sea*), *Striptease* (1962; Eng. trans., *Striptease*), and above all *Tango* (1964; Eng. trans., *Tango*), his most widely known work—as well as in stories collected in *Stoń* (1957; *The Elephant*), displayed an acute sense of satire and the grotesque, which he used to express a philosophy of life both topical and timeless. His comedy belonged partly to the Theatre of the Absurd and was distinguished by a subtlety of parody and highly stylized language.

New trends
in poetry
and drama

Poetry of the “second” postwar period was notable for expression of philosophical thought. Stanisław Jerzy Lec was a satirical poet noted for skeptical philosophical aphorisms in *Myśli nieuczesane* (published in series from 1957; *Unkempt Thoughts*). Zbigniew Herbert, whose most notable collection was *Studium przedmiotu* (1961; “Study of an Object”), was a representative of intellectual poetry (Eng. trans., *Selected Poems*). Perhaps the most interesting, however, was Tadeusz Różewicz, who had a profound influence on younger lyrical poets; from *Niepokój* (1947), his first collection, to *Głos anonima* (1961; “The Nameless Voice”), his work was occupied with moral themes. He also wrote plays resembling those of Ionesco: *Świadkowie albo nasza mała stabilizacja* (1962; “The Witnesses, or Our Little Stabilization”; translated in *The Witnesses and Other Plays*), and one published with poems in *Kartoteka* (1961; *The Card Index and Other Plays*). Modern problems also dominated the intellectual, ironic poetry of

Wisława Szymborska, collected in *Sól* (1962; “Salt”) and *Sto pociech* (1967; “A Barrel of Laughs”).

The lyrical poetry of the generation of poets born about 1930 was characterized by a variety of aims and styles. The controversial work of such poets as Miron Białoszewski showed extreme experimentalism; on the other hand, a poet such as Ernest Bryll reasserted traditional poetic forms. Some poets—Tadeusz Nowak and Jerzy Harasymowicz—turned for inspiration to the peasant culture; others, among them Jarosław M. Rymkiewicz, an outstanding translator of English and American poetry, based their poetic program upon the example of T.S. Eliot, in a return to Baroque and Neoclassical forms, and developed an erudite, allusive poetry. Most representative of the poets of this new generation was perhaps Stanisław Grochowiak, who created an expressive poetic style based on sudden contrasts and deliberate emphasis on grotesque aspects of life.

Critics and essayists included Artur Sandauer; Jan Kott (who emigrated to the United States), whose *Szkice o Szekspirze* (1961; *Shakespeare, Our Contemporary*) was widely translated and discussed; Kazimierz Wyka; Jan Błoński; and Andrzej Kijowski.

Political events in 1968 forced some writers to emigrate and publish abroad. Others, such as Paweł Jasienica and Stefan Kisielewski, were temporarily blacklisted. In the 1970s and early 1980s, Polish life was dominated by social tensions, political upheavals, and economic crises. Major outbreaks of unrest, in particular the workers' riots and strikes that led to the creation of the independent trade union Solidarity, encouraged writers to challenge the authorities and the official aesthetic. Censorship still forced many of them to publish abroad, but independent publishing houses emerged that allowed their works to be circulated in Poland and thus opened the way for hitherto proscribed foreign authors, such as George Orwell, and émigré authors, such as Miłosz and Gombrowicz. Books appeared that analyzed the political situation and delved into the recesses of Polish life and history. Among the most important and widely discussed books of the period were Konwicki's novels *Kompleks polski* (1977; *The Polish Complex*) and *Mała apokalipsa* (1979; *A Minor Apocalypse*); Andrzejewski's long-suppressed novel *Miazga* (1981; “Pulp”); and the ironic reflections recorded in a monthly diary called *Miesiące* (1981; *A Warsaw Diary 1978–1981*) by Kazimierz Brandys, who left Poland in 1981. Also important were the volumes of poetry and essays of Ryszard Krynicki and Stanisław Barańczak, who emigrated to the United States; the diaries of Gombrowicz; and two additional volumes of Herbert's poems, *Pan Cogito* (1974; “Mr. Cogito”; partially translated in *Selected Poems*), the poetic meditations of a kind of intellectual Everyman, and *Raport z oblężonego miasta* (1983; “A Report from a Town Besieged”).

Political Parties and Interest Groups

A political party is a group organized to achieve and exercise power within a political system. An interest group (or special-interest group) is an aggregate of individuals who, bound by one or more concerns or wants, makes claims upon other groups or upon society in general in order to maintain or promote its position or objectives.

An interest group that attempts to influence government becomes a "pressure group." It is distinguished from a political party in that, whereas a party puts up candidates for election to public office and carries out activities to secure their election, a pressure group seeks to influence both the government and the parties. The Roman Catholic interest in Italy, for instance, is served both by the Christian Democratic Party and also by the Catholic Action Society. The first is a party, and the second is a pressure group. Again the "natural" group of Swedes in Finland is served by the Swedish People's Party; this is clearly a special-interest group, yet it puts up candidates and is represented in the legislature because it thinks its members' interest is

best served by exerting pressure as part of a governmental coalition.

Thus, it may be that what begins as a pressure group becomes a political party. The British Labour Party, for example, had its origins in 1900, when trade unionists formed a Labour Representation Committee in order to elect working-class MP's to Parliament; later it broadened its membership and program to become the Labour Party. In France, Pierre Poujade's pressure group, the Union of Small Shopkeepers, was involved in the 1956 elections and won more than 40 seats, thus becoming a political party before reverting to pressure-group status in 1958. The reverse process can also occur, as when a political party engenders pressure groups; thus, Communist parties set up interest groups for women, youth, workers, and the like. (S.E.F./Ed.)

Political parties

Political parties originated in their modern form in Europe and the United States in the 19th century, along with the electoral and parliamentary systems whose development is reflected in their own evolution. The term party has since come to be applied to all organized groups seeking political power, whether by democratic elections or by revolution.

In earlier, prerevolutionary, aristocratic and monarchical regimes, the political process unfolded within restricted circles in which cliques and factions, grouped around particular noblemen or influential personalities, were opposed to one another. The establishment of parliamentary regimes and the appearance of parties at first scarcely changed this situation. To cliques formed around princes, dukes, counts, or marquesses there were added cliques formed around bankers, merchants, industrialists, and businessmen. Regimes supported by nobles were succeeded by regimes supported by other elites. These narrowly based parties were later transformed to a greater or lesser extent, for in the 19th century in Europe and America there emerged parties depending on mass support.

The 20th century saw the spread of political parties throughout the entire world. In Africa large parties have sometimes been formed in which a modern organization has a more traditional ethnic or tribal basis; in such cases the party leadership is frequently made up of tribal chiefs. In certain areas of Asia, membership in modern political parties is often determined largely by religious factors or by affiliation with ritual brotherhoods. Many political

parties in the developing countries are partly political, partly military. Certain Socialist and Communist parties in Europe earlier experienced the same tendencies.

These last-mentioned European parties have demonstrated an equal aptitude for functioning within multiparty democracies and as the sole political party in a dictatorship. Developing originally within the framework of liberal democracy in the 19th century, political parties have been used in the 20th century by dictatorships for entirely undemocratic purposes.

TYPES OF POLITICAL PARTY

A fundamental distinction can be made between cadre parties and mass-based parties. The two forms coexist in many countries, particularly in western Europe, where Communist and Socialist parties have emerged alongside the older conservative and liberal parties. Many parties do not fall exactly into either category but combine some characteristics of both.

Cadre parties. Cadre parties—i.e., parties dominated by politically elite groups of activists—developed in Europe and America during the 19th century. Except in some of the states of the United States, France from 1848, and the German Empire from 1871, the suffrage was largely restricted to taxpayers and property owners, and, even when the right to vote was given to larger numbers of people, political influence was essentially limited to a very small segment of the population. The mass of people were limited to the role of spectators rather than that of active participants.

Ubiquity of parties in the 20th century

The cadre parties of the 19th century reflected a fundamental conflict between two classes: the aristocracy on the one hand and the bourgeoisie on the other. The former, composed of landowners, depended upon rural estates on which a generally unlettered peasantry was held back by a traditionalist clergy. The bourgeoisie, made up of industrialists, merchants, tradesmen, bankers, financiers, and professional people, depended upon the lower classes of clerks and industrial workers in the cities. Both aristocracy and bourgeoisie evolved its own ideology. Bourgeois liberal ideology developed first, originating at the time of the English revolution of the 17th century in the writings of John Locke, an English philosopher. It was then developed by French philosophers of the 18th century. In its clamouring for formal legal equality and acceptance of the inequities of circumstance, liberal ideology reflected the interests of the bourgeoisie, who wished to destroy the privileges of the aristocracy and eliminate the lingering economic restraints of feudalism and mercantilism. But, insofar as it set forth an egalitarian ideal and a demand for liberty, bourgeois classical liberalism expressed aspirations common to all men. Conservative ideology, on the other hand, never succeeded in defining themes that would prove as attractive, for it appeared to be more closely allied to the interests of the aristocracy. For a considerable period, however, conservative sentiment did maintain a considerable impact among the people, since it was presented as the expression of the will of God. In Catholic countries, in which religion was based upon a hierarchically structured and authoritarian clergy, the conservative parties were often the clerical parties, as in France, Italy, and Belgium.

Conservative and liberal cadre parties dominated European politics in the 19th century. Developing during a period of great social and economic upheaval, they exercised power largely through electoral and parliamentary activity. Once in power, their leaders used the power of the army or of the police; the party itself was not generally organized for violent activity. Its local units were charged with assuring moral and financial backing to candidates at election time, as well as with maintaining continual contact between elected officials and the electorate. The national organization endeavoured to unify the party members who had been elected to the assemblies. In general, the local committees maintained a basic autonomy and each legislator a large measure of independence. The party discipline in voting established by the British parties—which were older because of the fact that the British Parliament was long established—was imitated on the Continent hardly at all.

The first United States political parties of the 19th century were not particularly different from European cadre parties, except that their confrontations were less violent and based less on ideology. The first United States form of the struggle between the aristocracy and the bourgeoisie, between conservative and liberal, was carried out in the form of the Revolutionary War, in which Great Britain embodied the power of the king and the nobility, and the insurgents that of bourgeoisie and liberalism. Such an interpretation is, of course, simplified. There were some aristocrats in the South and, in particular, an aristocratic spirit based on the institutions of slaveholding and paternalistic ownership of land. In this sense, the Civil War could be considered as a second phase of violent conflict between the conservatives and the liberals. Nevertheless, the United States was from the beginning an essentially bourgeois civilization, based on a deep sense of equality and of individual freedom. Federalists and Anti-Federalists, Republicans and Democrats—all belonged to the liberal family since all shared the same basic ideology and the same system of fundamental values and differed only in the means by which they would realize their beliefs.

In terms of party structure, United States parties in the beginning differed little from their European counterparts. Like them, the United States parties were composed of local notables. The ties of a local committee to a national organization were even weaker than in Europe. At the state level there was some effective coordination of local party organizations, but at the national level such

coordination did not exist. A more original structure was developed after the Civil War—in the South to exploit the vote of the blacks and along the East Coast to control the votes of immigrants. The extreme decentralization in the United States enabled a party to establish a local quasi-dictatorship in a city or county by capturing all of the key posts in an election. Not only the position of mayor but also the police, finances, and the courts came under the control of the party machine, and the machine was thus a development of the original cadre parties. The local party committee came typically to be composed of adventurers or gangsters who wanted to control the distribution of wealth and to ensure the continuation of their control. These men were themselves controlled by the power of the boss, the political leader who controlled the machine at the city, county, or state levels. At the direction of the committee, each constituency was carefully divided, and every precinct was watched closely by an agent of the party, the captain, who was responsible for securing votes for the party. Various rewards were offered to voters in return for the promise of their votes. The machine could offer such inducements as union jobs, trader's licences, immunity from the police, and the like. Operating in this manner, a party could frequently guarantee a majority in an election to the candidates of its choosing, and, once it was in control of local government, of the police, the courts, and public finances, etc., the machine and its clients were assured of impunity in illicit activities such as prostitution and gambling rings and of the granting of public contracts to favoured businessmen.

The degeneration of the party mechanism was not without benefits. The European immigrant who arrived in the United States lost and isolated in a huge and different world might find work and lodging in return for his commitment to the party. In a system of almost pure capitalism and at a time when social services were practically nonexistent, machines and bosses took upon themselves responsibilities that were indispensable to community life. But the moral and material cost of such a system was very high, and the machine was often purely exploitative, performing no services to the community.

By the end of the 19th century the excesses of the machines and the bosses and the closed character of the parties led to the development of primary elections, in which party nominees for office were selected. The primary movement deprived party leaders of the right to dictate candidates for election. A majority of the states adopted the primary system in one form or another between 1900 and 1920. The aim of the system was to make the parties more democratic by opening them up to the general public in the hope of counterbalancing the influence of the party committees. In practice, the aim was not realized, for the committees retained the upper hand in the selection of candidates for the primaries.

In its original form the British Labour Party constituted a new type of cadre party, forming an intermediate link with the mass-based parties. It was formed with the support of trade unions and left-wing intellectuals. At the base, each local organization sent representatives to a district labour committee, which was in turn represented at the national congress.

The early (pre-1918) Labour Party was thus structured of many local and regional organizations. It was not possible to join the party directly; membership came only through an affiliated body, such as a trade union. It thus represented a new type of party, depending not upon highly political individuals brought together as a result of their desire to acquire and wield power but upon the organized representatives of a broader interest—the working class. Certain Christian Democrat parties—the Belgian Social Christian Party between the two world wars and the Austrian Popular Party, for example—had an analogous structure: a federation of unions, agricultural organizations, middle class movements, employers' associations, etc. After 1918, the Labour Party developed a policy of direct membership on the model of the continental Socialist parties, individual members being permitted to join local-constituency branches. The majority of its membership, however, continued to be affiliated rather than direct.

United States parties in the 19th century

The British Labour Party

Mass-based parties. Cadre parties normally organize a relatively small number of party adherents. Mass-based parties, on the other hand, unite hundreds of thousands of followers, sometimes millions. But the number of members is not the only criterion of a mass-based party. The essential factor is that such a party attempts to base itself on an appeal to the masses. It attempts to organize not only those who are influential or well known or those who represent special interest groups but rather any citizen who is willing to join the party. If such a party succeeds in gathering only a few adherents, then it is mass based only in potential. It remains, nevertheless, different from the cadre-type parties.

Socialist
mass-based
parties

At the end of the 19th century the Socialist parties of continental Europe organized themselves on a mass basis in order to educate and to organize the growing population of labourers and wage earners, which industrialization was making increasingly large and which was becoming more important politically because of extensions of the suffrage, and to gather the money necessary for propaganda by mobilizing in a regular fashion the resources of those who, although poor, were numerous. Membership campaigns were conducted, and each member paid party dues. If its members became sufficiently numerous, the party emerged as a powerful organization, managing large funds and diffusing its ideas among an important segment of the population. Such was the case with the German Social Democratic Party, which by 1913 had more than 1,000,000 members.

Such organizations were necessarily rigidly structured. The party required an exact registration of membership, treasurers to collect dues, secretaries to call and lead local meetings, and a hierarchical framework for the coordination of the thousands of local sections. A tradition of collective action and group discipline, more developed among workers as a result of their participation in strikes and other union activity, favoured the development and centralization of party organization.

A complex party organization tends to give a great deal of influence to those who have responsibility at various levels in the hierarchy, resulting in certain oligarchical tendencies. The Socialist parties made an effort to control this tendency by developing democratic procedures in the choice of leaders. At every level those in responsible positions were elected by members of the party. Every local party group would elect delegates to regional and national congresses, at which party candidates and party leaders would be chosen and party policy decided.

The type of mass-based party described above was imitated by many non-Socialist parties. Some cadre-type parties in Europe, both conservative and liberal, attempted to transform themselves along similar lines. The Christian Democrat parties often developed organizations copied even more directly from the mass-based model. But non-Socialist parties were generally less successful in establishing rigid and disciplined organizations.

The first Communist parties were splinter groups of existing Socialist parties and at first adopted the organization of these parties. After 1924, as a result of a decision of the Comintern (the Third International, or federation of working class parties), all Communist parties were transformed along the lines of the Soviet model, becoming mass parties based on the membership of the largest possible number of citizens, although membership was and is limited to those who embraced and espoused the ideology of Marxism-Leninism.

Communist
mass-based
parties

The Communist parties developed a new structural organization: whereas the local committees of cadre and Socialist parties focussed their organizing efforts and drew their support from a particular geographical area, Communist groups formed their cells in the place of work. The workplace cell was the first original element in Communist party organization. It grouped together all party members who depended upon the same firm, workshop, or store or the same professional institution (school or university, for example). Party members thus tended to be tightly organized, their solidarity, resulting from a common occupation, being stronger than that based upon residence.

The work-place-cell system proved to be effective, and

other parties tried to imitate it, generally without success. Such an organization leads each cell to concern itself with problems of a corporate and professional nature rather than with those of a more political nature. These basic groups, however, smaller and, therefore, more numerous than the Socialist sections, tend to go their separate way. It is necessary to have a very strong party structure and for party leaders to have extensive authority if the groups are to resist such centrifugal pressure.

This has resulted in a second distinctive characteristic of the Communist parties: a high degree of centralization. Although all mass-based parties tend to be centralized, Communist parties are more so than others. There is, in principle, free discussion, which is supposedly developed at every level before a decision is made, but afterward all must adhere to the decision that has been made by the central body. The splintering that has from time to time divided or paralyzed the Socialist parties is forbidden in Communist parties, which have generally succeeded in maintaining their unity. A further distinctive characteristic of Communist parties is the importance given to ideology. All parties have a doctrine or at least a platform. The European Socialist parties, which were doctrinaire before 1914 and between the two wars, later became more pragmatic, not to say opportunistic. But, in Communist parties, ideology occupies a much more fundamental place, a primary concern of the party being to indoctrinate its members with Marxism.

The 1920s and '30s saw the emergence of Fascist parties that attempted, as do the Communist and Socialist parties, to organize the maximum number of members but that did not claim to represent the great masses of people. Their teaching was authoritarian and elitist. They thought that societies should be directed by the most talented and capable people—by an elite. The party leadership, grouped under the absolute authority of a supreme head, constituted such an elite. Party structure had as its goal the assurance of the obedience of the elite.

The Fascist
model

This structure resembled that of armies, which are also organized in such a way as to ensure, by means of rigorous discipline, the obedience of a large number of men to an elite leadership. The party structure, therefore, made use of a military-type organization, consisting of a pyramid made up of units that at the base were very tiny but that, when joined with other units, formed groups that got larger and larger. Uniforms, ranks, orders, salutes, marches, and unquestioning obedience were all aspects of Fascist parties. This similarity rests upon another factor; namely, that Fascist doctrine taught that power must be seized by organized minorities making use of force. The party thus made use of a militia intended to assure victory in the struggle for control over the unorganized masses.

Large parties built upon the Fascist model developed between the two wars in Italy and Germany, where they actually came into power. Fascist parties appeared also in most other countries of western Europe during this period but were unable to achieve power. The less-developed nations of eastern Europe and Latin America were equally infected by the movement. The victory of the Allies in 1945, as well as the revelation of the horrors of Nazism, stopped the growth of the Fascists and provoked their decline, but Fascist-type party organization and doctrine remain a potent means of exercising power.

PARTIES AND POLITICAL POWER

Whether they are conservative or revolutionary, whether they are a union of notables or an organization of the masses, whether they function in a pluralistic democracy or in a monolithic dictatorship, parties have one function in common: they all participate to some extent in the exercise of political power, whether by forming a government or by exercising the function of opposition, a function that is often of crucial importance in the determination of national policy.

The struggle for power. It is possible in theory to distinguish revolutionary parties, which attempt to gain power by violence (conspiracies, guerrilla warfare, etc.), from those parties working within the legal framework of elections. But the distinction is not always easy to make,

because the same parties may sometimes make use of both procedures, either simultaneously or successively, depending upon the circumstances. In the 1920s, for example, Communist parties sought power through elections at the same time that they were developing an underground activity of a revolutionary nature. In the 19th century, liberal parties were in the same situation, sometimes employing the techniques of conspiracy, as in Italy, Austria, Germany, Poland, and Russia, and sometimes confining their struggles to the ballot box, as in Great Britain and France.

Revolutionary methods vary greatly. Clandestine plots by which minority groups seize the centres of power presuppose monarchies or dictatorships in which the masses of people have little say in government. But terrorist and disruptive activity can serve to mobilize citizens and to demonstrate the powerlessness of any government. At the beginning of the 20th century leftist trade unionists extolled the revolutionary general strike, a total stoppage of all economic activity that would paralyze society completely and put the government at the revolutionaries' mercy. Rural guerrilla activity has often been used in countries with a predominantly agrarian society; urban guerrilla warfare was effective in the European revolutions of the 19th century, but the development of techniques of police and military control has made such activity more difficult.

Functions
of parties
within a
democracy

Revolutionary parties are less numerous than parties that work within the law: the contest at election time is the means normally used in the struggle for power. Such activity corresponds, moreover, to the original nature of political parties and involves three factors: the organization of propaganda, the selection of candidates, and the financing of campaigns. The first function is the most visible. The party first of all gives the candidate a label that serves to introduce him to the voters and to identify his position. Because of this party label the voters are better able to distinguish the candidates. The promises and declarations of individuals are seldom taken with too much seriousness, and it means more to indicate that one candidate is a Communist, another a Socialist, a third a Fascist, and a fourth a liberal. Finally, the party also furnishes the candidate with workers to raise funds, put up his posters, distribute his literature, organize his meetings, and canvass from door to door.

The function of selecting candidates is exercised in three ways. In cadre parties, candidates are selected by committees of the party activists who make up the party—the caucus system, as it is known in the United States. In general, local committees play essential roles in this regard. In some countries, however, the selection is centralized by a national caucus, as, for example, by the Conservative Party in Britain and the Union of Democrats in France. In mass-based parties, selection is made by members of the regional and national congresses according to apparently democratic procedures; in actual practice, the governing committees play an essential role, the local constituency members generally ratifying their choice. Thirdly, in the United States the mechanism of primary elections has established a system for selecting candidates by means of the votes of all party members or all voters within a particular electoral district.

The various processes of selecting candidates do not, however, differ significantly in their results, for it is almost always the party leaders who play the essential role. This introduces an oligarchical tendency into party politics, a tendency that has not been overcome by the congresses of the mass-based parties or the United States primaries, which provide only a partial limitation on the power of the governing committees.

An important aspect of the struggle for power between political parties is the financing of campaigns. Cadre parties always have in their committees some key figure having connections with businessmen who is responsible for collecting gifts from them. In mass-based parties, rather than looking for large sums of money from a few people, leaders gather smaller sums from a large number of people who usually give on a monthly or annual basis. This method has been viewed as one of the distinguishing characteristics of mass-based parties. Sometimes the law inter-

venes in the financing of elections and of parties. Laws often limit campaign expenses and attempt to restrict the resources of the parties, but they are generally inoperative because it is quite easy to circumvent them. In some countries the state contributes public funds to the parties. At first, such financial participation was limited to expenses for campaigns and was based on the uniform treatment of candidates (as in France), but in Sweden and Finland the state contributes to the general finances of parties.

Participation in power. Only the functions of parties in democratic regimes will be considered at this time. The role of the single party in a dictatorship will be analyzed separately.

Once a political party has achieved electoral victory, the question arises of how much influence the party is to have on the government. The influence of the party on members in elective office is frequently quite weak. It defines the general lines of their activity, but these lines can be quite hazy, and few decisions are taken in the periodic meetings between officeholders and their party. Each member of the legislature retains personal freedom of action in his participation in debates, in his participation in government, and, especially, in his voting. The party may, of course, attempt to enforce the party line, but parliamentary or congressional members cannot be compelled to vote the way the party wants them to. Such is the situation in the United States, within most of the liberal and conservative European parties, and within cadre parties in general.

The question of how disciplined a party is, of the extent to which it will always present a united front, enables a distinction to be made between what may be termed rigid and flexible parties; that is, between those that attempt always to be united and disciplined, following what is most often an ideologically based party line, and those that, representing a broader range of interests and points of view, form legislatures that are assemblies of individuals rather than of parties.

Flexible
and rigid
parties

Whether the parties operating within a particular system will be rigid or flexible depends largely on the constitutional provisions that determine the circumstances in which a government may continue in office. This is clearly illustrated by comparing the situation in the United States with that in Great Britain. In the United States the president and his government continue in office for the constitutionally defined period of four years, regardless of whether a majority in the legislature supports him or not. Since a united party is thus not crucial to the immediate survival of the government, both major parties are able to contain broad coalitions of interests, and votes on issues of major importance frequently split each party. In the United Kingdom the situation is quite different. There, government can continue in office only so long as it commands a majority in the legislature. A single adverse vote can result in the dissolution of Parliament and a general election. Party discipline and unity are thus of crucial importance, and this fact has far-reaching consequences for the composition, organization, and policies of each party. The consequences of party disunity within such a constitutional framework are well illustrated by the weakness and instability of the governments of the Third and Fourth French republics.

The distinction between flexible and rigid parties applies equally to parties in power and to those forming the opposition. Votes of censure or of lack of confidence, votes on proposed legislation or on the budget, questions put to ministers or challenges made to them—in short, all the functions of an opposition party—are worked out differently in flexible and rigid party systems.

In flexible party systems the absence of strong discipline is often of great consequence to the opposition party because only rigid parties can constitute an opposition force sufficiently strong to counterbalance the strength of the party in power. At the same time, party discipline permits the opposition to present the public with an alternative to the majority party; the logical consequence of such a situation is Britain's "shadow cabinet," which accustoms the electorate to the idea that a new group is ready to take over the reins of government.

Parties provide, moreover, a channel of communication

between opposition legislators and the public. The governing party performs a similar service for the government, although it is less necessary, since the government has at its disposal numerous means of communicating with the public. Opposition parties thus provide a means of expressing negative reaction to decisions of government and proposing alternatives. This role justifies the official recognition given to opposition parties, as is the case in Great Britain and Scandinavia.

Power and representation. It is difficult to envisage how representative democracy could function in a large industrialized society without political parties. In order for citizens to be able to make an intelligent choice of representative or president, it is necessary for them to know the real political orientation of each candidate. Party membership provides the clearest indication of this. The programs and promises of each individual candidate are not too significant or informative, because most candidates, in their attempt to gain the most votes, try to avoid difficult subjects; they all tend to speak the same language; that is, to camouflage their real opinions. The fact that one is a Socialist, another a conservative, a third a liberal, and a fourth a Communist provides a far better clue as to how the candidate will perform when in office. In the legislature the discipline of the party limits the possibility that elected representatives will change their minds and their politics, and thus the party label acts as a sort of guarantee that there will be at least some correspondence between promise and performance. Parties make possible the representation of varying shades of opinion by synthesizing different positions into a stance that each representative adopts to a greater or lesser extent.

But parties, like all organizations, tend to manipulate their members, to bring them under the control of an inner circle of leaders that often perpetuates itself by cooptation. In cadre parties, members are manipulated by powerful committees containing cliques of influential party leaders. In mass-based parties, leaders are chosen by the members, but incumbents are very often re-elected because they control the party apparatus, using it to ensure their continuation in power.

Democratic political systems, while performing the function of representation, thus rest more or less on the competition of rival oligarchies. But these oligarchies consist of political elites that are open to all with political ambition. No modern democracy could function without parties, the oligarchical tendencies of which are best regarded as a necessary evil.

PARTY SYSTEMS

Party systems may be broken down into three broad categories: two-party, multiparty, and single-party. Such a classification is based not merely on the number of parties operating within a particular country but on a variety of distinctive features that the three systems exhibit. Two-party and multiparty systems represent means of organizing political conflict within pluralistic societies and are thus part of the apparatus of democracy. Single parties usually operate in situations in which genuine political conflict is not tolerated. This broad statement is, however, subject to qualification, for, although single parties do not usually permit the expression of points of view that are fundamentally opposed to the party line or ideology, there may well be intense conflict within these limits over policy within the party itself. And even within a two-party or a multiparty system, debate may become so stymied and a particular coalition of interests so entrenched that the democratic process is seriously compromised.

The distinction between two-party and multiparty systems is not as easily made as it might appear. In any two-party system there are invariably some tiny parties in addition to the two major parties, and there is always the possibility that such small parties might prevent one of the two main parties from gaining a majority of seats in the legislature. This is the case with regard to the Liberal Party in Great Britain, for example. Other countries do not fall clearly into either category; thus, Austria and the Federal Republic of Germany only approximate the two-party system. It is not simply a question of the number

of parties that determines the nature of the two-party system; many other elements are of importance, the extent of party discipline in particular.

Multiparty systems. In Anglo-Saxon countries there is a tendency to consider the two-party system as normal and the multiparty system as the exceptional case. But, in fact, the two-party system that operates in Great Britain, the United States, and New Zealand is much rarer than the multiparty system, which is found in almost all of western Europe.

In western Europe, three major categories of parties have developed since the beginning of the 19th century: conservative, liberal, and Socialist. Each reflects the interests of a particular social class and expounds a particular political ideology. After World War I other categories of parties developed that were partly the result of divisions or transformations of older parties. Communist parties began as splinter groups of Socialist parties, and Christian Democrat parties attempted to weld together moderate Socialists and conservatives and some liberals. Other distinctive types of party emerged in some countries. In Scandinavia, liberal rural parties developed in the 19th century, reflecting a long tradition of separate representation of the rural population. In many countries ethnic minorities formed the basis of nationalist parties, which then either joined existing parties or divided them.

The appearance of Socialism in the 19th century upset the earlier lines of battle between conservatives and liberals and tended to throw the latter two groups into a common defense of capitalism. Logically, this situation should have led to the fusion of conservatives and liberals into one bourgeois party that would have presented a united stand against Socialism. This is, in fact, what happened in Great Britain after World War I.

One of the most important factors determining the number of parties operating within a particular country is the electoral system. Proportional representation tends to favour the development of multiparty systems because it ensures representation in the legislature for even small parties. The majority, single-ballot system tends to produce a two-party system, because it excludes parties that may gain substantial numbers of votes but not the majority of votes necessary to elect a representative within a constituency. The majority system with a second ballot favours a multiparty system tempered by alliances between parties. Such a system is very rare, found only in the German Empire (1871–1914) and in the French Third (1870–1940) and Fifth (since 1958) republics. Voters choose between the parties that did best in a first ballot. This leaves small parties at a disadvantage but, nevertheless, gives them opportunity to strengthen their role during the second balloting as long as they are willing to enter into alliances with the leading parties.

Another factor producing multiparty systems is the intensity of political conflicts. If, within a given political movement, extremists are numerous, then it is difficult for the moderates in that party to join with them in a united front. Two rival parties are likely to be formed. Thus, the power of the Jacobins among 19th-century French liberals contributed to the inability of the moderates to form one great liberal party, as was successfully achieved in Great Britain. Likewise, the power of the extremists among the conservatives was an obstacle to the development of a strong conservative party.

The distinction between the multiparty system and the two-party system corresponds largely to a distinction between two types of Western political regime. In a two-party situation the administration has, in effect, an assurance of a majority in the legislature, deriving from the predominance of one party; it has, therefore, a guarantee of continuance and effectiveness. Such a system is often referred to as majority parliamentarianism. In a multiparty situation, on the other hand, it is quite rare for one party to have a majority in the legislature; governments must, therefore, be founded on coalitions, which are always more heterogeneous and more fragile than a single party. The result is less stability and less political power. Such systems may be referred to as nonmajority parliamentarianism.

system
on the
number of
parties

In practice, majority and nonmajority parliamentary systems do not coincide exactly with two-party systems and multiparty systems. For, if each of the two parties is flexible and does not control the voting patterns of its members (as is the case in the United States), the numerical majority of one of the parties matters little. It can happen, moreover, that one party in a multiparty system will hold an absolute majority of seats in the legislature so that no coalition is required. Such a situation is unusual but has occurred in West Germany, Italy, and Belgium at various times since 1945.

Ordinarily, however, a coalition will be the only means of attaining a parliamentary majority within the framework of the multiparty system. Coalitions are by nature more heterogeneous and more unstable than a grouping made up of one party, but their effectiveness varies greatly according to the discipline and organization of the parties involved. In the case of flexible parties that are undisciplined and that allow each legislator to vote on his own, the coalition will be weak and probably short-lived. The instability and weakness of governments is at its maximum in such situations, of which the Third French Republic provides a good example.

If, on the other hand, the parties involved in a coalition are rigid and disciplined, it is possible for a system quite similar to the two-party system to develop. This is often the case when two opposing alliances are formed, one on the left and one on the right, and when both are strong enough to endure through the legislative session. This type of coalition, referred to as bipolarized, introduces elements of the two-party system into a multiparty framework. A situation of this type has developed in Sweden, where conservative, liberal, and agrarian parties have been aligned against the Social Democrat Party, which eventually allied itself with the Communist Party (1970).

The system of bipolar alliances may be contrasted with the system of a centrist alliance. Rather than the parties on the right forming a centre-right coalition to oppose a centre-left coalition, there is the possibility that the centre-left and the centre-right will join forces and reject the extremes at both ends of the political spectrum. Such a situation occurred in Germany during the Weimar Republic, when the government rested on a majority formed of a coalition of Catholic Centrists and Social Democrats, with opposition coming from the Communists and the nationalists on the extreme left and right.

Centrist coalitions all tend to give the average citizen a sense of political alienation. In rejecting both extremes, coalitions may well be isolating the radical, unstable elements, but the governing coalition may tend to be unresponsive to new ideas, uninspiringly pragmatic, and too ready to compromise. This situation gives rise to a more or less permanent breach between practical politics and political ideals. An advantage of bipolarization or of the two-party system is that the moderates of both sides must collaborate with those who are more extreme in their views, and the extremists must be willing to work with those who are more moderate; the pressure from the extremists prevents the moderates from getting bogged down, while collaboration with the moderates lends a touch of realism to the policies of the extremists.

Two-party systems. A fundamental distinction must be made between the two-party system as it is found in the United States and as it is found in Great Britain. Although two major parties dominate political life in the two countries, the system operates in quite different ways.

The American two-party system. The United States has always had a two-party system, first in the opposition between the Federalists and the Anti-Federalists, then in the competition between the Republicans and the Democrats. There have been frequent third-party movements in the history of the country, but they have always failed. Presidential elections seem to have played an important role in the formation of this type of two-party system. The mechanism of a national election in so large a country has necessitated very large political organizations and, at the same time, relatively simplified choices for the voter.

American parties are different from their counterparts in other Western countries. They are not tied in the same

way to the great social and ideological movements that have so influenced the development of political life in Europe during the last two centuries. There have been Socialist parties at various times in the history of the United States, but they have never challenged the dominance of the two major parties. It can be argued that the main reason for the failure of Socialist parties in America has been the high degree of upward mobility permitted by a rich and continually expanding economy. The consequence of this mobility has been that class consciousness has never developed in the United States in a manner that would encourage the formation of large Socialist or Communist parties.

In comparison with European political movements, therefore, American parties have appeared as two varieties of one liberal party, and within each party can be found a wide range of opinion, going from the right to the left.

The American parties have a flexible and decentralized structure, marked by the absence of discipline and rigid hierarchy. This was the structure of most of the cadre-type parties of the 19th century, a structure that most liberal parties have retained. Federalism and a concern for local autonomy accentuate the lack of rigid structure and the weakness of lines of authority in the parties. Organization may be relatively strong and homogeneous at the local level, but such control is much weaker on the state level and practically nonexistent on the national level. There is some truth to the observation that the United States has not two parties but 100—that is, two in each state. But it is also true that each party develops a certain degree of national unity for the presidential election and that the leadership of the president within his party gives the victorious party some cohesion.

In voting, Republicans and Democrats are usually found on both sides. An alliance between liberal Republicans and Democrats against conservative Republicans and Democrats tends to develop. But neither bloc is stable, and the alignment varies from one vote to another. As a consequence, despite the existence of a two-party system, no stable legislative majority is possible. In order to have his budget adopted and his legislation passed, the president of the United States must patiently try to gather the necessary votes on every question; like Penelope, he has the wearisome task of beginning anew each day. The American two-party system is thus a pseudo-two-party system, because each party provides only a loose framework within which shifting coalitions are formed.

The British two-party system. Another form of the two-party system is operative in Great Britain and in New Zealand. The situation in Australia is affected somewhat by the presence of a third party, the Country Party. A tight alliance between the Australian Liberal Party and the Country Party introduces, however, a rather rigid bipolarization with the Labour Party. The system thus tends to operate on a two-party basis. Canada also possesses what is essentially a two-party system, Liberals or Conservatives usually being able to form a working majority without the help of the small, regionally based parties.

Great Britain has had two successive two-party alignments: Conservative and Liberal prior to 1914 and Conservative and Labour since 1935. The period from 1920 to 1935 constituted an intermediate phase between the two. Britain's Conservative Party is actually a Conservative-Liberal Party, resulting from a fusion of the essential elements of the two great 19th-century parties. Despite the name Conservative, its ideology corresponds to political and economic liberalism. A similar observation could be made about the other major European conservative parties, such as the German Christian Democratic Party and the Belgian Social Christian Party.

The British two-party system depends on the existence of rigid parties; that is, parties in which there is effective discipline regarding parliamentary voting patterns. In every important vote, all party members are required to vote as a bloc and to follow to the letter the directives that they agreed upon in common or that were decided for them by the party leaders. A relative flexibility may at times be tolerated, but only to the extent that such a policy does not compromise the action of the government. It may

Coalition voting patterns in the U.S. Congress

Benefits and disadvantages of coalition politics

Importance of rigid party lines in the British system

be admissible for some party members to abstain from voting if their abstention does not alter the results of the vote. Thus, the leader of the majority party (who is at the same time the prime minister) is likely to remain in power throughout the session of Parliament, and the legislation he or she proposes will likely be adopted. There is no longer any real separation of power between the executive and legislative branches, for the government and its parliamentary majority form a homogeneous and solid bloc before which the opposition has no power other than to make its criticisms known. During the four or five years for which a Parliament meets, the majority in power is completely in control, and only internal difficulties within the majority party can limit its power.

Since each party is made up of a disciplined group with a recognized leader who becomes prime minister if his or her party wins the legislative elections, these elections perform the function of selecting both the legislature and the government. In voting to make one of the party leaders the head of the government, the British assure the leader of a disciplined parliamentary majority. The result is a political system that is at once stable, democratic, and strong; and many would argue that it is more stable, more democratic, and stronger than systems anywhere else.

This situation presupposes that both parties are in agreement with regard to the fundamental rules of a democracy. If a Fascist party and a Communist party were opposed to one another in Great Britain, the two-party system would not last very long. The winner would zealously suppress the opponent and rule alone.

The system, of course, does have its weak points, especially insofar as it tends to frustrate the innovative elements within both parties. But it is possible that this situation is preferable to what would happen if the more extreme elements within the parties were permitted to engage in unrealistic policies. The risk of immobility is in fact a problem for any party in a modern industrial society, and not just for those in a two-party situation. The problem is related to the difficulties involved in creating new organizations capable of being taken seriously by an important segment of the population and in revitalizing long-standing organizations encumbered by established practices and entrenched interests.

Single-party systems. There have been three historical forms of the single-party system: Communist, Fascist, and that found in the developing countries.

The Communist model. In Communist countries the party is considered to be the spearhead of the urban working class and of other workers united with it (peasants, intellectuals, etc.). Its role is to aid in the building of a Socialist regime during the transitory phase between capitalism and pure Socialism, called the dictatorship of the proletariat. An understanding of the exact role of the party requires an appreciation of the Marxist conception of the evolution of the state. In countries based on private ownership of the means of production, the power of the state, according to the Marxist point of view, is used to further the interests of the controlling capitalists. In the first stage of revolution the power of the state is broken. Power, however, still has to be wielded to prevent counter-revolution and to facilitate the transition to Communism, at which stage coercion will no longer be necessary. Thus, the party, in effect, assumes the coercive functions of the state during the dictatorship of the proletariat or, to be more accurate, during the dictatorship of the party in the name of the proletariat.

In all Communist countries, the structure of the party has been determined largely by the need for it to govern firmly while at the same time maintaining its contact with the masses of the people. Party members are a part of the general public, of which they are the most active and most politically conscious members. They remain in contact with the masses by means of a network of party cells that are present everywhere. Party leaders are thus always "listening in on the masses," and the masses are always informed of decisions of party leaders, as long as the communication network is working in both directions.

The party is not only a permanent means of contact between the people and party leaders but also a propa-

ganda instrument. Political indoctrination is essential to the survival of Communist parties, and many resources are devoted to it. Indoctrination is accomplished in training schools, by means of "education" campaigns, by censorship, and through the untiring efforts of militants, who play a role similar to that of the clergy in organized religion. The party is thus the guardian of orthodoxy and has the power to condemn and to excommunicate.

In the traditional Communist model, the party hierarchy, then, and not the official state hierarchy, has the real power. The first secretary of the party is the most important figure of the regime, and, whether the party leadership is in the hands of one man or several, the party remains the centre of political power.

Near the end of the 20th century, however, the Communist model began to change as the centre of power began shifting toward a popularly elected state hierarchy. A younger generation of Communist leaders, openly critical of the party's inefficient, unresponsive, and domineering management of the government—particularly the economy—sought a return to Lenin's original concepts of democratic centralism and socialism. In some countries, democratic concepts were emphasized, and constitutional amendments eliminated the party's official control, clearing the way for a multiparty system.

The Fascist model. Fascist parties in a single-party state have never played as important a role as Communist parties in an analogous situation. In Italy, the Fascist party was never the single most important element in the regime, and its influence was often secondary. In Spain the Falange never played a crucial role, and in Portugal the National Union was a very weak organization even at the height of dictator António Salazar's strength. Only in Germany did the National Socialist Party have a great influence on the state. But, in the end, Hitler's dictatorship was dependent on his private army, the SS (Schutzstaffel), which formed a separate element within the party and which was closed to outside influences, and on the Gestapo, which was a state organization and not an organization of the party. The Fascist party in the single-party state has a policing or military function rather than an ideological one.

After their rise to power, the Fascist parties in both Germany and Italy gradually ceased to perform the function of maintaining contact between the people and the government, a function that is usually performed by the party in a single-party situation. It was possible to observe a tendency for the party to close in upon itself while suppressing its deviant members. The renewal of the party was then assured through recruitment from youth organizations, from which the most fanatical elements, the products of a gradual selection process starting at a very early age, entered the party. The party tended, therefore, to constitute a closed order.

The single party in the developing countries. Some of the Communist parties in power in developing countries do not differ significantly from their counterparts in industrialized countries. This is certainly true of the Communist Party of the Socialist Republic of Vietnam and the Workers' Party of North Korea. There have always been, however, countries in which the single party in power could not be characterized in terms of a traditional European counterpart. This observation applies to, for example, the former Arab Socialist Union in Egypt, the Neo-Destour Party in Tunisia (renamed the Destour Democratic Rally), and the National Liberation Front in Algeria, as well as many other parties in black Africa.

Most of these parties claimed to be more or less Socialist or at least progressive, while remaining far removed from Communism and, in some cases, ardent foes of Communism. President Nasser attempted to establish a moderate and nationalistic Socialism in Egypt. In Tunisia the Neo-Destour Party was more republican than Socialist and was inspired more by the example of the reforms in Turkey under Kemal Atatürk than by Nasserism. In black Africa, single parties have often claimed to be Socialist, but with few exceptions they rarely are in practice.

Single parties in developing countries are rarely as well organized as Communist parties. In Turkey the Republican People's Party was more a cadre party than a mass-

Functions
of Fascist
parties

Role of the
party in
Communist states

based party. In Egypt it has been necessary to organize a core of professional politicians within the framework of a pseudoparty of the masses. In black Africa the parties are most often genuinely mass based, but the membership appears to be motivated primarily by personal attachment to the leader or by tribal loyalties, and organization is not usually very strong. It is this weakness in organization that explains the secondary role played by such parties in government.

Some regimes, however, have endeavoured to develop the role of the party to the fullest extent possible. The politics of Atatürk in Turkey were an interesting case study in this regard. It was also Nasser's goal to increase the influence of the Arab Socialist Union, thereby making it the backbone of the regime. This process is significant in that it represents an attempt to move away from the old-fashioned dictatorship, supported by the army or based on tribal traditions or on charismatic leadership, toward a modern dictatorship, supported by one political party. Single-party systems can institutionalize dictatorships by making them survive the life of one dominant figure.

FUTURE OF POLITICAL PARTIES

The necessity of parties in democratic systems

It has often been said in the West that political parties are in a state of decline. Actually, this has been a long-standing opinion in certain conservative circles, arising largely out of a latent hostility to parties, which are viewed as a divisive force among citizens, a threat to national unity, and an enticement to corruption and demagoguery. In certain European countries—France, for example—right-wing political organizations have even refused to call themselves parties, using instead such terms as movement, union, federation, and centre. And it cannot be denied that to some extent the major European and American parties of the late 20th century do appear old and rigid in comparison with their condition at the turn of the century or immediately following World War I. Even relatively new parties, such as the Christian Democratic parties of Germany and Italy (founded in 1945), seem somewhat lifeless.

In terms of size and number, however, political parties are not declining but growing. At the turn of the century they were confined mainly to Europe and North America; elsewhere they were quite weak or nonexistent. In the late 20th century, parties are found practically everywhere in the world. And in Europe and North America there are generally far more people holding membership in parties than prior to 1914. Parties of the late 20th century are larger, stronger, and better organized than those of the late 19th century. In the industrialized nations, especially in western Europe, parties have become less revolutionary and innovative, and this factor may explain the rigid and worn-out image that they sometimes present. But even this phenomenon is found only in a limited area and may, perhaps, pass.

The growth of parties into very large organizations may be responsible for the feelings of powerlessness on the part of many individuals who are involved in them. This is a problem experienced by people who find themselves part of any large organization, whether it be a political party, business enterprise, corporation, or union. The difficulties involved in reforming or changing political parties that have become large and institutionalized, coupled with the next-to-impossible task of creating new parties likely to reach sufficient strength to be taken seriously by the electorate, have resulted in much frustration and impatience with the party system. But it is difficult to imagine how democracy could function in a large industrialized country without political parties. In the modern world, democracy and political parties are two facets of the same reality, the inside and outside of the same fabric. (M.Du./Ed.)

Interest groups

TYPES OF INTEREST GROUP

Categories defined by motivation. Within the broad definition of interest groups, two polar types are recognizable: first, interest groups proper, such as trade unions, farmers' unions, and employers' associations, which have as

their primary purpose the enhancement of the advantage of their members; and, second, promotional groups, such as the societies for the prevention of cruelty to children or various voluntary relief agencies, which exist primarily or entirely to enhance the advantage not of their own members but of the population, even perhaps to the discomfort or disadvantage of their own members. Some of these, such as churches or various evangelizing groups, exist to promulgate a distinctive set of values to be applied to society as a whole. The distinction between interest groups proper and promotional groups is not sharp for two reasons. In the first place, most interest groups proper sincerely believe that in furthering their own material advantage they are also serving that of society as a whole—by promoting "free enterprise" or a healthy and wealthy body of farmers or a well-paid and enthusiastic corps of school teachers. But the propagation of such beliefs is certainly not the primary purpose of such organizations, thus distinguishing them from promotional groups. The second reason is that some groups—for instance, organized churches—fall between the two types; they can simultaneously pursue advantages for their own sect and seek to inculcate a distinctive set of values in a whole society.

Categories defined by structure. In primitive or developing societies, the most prominent type of interest group is the natural (*i.e.*, primordial or communal) one—that is, one based on kinship, lineage, neighbourhood, or religious confession. In Western, industrialized societies, though such groups do sometimes retain influence (as do the nationalities in Yugoslavia or Czechoslovakia), the most prominent interest group is the associational (*i.e.*, secondary or factitious) type, like the trade union or Campaign for Nuclear Disarmament, which is deliberately created to serve defined purposes. Often, associational (or factitious) groups are created for the sake of the specialized purposes of the first type; the Indian Workers Union, for instance, was created from the community of Indian persons in Britain.

Within the class of associational groups, further qualifications must be made:

1. Not all associational groups possess formal structure. "Wall Street" in the United States, or the "City" in London, though consisting of a loose network of persons or functions, may nevertheless exert powerful collective pressures.

2. Some associational groups are collectivities; but others are single, discreet organizations. Thus General Motors Corporation exerts its own strong influence vis-à-vis the U.S. government irrespective of the influence of the more general employers' organization to which it possibly belongs, like the National Association of Manufacturers.

3. Some associational groups are temporary or *ad hoc*. Such are the so-called anomic groups, such as enraged French farmers who come together briefly to put logs across roads in order to draw governmental attention to their grievances.

4. Some associational groups are "latent." There may be a common interest among certain members of the public even though these individuals may not have combined into a formal or informal organization. The individuals may be unaware that they have a common interest or, if aware, see no reason to defend or promote it. Or, even if the members consciously wish to defend or promote an interest, the laws may restrict or control their ability to associate for such a purpose.

Categories defined by political activity. If or when any interest group tries to influence the government in the pursuit of its aims, it becomes a "pressure group." Not all interest groups proper try to exert influence on governments; many (such as businesses and trade unions) do so only as a part of their more general activities of promoting their own interests. Promotional groups, on the other hand, spend much or all their time precisely in trying to influence the government to favour their aims. Groups such as an anglers' association may, therefore, turn into pressure groups for a time—the time when they seek to influence the government for one of their purposes—and then revert to simple interest-group status. A pressure group is therefore definable as "any interest group that

Natural and associational groups

Pressure groups

is not a part of the government and does not itself seek to govern the country in its own name, but does seek to influence that government for its own purposes."

Difficulties of definition arise, however. Some groups are neither a governmental agency nor entirely a private group. In autocratic states, Communist or otherwise, for instance, trade unions are often controlled by the government or the governing party. In the Western liberal democracies, again, agencies like the Tennessee Valley Authority (in the U.S.) or the British Broadcasting Corporation, though subject to the overriding control of the government, enjoy substantial autonomy in certain broad areas.

Also, as noted at the beginning of this article, some pressure groups eventually turn into political parties, or vice versa.

CHARACTERISTICS OF PRESSURE GROUPS

Power elements. Even in the most pluralistic of the Western liberal democratic states, it is wrong to picture public policy as simply the result of a parallelogram of group forces. The groups are themselves restrained by institutions, procedures, and public beliefs. Among the *institutions*, the most important are the public bureaucracy, the political parties, and the independent branches of the government (the executive, legislature, and judiciary—or some combination of these, depending on the structure of government). To the extent that each or all of these institutions have strong traditions, no interest group supplants them but instead has to deal with them. The governmental procedures in force also affect groups' performance. To the extent that public issues are traditionally subject to publicity and wide discussion, groups are limited in the kind of activities that they can pursue. They are constrained by public *beliefs* as to what is in "the public interest," by what is a proper or improper procedure, or by what causes are respectable and what are not. If any of these three entities—institutions, procedures, or public beliefs—become feeble, interest groups can intrude into them. By allying with or gaining power over the parties, the legislature, or the bureaucracy, for instance, groups can tend to substitute themselves for such organs in the decision-making process.

Inside every country the power that pressure groups wield against the government and that each group wields relative to its rivals depends on a combination of the following variables, some of which are mutually dependent:

1. Density is the ratio of actual membership to potential membership. The higher the density, the more "representative" is the group of all the people whose interests it purports to represent and the greater will be the inclination for governments to recognize and consult it. On the other hand, too wide a membership brings with it internal cleavages, so that on certain issues the organization may not be able to tender clear-cut advice or, indeed, may have to refrain from offering advice altogether.
2. Wealth not only helps a group to develop a skilled management and bureaucracy but also enables it to propagandize and to finance political parties.
3. Prestige lends a group the ability to get a favourable initial hearing from government and public, even though its numbers may be small and its wealth meagre.
4. Organization consists notably of the ability to brief legislators and administrators well and quickly, to mobilize members and the public rapidly, and to receive advance intelligence of likely trends in policy.
5. Socioeconomic leverage is strong among some groups (such as trade unions) that can disrupt social life and low among others (such as consumers associations).
6. Militancy consists of making an effective nuisance of oneself, so that, hopefully, governments will be willing to "buy" time or peace.
7. Specialized information and skills add the weight of authority.
8. Electoral strength refers to the power of some groups that, though poorly organized or having a low density, nevertheless command wide support in the electorate and so find themselves courted by rival political parties.

Strategy and tactics. Although all groups seek out the most influential agencies of government, the most influ-

ential may not be accessible; and resort must be had to the next most influential organ that *is* accessible. Because the Communist trade unions in Italy, for instance, are not welcome at the Roman Catholic controlled Ministry of Labour, they try to penetrate the legislature through political election. Indeed, in any system the influence of the various organs of government varies. In France the president and bureaucracy are more influential than the majority party and Parliament; in the United States, the president and Congress balance each other, with control of the bureaucracy shared between the two. Strategy, for an interest group, consists of determining and going to the most influential organ that is accessible.

The tactics of an interest group range from the constitutional to the unconstitutional (or "direct action"), the legal to the illegal—all subject, as noted above, to the restraints of institutions, public procedures, and public beliefs. When the target of the tactics is the executive and the governmental bureaucracy, the following are the prime methods: *Constitutional operations* include (1) advice via advisory bodies attached to the ministries (as in Britain and France), (2) official hearings outside the ministries (as in Royal Commissions in the U.K. and presidential commissions in the U.S.) or inside the ministries (as in Germany or Sweden), and (3) ad hoc consultations and cooperation. *Semiconstitutional operations* include (1) recruitment of state civil servants into the private bureaucracies of the interest groups, or vice versa, and (2) bribery and favours, which need not necessarily mean passing of money but can take the form of providing entertainment, gifts, or meals. *Semidirect operations* include such measures as refusing to provide information or to cooperate in administering legislation and thus generally withdrawing from advisory functions. *Direct action* includes such measures as the withdrawal of labour (the British Medical Association, for instance, advised its members to withdraw from the state medical service in 1965 unless its demands were met) or even violence such as the roadblocking activities of enraged French farmers in the 1960s).

When the target is the legislature, the following are the chief kinds of tactics used by interest groups: *Constitutional operations* include (1) testimony before legislative committee hearings (extremely important in the U.S. and somewhat important in Sweden, the German Federal Republic, Japan, and Italy); (2) direct representation in the legislature, which involves having individual businessmen, financiers, farmers, school teachers, journalists, and other professionals representing the larger interests of their profession or sponsoring group (in Great Britain in 1955 some 30 percent of Labour's MP's were trade-union sponsored); and (3) lobbying, which refers to the activities of salaried or nonsalaried persons who try to promote their interest groups' aims by seeking personal contacts with legislators, by sending communications or information to legislators or persuading others to do so, and by rendering campaign assistance to favoured legislators. (In the U.S., lobbying is conducted not only by private interest groups but also by certain members of the executive branch and the bureaucracy.) *Semiconstitutional operations* include subvention or payment of retainers as well as providing campaign contributions, secretarial help, office accommodations, and the like, which are restricted but not forbidden by law. *Semidirect action* includes mass lobbying, such as promoting mass demonstrations before legislators, ostensibly to relate grievances but in fact to impress public opinion. *Direct action* includes threatening legislators with a withdrawal of financial assistance, with physical violence, or with riots (as in Japan, where snake dances and riots become a means of protest).

When political parties are powerful, they may prove a highly preferred target. Tactics in such cases include the following: *Constitutional operations*, such as, (1) exacting election pledges, which is most important and fruitful in countries (such as the U.S.) where there is relatively little national-party discipline, where representatives owe a certain allegiance to local-party groups and constituents, and where, most important, representatives do possess legislative power; (2) financing the party, which in all systems is perhaps the most effective operation and which in most

political
parties

Western parliaments—and in Western-style parliaments like Japan's—is systematically done by trade unions, employers associations, and individual firms; and (3) lobbying the party machinery, a method that is virtually nonexistent in the United States but is significant in such countries as Great Britain and Germany.

A final target of interest groups is public opinion. The general opinion of the public at large can be of importance in issues where questions of "fairness" or "justice" arise (on which most people feel they can pronounce). These questions involve such matters as capital punishment, the use of nuclear weapons, or certain wars, about which large numbers of people feel very strongly.

ROLE OF INTEREST GROUPS IN VARIOUS POLITICAL SYSTEMS

The Anglo-American and Swedish patterns. In the United States, Great Britain, and Sweden, the general population is not irreparably divided on ideological or cultural lines. Although there arise from time to time some small extremist groups, the population at large is not split into irreconcilable blocks. Given this situation, the most influential and prominent groups are "secondary" associations that have highly specialized objectives, form freely without the requirement of prior governmental permission, and carry out their activities autonomously. With the exception of the affiliation of the trade-union movement to the Labour Party in Britain and in Sweden, the groups are politically neutral; and even the alignment of British and Swedish trade unions and cooperatives does not prevent them from cooperating with other parties nor hinder their free access to government departments. Latent groups are few, since freedom of speech and association and the right to petition the government permit most interests to organize, while good communication media facilitate such organization. Public participation in such groups is, by world standards, high. The pressure groups play highly specialized roles and are sharply differentiated from the political parties.

National
differences

Although American and British means of influencing the executive are similar (by advisory committees, special inquiries, and day-to-day consultation and mutual assistance), these relations are more institutionalized in Britain than in the U.S. British groups seek to influence the parties by affiliation or by securing their members' nomination as candidates, neither mode being employed in the U.S., and by financial assistance, which occurs in both states but in quite different ways owing to the very different legislation on this matter in the two countries. British groups seek to influence the legislature by securing direct representation through participation in party caucuses and by promoting amendments in the committee stage. In the U.S. the methods employed consist of lobbying influential congressmen and appearing at committee hearings, which are far more important in Congress than in the House of Commons. In influencing public opinion, American groups spend far more than their British counterparts—one reason being that purchase of time on radio and television networks is permissible in the U.S., whereas in Britain it is not. In addition, access to the presidency can prove decisive in the U.S.; and some groups such as the National Association for the Advancement of Colored People have scored notable successes by seeking court action.

In Sweden the tactics are somewhat different, owing to three factors: the existence of a multiparty system and the existence of coalition cabinets, the structure of the bureaucracy, and the much greater institutionalization of pressure groups. Sweden, Denmark, and Norway each possess a multiparty system; but when coalitions are formed, they are highly stable. Consensus is achieved in a three-tier operation—first at interparty (electoral) level, then at the interparty-coalition (legislative) level, and finally at the bureaucratic level. In Sweden groups seek to influence the parties by affiliation (the trade unions being affiliated to the Labour Party), by financing them (trade unions giving to the Labour Party, employers groups to the antisocialist parties), and by securing direct representation through the nomination of members as parliamentary candidates. The parties respond by trying to compose a balanced ticket of the spectrum of interests. Hence the groups can affect

the legislature through their representatives inside each of the parties and may, on occasion, form a cross-party legislative pressure group in defense of their common interest; and they also seek access to the party caucus and influence the committee stage of legislation. In the latter case they are assisted by the standard Swedish procedure by which the "comments" of outside interests are attached to the government's bill, even if they contradict the bill's purposes. Groups have ready access to the legislature in the same ways that Anglo-American groups do, except that the procedure is highly institutionalized; the "Royal Commission" with representatives of the bureaucracy, the parties, and the interest groups seek to reach initial agreement on a bill to be presented to the legislature; and when this device is not used, "comments" appended to the bill serve to put the measure in the context of the avowed interests of various groups.

Not unlike the system in Britain, the U.S., and Sweden is the system in Japan, which, despite sharp ideological divisions, has a strong and stable two-party arrangement. This has led to the emergence of a pattern of highly institutionalized pressure groups of the "secondary" type, the most influential of these being business and organized labour. Business, on the whole, is aligned with the conservative Liberal-Democratic party, supplies the bulk of its funds, and has a large say in policy formation. Organized labour constitutes a powerful element within the Japanese Socialist Party. In an earlier day, rural farm groups carried considerable political weight—for the conservatives—but the increasing industrialization and urbanization of the country have tended to reduce its importance.

The French and Italian patterns. In France and Italy the political pattern is characterized by deep ideological cleavages. The Roman Catholic Church, for example, operates through both its own political party and its own interest groups, such as the Catholic Action Society and Catholic youth and women's group. By the same token, the highly ideological and sectarian Communist Party establishes its own pressure groups, such as trade unions, farmers associations, and youth movements. Several rival groups thus compete for the same clientele aligned or affiliated with rival political parties.

Under France's Fifth Republic, the executive branch currently controls the majority party in the legislature, and the role of the legislature has been reduced; whereas, under Italy's current system, feeble and fragile coalition cabinets have weakened executive leadership of the legislature, and the legislature itself is highly fragmented among numerous parties. Because contacts between interest groups on the one hand and the parties, civil service departments, and legislature on the other are poorly institutionalized, semidirect action or even direct action against the executive and the legislature are more common, and lawless activities of crowds and violent organizations have proved more widespread.

The means of influencing the chosen targets also vary. In France attention has shifted from the legislature (under the Fourth Republic) to the president and bureaucracy (under the Fifth); interest groups now act through the numerous advisory bodies, private contacts, and such official institutions as the Economic and Social Council. Interest groups secure contacts by putting former civil servants on their own payrolls. The fact that many civil servants and business executives come from the same schools facilitates private collusion.

In Italy interest groups direct their attention mainly to three targets. First, the bureaucracy, even though it is highly fragmented and provides few formal advisory channels of communication, is open to ad hoc and personal consultations (except to groups deemed ideologically distasteful, such as the Communists). Second, the parties are often twinned to interest groups, as noted earlier; and thus the groups seek and achieve direct representation in the legislature. Third, the legislature, because it is composed of interest groups, is heavily influenced in specialized legislative committees. In general, therefore, interest groups have tended to "intrude" into the organs of government, forming close alliances with certain departments and legislative commissions and inserting themselves into others

via their membership in political parties. In short, interest groups are not "contained" as they are in Anglo-American and Scandinavian countries—political institutions are fragmented and weak, procedures are irregular or personal and not formal, and public beliefs are polarized into uncompromising ideologies.

Patterns in developing countries. Although there is no one typical pattern for all developing countries, which of course embrace more than two-thirds of the world's sovereign states, there are a few common characteristics that can be suggested.

First, political culture in each of these countries is fragmented, sometimes because of ideological differences, sometimes because of the mutual hostility of "natural" groupings based on kinship, lineage, tribe, or language. Second, nascent interest groups representing new modernizing and industrializing forces tend to range against rural natural groupings. The modernizers have defined and specialized objectives, whereas the traditionalists usually represent a spectrum of attitudes, beliefs, values, and interests. Both, in any case, tend to sponsor or generate their own political parties. Third, during preindependence days in some countries, trade unions and other movements (such as the Somali Youth League) carried on activities that would otherwise have been carried on by political parties; when independence came, these groups continued such activities, thus blurring the functional distinctions between parties and interest groups. Fourth, associations in these countries tend to have low membership densities; and in most of these countries the principal "interest"—that is, the peasantry—is hardly organized at all. Attempts to develop widely represented peasant movements have had only limited success. Fifth, although organization and established procedures may be poor, latent interest is usually high. In a particularly divisive and administratively feeble country, this interest latency may reveal itself in lawless and violent group activity—such as strikes, riots, guerrilla movements, and assassinations.

Countries with one-party or military government

In some countries "parties" in elections are not really parties but simply electoral coalitions of various interest groups—the most influential groups consisting of cliques of landlords; leaders of religious, ethnic, or linguistic groups; and the like. Legislatures tend to reflect these divisions and temporary arrangements in society and so enjoy only feeble authority.

In countries with single-party regimes, such as Kenya and Tanzania, the parties tend to lose their mass following and fairly well-defined organization in the years following independence. To enhance their authority, the party leaders try to limit or abolish the autonomy of such interest groups as trade unions, cooperative movements, and youth and women's movements and try to turn these groups into ancillaries of the party.

In some countries the military has taken over, either alone or with civilian elements, and imposed an authoritarian rule. In such cases, the most prominent groups are governmental—the military and the executive. Unless interest groups enjoy a long history of organization (as does the Roman Catholic hierarchy in Latin America), they are often turned into governmental ancillaries or suppressed. In these countries ruled by the military or single parties, the political process turns into a highly informal medley of pressures and personal contacts between the government, the military forces, the various "natural" groups, and some of the more strategically placed groups (such as the church hierarchy or private industry). The "system" is constantly threatened with government coercion or violent outbreaks by sections of the population.

Patterns in Communist states. Like Western states, but unlike developing countries, Communist countries contain various associational groups (trade unions, cooperatives, and the like) but few, if any, promotional groups. In addition, such countries as the Soviet Union, Czechoslovakia, Yugoslavia, Romania, and the People's Republic of China contain many ethnic groups; and Poland, Hungary, and East Germany contain influential organized churches. But unlike the Western states and like a good many of the developing countries, Communist countries have characteristically granted such groups very little autonomy. The

government has long been firmly controlled by a single party, is highly centralized, and has tried to control a great deal of life. The Communist Party has allowed other parties to exist in coalition under conditions that the party itself has laid down. The leading party has assured its power, however, by controlling the nomination (in all but minor cases tantamount to election) of the leadership of all minor parties and interest groups. And even when an interest group is allowed to formally organize, it rarely can exert any influence on the government, for governmental leaders, having been nominated by the Communist Party, are responsible to the party alone and not to various interests.

An outstanding exception to this rule is the success of the Polish trade union Solidarity, the first independent trade union in a Soviet-bloc country. The union first exerted pressure on the government for free elections and economic improvements in the early 1980s through massive strikes. It was subsequently outlawed, but in 1989, in the face of a new wave of strikes and labour unrest and through increasing international pressure, the government was forced to make concessions; it reinstated the union and allowed partially free elections.

In the Soviet Union there exist large trade unions, co-operative associations, and professional societies; many scientific, defense, and sports societies; as well as some 100,000 house committees, sanitary teams, parent-teacher associations, and the like. All have been party led and controlled; and they were formed to serve, in Stalin's words, as "transmission belts from the party to the masses." One must not infer, however, that such associations have been entirely without other significance. In the first place, the party is not identical with the state bureaucracy, though it has long controlled the latter; hence divergences and collisions can occur between an interest group (such as the trade unions) and a concerned ministry regarding the interpretation or implementation of a party's directive. The result often is a triangular meeting of interest group, officials, and party functionaries, with the latter mediating. Second, the Soviet constitution provides that these so-called mass organizations should be consulted on selected issues, as they indeed were in regard to the education act of 1958.

Groups in Poland, besides Solidarity and other trade unions, include the Peasant Self-Aid and such professional groups as the General Technical Organization and the Writers' Union, as well as the Socialist Youth League; the Rural Youth League; the Women's League; and various cultural-ethnic associations for minorities. In all of them, party leadership has been assured (with some exceptions), and they have had relations with the bureaucracy and party mediators similar to those in the Soviet Union. In Poland, however, there is the exceptional role of the Roman Catholic Church, which has established some kind of equipoise with the party and has its own press, organizations, and clubs, even though its electoral freedom has been severely restricted (only certain pro-Socialist Catholics have been allowed to form "parties," such as the Znak, Pax, and the Christian Socialist Association, which participated in elections on the joint list with the Communist Party and other parties).

In other Communist states

Yugoslavia has a longer record than other Communist countries in recognizing interest groups. The society contains many conflicting interests—nationalities; religious communities; a free-enterprise peasant sector; a decentralized network of workers' councils; and a large number of cultural, economic, and professional associations. The 1963 constitution gives institutional expression to these groups: in the five-chamber legislature, legislation is processed through the Federal Chamber, representing the population at large and individual republics; the Politico-Economic Chamber, representing management agencies and sociopolitical organizations; and the Chambers of Economics, of Education, and of Social Welfare and Health, representing their respective fields. Factionalism inside the ruling "National Alliance," the centrifugal pulls of the peasant sector and the workers' councils, and the rivalry of the nationalities have combined to make these legal provisions much more than a formality. BIBLIOGRAPHY

- Political parties:* ROBERT MICHELS, *Les Partis politiques: essai sur les tendances oligarchiques des democraties* (1914; Eng. trans., *Political Parties: A Sociological Study of the Oligarchical Tendencies of Modern Democracies*, 1915), provides the first modern theory of political parties, stemming from the doctrines of the "elite," or "ruling class," of Gaetano Mosca. The book is based largely on the example of German social democracy. MAURICE DUVERGER, *Les Partis Politiques* (1951; Eng. trans., *Political Parties: Their Organization and Activity in the Modern State*, 2nd ed., 1964), gives a comparative and systematic study of political parties, emphasizing the experience of the European countries. JOSEPH G. LA PALOMBARA and MYRON WEINER (eds.), *Political Parties and Political Development* (1966), is a collection of contributions by various authors and is the best recent comparative explication of problems concerning political parties. D.W. RAE, *The Political Consequences of Electoral Laws* (1967), provides, on the basis of an examination of the balloting in numerous countries since 1945, an analysis of the relationship between the electoral system and political parties. It is a model of comparative study. Works about American parties are very numerous. Recommended are SAMUEL J. ELDERSVELD, *Political Parties: A Behavioral Analysis* (1964); and WILLIAM N. CHAMBERS and WALTER D. BURNHAM (eds.), *The American Party Systems* (1967). There are very few works that study European political parties comparatively. STANLEY HENIG and JOHN PINDER (eds.), *European Political Parties* (1969), however, provides much factual information in a concise and systematic format. On Great Britain, SAMUEL H. BEER, *Modern British Politics: A Study of Parties and Pressure Groups* (1965); and R.T. MCKENZIE, *British Political Parties: The Distribution of Power Within the Conservative and Labour Parties*, 2nd rev. ed. (1963), are particularly useful. D.E. APTER, *The Politics of Modernization* (1965); THOMAS L. HODGKIN, *African Political Parties* (1961); and A. MAHIOU, *L'Avenement du parti unique en Afrique noire* (1969), provide informative accounts of the operations of political parties in developing countries. JEROME M. CLUBB, W.H. FLANIGAN, and N.H. ZINGALE, *Partisan Realignment: Voters, Parties, and Government in American History* (1980), a study of voter realignment as effected by government performance.
- Interest groups:* G.A. ALMOND and J.S. COLEMAN (eds.), *The Politics of the Developing Areas* (1960), a synoptic view of government in Latin America, Asia, and Africa that places special-interest groups in the setting of the politics of developing countries; K. VON BEHME, *Interessengruppen in der Demokratie* (1969), a classification of the types, strategies, and tactics of groups in the Western democratic states; A.F. BENTLEY, *The Process of Government*, ed. by P.H. ODEGARD (1967, orig. pub. in 1908), the major theoretical source for all subsequent Western democratic writing, advocating the theory by which all political activity is reduced to group activity; D.C. BLAISDELL, *American Democracy under Pressure* (1957), one of the best of many surveys of the role of groups in American society; S.E. FINER, *Anonymous Empire: A Study of the Lobby in Great Britain*, 2nd ed. (1966), a brief analysis of the types, strategies, and tactics of groups in Britain; H.W. EHRLMANN, *Organized Business in France* (1957), a highly detailed account of the typical methods of groups in France, and (ed.), *Interest Groups on Four Continents* (1958), a collection of papers, together with summaries of the discussions based upon them, that is one of the best country-by-country accounts of the operation of groups; J. MEYNAUD, *Les Groupes de pression en France* (1958), a detailed analysis of group activity in France; J.G. LA PALOMBARA, *Interest Groups in Italian Politics* (1964), a detailed analysis, much of it based upon interview and behavioral data; ALEC BARBROOK and CHRISTINE BOLT, *Power and Protest in American Life* (1980), a study of women, ethnic minority, and public interest groups.

The History of Western Political Philosophy

The central problem of political philosophy is how to deploy or limit public power so as to maintain the survival and enhance the quality of human life. Like all aspects of human experience, it is conditioned by environment and by the scope and limitations of mind; and the answers given by successive political philosophers to perennial problems reflect the knowledge and the assumptions of their times. Political philosophy, as distinct from the study of political and administrative organization, is more theoretical and normative than descriptive. It is inevitably related to general philosophy and is itself a subject of social anthropology, sociology, and the sociology of knowledge. As a normative discipline it is thus concerned with what ought, on various assumptions, to be and how this purpose can be promoted, rather than with a description of facts—although any realistic political theory is necessarily related to these facts. The political philosopher is thus not concerned so much, for example, with how pressure groups work or how, by various systems of voting, decisions are arrived at, as with what the aims of the whole political process should be in the light of a particular philosophy of life.

There is thus a distinction between political philosophy, which reflects the world outlook of successive theorists and which demands an appreciation of their historical settings, and modern political science proper, which, insofar as it can be called a science, is empirical and descriptive. Political philosophy, however, is not merely unpractical speculation, though it may give rise to highly impractical myths: it is a vitally important aspect of life, and one that, for good or evil, has had decisive results on political action; for the assumptions on which political life is conducted clearly must influence what actually happens. Political philosophy may thus be viewed as one of the most

important intellectual disciplines, for it sets standards of judgment and defines constructive purposes for the use of public power. Such consideration of the purposes for which power should be used is in a sense more urgent today than it has been in earlier periods, for mankind has at its disposal the power either to create a world civilization in which modern technology can benefit the human race or to destroy itself in pursuit of political myths. The scope for political philosophy is thus great, the clarification of its purpose and limitations urgent—an aspect, indeed, of civilization's survival.

Despite this unique aspect of the contemporary situation and although ancient political philosophies were formulated under very different conditions, their study still illuminates questions vital today. Questions concerning the aims of government, the grounds of political obligation, the rights of individuals against the state, the basis of sovereignty, the relation of executive to legislative power, and the nature of political liberty and social justice have been asked and answered in many ways over the centuries. They are all fundamental to political philosophy and demand answers in terms of modern knowledge and opinion.

This article describes how these questions have been asked and answered by representative and influential political philosophers, from Greco-Roman antiquity through the Middle Ages, early modern times, and the 19th and early 20th centuries. During so long a time span the historical context of these formulations has changed profoundly, and an understanding of the political philosophers selected demands some account of their background. Because of limitations of space, only political philosophers of outstanding importance have been at all fully described, although many minor figures also are briefly discussed.

The history of political philosophy in the West to the end of the 19th century

ANTIQUITY

Although in antiquity great civilizations arose in Egypt and Mesopotamia, in the Indus Valley, and in China, there was little speculation about the problems of political philosophy as formulated in the West and since predominant. The laws of Hammurabi of Babylon (c. 1750 BC) are rules propounded by the monarch as a representative of God on Earth and are mainly concerned with order, trade, and irrigation; the *Admonitions* of the Egyptian vizier Ptahhotep (c. 2300 BC) are shrewd advice on how to prosper in a bureaucracy; and the *Arthaśāstra* of Kauṭilya, grand

vizier to the Indian Candragupta Maurya in the late 4th century BC, are Machiavellian precepts on how to survive under an arbitrary power. To be sure, the Buddhist concept of *dharma* (social custom and duty), which inspired the Indian emperor Aśoka in the 3rd century BC, implies a moralization of public power, and the teachings of Confucius in the 6th century BC are a code of conduct designed to stabilize society; but there is not, outside Europe, much speculation about the basis of political obligation and the purpose of the state, with both of which Western political philosophy is mainly concerned. An authoritarian society is taken for granted, backed by religious sanctions, and a conservative and arbitrary power is generally accepted.

In contrast to this overwhelming conservatism, paralleled

by the rule of custom and tribal elders in most primitive societies, the political philosophers of ancient Greece question the basis and purpose of government; and, though they do not separate political speculation from shrewd observations that today would be regarded as empirical political science, they created the vocabulary of Western political thought.

Plato. The first elaborate work of European political philosophy is *The Republic* of Plato (c. 378 BC), a masterpiece of insight and feeling, superbly expressed in dialogue form and probably meant for recitation. Further development of Plato's ideas is undertaken in his *Statesman* and *Laws*, the latter prescribing the ruthless methods whereby they might be imposed. Plato grew up during the great war between Athens and Sparta in which Athens suffered defeat and, like many political philosophers, tried to find remedies for prevalent political injustice and decline. Indeed, *The Republic* is the first of the utopias, though not one of the more attractive; and it is the first classic attempt of a European philosopher to moralize political life.

Cast as a lively discussion between Socrates, whose wisdom Plato is recounting, and various leisured Athenians, Books V, VII–VIII, and IX of *The Republic* state the major themes of political philosophy with poetic power. Plato's work has been criticized as static and class bound, reflecting the moral and aesthetic assumptions of an elite in a slave-owning civilization and bound by the narrow limits of the city-state. The work is indeed a classic example of a philosopher's vivisection of society, imposing by relatively humane means the rule of a high-minded minority.

The Republic is a criticism of current Hellenic politics—often an indictment. It is based upon a metaphysical act of faith, for Plato believes that a world of permanent Forms exists beyond the limitations of human experience and that morality and the good life, which the state should promote, are reflections of these ideal Forms (see PLATONISM). The point is best made in the famous simile of the cave, in which men are chained with their faces to the wall and their backs to the light, so that they see only the shadows of reality. So constrained, they shrink from what is truly “real” and permanent and need to be forced to face it. This idealistic doctrine, known misleadingly as Realism (in nontechnical language it is hardly realistic), pervades all Plato's philosophy: its opposite doctrine, Nominalism, declares that only particular and observed “named” data are accessible to the mind. On his Realist assumption, Plato, who was perhaps influenced by Indian thought, regards most ordinary life as illusion and the current evils of politics as the result of men pursuing brute instinct. It follows that

unless philosophers bear kingly rule in cities or those who are now called kings and princes become genuine and adequate philosophers, and political power and philosophy are brought together . . . there will be no respite from evil for cities.

Only philosopher-statesmen can apprehend permanent and transcendent Forms and turn to “face the brightest blaze of being” outside the cave, and only philosophically minded men of action can be the saviours and helpers of the people.

Plato is thus indirectly the pioneer of modern beliefs that only a party organization, inspired by correct and “scientific” doctrines, formulated by the written word and interpreted by authority, can rightly guide the state. His rulers would form an elite, not responsible to the mass of the people. Thus, in spite of his high moral purpose, he has been called an enemy of the open society and the father of totalitarian lies. But he is also an anatomist of the evils of unbridled appetite and political corruption and insists on the need to use public power to moral ends.

Having described his utopia, Plato turns to analyze the existing types of government in human terms with great insight. Kingly government is the best but impracticable; in oligarchies the rule of the few and the pursuit of wealth divide societies—the rich become demoralized and the poor envious, and there is no harmony in the state. In democracy, in which the poor get the upper hand, demagogues distribute “a peculiar kind of equality to equals and unequals impartially,” and the old flatter the young, fawning on their juniors to avoid the appearance of be-

ing sour or despotic. The leaders plunder the propertied classes and divide the spoils among themselves and the people until confusion and corruption lead to tyranny, a worse form of government. For the tyrant becomes a wolf instead of a man and “lops off” potential rivals and starts wars to distract the people from their discontent. “Then, by Zeus,” Plato concludes, “the public learns what a monster they have begotten.”

In the *Statesman* Plato admits that, although there is a correct science of government, like geometry, it cannot be realized, and he stresses the need for the rule of law, since no man can be trusted with unbridled power. He then examines which of the current forms of government is the least difficult to live with, for the ruler, after all, is an artist who has to work within the limits of his medium. In the *Laws*, purporting to be a discussion of how best to found a polis in Crete, he presents a detailed program in which a state with some 5,000 citizens is ruled by 37 curators of laws and a council of 360. But the keystone of the arch is a sinister and secret Nocturnal Council to be “the sheet anchor of the state,” established in its “central fortress as guardian.” Poets and musicians will be discouraged and the young subjected to a rigid, austere, and exacting education. The stark consequence of Plato's political philosophy here becomes apparent. He had, nonetheless, stated, in the dawn of European political thought, the normative principle that the state should aim at promoting the good life and social harmony and that the rule of law, in the absence of the rule of philosopher-kings, is essential to this purpose.

Aristotle. Aristotle, who was a pupil in the Academy of Plato, remarks that “all the writings of Plato are original: they show ingenuity, novelty of view and a spirit of enquiry. But perfection in everything is perhaps a difficult thing.” Aristotle was a scientist rather than a prophet, and his *Politics* (c. 335–322 BC), written while he was teaching at the Lyceum at Athens, is only part of an encyclopaedic account of nature and society, in which he analyzes society as if he were a doctor and prescribes remedies for its ills. Political behaviour is here regarded as a branch of biology, as well as of ethics; in contrast to Plato, Aristotle was an empirical political philosopher. He criticizes many of Plato's ideas as impracticable, but, like Plato, he admires balance and moderation and aims at a harmonious city under the rule of law. The book is composed of lecture notes and is arranged in a confusing way—a quarry of arguments and definitions of great value but hard to master. The first book, though probably the last written, is a general introduction; Books II, III, and VII–VIII, probably the earliest, deal with the ideal state; and Books IV–VII analyze actual states and politics. The treatise is thus, in modern terms, a mixture of political philosophy and political science. (See also ARISTOTELIANISM.)

Like Plato, Aristotle naturally thinks in terms of the city-state, which he regards as the natural form of civilized life, social and political, and the best medium in which men's capacities can be realized. Hence his famous definition of man as a “political animal,” distinguished from the other animals by his gift of speech and power of moral judgment. “Man, when perfected,” he writes,

is the best of animals, but when separated from law and justice he is the worst of all, since armed injustice is the most dangerous, and he is equipped at birth with the arms of intelligence and wit, moral qualities which he may use for the worst ends.

Since all nature is pervaded by purpose and since men “aim at the good,” the city-state, which is the highest form of human community, aims at the highest good. Like sailors with their separate functions, who yet have a common object in safety in navigation, citizens, too, have a common aim—in modern terms survival, security, and the enhancement of the quality of life. In the context of the city-state, this high quality of life can be realized only by a minority, and Aristotle, like Plato, excludes those who are not full citizens or who are slaves; indeed, he says that some men are “slaves by nature” and deserve their status. Plato and Aristotle aim at an aristocratic and exacting way of life, reflecting, in more sophisticated forms, the ideas of the warrior aristocracies depicted by Homer.

Aristotle's
view
of the
role of
law in
the
city-state

Having stated that the aim of the city-state is to promote the good life, Aristotle insists that it can be achieved only under the rule of law.

The rule of law is preferable to that of a single citizen; if it be the better course to have individuals ruling, they should be made law guardians or ministers of the laws.

The rule of law is better than that even of the best men, for "he who bids law rule may be deemed to bid God and reason alone rule, but he who bids men rule adds the element of the beast; for desire is a wild beast, and passion perverts the minds of rulers, even if they are the best of men." This doctrine, which distinguishes between lawful government and tyranny, survived the Middle Ages and, by subjecting the ruler to law, became the theoretical sanction of modern constitutional government.

Aristotle also vindicates the rule of custom and justifies the obligations accepted by members of society: the solitary man, he writes, "is either a beast or a God." This outlook at once reflects the respect for custom and solidarity that have promoted survival in primitive tribal societies, even at the price of sacrificing individuals, and gives a theoretical justification for the acceptance of political obligation.

Like Plato, Aristotle analyzes the different kinds of city-states. While states are bound, like animals, to be different, he considers a balanced "mixed" constitution the best—it reflects the ideal of justice (*dikē*) and fair dealing, which gives every man his due in a conservative social order in which citizens of the middle condition preponderate. And he attacks oligarchy, democracy, and tyranny. Under democracy, he argues, demagogues attain power by bribing the electorate and waste accumulated wealth. But it is tyranny that Aristotle most detests; the arbitrary power of an individual above the law who is "responsible to no-one and who governs all alike with a view to his own advantage and not of his subjects, and therefore against their will. No free man can endure such a government."

The *Politics* contains not only a firm statement of these principles but also a penetrating analysis of how city-states are governed, as well as of the causes of revolutions, in which "inferiors revolt in order that they may be equal, and equals that they may be superior." The treatise concludes with an elaborate plan for educating the citizens to attain the "mean," the "possible," and the "becoming." The first implies a balanced development of body and mind, ability and imagination; the second, the recognition of the limits of mind and the range and limitations of talent; the third, an outcome of the other two, is the style and self-assurance that come from the resulting self-control and confidence.

While, therefore, Aristotle accepts a conservative and hierarchical social order, he states firmly that public power should aim at promoting the good life and that only through the rule of law and justice can the good life be attained. These principles were novel in the context of his time, when the great extra-European civilizations were ruled, justly or unjustly, by the arbitrary power of semidivine rulers and when other peoples, though respecting tribal custom and the authority of tribal elders, were increasingly organized under war leaders for depredation.

Cicero and the Stoics. Both Plato and Aristotle had thought in terms of the city-state. But Aristotle's pupil Alexander the Great swamped the cities of old Greece and brought them into a vast empire that included Egypt, Persia, and the Levant. Though the civilization of antiquity remained concentrated in city-states, they became part of an imperial power that broke up into kingdoms under Alexander's successors. This imperial power was reasserted on an even greater scale by Rome, whose empire at its greatest extent reached from central Scotland to the Euphrates and from Spain to eastern Anatolia. Civilization itself became identified with empire, and the development of eastern and western Europe was conditioned by it.

Since the city-state was no longer self-sufficient, universal philosophies developed that gave men something to live by in a wider world. Of these philosophies, Stoicism and Epicureanism were the most influential. The former inspired a rather grim self-sufficiency and sense of duty,

as exemplified by the writings of the Roman emperor Marcus Aurelius; the latter, a prudent withdrawal from the world of affairs.

The setting for political philosophy thus became much wider, relating individuals to universal empire, thought of, as in China, as coterminous with the civilization itself. Its inspiration remained Hellenic; but derivative Roman philosophers reinterpreted it, and Roman legists enclosed the old concepts of political justice in a carapace of legal definitions, capable of surviving their civilization's decline.

Cicero lived in a time of political confusion during which the old institutions of the republic were breaking down before military dictators. His *De republica* and *Laws* are both dialogues and reflect the classical sense of purpose: "to make human life better by our thought and effort." Cicero defined the *res publica* (commonwealth) as an association held together by law; he further asserted, as Plato had maintained with his doctrine of Forms manifest in the just city, that government was sanctioned by a universal natural law that reflected the cosmic order. Cicero expresses the pre-Christian Stoic attempt to moralize public power, apparent in the exacting sense of public responsibility shown by Hadrian and Marcus Aurelius in the 2nd century AD.

St. Augustine. With the conversion of the emperor Constantine (AD 312), when Christianity, long influential, became the predominant creed of the empire, and, under Theodosius (379–395), the sole official religion, political philosophy changed profoundly. St. Augustine's *City of God* (413–426), written when the empire was under attack by barbarians within and without, sums up and defines a new division between church and state and a conflict between "matter" and "spirit" resulting from the Fall of man and original sin.

St. Augustine, whose *Confessiones* are a record of a new sort of introspection, combined a classical and Hebraic dualism. From the Stoics and Virgil he inherited an austere sense of duty, from Plato and the Neoplatonists a contempt for the illusions of appetite, and from the Pauline and patristic interpretation of Christianity a sense of the conflict between Light and Darkness that reflects Zoroastrian and Manichaean doctrines emanating from Iran. In this context worldly interests and government itself are dwarfed by the importance of attaining salvation and of escaping from an astrologically determined fate and from the demons who embody the darkness. Life becomes illuminated for the elect minority by the prospect of eternal salvation or, for those without grace, shrivels under the glare of eternal fires.

St. Augustine regarded salvation as predestinate and the cosmic process as designed to "gather" an elect to fill the places of the fallen angels and so "preserve and perhaps augment the number of the heavenly inhabitants." The role of government and indeed of society itself becomes subordinated into a "secular arm," part of an earthly city, as opposed to the "City of God." The function of government is to keep order in a world intrinsically evil.

Since Christianity had long played the main role in defense of the veneer of a precarious urban civilization in antiquity, this claim is not surprising. Constantine came of crude Balkan origins, a soldier putting to rights a breakdown in government that would continue in the West with the abdication of the last Western emperor in 476, though in the East the empire would carry on with great wealth and power, centred in the new capital of Constantinople (Byzantium).

St. Augustine thus no longer assumed, as did Plato and Aristotle, that a harmonious and self-sufficient good life could be achieved within a properly organized city-state; he projected his political philosophy into a cosmic and lurid drama working out to a predestinate end. The normal interests and amenities of life became insignificant or disgusting, and the Christian Church alone exercised a spiritual authority that could sanction government. This outlook, reinforced by other patristic writings, would long dominate medieval thought, for with the decline of civilization in the West the church became more completely the repository of learning and of the remnants of the old civilized life.

philosophies

THE MIDDLE AGES

The decline of ancient civilization in the West was severe; not, indeed, in technology, for the horse collar, the stirrup, and the heavy plow now came in; but political philosophy, like other intellectual interests, became elementary. In the Byzantine Empire, on the other hand, Justinian's lawyers in 529–533 produced the *Codex Constitutionum*, the *Digest*, the *Institutes*, which defined and condensed Roman law, and the *Novels*. The Byzantine *basileus*, or autocrat, had moral responsibility for guarding and harmonizing an elaborate state, a "colony" of heaven in which reason and not mere will ought to rule. And this autocracy and the orthodox form of Christianity were inherited by the Christianized rulers of the Balkans, of Kievan Russia, and of Muscovy.

In the West, two essential principles of Hellenic and Christian political philosophy were transmitted, if only in elementary definitions, in rudimentary encyclopaedias. Isidore of Seville in his 7th-century *Etymologiae*, for example, asserts that kings rule only on condition of doing right and that the rule reflects a Ciceronic law of nature "common to all people and mankind everywhere by natural instinct." Further, the barbarians respected the civilization they took over and exploited. When converted, they revered the papacy, and in 800 the Frankish Charlemagne even revived the Western Empire as holy and Roman. The idea of Christian empire coterminous with civilization thus survived in Western as well as Eastern Christendom.

John of Salisbury. After Augustine, not until the 12th-century Renaissance did another full-length speculative work of political philosophy appear in the West. The *Policraticus* of John of Salisbury (c. 1159) is the work of a man experienced in politics who became bishop of Chartres. Based on wide classical reading, it centres on the ideal ruler, who represents a "public power." John admired Augustus and the Roman emperor Trajan, and, in a still predominantly feudal world, his book carried on the Roman tradition of centralized authority, though without its Byzantine autocracy. The prince, he insists, is he who rules in accordance with law, while a tyrant is one who oppresses the people by irresponsible power. This distinction, which derives from the Greeks, Cicero, and St. Augustine, is fundamental to Western concepts of liberty and the trusteeship of power.

John did not know Aristotle's *Politics*, but his learning is nevertheless remarkable, even if his political similes are unsophisticated. His favourite metaphor for the body politic is the human body: the place of the head is filled by the prince, who is subject only to God; the place of the heart by the senate; the eyes, ears, and tongue are the judges, provincial governors, and soldiers; and the officials are the hands. The tax gatherers are the intestines and ought not to retain their accumulations too long; and the farmers and peasants are the feet. John also compares a commonwealth to a hive and even to a centipede.

This vision of a centralized government, more appropriate to the memory of the Roman Empire than to a medieval monarchy operating in a still semifederal world, is a landmark of the 12th-century revival of speculative thought and reflects the better organized monarchy that Henry II was then building up.

Aquinas. It is a far cry from this practical 12th-century treatise by a man of affairs to the elaborate justification of Christian kingship and natural law created by St. Thomas Aquinas in the 13th century, during the climax of medieval Western civilization. His political philosophy is only part of a metaphysical construction of Aristotelian range—for Aristotle had now been assimilated from Arabic sources and given a new Christian content, with the added universality of the Stoic and Augustinian world outlook. Aquinas' *Summa theologiae* purports to answer all the major questions of existence, including those of political philosophy. Like Aristotle, Aquinas thinks in terms of an ethical purpose. Natural law is discussed in the first part of the second book as part of the discussion of original sin and what would now be termed psychology, while war comes under the second part of the second book as an aspect of virtue and vice. Law is defined as "that which is regulation and measure." It is designed to

promote the "felicity and beatitude" that are the ends of human life. Aquinas agrees with Aristotle that "the city is the perfection of community" and that the purpose of public power should be to promote the common good. The only legitimate power is from the community, which is the sole medium of man's well being. In his *De regimine* he compares society to a ship in need of a helmsman and repeats Aristotle's definition of man as a social and political animal. Again following Aristotle, he considers oligarchy unjust and democracy evil. Rulers should aim to make the "life of the multitude good in accordance with the purpose of life which is heavenly happiness." They should also create peace, conserve life, and preserve the state—a threefold responsibility. Here is a complete program for a hierarchical society within a cosmic order. It combines the Hellenic sense of purpose with Christian aims and asserts that, under God, power resides in the community, embodied in the ruler but only for so long as he does right. Hence the comment that "St. Thomas Aquinas was the first Whig"—a pioneer of the theory of constitutional government. The society he envisages, however, is medieval, static, hierarchical, conservative, and based on limited agriculture and even more limited technology. Nonetheless, Thomism remains the most complete and lasting political doctrine of the Catholic Church, since modified and adapted but not in principle superseded.

Dante. By the early 14th century the great European institutions, empire and papacy, were breaking down through mutual conflict and the emergence of national realms. But this conflict gave rise to the most complete political theory of universal and secular empire formulated in the medieval West. Dante's *De monarchia* (c. 1313), still in principle highly relevant, insists that only through universal peace can human faculties come to their full compass. But only "temporal Monarchy" can achieve this: "a unique principedom extending over all persons in time." The aim of civilization is to actualize human potentialities, and to achieve that "fullness of life which comes from the fulfillment of our being."

Monarchy, Dante argues, is necessary as a means to this end. The imperial authority of the Holy Roman emperor, moreover, comes direct from God and not through the pope. The empire is the direct heir of the Roman Empire, a legitimate authority, or Christ would not have chosen to be born under it. In subjecting the world to itself, the Roman Empire had contemplated the public good.

This high-flown argument, part of the political warfare between the partisans of the emperor and pope that was then affecting Italy, drives to essentials: that world peace can be secure only under a world authority. That Dante's argument was impractical did not concern this medieval genius, who was writing more the epitaph than the prospectus of the Holy Roman Empire; he was concerned, like St. Thomas, to create a political philosophy with a clear-cut aim and a universal view.

Out of the grand but impractical visions of the High Middle Ages in the 13th-century climax of Christian civilization there emerged by early modern times the idea of a well-governed realm, its authority derived from the community itself, with a program designed to ensure the solvency and administrative efficiency of a secular state. In spite of the decline of the civilization of antiquity in the West, the Greco-Roman sense of purpose, of the rule of law, and of the responsibility of power survived in Christian form.

THE 16TH TO THE 18TH CENTURIES

Machiavelli. In the thought of the Italian political philosopher Niccolò Machiavelli may be seen a complete secularization of political philosophy. Machiavelli was an experienced diplomat and administrator, and, since he stated flatly how the power struggle was conducted in Renaissance Italy, he won a shocking reputation. He was not, however, without idealism about the old Roman republic, and he admired the independent spirit of the German and Swiss cities. This idealism made him all the more disgusted with Italian politics, of which he makes a disillusioned and objective analysis. Writing in retirement after political disgrace, Machiavelli states firmly that,

Machiavelli's view of human nature

Since this is to be asserted in general of men, that they are ungrateful, fickle, false, cowards, covetous, and as long as you succeed they are yours entirely: they will offer you their blood, property, life, and children . . . when the need is far distant; but when it approaches they turn against you.

And again,

since the desires of men are insatiable, nature prompting them to desire all things and fortune permitting them to enjoy but few, there results a constant discontent in their minds, and a loathing of what they possess.

This view of human nature, already expressed by Plato and St. Augustine, is here unredeemed by Plato's doctrine of form and illusion or by St. Augustine's dogma of salvation through grace. Machiavelli accepts the facts and advises the ruler to act accordingly. The prince, he states, must combine the strength of the lion with the cunning of the fox: he must always be vigilant, ruthless, and prompt, striking down or neutralizing his adversaries without warning. And when he does an injury it must be total. For "men ought to be either well treated or crushed, because they can avenge themselves of lighter injuries, of more serious ones they cannot." Moreover, "irresolute princes who follow a neutral path are generally ruined." He advises that it is best to come down at the right moment on the winning side and that conquered cities ought to be either governed directly by the tyrant himself residing there or destroyed. Princes, furthermore, unlike private men, need not keep faith: since politics reflects the law of the jungle, the state is a law unto itself, and normal moral rules do not apply to it.

Machiavelli had stated with unblinking realism how, in fact, tyrants behave; and, far from criticizing their conduct or distinguishing between the just prince who rules by law and the tyrant whose laws are in his own breast, he considers that the successful ruler has to be beyond morality since the safety of and expansion of the state are the supreme objective. In this myopic view, the cosmic visions of Aquinas and Dante are disregarded, and politics becomes a fight for survival. Within his terms of reference, Machiavelli made a convincing case, although as an experienced diplomat he might have realized that dependability in fact pays and that systematic deceit, treachery, and violence usually bring about their own nemesis.

Hobbes. The 17th-century English political philosopher Thomas Hobbes, who spent his life as a tutor and companion to great noblemen, was a writer of genius with a greater power of phrase than any other English political philosopher. He was not, as he is sometimes misrepresented, a prophet of "bourgeois" individualism, advocating free competition in a capitalistic free market. On the contrary, he was writing in a preindustrial, if increasingly commercial, society and did not much admire wealth as such but rather "honours." He was socially conservative and anxious to give a new philosophical sanction to a hierarchical, if businesslike, commonwealth in which family authority was most important.

Philosophically, Hobbes was influenced by nominalist scholastic philosophy, which had discarded Thomist metaphysics and had accepted a strict limitation of mind. He therefore based his conclusions on the rudimentary mathematical physics and psychology of his day and aimed at practical objectives—order and stability. He believed that the fundamental physical law of life was motion and that the predominant human impulses were fear and, among those above the poverty level, pride and vanity. Men, Hobbes argued, are strictly conditioned and limited by these laws, and he tried to create a science of politics that would reflect them. "The skill of making, and maintaining Common-wealths," therefore, "consisteth in certain Rules, as doth Arithmetique and Geometry; not (as Tennis play) on Practise only: which Rules, neither poor men have the leisure, nor men that have had the leisure, have hitherto had the curiosity, or the method to find out."

Hobbes ignores the classical and Thomist concepts of a transcendent law of nature, itself reflecting divine law, and of a "chain of being" whereby the universe is held harmoniously together and, following Descartes's practical method of investigation, states plainly that power creates law, not law power. For law is law only if it can be en-

forced, and the price of security is one supreme sovereign public power. For, without it, such is the competitive nature of men, that once more than subsistence has been achieved they are actuated by vanity and ambition, and there is a war of all against all. The true law of nature is self-preservation, he argues, which can be achieved only if the citizens make a compact among themselves to transfer their individual power to the "leviathan" (ruler), who alone can preserve them in security. Such a commonwealth has no intrinsic supernatural or moral sanction: it derives its original authority from the people and can command loyalty only so long as it succeeds in keeping the peace. He thus uses both the old concepts of natural law and contract, often invoked to justify resistance to authority, as a sanction for it.

Hobbes, like Machiavelli, starts from an assumption of basic human folly, competitiveness, and depravity, and contradicts Aristotle's assumption that man is by nature a "political animal." On the contrary, he is naturally anti-social; and, even when men meet for business and profit, only "a certain market-fellowship" is engendered. All society is only for gain or glory, and the only true equality among men is their power to kill each other. Hobbes sees and desires no other equality. Indeed, he specifically discouraged "men of low degree from a saucy behaviour towards their betters."

The *Leviathan* horrified most of his contemporaries; Hobbes was accused of atheism and of "maligning the Human Nature." But, if his remedies were tactically impractical, in political philosophy he had gone very deep by providing the sovereign nation-state with a pragmatic justification and directing it to utilitarian ends.

Spinoza. The 17th-century Dutch philosopher Benedict de Spinoza also tried to make a scientific political theory, but it was more humane and more modern. Hobbes assumes a preindustrial and economically conservative society, but Spinoza, a Portuguese Jew born in Amsterdam, assumes a more urban setting. Like Hobbes, he is Cartesian, aiming at a scientific basis for political philosophy; but, whereas Hobbes was dogmatic and authoritarian, Spinoza desired toleration and intellectual liberty, by which alone human life achieves its highest quality. Spinoza, reacting against the ideological wars of religion and skeptical of both metaphysics and religious dogma, was a scientific humanist who justified political power solely by its usefulness. If state power breaks down and can no longer protect him or if it turns against him, frustrates, or ruins his life, then any man is justified in resisting it, since it no longer fulfills its purpose. It has no intrinsic divine or metaphysical authority.

In *Tractatus Theologico-Politicus* and the *Tractatus Politicus* Spinoza develops this theme. He intends, he writes, "not to laugh at men or weep over them or hate them, but to understand them." In contrast to St. Augustine, he glorifies life and holds that governments should not try to "change men from rational beings into beasts or puppets, but enable them to develop their minds and bodies in security and to employ their reason unshackled." The more life is enjoyed, he declares, the more the individual participates in the divine nature. God is immanent in the entire process of nature, in which all creatures follow the laws of their own being to the limit of their powers. All are bound by their own consciousness, and man creates his own values.

It seems that Spinoza thought good government approximated to that of the free burgesses of Amsterdam, a city in which religious toleration and relative political liberty had been realized. He is thus a pioneer of a scientific humanist view of government and of the neutrality of the state in matters of belief.

Richard Hooker's adapted Thomism. While out of the breakup of the medieval social order there emerged the humanist but sceptical outlook of Machiavelli, then the scientific humanist principles of Descartes, Hobbes, and Spinoza, from which the utilitarian and pragmatic outlook of modern times derives, another influential and politically important strain of political philosophy also emerged. During the Reformation and Counter-Reformation, Protestant and Catholic dogmatists denounced each other and even

Significance of the *Leviathan*

Philosophical influences on Hobbes

attacked the authority of princes who, from interest or conviction, supported one side or the other. Political assassination became endemic, for both Protestant and Catholic divines declared that it was legitimate to kill an heretical ruler. Appeal was made to rival religious authority as well as to conscience. Men would resist authority and suffer execution rather than risk damnation, and in the resulting welter Hobbes and Spinoza advocated a sovereign state as the remedy. But other political philosophers salvaged the old Thomist concept of a divine cosmic order and of natural and human laws sanctioning the state. They also put forth the classical and medieval idea of the derivation of public power from the commonwealth as a whole and the responsibility of princes to the law. When Hobbes wrote that might makes right, he outraged such critics, who continued to assert that public power was responsible to God and the laws and that it was right to resist a tyrant who declared that the laws were in his own breast. This political theory was most influentially developed in England, where it inspired the constitutionalism that would also predominate in the United States.

Richard Hooker, an Anglican divine who wrote *Of the lawes of ecclesiasticall politie* (1593–1662), reconciled Thomist doctrines of transcendent and natural law, binding on all men, with the authority of the Elizabethan Anglican Church, which he defended against the Puritan appeal to conscience. Society, he argued, is itself the fulfillment of natural law, of which human and positive law are reflections, adapted to society. And public power is not something personal, for it derives from the community under law. Thus,

The lawful power of making laws to command whole politic societies of men belongeth so properly unto the same entire societies, that for any prince . . . to exercise the same of himself . . . is no better than mere tyranny.

Such power can derive either directly from God or else from the people. The prince is responsible to God and the community; he is not, like Hobbes's ruler, a law unto himself. Law makes the king, not the king law.

Hooker, indeed, insisted that "the prince has a delegated power, from the Parliament of England, together with the convocation (of clergy) annexed thereto . . . whereupon the very essence of all government doth depend." This is the power of the crown in parliament in a balanced constitution. Hence an idea of harmonious government by consent. The Thomist medieval universal harmony had been adapted to the nation-state.

Locke. It was John Locke, politically the most influential English philosopher, who further developed this doctrine. His *Two Treatises of Government* (1690) were written to justify the Glorious Revolution of 1688–89, and his *Letter Concerning Toleration* (1689) was written with a plain and easy urbanity, in contrast to the baroque eloquence of Hobbes. Locke was a scholar, physician, and man of affairs, well-experienced in politics and business. As a philosopher he accepted strict limitations for mind, and his political philosophy is moderate and sensible, aimed at a balance among executive, judicial, and legislative powers, although with a bias toward the last.

His first *Treatise* was devoted to confuting the Royalist doctrine of patriarchal divine right by descent from Adam, an argument then taken very seriously and reflecting the idea of government as an aspect of a divinely ordained chain of being. If this order were broken, chaos would come about. The argument was part of the contemporary conflict of the ancients and the moderns.

Locke tried to provide an answer by defining a limited purpose for political power, which purpose he considered to be "a right of making laws with penalties of death, and consequently all less penalties, for the regulating and preserving of property, and of employing the force of the community in execution of such laws, and in the defense of the commonwealth from foreign injury, and all this only for the public good." The authority of government derives from a contract between the rulers and the people, and the contract binds both parties. It is thus a limited power, proceeding according to established laws and "directed to no other end but the peace, safety, and public good of the people."

Whatever its form, government, to be legitimate, must govern by "declared and reasoned laws," and, since every man has a "property" in his own person and has "mixed his labour" with what he owns, government has no right to take it from him without his consent. It was the threat of attack on the laws, property, and the Protestant religion that had roused resistance to James II. Locke is expressing the concerns and interests of the landed and moneyed men by whose consent James's successor, William III, came to the throne, and his commonwealth is strictly conservative, limiting the franchise and the preponderant power to the propertied classes. Locke was thus no democrat in the modern sense and was much concerned to make the poor work harder. Like Hooker, he assumes a conservative social hierarchy with a relatively weak executive power and defends the propertied classes both against a ruler by divine right and against radicals. In advocating toleration in religion he was more liberal: freedom of conscience, like property, he argued, is a natural right of all men. Within the possibilities of the time, Locke thus advocated a constitutional mixed government, limited by parliamentary control of the armed forces and of supply. Designed mainly to protect the rights of property, it was deprived of the right of arbitrary taxation or imprisonment without trial and was in theory responsible to all the people through the politically conscious minority who were thought to represent them.

Though he was socially conservative, Locke's writings are very important in the rise of liberal political philosophy. He vindicates the responsibility of government to the governed, the rule of law through impartial judges, and the toleration of religious and speculative opinion. He is an enemy of the totalitarian state, drawing on medieval arguments and deploying them in practical, modern terms.

Burke. The Irishman Edmund Burke, while elaborating Whig constitutional doctrine expressed with such common sense by Locke, wrote with more emotion and took more account of time and tradition. While reiterating that government is responsible to the governed and distinguishing between a political society and a mere mob, he thought that governments were trustees for previous generations and for posterity. He made the predominant political philosophy of the 18th-century establishment appear more attractive and moral, but he wrote no great single work of political philosophy, expressing himself instead in numerous pamphlets and speeches.

In his early *Vindication of Natural Society* Burke is critical of the sufferings imposed by government, but his "Thoughts on the Cause of the Present Discontents" defines and defends the principles of the Whig establishment. He invoked a transcendent morality to sanction a constitutional commonwealth, but he detested abstract political theories in whose name men are likely to vivisection society. He set great store by ordered liberty and denounced the arbitrary power of the Jacobins who had captured the French Revolution. In his *Reflections on the Revolution in France* (1790) and *An Appeal from the New to the Old Whigs* (1791), he discerned in the doctrine of sovereignty of the people, in whose name the revolutionaries were destroying the old order, another and worse form of arbitrary power. No one generation has the right to destroy the agreed and inherited fabric of society, and "Neither the few nor the many have the right to govern by their will." A country is not a mere physical locality, he argued, but a community in time into which men are born, and only within the existing constitution and by the consent of its representatives can changes legitimately be made. Once the frame of society is smashed and its law violated, the people become a "mere multitude told by the head," at the mercy of any dictator who can seize power. He was realistic in predicting the consequences of violent revolution, which usually ends up in some kind of dictatorship. Burke, in sophisticated accents, spoke for the ancient and worldwide rule of custom and conservatism and supplied a needed romanticism to the calculating good sense of Locke.

Vico. The political philosophies hitherto surveyed contained little idea of progress. In antiquity the idea of cyclic recurrence predominated, and even 18th-century Chris-

Burke's concept of an obligation to posterity

Locke's view of the role and limits of public power

tians believed that the world had been created in 4004 BC and would end in the Second Coming of Christ and a judgment. The 14th-century Arab philosopher of history Ibn Khaldūn of Tunis, in the *Muqaddimah* to his *Kitāb al-'ibar*, had pioneered a vast sociological view of the historical process; but in western Europe it was a neglected Neapolitan philosopher, Giambattista Vico (1668–1744), who first interpreted the past in terms of the changing consciousness of mankind. His *Scienza nuova* (1725; revised edition 1744) interpreted history as an organic process involving language, literature, and religion and attempted to reveal the mentality or ethos of earlier ages: the age of the gods, the heroic age, and the human age, its climax and decadence. These ages recur, and each is distinguished by mythology, heroic poetry, and rational speculation respectively. In contrast to the legalistic, contractual, and static political philosophies then prevalent, Vico had discerned new horizons.

Montesquieu. This sort of vision was developed and elegantly popularized by the cosmopolitan French savant Montesquieu, whose work *The Spirit of Laws* (Eng. trans. 1750) won immense influence. It was an ambitious treatise on human institutions and a pioneer work of anthropology and sociology. Believing in an ordered universe—for “how could blind fate have produced intelligent beings?”—Montesquieu examined the varieties of natural law, varying customs, laws, and civilizations in different environments. He made the pedestrian good sense of Locke seem provincial, although he admired him and the British constitution. Unfortunately, he overemphasized the separation of executive, judicial, and legislative powers, considerable in Locke’s day but by his own time tending to be concentrated in the sovereignty of Parliament. This doctrine much influenced the founders of the United States and the early French Revolutionaries.

Rousseau. The revolutionary romanticism of the Swiss-French philosopher Jean-Jacques Rousseau may be interpreted in part as a reaction to the analytic rationalism of the Enlightenment. He was trying to escape the aridity of a purely empirical and utilitarian outlook and attempting to create a substitute for revealed religion. Rousseau’s *Émile* (1762) and *Du contrat social* (1762) proved revolutionary documents, and his posthumous *Considérations sur le gouvernement de Pologne* (“Considerations on the Government of Poland”) contains desultory but often valuable reflections on specific problems.

There had been radical political slogans coined in medieval peasant revolts and in the 17th century, as in the Putney debates (1647) in the Cromwellian army, when a Puritan officer declared that “the poorest hee that is in England hath a life to live as the greatest hee,” but the inspiration of these movements had been religion. Now Rousseau proclaimed a secular egalitarianism and a romantic cult of the common man. His famous sentence, “man is born free, but he is everywhere in chains,” called into question the traditional social hierarchy: hitherto, political philosophers had thought in terms of elites, but now the mass of the people had found a champion and were becoming politically conscious.

Rousseau was a romantic, given to weeping under the willows on Lake Geneva, and the *Social Contract* and *Discourses* are hypnotically readable, flaming protests by one who found the hard rationality of the 18th century too exacting. But man is not, as Rousseau claims, born free. Man is born into society, which imposes restraints on him. Casting about to reconcile his artificial antithesis between man’s purported natural state of freedom and his condition in society, Rousseau utilizes the old theories of contract and transforms them into the concept of the “general will.” This general will, a moral will that aims at the common good and in which all participate directly, reconciles the individual and the community by representing the will of the community as deriving from the will of moral individuals, so that to obey the laws of such a community is in a sense to follow one’s own will, assuming that one is a moral individual.

Similar ideas to that of the general will became accepted as a basis for both the social-democratic welfare state and for totalitarian dictatorships. And, since the idea was mis-

applied from small village or civic communities to great sovereign nation-states, Rousseau was also a prophet of a nationalism that he never advocated. Rousseau himself wanted a federal Europe. He never wrote the proposed sequel to the *Du contrat social* in which he meant to deal with international politics, but he declared that existing governments lived in a state of nature, that their obsession with conquest was imbecilic, and that “if we could realize a European republic for one day, it would be enough to make it last for ever” (*Political Writings* I, pp. 365–388). But, with a flash of realism, he thinks the project impracticable, owing to the folly of men.

The incursion of this revolutionary romantic into political philosophy changed the climate of political opinion, for it coincided with the breakdown of the old dynastic order and the emergence first of the middle classes and then of the masses to political consciousness and power.

That the concept of general will was vague only increased its adaptability and prestige: it would both make constitutionalism more liberal and dynamic and give demagogues and dictators the excuse for “forcing people to be free” (that is, forcing people to follow the general will, as interpreted by the ruling forces). Rousseau could inspire liberals, such as the 19th-century English philosopher T.H. Green, to a creative view of a state helping people to make the best of their potential through a variety of free institutions. It could also play into the hands of demagogues claiming to represent the general will and bent on molding society according to their own abstractions.

THE 19TH CENTURY

Utilitarianism. A major force in the political and social thought of the 19th century was Utilitarianism, the doctrine that the actions of governments should be judged simply by the extent to which they promoted the “greatest happiness of the greatest number.” The founder of the Utilitarian school was Jeremy Bentham, an eccentric Englishman trained in the law.

Bentham judged all laws and institutions by their utility thus defined. “The Fabric of Felicity,” he wrote, “must be reared by the hands of reason and Law.”

Bentham’s *Fragment, on Government* (1776) and *Introduction to the Principles of Morals and Legislation* (1789) elaborated a Utilitarian political philosophy. Bentham was an atheist and an exponent of the new laissez-faire economics of Adam Smith and David Ricardo, but he inspired the spate of legislation that, after the Reform Bill of 1832, had tackled the worst consequences of 18th-century inefficiency and of the Industrial Revolution. His influence, moreover, spread widely abroad. At first a simple reformer of law, Bentham attacked notions of contract and natural law as superfluous, “The indestructible prerogatives of mankind,” he wrote, “have no need to be supported upon the sandy foundation of a fiction.” The justification of government is pragmatic, its aim improvement and to release the free choice of individuals and the play of market forces that will create prosperity. Bentham thought men far more reasonable and calculating than they are and brushed aside all the Christian and humanist ideas rationalizing instinctive loyalty and awe. He thought society could advance by calculation of pleasure and pain, and his *Introduction* even tries to work out “the value of a lot of pleasure and pain, how now to be measured.” He compared the relative gratifications of health, wealth, power, friendship, and benevolence, as well as those of “irascible appetite” and “antipathy.” He also thought of punishment purely as a deterrent, not as retribution, and graded offenses on the harm they did to happiness, not on how much they offended God or tradition.

If Bentham’s psychology was naive, that of his disciple James Mill was philistine. Mill postulated an economic man whose decisions, if freely taken, would always be in his own interest, and he believed that universal suffrage, along with Utilitarian legislation by a sovereign parliament, would produce the kind of happiness and well-being that Bentham desired. In his *Essay on Government* (1828) Mill thus shows a doctrinaire faith in a literate electorate as the means to good government and in laissez-faire economics as a means to social harmony.

Bentham’s calculation of pain and pleasure

Rousseau’s idea of the general will

This Utilitarian tradition was humanized by James Mill's son, John Stuart Mill, one of the most influential of mid-Victorian liberals.

Whereas James Mill had been entirely pragmatic, his son tried to enhance more sophisticated values. He thought that civilization depended on a tiny minority of creative minds and on the free play of speculative intelligence. He detested conventional public opinion and feared that complete democracy, far from emancipating opinion, would make it more restrictive. Amid the dogmatic and strident voices of mid-19th-century nationalists, utopians, and revolutionaries, the quiet, if sometimes priggish, voice of mid-Victorian liberalism proved extremely influential in the ruling circles of Victorian England.

Accepting democracy as inevitable, J.S. Mill expressed the still optimistic and progressive views of an intellectual elite. Without complete liberty of opinion, he insisted, civilizations ossify. The quality of progress results not merely from the blind forces of economic competition but from the free play of mind. The worth of the state in the long run is only the worth of the individuals composing it, and without men of genius society would become a "stagnant pool." This militant humanist, unlike his father, was aware of the dangers of even benevolent bureaucratic power and declared that a state that "dwarfs its men" is culturally insignificant.

Mill also advocated the legal and social emancipation of women, holding that ability was wasted by mid-Victorian conventions. He believed that the masses could be educated into accepting the values of liberal civilization, but he defended private property and was as wary of rapid extensions of the franchise as of bureaucratic power.

Tocqueville. Mill's friend Alexis de Tocqueville, whose *De la démocratie en Amérique* (*Democracy in America*) appeared in 1835–40, was a French civil servant also concerned with maintaining the standards and creativeness of civilization in face of the rising tide of mass democracy. Since the United States was then the only large-scale democracy extant, Tocqueville decided to go there, and as a result of his visit wrote a classic account of early 19th-century American civilization. "We cannot," he wrote, "prevent the conditions of men from becoming equal, but it depends upon ourselves whether the principle of equality will lead them to servitude or freedom, to knowledge or barbarism, to prosperity or wretchedness." He feared the possible abuse of power by centralized government, unrestrained by the power of the old privileged classes, and thought it essential to "educate democracy" so that, although it would never have the "wild virtues" of the old regimes, it would have its own dignity, good sense, and even benevolence. Tocqueville greatly admired American representative institutions and made a penetrating analysis of the new power of the press. He realized, as few people then did, that the United States and Russia would become world powers, and he contrasted the freedom of the one and the despotism of the other. He also foresaw that under democracy education would be respected more as a ladder to success than for its intrinsic content and might thus become mediocre. He was alive to the dangers of uniform mediocrity but believed, like Mill, that democracy could be permeated by creative ideas.

T.H. Green. This kind of humanism was given a more elaborate philosophical content by the English philosopher T.H. Green, whose *Lectures on the Principles of Political Obligation* (1895; reprinted from *Philosophical Works*, vol. 2, 1885) greatly influenced the Liberals in the British governments of the period 1906–15. Green, like J.S. Mill and Tocqueville, wished to extend the minority culture to the people and even to use state power to "hinder hindrances to the good life." He had absorbed from Aristotle, Spinoza, Rousseau, and Hegel an organic theory of the state. The latter, by promoting the free play of spontaneous institutions, ought to help individuals both to "secure the common good of society [and] enable them to make the best of themselves."

While hostile to the abuse of landed property, Green was not a Socialist. He accepted the idea that property should be private and unequally distributed and thought the operation of the free market the best way to benefit the

whole society; for free trade would, he thought, diminish the inequalities of wealth in a common prosperity. But Green would have extended the power of the state over education, health, housing and town planning, and the relief of unemployment—a new departure in Liberal thought. These recommendations are embedded in the most elaborate and close-knit intellectual construction made by any modern British political philosopher, and they laid the foundation of the British welfare state.

Liberal nationalism. Whereas Green shirked the extension of liberal and constitutional principles into international affairs, the Italian patriot and revolutionary prophet Giuseppe Mazzini made it his vision and became the most influential prophet of liberal nationalism. In his *The Duties of Man and Essays* he envisaged a harmony of free peoples—a "sisterhood of nations," in which the rule of military empires would be thrown off, the destruction of clerical and feudal privileges accomplished, and in which the emancipated peoples would be regenerated by means of education and universal suffrage. This vision inspired the more idealistic aspects of the Italian Risorgimento (national revival or resurrection) and of nationalistic revolts in Europe and beyond. Though, in fact, fervid nationalism often proved destructive, Mazzini advocated a united Europe of free peoples, in which national singularities would be transcended in a pan-European harmony. This sort of liberal democratic idealism was catching, and even if it frequently inspired Machiavellian policies, it also inspired President Woodrow Wilson of the United States, who, had he not been thwarted by domestic opposition, might well have made a Mazzinian-type League of Nations a success. Moreover, the Europe of the Common Market owes much to the apparently impractical liberal idealism of Mazzini.

American constitutionalism. The United States was founded by men deeply influenced by republicanism, by Locke, and by the optimism of the French Enlightenment. George Washington, John Adams, and Thomas Jefferson all concurred that laws, rather than men, should be the final sanction and that government should be responsible to the governed. But the influence of Locke and the Enlightenment was not entirely happy. John Adams, who followed Washington as president, prescribed a constitution with a balance of executive and legislative power checked by an independent judiciary. The federal constitution, moreover, could be amended only by a unanimous vote of the states. Anxious to safeguard state liberties and the rights of property, the founding fathers gave the federal government insufficient revenues and coercive powers, as a result of which the constitution was stigmatized as being "no more than a Treaty of Alliance." Yet the federal union was preserved. The civil power controlled the military, and there was religious toleration and freedom of the press and of economic enterprise. Most significantly, the concept of natural rights had found expression in the Declaration of Independence and was to influence markedly political and legal developments in the ensuing decades, as well as inspire the French Declaration of the Rights of Man.

Anarchism and utopianism. While a liberal political philosophy within a framework of capitalistic free trade and constitutional self-government dominated the greatest Western powers, mounting criticism developed against centralized government itself. Radical utopian and anarchist views, previously expounded mainly by religious sects, became secularized in such works as William Godwin's *Political Justice* (1793), Robert Owen's *New View of Society* (1813), and Pierre-Joseph Proudhon's voluminous and anticlerical writings.

The English philosopher William Godwin, an extreme individualist, shared Bentham's confidence in the reasonableness of mankind. He denounced the wars accepted by most political philosophers and all centralized coercive states. The tyranny of demagogues and of "multitudes drunk with power" he regarded as being as bad as that of kings and oligarchs. The remedy, he thought, was not violent revolution, which produces tyranny, but education and freedom, including sexual freedom. His was a program of high-minded, atheistic anarchism.

The English Socialist Robert Owen, a cotton spinner who had made a fortune, also insisted that bad institu-

Green's writing on social reform

Natural rights in American constitutional thought

tions, not original sin or intrinsic folly, caused the evils of society, and he sought to remedy them by changing the economic and educational system. He thus devised a scheme of model cooperative communities that would increase production, permit humane education, and release the naturally benevolent qualities of mankind.

The French moralist and advocate of social reform Pierre-Joseph Proudhon attacked the "tentacular" nation-state and aimed at a classless society in which major capitalism would be abolished. Self-governing producers, no longer slaves of bureaucrats and capitalists, would permit the realization of an intrinsic human dignity, and federation would replace the accepted condition of war between sovereign states. Proudhon tried to transform society by rousing the mass of the people to cooperative humanitarian consciousness.

Saint-Simon and Comte. Another revolt against the prevalent establishment, national and international, was made by the French social philosopher Henri de Saint-Simon. Saint-Simon wanted to develop the Industrial Revolution so as to ameliorate the condition of the poorest class. This would be achieved not through political revolution, but through a government of bankers and administrators who would supersede kings, aristocrats, and politicians. If France were suddenly deprived of three thousand leading scientists, engineers, bankers, painters, poets, and writers, he argued, the result would be catastrophic; but if all the courtiers and bishops and 10,000 landowners vanished, the loss, though deplorable, would be much less severe. Saint-Simon also demanded a united Europe, superseding the warring nation-states, with a European parliament and a joint development of industry and communication. He also invented a synthetic religion appropriate to a scientific phase of history, with a cult of Newton and the great men of science.

Comte's
"religion
of
humanity"

Saint-Simon's disciple Auguste Comte went further. His *Course of Positive Philosophy* (1830–42) and *System of Positive Polity* (1851–54) elaborated a "religion of humanity," with ritual, calendar, and a priesthood of scientists, and secular saints, including Julius Caesar, Dante, and Joan of Arc. Society would be ruled by bankers and technocrats and Europe united into a Western republic. This doctrine, backed by pioneering sociology, won much influence among intellectuals. Comte, like Saint-Simon, tackled the essential questions: how to deploy the power of modern technology for the benefit of all mankind; how to avoid wars between sovereign states; and how to fill the void left by the waning of Christian beliefs.

Hegel. Whereas the utopian reformers had discarded metaphysical arguments, the German philosopher G.W.F. Hegel claimed to apprehend the totality of the cosmos by speculative cognition. Like Vico, he saw the past in terms of changing consciousness, but he viewed the historical process as one of "becoming" rather than as one of eternal recurrence. Hegel had no adequate historical data for his intuitions, since the whole of world history was even less known then than it is today, but his novel sweep and range of theory proved an intoxicating substitute for religion. He divided world history into four epochs: the patriarchal Eastern empire, the brilliant Greek boyhood, the severe manhood of Rome, and the Germanic phase after the Reformation. The "Absolute," like a conductor, summons each people to their finest hour, and neither individuals nor states have any rights against them during their historically determined period of supremacy. Many felt some sense of anticlimax, however, when he claimed that the Prussian state embodied the hitherto highest self-realization of the "Absolute" (see HEGELIANISM). Not since St. Augustine had so compelling a drama been adumbrated. Hegel's drama, moreover, culminates in this world, for "the state is the divine idea as it exists on earth."

Marx and Engels. Hegel was a conservative, but his influence on the revolutionaries Karl Marx and his collaborator Friedrich Engels was profound. They inherited the Hegelian claim to understand the "totality" of history and life as it progressed through a dialectic of thesis, antithesis, and synthesis. But, whereas Hegel envisaged a conflict of nation-states, Marx and Engels thought that the dynamism of history was generated by inevitable class

conflict economically determined. This was an idea even more dynamic than Hegel's and more relevant to the social upheavals that were a consequence of the Industrial Revolution. Marx was a formidable prophet whose writings lead up to an apocalypse and redemption. A deeply learned humanist, his ideal was the fullest development of the human personality. But, whereas Plato was concerned with an elite, Marx cared passionately for the elevation of whole peoples.

The Marxist credo was all the more effective as it expressed with eloquent ferocity the grievances of the poor, while prophesying retribution and a happy ending. For the state, once captured by the class-conscious vanguard of the proletariat, would take over the means of production from the capitalists, and a brief "dictatorship of the proletariat" would establish a truly communist society. The state would then wither away and man at last become "fully human" in a classless society.

The powerful slogans of Marx and Engels were a natural result of the unbridled capitalism of laissez-faire, but politically they were naïve. In classical, medieval, and humanistic political philosophy the essential problem is the control of power, and to imagine that a dictatorship, once established, will wither away is utopian. As even Marx's fellow revolutionary the Russian anarchist M.A. Bakunin observed,

The revolutionary dictatorship of the doctrinaires who put science before life would differ from the established state only in external trappings. The substance of both are a tyranny of the minority over the majority—in the name of the many and the supreme wisdom of the few.

The revolutionaries would vivisection society in the name of dogmas and "destroy the present order, only to erect their own rigid dictatorship among its ruins." For a full account of Marxist philosophy, see MARXISM.

Political philosophy in the 20th century

Nineteenth-century European civilization had been the first to dominate and pervade the whole world and to create a new self-sustaining productivity in which all eventually might share. But, as Saint-Simon had pointed out, this civilization had a fatal flaw. The rule of law, accepted within the politically advanced states, had never been achieved among them. Heavily armed nations and empires remained in a Hobbesian "posture of war," and classical and medieval ideals of world order had long been discarded. Within states, also, laissez-faire capitalism had exacerbated class conflicts, while the decline of religious belief had undermined traditional solidarity. And in 1914, when a general European war broke out, the peoples, contrary to the hopes of cosmopolitan revolutionaries, rallied behind their national governments. When the victorious powers failed to promote world order through the League of Nations, a second global conflict followed, during which were developed weapons so destructive as to threaten life everywhere.

In the aftermath of these catastrophes and the worldwide revulsion they occasioned, not least against the European colonial powers, three mainstreams of mid-20th-century political philosophy may be discerned.

In liberal-constitutional states, with modified, managerial capitalism and various degrees of public welfare, a political pragmatism has emerged, still maintaining the Aristotelian distinction between the rule of law and government by consent, on the one hand, and tyranny on the other. Second, there has been a reaffirmation of religious or quasi-religious values appealing to conscience and the inner man, expressed persuasively in Existentialist writings. Third, revolutionary ideas have also developed, most of them along Marxist lines. Other revolutionary doctrines appeal to anarchist traditions and are elaborated with neo-Marxist and neo-Freudian insights. Within these categories many shades of opinion are expressed, and only a sampling of representative views is presented here.

POLITICAL PRAGMATISM

The first, pragmatist approach probably has been most powerfully asserted in the United States and Great Britain.

The American writer Lewis Mumford, for example, has advocated a militant humanism, defending people against the alienations of megalopolitan life and attacking mechanization and materialism. Like the Greek philosophers and like Tocqueville, whom he admires, Mumford declares, "In the end, all our contrivances have but one object; the continued growth of human personalities and the cultivation of the best life possible." The American philosopher and educationist John Dewey, on the other hand, sought to counteract the dehumanization of industrial mass society by a freer form of education, liberating the personality.

Both these writers criticize the existing structure of society and its modified capitalism, but try to work within it. Another humanist, the English philosopher Bertrand Russell, was more radical. Russell carried into political philosophy an aristocratic individualism, campaigning for toleration, sexual freedom, compassion, and common sense. He broadcast elite values to a mass society and attacked materialism, crass bureaucracy, and war. He twice went to prison in pacifist protest and was obsessed with the universal menace of nuclear weapons. He denounced warlike political theories: "Remember your humanity," he said, "and forget the rest." On political tactics often inept, Russell won wide influence as a man of principle, concerned to adapt archaic institutions to the changed environment of mankind.

The Austrian-born British philosopher Sir Karl Popper has demonstrated the pretensions of the 19th-century determinist philosophies such as those of Hegel and Marx, while an English historian and philosopher, Sir Isaiah Berlin, has ridiculed the idea of a supposedly objective march of history. Berlin also rejects the Marxist belief that all values are conditioned by the place men occupy on the "moving stair of time." Marx, he points out, was as romantic as Hegel in envisaging a "world which moves from explosion to explosion in order to fulfil the great cosmic design." Moral values, he insists, are not just a "subjective gloss unworthy of consideration on the great hard edifice of historical construction." No single formula can be found, Berlin argues, whereby the various objectives of men can be harmoniously realized. There are many human goals, which may well be in conflict with one another.

This empirical, pluralist, and liberal political philosophy has much in common with the approach of the Frenchman Émile Durkheim and the Englishman Graham Wallas, both founding fathers of modern sociology. Statesmen and political philosophers, they contend, should not play the part of prophets but rather confine themselves to investigating social patterns and the ideas that are part of them. Ways might thus be found of promoting the survival and vitality of a given society in its particular setting.

Graham Wallas was concerned to adapt constitutional societies by consent. He wanted to nationalize many essential means of production, including transport and communications, and through increased taxation strengthen social democracy by greater economic and social equality. He was not a revolutionary but a reformer, who understood the precariousness of civilization and the dangers of nationalism, which could only bring, he prophesied, centuries of warfare and regression. He advocated a worldwide and constitutionalist scientific humanism, inspired by the idea of the solidarity of the whole species, for "the master task of civilized mankind is to promote the conditions leading to the good life."

Other political sociologists who accepted the established order did not expect to improve it. The Italian Vilfredo Pareto, and Gaetano Mosca, a Sicilian-born lawyer, set themselves not to state what they wanted but to record what occurs in society. Pareto's *Mind and Society* (1916) is an elaborate, quasi-mathematical classification of non-logical political myths. Its form is daunting, but its insights are penetrating, especially a hilarious dissection of Rousseau's *General Will*, of which, Pareto concludes, "the intrinsic logico-experimental value . . . is zero." Ranging sardonically over history, Pareto insists that elites will always manipulate society, power merely shifting from one set of rulers to another.

Mosca, in *The Ruling Class* (1939), analyzed how political myths are exploited. He also concluded that elites everywhere are bound to rule and that the least bad government occurs when abuse of power is checked by legal means; that is, by the rule of law. Mosca admired the liberal constitutionalism of the 19th century, although he was aware of its precariousness and limitations. He argued that there is no total explanation of history, which has always been the unpredictable outcome of competing and interacting interests. One thing is certain, nevertheless: in various forms there will always be a struggle for predominance. Mosca's views, more clearly set out than Pareto's, have a salutary realism.

The American philosopher and critic James Burnham also analyzed shifts of power. In *The Managerial Revolution* (1941) he propounded a theory of bureaucratic revolution: the rulers of the new society, the class with power and privilege, will be the bureaucratic managers of "super states." In *The Machiavellians, Defenders of Freedom* (1943), he reinterprets Machiavelli and cites Mosca as a modern Machiavellian. Following Pareto's idea of the "circulation of elites," he asserts that, when a ruling class becomes inadequate, frivolous, or bored, loses confidence in itself and its myths, and becomes irresolute in deploying necessary force, new elites are bound to take over—as in the managerial revolution of the 20th century.

RELIGIOUS AND EXISTENTIALIST APPROACHES

In the second religious and quasi-religious group of political philosophies, the Catholic hierarchy has reiterated its ancient neo-Thomist doctrine of original sin and redemption. Pope Leo XIII, in the encyclicals *Inscrutabili Dei Consilio* (1878), *Immortale Dei* (1885), and *Rerum Novarum* (1891), dismissed all anthropocentric political philosophies as new versions of old heresies. The world, "through an insatiable craving for things perishable," was "rushing wildly upon the straight road to destruction." Society is intelligible only in the light of the Christian revelation and a future life:

exclude the idea of futurity and forthwith the very notion of what is good and right would perish, nay, the whole scheme of the universe would become a dark and unfathomable mystery.

Such is the human condition that visionary innovations are fruitless, and "venomous" teachings can only bring "death-bearing fruit." Society, as St. Augustine had declared, if organized without God, can only be a present hell. Hierarchy, authority, and censorship can alone "control the excesses of the unbridled intellect, which unfaithfully end in the oppression of the untutored multitude." Property is essential to the family, on which the social order depends, and inequality is inherent in all human societies. Only a harmonious Christian commonwealth can assuage the consequences of sin, and within that social order the state should therefore encourage Christian trade unions and promote the welfare of the poor. Thus, with these views the papacy, maintaining its monopoly of revelation, tried to come to terms with the demands of industrial civilization.

During the rise of 19th-century nationalism and of Communist, Fascist, and Nazi dictatorships, and in face of the increasing dominance of governments and large-scale industry in all mass societies, the importance of individual responsibility with regard to moral issues was emphasized by a divergent group of thinkers who have come to be described as Existentialists. Søren Kierkegaard (died 1855), a Danish philosopher, declared that "truth is subjectivity" and that only by means of inward revelation can man know God. Jean-Paul Sartre, a brilliant French Existentialist, tried to come to terms with dialectical Materialism. His *Existentialism and Humanism* (1948) comprises an affirmation of human dignity. "If," he writes, "I have excluded God the Father, there must be someone to invent values." Man, who has abandoned God, "must liberate himself by some practical commitment," for only then can he become fully human. Sartre's elaborate *L'Être et le néant* (1943; Eng. trans., *Being and Nothingness*, 1956) is at once Cartesian and laborious, complete with a "key" to its special and pedantic terms. It investigates the loneliness of the human condition, attitudes to others, love,

Sartre's
view of
human
dignity

humanism
of
Graham
Wallas

masochism, indifference, desire, and hate. This intense introspection is even more vividly expressed in his fiction and drama. The Algerian-born Albert Camus in *The Myth of Sisyphus* (1942) and *The Rebel* (1951) also agonizes brilliantly over the current human condition, and in *Man in Revolt* he discards hope of pragmatic improvement.

REVOLUTIONARY DOCTRINES

The third stream of contemporary political philosophy is Marxist-Leninist totalitarian and neo-Marxist anarchist. Many of Marx's original insights into the socio-economic process and its effect on ideas are now generally accepted. His prophecies, on the other hand, have not been fulfilled. The proletarian revolution, for example, came not in an economically advanced country but in one of the most backward; and the state, far from withering away or being diminished by inexorable economic trends, has in fact become more powerful both in Communist and in social-democratic countries. Those who have accepted the total Marxist revelation as superseding all else have had thus to adapt and revise it. Hence, much tortuous and artificial debate has ensued. All orthodox Marxists accept the Hegelian position that one can get beyond empirical knowledge and perceive the historically revealed installments of a total explanation. They also start from Marx's 19th-century belief that economically determined conflicts among feudal, bourgeois, and proletarian classes are the dynamic of history and that the rule of law is not a safeguard for the whole society against arbitrary power but merely the expression of class interest.

Lenin. The first and by far the most significant interpretation of Marx's doctrine as realized in the Soviet Union was made by Lenin and developed by Stalin and is entirely authoritarian. According to Marx and Engels, the revolution could occur only after the bourgeois phase of production had "contradicted" the tsarist order, but Lenin determined to take advantage of the opportunities provided by World War I and settle accounts directly with the "accursed heritage of serfdom, of Asiatic barbarism . . . an insult to mankind," and in 1917 he engineered a coup that secured the support of the peasantry and the industrial workers. He also adopted the revolutionary theorist Leon Trotsky's idea of a "permanent revolution" from above by a small revolutionary elite.

Already in *What Is To Be Done?* (1902), Lenin had argued that an educated elite must direct the proletarian revolution, and when he came to power he dissolved the constituent assembly and ruled through a "revolutionary and democratic dictatorship supported by the state power of the armed workers." In asserting the need for an elite of professional revolutionaries to seize power, Lenin reverted to Marx's program in *The Communist Manifesto*, rather than conforming to the fated pattern of economic development worked out in *Das Kapital*.

In 1921 he further adapted theory to the times. His new economic policy sanctioned the development of a class of prosperous "kulak" peasantry to keep the economy viable. For Lenin thought always in terms of world revolution; and in spite of the failure of the Marxists in central Europe and the defeat of the Red armies in Poland, he died in the expectation of a global sequel. Thus, in *Imperialism, the Highest Stage of Capitalism* (1917), he had extended the class war into an inevitable conflict between European imperialism and the colonial peoples involved. He had been influenced by the English historian J.A. Hobson's *Imperialism, a Study* (1902), which alleged that decadent capitalism was bound to turn from glutted markets at home to exploit the toil of "reluctant and unassimilated peoples."

But, as observed by classical, medieval, and modern constitutionalist political philosophers, authoritarian regimes suffer the tensions of all autocracies. Marx himself might have thought that such planned autocracies had made the worst of his revelation.

Other Marxist approaches. Many Marxist revisionists tend toward anarchism, stressing the Hegelian and utopian elements of his theory. The Hungarian György Lukács, for example, and the German Herbert Marcuse, who fled from the Nazis to the United States, have won some

following among those in revolt against both authoritarian "peoples' democracies" and the diffused capitalism and meritocracy of the managerial welfare state. Lukács' *Geschichte und Klassenbewusstsein* (1923; Eng. trans., *History and Class Consciousness*, 1971), a neo-Hegelian work, claims that only the intuition of the proletariat can properly apprehend the totality of history. But world revolution is contingent, not inevitable, and Marxism is an instrument, not a prediction. Lukács renounced this heresy after residence in the Soviet Union under Stalin, but he maintained influence through literary and dramatic criticism. After Khrushchev's denunciation of Stalin, Lukács advocated peaceful coexistence and intellectual rather than political subversion. In *The Meaning of Contemporary Realism* (trans. 1963), he again relates Marx to Hegel and even to Aristotle, against the Stalinist claim that Marx made a radically new departure. Lukács' neo-Marxist literary criticism can be tendentious, but his neo-Hegelian insights, strikingly expressed, have appealed to those anxious to salvage the more humane aspects of Marxism and to promote revolution, even against a modified capitalism and social democracy, by intellectual rather than by political means.

Marcuse also reached back to the more utopian Marx. Now that most of the proletariat has been absorbed into a conformist managerial capitalism or has been regimented into bureaucratic peoples' democracies, freedom, argues Marcuse, is in retreat. In Western affluent societies most employers and workers are equally philistine, dominated by the commercialized mass media, or "cogs in a culture machine." The Soviet Union has reverted to an even more philistine monolithic repression, distorting art and literature. This enslavement of man by his own industrial productivity has been clinched by the colossal power of governments, which renders the old brief and brisk class warfare a romantic, impracticable idea. Marcuse attacked all establishments and transferred the redeeming mission of the proletariat to a fringe of alienated minorities—radical students and the exponents of the "hippie" way of life—as well as to Viet Cong guerrillas and Black Power militants. Such groups, he declared, could apparently form liberating elites and destroy the managerial society. Thus reappeared the old Marxist-Hebraic pattern of redemption through struggle by a chosen people.

The Italian Communist Antonio Gramsci deployed a vivid rhetorical talent in attacking existing society. Like Marcuse, Gramsci was alarmed that the proletariat was being assimilated by the capitalist order. He took his stand on the already obsolescent Marxist doctrine of irreconcilable class war between bourgeois and proletariat. He aimed to unmask the bourgeois idea of liberty and to replace parliaments by an "implacable machine" of workers' councils, which would destroy the current social order through a dictatorship of the proletariat. "Democracy," he wrote, "is our worst enemy. We must be ready to fight it because it blurs the clear separation of classes."

Not only would parliamentary democracy and established law be unmasked, but culture, too, would be transformed. A workers' civilization, with its great industry, large cities, and "tumultuous and intense life," would create a new civilization with new poetry, art, drama, fashions, and language. Gramsci insisted that the old culture should be destroyed and that education should be wrenched from the grip of the ruling classes and the church.

But this militant revolution was also a utopian. He turned bitterly hostile to Stalin's regime, for he believed, like Engels, that the dictatorship of the workers' state would wither away. "We do not wish," he wrote, "to freeze the dictatorship." Following world revolution, a classless society would emerge, and mankind would be free to master nature instead of being involved in a class war.

Since World War II, Gramsci's notions have enjoyed a minor revival. They appeal to the fringe of revolutionaries who admire Marcuse and detest the embourgeoisement of an idealized proletariat. But, in a civilization in which, if total war can be avoided, material prospects are good, the destruction of the old culture out of rage, envy, and naïve idealism appears to be a pointless program. Like Marcuse's doctrine, it is a cry of pain, typical of the 1920s in Italy.

Conclusion

The history of political philosophy from Plato until the present day makes plain that modern political philosophy is still faced with the basic problems defined by the Greeks. The need to redeploy public power in order to maintain the survival and enhance the quality of human life, for example, has never been so essential. And if the opportunities for promoting well-being are now far greater, the penalties of the abuse of power are nothing less than the destruction or gross degradation of all life on the planet.

In these circumstances it is of no great importance that some analytical philosophers have declared themselves neutral; they have at least often discredited pretentious metaphysical myths. On the empirical evidence, constitutionalism and the rule of law, with the ancient classic, medieval, and humanist traditions behind them, have proved themselves a more successful response to the environment than tyranny and repression. In the current and more sophisticated view, there are no shortcuts to the millennium. As Mosca points out, utopian ideas become

dangerous when they succeed in bringing a large mass of intellectual and moral energies to bear upon an end that can never be achieved, and that in the day of purported achievement can mean nothing more than the triumph of the worst people and distress and disappointment for the good.

There will perhaps always be a struggle for preeminence in any society, and public laws are necessary to regulate it. Too much cannot be hoped of government, and the best society is that in which tyranny and caprice of power are prevented and in which men are free to create diverse and spontaneous institutions within the framework of law. Only within such a framework of a tolerably well-organized constitutionalism, gradually extended to relations between states, can the swiftly mounting opportunities provided by applied science be taken and the pattern of social life adjusted, so that the human species, instead of being thwarted and deformed by its institutions, can realize its full potentialities.

BIBLIOGRAPHY. The following editions of standard works and commentaries may be consulted.

Classical: PLATO: *The Republic*, trans. with an introduction by A.D. LINDSAY (1957); *The Statesman* (Loeb edition, 1925); *The Laws*, ed. by A.E. TAYLOR (1934). *The Politics of Aristotle*, trans. with introduction by ERNEST BARKER is still the best edition (1946). For the social background of Greek thought, see MAURICE BOWRA, *The Greek Experience* (1957). CICERO, *On the Commonwealth* (*De re publica*) is available in translation by G.H. SABINE and S.B. SMITH (1929). For *De legibus*, see the Loeb edition (1928, reprinted 1966). ST. AUGUSTINE, *The City of God* has been translated by JOHN HEALEY, with an introduction by ERNEST BARKER (1931). For the background, see PETER BROWN, *Augustine of Hippo* (1967) and *The World of Late Antiquity* (1971). C.N. COCHRANE, *Christianity and Classical Culture* (1940), is worth consultation; and H. OSBORN TAYLOR, *The Medieval Mind*, 4th ed., vol. 2 (1925), is still valuable for patristic and medieval thought. See also JULIA ANNAS, *An Introduction to Plato's Republic* (1981).

Medieval: The most convenient edition of John of Salisbury is *The Statesman's Book of John Salisbury*, trans. and selected by J. DICKSON (1927). For St. Thomas Aquinas, see the *Selected Political Writings*, ed. by A.P. D'ENTREVES (1959). The full texts are in *The "Summa Theologiae" of St. Thomas Aquinas*, 2nd ed., 22 vol., trans. by the FATHERS OF THE ENGLISH DOMINICAN PROVINCE (1921–32). For DANTE'S *Monarchia*, see P.H. WICKSTEED'S translation in *The Latin Works of Dante* (1904), and that by D. NICHOLL (1954). See also A.P. D'ENTREVES, *Dante As a Political Thinker* (1952). The best general survey is R.W. and A.J. CARLYLE, *A History of Medieval Political Theory in the West*, 6 vol. (1903–36). A.L. SMITH, *Church and State in the Middle Ages* (1913); and C.H. MCILWAIN, *The Growth of Political Thought in the West, from the Greeks to the End of the Middle Ages* (1932), are still valuable.

16th–18th centuries: NICCOLO MACHIAVELLI, *The Prince and Discourses on the First Decade of Titus Livius* are edited with an introduction by MAX LERNER (1950); his *Literary Works* are edited and translated by J.R. HALE (1961). See also ALLAN H. GILBERT, *Machiavelli's Prince and Its Forerunners* (1938); HERBERT BUTTERFIELD, *The Statecraft of Machiavelli* (1962); and FELIX RAAB, *The English Face of Machiavelli* (1964). THOMAS HOBBS, *The Leviathan, or the Matter, Forme and Power of a Commonwealth, Ecclesiastical and*

Civil is edited by A.D. LINDSEY (1950); see also *The Complete Works*, ed. by WILLIAM MOLESWORTH, 11 vol. (1839–45). K.V. THOMAS, "The Social Origins of Hobbes's Political Thought," in *Hobbes Studies*, ed. by K.C. BROWN (1965), is the best account. JOHN BOWLE, *Hobbes and His Critics* (1951), describes Hobbes's political impact and the contemporary reaction to it. SPINOZA'S *Tractatus Theologico-Politicus* (in part) and the full *Tractatus Politicus* have been edited by A.G. WERNHAM (1958). See also STUART HAMPSHIRE, *Spinoza* (1951). For general background, see ALFRED NORTH WHITEHEAD, *Science and the Modern World* (1925). RICHARD HOOKER, *The Laws of Ecclesiastical Polity*, ed. by JOHN KEBLE, 3 vol. (1836), was revised by R.W. CHURCH and F. PAGET (1888). See also C.J. SISSON, *The Judicious Marriage of Mr. Hooker and the Birth of The Laws of Ecclesiastical Polity* (1940). JOHN LOCKE, *Two Treatises on Civil Government* has been edited by PETER LASLETT (1960); *The Second Treatise of Civil Government and A Letter Concerning Toleration* by J.W. GOUGH (1947). For EDMUND BURKE, see his *Complete Works* (Bohn's Classics, 1853) and *Selected Writings*, ed. by R.J.S. HOFFMAN and P. LEVACK (1949). See also PHILIP MAGNUS, *Edmund Burke: A Life* (1939); and ALFRED COBBAN, *Edmund Burke and the Revolt Against the Eighteenth Century*, 2nd ed. (1960). GIOVANNI BATTISTA VICO, *The New Science* is translated by T.G. BERGIN and M.A. FISCH (1961). See HENRY P. ADAMS, *The Life and Writings of Giambattista Vico* (1935); and BENEDETTO CROCE, *The Philosophy of Giambattista Vico*, trans. by T.G. COLLINGWOOD (1964); also CHARLES LOUIS DE SECONDAT, *Oeuvres choisies*, trans. by J. CHAIX-RUY (1946). MONTESQUIEU, *The Spirit of the Laws* is translated by THOMAS NUGENT, with an introduction by FRANZ NEUMAN (1949). For the French Enlightenment generally, see J.B. BURY, *The Idea of Progress* (1921); and CARL BECKER, *The Heavenly City of the Eighteenth Century Philosophers* (1933). The best translation of JEAN-JACQUES ROUSSEAU'S *Social Contract*, with an introduction, is that of ERNEST BARKER (1947). See also *The Political Writings of Jean Jacques Rousseau*, ed. by C.E. VAUGHAN, 2 vol. (1915). WILLIAM H. BLANCHARD, *Rousseau and the Spirit of Revolt* (1967); and J. MCMANNERS, *The Social Contract and Rousseau's Revolt Against Society* (1968), are both illuminating. DAVID HUME, "Of the Original Contract" is available in *Social Contract*, ed. by BARKER (*op. cit.*).

The 19th century: JEREMY BENTHAM, *A Fragment on Government and An Introduction to the Principles of Morals and Legislation* are edited by WILFRED HARRISON (1948). See also JOHN FLAMENATZ, *The English Utilitarians*, 2nd rev. ed. (1948), particularly for Mill. J.S. MILL, *On Liberty and Considerations on Representative Government* are edited by R.B. MCCALLUM (1946). ALEXIS DE TOCQUEVILLE, *De la démocratie en Amérique* (Eng. trans., *Democracy in America*), ed. by PHILIPS BRADLEY, 2 vol. (1945), is the best edition. For a good abridgment, see H. REEVES'S translation, ed. by H.S. COMMAGER (1946). *L'Ancien Régime* was edited by G.W. HEADLAM (1904). AUGUSTE COMTE, *Système de politique positive* (*System of Positive Polity*) is translated by J.H. BRIDGES, 4 vol. (1875–77). See J.S. MILL, *Auguste Comte and Positivism* (1865); and EDWARD CAIRD, *The Social Philosophy and Religion of Comte* (1885). BASIL WILLEY in *Nineteenth Century Studies* (1949), has a good essay. *Hegel's Philosophy of Right* is translated by T.M. KNOX (1942); his *Philosophy of History* by J. SIBREE, rev. ed. (1944). HERBERT MARCUSE, *Reason and Revolution: Hegel and the Rise of Social Theory*, 2nd ed. (1960), makes a new interpretation. ROBERT OWEN, *A New View of Society and Other Writings* are edited by G.D.H. COLE (1927). PIERRE-JOSEPH PROUDHON, *Qu'est-ce que la propriété? (What Is Property? An Enquiry into the Principles of Right and Government)* is edited by J.A. LANGLOIS (1966). See his *Oeuvres complètes*, ed. by C. BOUGLE and H. MOYSSSET, 15 vol. (1923–36)—also D.W. BROGAN, *Proudhon* (1934). KARL MARX, *A Contribution to the Critique of Political Economy* was translated by N.T. STONE, 2nd rev. ed. (1904). See also *The Communist Manifesto*, ed. by HAROLD J. LASKI (1948); *Capital: A Critique of Political Economy*, trans. by E. and C. PAUL (1928); *Capital: The Process of Capitalist Production As a Whole and The Process of Circulation of Capital*, trans. by ERNEST UNTERMANN (1909); *The Holy Family* (1956); and *Selected Writings in Sociology and Social Philosophy*, ed. by T.B. BOTTOMORE and M. RUBEL (1964). Studies of Marx particularly recommended are FRANZ MEHRING, *Karl Marx: Geschichte seines Lebens* (1933; Eng. trans., *Karl Marx: The Story of His Life*, 1948); and ISIAH BERLIN, *Karl Marx: His Life and Environment*, 4th ed. reprinted with corrections (1960). JOHN FLAMENATZ, *German Marxism and Russian Communism* (1954), is illuminating. FRIEDRICH ENGELS' works in translation include *The Condition of the Working Classes in England in 1844* (1958); *The Anti-Dühring: Herr Eugen Dühring's Revolution in Science* (1959); and *The Origin of the Family, Private Property and the State* (1884). The standard biography is by GUSTAV MAYER, *Friedrich Engels*, 2 vol. (1934; Eng. trans. 1936). GEORGES SOREL, *Réflexions sur la violence* (1912; *Reflections on Violence*), was translated by T.E. HULME (1915), and by J. ROTH

(1950). See also *Les Illusions du progrès* (1908; 5th ed., 1947); and P.L. PERRON, *Les Idées sociales de George Sorel* (1935).

The 20th century: ISIAH BERLIN, *Historical Inevitability* (1954) and *Two Concepts of Liberty* (1958); EMILE DURKHEIM, *The Rules of Sociological Method*, trans. by S.A. SOLVAY and J.H. MUELLER, ed. by C.E.G. CATLIN (1938); VILFREDO PARETO, *Trattato di sociologia generale*, 2nd ed. (1923; Eng. trans., *The Mind and Society*, ed. by A. LIVINGSTON, trans. by A. BONGIONNO and A. LIVINGSTON, 4 vol., 1935); GAETANO MOSCA, *Elementi di scienza politica*, 2nd ed. (1923; Eng. trans., *The Ruling Class*, ed. by A. LIVINGSTON and trans. by H.D. KHAN, 1939); LEO XIII, *The Pope and the People: Select Letters and Addresses on Social Questions* (1929); JEAN-PAUL SARTRE, *L'Être et le néant (Being and Nothingness: An Essay in Phenomenological Ontology)*, trans. and ed. by H.E. BARNES (1957); *Existentialism and Humanism*, trans. and ed. by PHILIP MAIRET (1948); LENIN, *The Development of Capitalism in Russia* (1899); *Collected Works*, 4th ed. (1960), vol. 3, *What Is To Be Done?*, vol. 5, *The State and Revolution*, vol. 25, *Imperialism: The Highest Stage of Capitalism* (1916); see also his *Selected Works*, 12 vol. (1936–39). GEORGE LICHTHEIM, *Marxism: An Historical and Critical Study*, 2nd rev. ed. (1964), is a good short account. See also HERBERT MARCUSE, *Reason and Revolution: Hegel and the Rise of Social Theory*, 2nd ed. (1960), *Eros and Civilization* (1955), *Soviet Marxism: A Critical Analysis* (1958), and *One Dimensional Man* (1964); ALASDAIR MACINTYRE, *Marcuse* (1970); GYORGY

LUKACS, *Goethe und seine Zeit* (1947; *Goethe and His Age*, trans. by ROBERT ANCHOR, 1968); *Der historische Roman* (1955; *The Historical Novel*, trans. by H. and G. MITCHELL, 1962); and JAMES JOLL, *The Anarchists* (1965). For A. Gramsci, see *The Modern Prince and Other Writings*, trans. and introduced by L. MARKS (1957); J.M. CAMMETT, *Antonio Gramsci and the Origins of Italian Communism* (1967); A. POZZOLINI, *Antonio Gramsci: An Introduction to His Thought* (1970). See also MARK BLITZ, *Heidegger's 'Being and Time' and the Possibility of Political Philosophy* (1981); GEORGE FRIGOMAN, *The Political Philosophy of the Frankfurt School* (1981).

General histories of political philosophy: G.H. SABINE, *A History of Political Theory*, 3rd ed. (1961), is the most comprehensive survey. W.A. DUNNING, *A History of Political Theories*, vol. 1, *Ancient and Medieval*, vol. 2, *From Luther to Montesquieu*, vol. 3, *From Rousseau to Spencer* (1902–20, reprinted 1936–38), is still valuable. See also KARL POPPER, *The Open Society and Its Enemies*, 5th rev. ed., vol. 1, *The Spell of Plato* and vol. 2, *The High Tide of Prophecy: Hegel, Marx and the Aftermath* (1966). ERNEST BARKER, *The Principles of Social and Political Theory* (1951), analyses essential problems. JOHN BOWLE, *Politics and Opinion in the Nineteenth Century* (1954, paperback 1964); and WILLIAM EBENSTEIN, *Modern Political Thought: The Great Issues*, 2nd ed. (1960), are valuable, as is HAROLD D. LASSWELL, *The Future of Political Science* (1963).

(J.E.B.)

Political Systems

The term political system may be used either narrowly or broadly. Narrowly defined, it is the set of formal legal institutions that constitute a "government" or a "state." This is the definition adopted by many studies of the legal or constitutional arrangements of advanced political orders. More broadly defined, it comprehends actual as well as prescribed forms of political behaviour, not only the legal organization of the state but also the realities of political life. Still more broadly defined, the political system is seen as a set of "processes of interaction" or as a subsystem of the social system interacting with other nonpolitical subsystems, such as the economic system. This usage guides attention to the importance of informal sociopolitical processes and emphasizes the study of political development.

None of these approaches may be neglected. Traditional

legal or constitutional analysis, using the first definition, has produced a huge body of literature on governmental structures, many of the specialized terms that are a part of the traditional vocabulary of political science, and several classifying schemes that are still instructive. Similarly, empirical analysis of political processes and the effort to identify the underlying realities of governmental forms have yielded a rich store of data and an important body of comparative theory. The third definition has inspired much recent scholarly work, particularly on non-Western states, that employs new kinds of data, new terms, and some new concepts and categories of analysis. The discussion that follows will draw upon all three approaches to the study of political systems. (See also SOCIAL SCIENCES: *Political science*.)

The article is divided into the following sections:

Typologies of government	1004	City and local government	
Supranational political systems	1004	Contemporary divisions of government	1018
Empires		The legislature	
Leagues		The executive	
Confederations		The judiciary

Regional and state government			

Typologies of government

The most important type of political system in the modern world is the nation-state. The world today is divided territorially into more than 150 states, in each of which a national government claims to exercise sovereignty—or the power of final authority—and seeks to compel obedience to its will by its citizens. This fact of the world's political organization suggests the distinction employed in the following section among supranational, national, and subnational political systems.

SUPRANATIONAL POLITICAL SYSTEMS

A principal result of the division of the world into a number of separate national entities, or states, that have contact with one another, share goals or needs, and face common threats is the formation of supranational relationships. In some cases, as in many alliances, these relationships are short-lived and fail to result in significant institutional development. In other cases, they lead to interstate organizations and supranational systems. The

discussion below examines several types of supranational political systems, together with historical and contemporary examples of each.

Empires. All empires, since they are composed of peoples of different cultures and ethnic backgrounds, are ultimately held together by coercion and the threat of forcible reconquest. Imposing their rule on diverse political structures, they are characterized by the centralization of power and the absence of effective representation of their component parts. Although force is thus the primary instrument of imperial rule, it is also true that history records many cases of multi-ethnic empires that were governed peaceably for considerable periods and were often quite successful in maintaining order within their boundaries. The history of the ancient world is the history of great empires—Egypt, China, Persia, and imperial Rome—whose autocratic regimes provided relatively stable government for many subject peoples in immense territories over many centuries. Based on military force and religious belief, the ancient despotisms were legitimized also by their achievements in building great bureaucratic and legal structures,

Ancient
and
modern
empires

in developing vast irrigation and road systems, and in providing the conditions for the support of high civilizations. Enhancing and transcending all other political structures in their sphere, they could claim to function as effective schemes of universal order.

In contrast to the empires of the ancient world, the colonial empires of recent times fell far short of universal status. In part, these modern European empires were made up of "colonies" in the original Greek sense; peopled by immigrants from the mother country, the colonies usually established political structures similar to those of the metropolitan centre and were often able to exercise a substantial measure of self-government. In part, also, the European empires were composed of territories inhabited by native populations and administered by imperial bureaucracies. The government of these territories was generally more coercive than in the European colonies and more concerned with protection and supervision of the commercial, industrial, and other exploitative interests of the imperial power. The disintegration of these empires occurred with astonishing speed. The two world wars of the 20th century sapped the power of the metropolitan centres, while their own doctrines of democracy, equality, and self-determination undermined the principle of imperial rule. Powers such as Britain and France found it increasingly difficult to resist claims to independence couched in terms of the representative concepts on which their home governments were based, and they lacked the military and economic strength to continue their rule over restive native populations. In the two decades after 1945 nearly all the major colonial territories won their independence; the great colonial empires that had once ruled more than half the world were finally dismembered.

Leagues. One of the commonest forms of supranational organization in history is that of leagues, generally composed of states seeking to resist some common military or economic threat by combining their forces. This was the case with the early city leagues, such as the Achaean and Aetolian leagues in ancient Greece and the Hanseatic and the Swabian leagues in Europe; and to a great extent it was the case with the League of Nations. Other common features of leagues include the existence of some form of charter or agreement among the member states, an assembly of representatives of the constituent members, an executive organ for the implementation of the decisions of the assembly of representatives, and an arbitral or judicial body for adjudicating disputes.

The
League of
Nations

The League of Nations was one of the great experiments in supranational organization of the 20th century and the predecessor in several important respects of the United Nations. The Covenant of the League was drafted by a special commission of the Peace Conference after World War I, with Pres. Woodrow Wilson of the United States as its leading advocate, and approved by a plenary conference of the victorious powers in 1919. The initial membership of the League consisted of 20 states. The United States failed to take membership in the League, but by 1928 the organization had a total membership of 54. The machinery of the League consisted of an Assembly of all the member nations, acting through agents of their governments; a council on which the great powers were permanently represented and to which the other member powers were elected by the Assembly for three-year terms; a Secretariat to administer the internal affairs of the League; and a number of specialized agencies, such as the International Labour Organisation, that were responsible for implementing various economic and humanitarian programs on an international basis. The Covenant required that international disputes be submitted to peaceful settlement with a provision for adjudication or arbitration by the Permanent Court of International Justice or for intervention by the Council of the League. The Covenant also provided for the use of financial and economic penalties, such as embargoes, to enforce the decisions of the League and for joint military action against convicted aggressors. In practice, however, the League failed its most important tests and was unable to master the crises that led to World War II and its own collapse.

Confederations. Confederations are voluntary associa-

tions of independent states that, to secure some common purpose, agree to certain limitations on their freedom of action and establish some joint machinery of consultation or deliberation. The limitations on the freedom of action of the member states may be as trivial as an acknowledgment of their duty to consult with each other before taking some independent action or as significant as the obligation to be bound by majority decisions of the member states. Confederations usually fail to provide for an effective executive authority and lack viable central governments; their member states typically retain their separate military establishments and separate diplomatic representation; and members are generally accorded equal status with an acknowledged right of secession from the confederation. Historically, confederations have often proved to be a first or second step toward the establishment of a national state, usually as a federal union. Thus, the federal union of modern Switzerland was preceded by a confederation of the Swiss cantons; West Germany's modern federal arrangements may be traced to the German Confederation of the 19th century (the *Deutsche Bund*); and the federal constitution of the United States is the successor to the government of the Articles of Confederation. In some other cases confederations have replaced more centralized arrangements, as, for example, when empires disintegrate and are replaced by voluntary associations of their former colonies. The British Commonwealth, or Commonwealth of Nations, and the French Community are cases of this type.

An example of confederal arrangements that gave birth to a federal union is the Articles of Confederation (1781–89) that preceded the Constitution of the United States. The Articles established a Congress of the confederation as a unicameral assembly of ambassadors from the 13 states, each possessing a single vote. The Congress was authorized to appoint an executive committee of states

The
Articles of
Confeder-
ation

to execute, in the recess of Congress, such of the powers of Congress as the United States, in Congress assembled, by the consent of nine States, shall from time to time think expedient to vest them with;

in turn, the committee of states could appoint a presiding officer or president for a term of one year. The Congress could also appoint such other committees and "civil officers as may be necessary for managing the general affairs of the United States," and was given the authority to serve as "the last resort or appeal in all disputes and differences, now subsisting or that hereafter may arise between two or more states." Although the Congress was given authority in important areas such as the regulation of foreign affairs, the establishment of coinage and weights and measures, the appointment of officers in the confederation's land and naval forces, and the issuance of bills of credit, all its powers were in fact dependent for their enforcement upon the states. The Congress lacked both an independent source of revenue and the executive machinery to enforce its will directly upon individuals. As the language of the Articles summarized the situation,

each State retains its sovereignty, freedom and independence, and every power, jurisdiction and right, which is not by this Confederation expressly delegated to the United States in Congress assembled.

The Commonwealth of Nations is an example of a confederation born as the result of the decentralization and eventual disintegration of an empire. A number of former British colonies and dominions, together with the United Kingdom, composed the commonwealth in 1972: Australia, Barbados, Botswana, Canada, Cyprus, Fiji, The Gambia, Ghana, Guyana, India, Jamaica, Kenya, Lesotho, Malawi, Malaysia, Malta, Mauritius, Nauru, New Zealand, Nigeria, Sierra Leone, Singapore, Sri Lanka (Ceylon), Swaziland, Tanzania, Tonga, Trinidad and Tobago, Uganda, Western Samoa, and Zambia. Ireland and South Africa had seceded from the commonwealth, and Rhodesia's status was unclear after a lengthy dispute with Britain and the other member nations. All Commonwealth states recognized the Queen as the head of the commonwealth. Barbados, Canada, Jamaica, Malta, and Trinidad and Tobago were monarchies in which the Queen was represented by a governor-general appointed on the recommendation

The
Common-
wealth of
Nations

of the government of the country concerned and acting in accord with its own constitutional practice; Botswana, Cyprus, Ghana, India, Kenya, Nigeria, Sri Lanka, Tanzania, and Zambia were republics; Malaysia and Lesotho had their own sovereigns; and Uganda had a prime minister who was head of state. Commonwealth governments were represented in the capitals of other commonwealth countries by high commissioners equal in status to ambassadors. The nations of the commonwealth rarely acted in concert on the international scene, and, despite fairly regular meetings of the commonwealth prime ministers, there were at times severe strains in the relations among several of the member states. The fairly general use of the English language and of English common law, together with some common symbols and remaining cultural affinities, appeared to be the major ties binding together this loose association of former British imperial possessions.

Federations. The term federation is used to refer to groupings of states, often on a regional basis, that establish central executive machinery to implement policies or to supervise joint activities. In some cases such groupings are motivated primarily by political or economic concerns; in others, military objectives are paramount. Examples of the former include the association of Belgium, France, The Netherlands, Italy, Luxembourg, and West Germany in what is usually referred to as the Western European Community but is actually a combination of three main structures—the European Coal and Steel Community, established in 1952; the European Economic Community (Common Market), established in 1958; and the European Atomic Energy Community (Euratom), established in 1958. The Community quickly developed executive machinery exercising significant regulatory and directive authority over the governments and private business firms of the member countries. Although each of the member governments retains a substantial measure of sovereignty, and a systematic effort by one or more of the governments to resist the authority of the Community's agencies could endanger the whole fabric of cooperative effort, the Community has developed significant supranational features. These include the staffing of executive organs with persons other than governmental representatives, the making of binding decisions on important matters by majority vote, and the capability of the Community agencies to deal directly and authoritatively with individuals and companies within the member states. For example, the high authority of the Coal and Steel Community acts by majority vote of its members, without instruction from any of the governments, to "assure the achievement of the purposes stated in the Treaty"; and in pursuing this function it involves itself deeply in the economies of each of the member nations.

The North Atlantic Treaty Organization (NATO), established in April 1949, is an example of a modern military alliance endowed with complex and permanent executive machinery, employing multilateral procedures, and involving the continuous elaboration of plans for the conduct of joint military action by its member states (Belgium, Canada, Denmark, Greece, Iceland, Italy, Luxembourg, The Netherlands, Norway, Portugal, Turkey, the United Kingdom, the United States, and West Germany; France is associated with the NATO nations for some purposes). As stated in its treaty, the purpose of NATO is to maintain the security of the North Atlantic area by exercise of the right of collective security recognized in the Charter of the United Nations. An impressive array of institutional mechanisms was established, including a secretary general and a permanent staff, a council, a network of committees, a military command structure, various study groups, and liaison staffs; and an ongoing system of collaboration in planning and joint military exercises was brought into being. With the continued development of its organization, NATO gradually added a number of economic and cultural activities to its functions until it came to possess several of the features of a multipurpose supranational organization.

The United Nations organization. A supranational political system that does not fit precisely any of the conventional classifications of such systems is the United Nations, a voluntary association of most of the world's

nation-states. Its membership had grown from an original 51 states to a total of 130 in 1971, when the government of the People's Republic of China was admitted in place of the government of the Republic of China (Taiwan). Founded at a conference in San Francisco in 1945 attended by representatives of all the nations that had declared war on Germany or Japan, the purposes of the organization are declared in its Charter to be the maintenance of international peace and security, the development of friendly relations among states, and international cooperation in solving the political, economic, social, cultural, and humanitarian problems of the world. Its organizational structure consists of a Security Council of five permanent members (China, France, the Soviet Union, the United Kingdom, and the United States) and ten nonpermanent members elected for two-year terms, a General Assembly, a Secretary General and a Secretariat, an Economic and Social Council, a Trusteeship Council, and the International Court of Justice. Attached to the United Nations are a number of specialized agencies, including the Food and Agriculture Organization, the International Atomic Energy Agency, the International Civil Aviation Organization, the International Labour Organization, the International Monetary Fund, the International Telecommunications Union, the Universal Postal Union, the United Nations Educational, Scientific and Cultural Organization, the World Health Organization, and the International Bank for Reconstruction and Development (World Bank).

Aside from the rather generally stated and decidedly elusive aims of the Charter, the member states of the United Nations cannot be said to have any common goal; they lack even the unity that a common external threat to security brings to many supranational organizations. There is also difficulty in reaching and implementing decisions. Two different formulas are employed for voting in the two principal organs, the General Assembly and the Security Council. In the General Assembly a two-thirds majority decides on important matters; but, since the Assembly's decisions are not binding and are merely recommendations, this qualified majority principle must be viewed as of little significance. Although, on the other hand, the decisions of the Security Council may be binding, a unanimous vote of all five of the permanent members joined by the votes of at least four of the nonpermanent members is required; whenever important questions of peace and security are at stake, it is rarely possible to achieve agreement among the five great powers of the council. These difficulties, which might be fatal to the survival of many supranational organizations, are not in fact totally debilitating. The United Nations continues to serve as a very important forum for international debate and negotiation, and its specialized agencies play an important role in what is sometimes referred to as "the functional approach to peace."

NATIONAL POLITICAL SYSTEMS

The term nation-state is used so commonly but defined so variously that it will be well to indicate its usage in this article with some precision and to give historical and contemporary examples of nation-states. To begin with, there is no single basis upon which such systems are established. Many states were formed at a point in time when a people sharing a common history, culture, and language discovered a sense of identity. This was true in the cases of England and France, which were the first nation-states to emerge in the modern period, and of Italy and Germany, which were established as nation-states in the 19th century. In contrast, however, other states, such as India, the Soviet Union, and Switzerland, have come into existence without a common basis in race, culture, or language. It must also be emphasized that contemporary nation-states are creations of different historical periods and of very varied circumstances. Before the close of the 19th century the effective mobilization of governmental powers on a national basis had occurred only in Europe, the United States, and Japan. It was not until the 20th century and the collapse of the Ottoman, Habsburg, French, and British empires that the world could be fully orga-

state
defined

nized on a national basis. In 1920 the League of Nations recognized seven nation-states as "Great Powers" (Britain, France, the United States, Germany, Italy, Japan, and Russia) and eventually admitted more than 40 other states to membership; in 1946 the United Nations admitted 51 states to membership, but the number had grown to 130 by 1971. The nation-states in today's world include the three "superpowers," the United States, the Soviet Union, and China; the established powers of second rank, Britain, France, Japan, and West Germany; emerging powers such as India and Indochina; and a host of old and new lesser states, such as Denmark, The Gambia, Switzerland, Cyprus, Belgium, Malaysia, Norway, Chile, and others.

The characteristics that qualify these variously composed and historically differing entities as nation-states and distinguish them from other forms of social and political organization amount in sum to the independent power to compel obedience from the populations within their territories. The state is, in other words, a territorial association that may range in size from the Soviet Union to Singapore, in population from China to Luxembourg, and that claims supremacy over all other associations within its boundaries. As an association, the state is peculiar in several respects: membership is compulsory for its citizens; it claims a monopoly of the use of armed force within its borders; and its officers, who are the government of the state, claim the right to act in the name of the land and its people.

A definition of the state in terms only of its powers over its members is not wholly satisfactory, however. Although all states make a claim to supremacy within their boundaries, they differ widely in their ability to make good their claims. States are, in fact, often challenged by competing associations within their boundaries; their supremacy is often more formal than real; and they are sometimes unable to maintain their existence. Moreover, a definition in terms of power alone ignores the fact that there are great differences among states in the structures they employ for the exercise of power, in the ways they use power, and in the ends to which they turn their power. Some of these differences are explored in the discussion that follows of two general categories of nation-states: the unitary state and the federal state. Partly from administrative necessity and partly because of the pressures of territorial interests, nearly all modern states provide for some distribution of governmental authority on a territorial basis. Systems in which power is delegated from the central government to subnational units and in which the grant of power may be rescinded at the will of the central government are termed unitary systems. Systems in which a balance is established between two autonomous sets of governments, one national and the other provincial, are termed federal. In federal systems, the provincial units are usually empowered to grant and take away the authority of their own subunits in the same manner as national governments in unitary systems. Thus, although the United States is federally organized at the national level, each of the 50 states is in a unitary relationship to the cities and local governments within its own territory.

Unitary nation-states. A majority of all the world's nation-states are unitary systems, including Belgium, Bulgaria, France, Great Britain, The Netherlands, Japan, Poland, Romania, the Scandinavian countries, Spain, and many of the Latin American and African countries. There are great differences among these unitary states, however, in the institutions and procedures through which their central governments interact with their territorial subunits.

In one type of unitary system, decentralization of power among subnational governments goes so far that in practice, although not in constitutional principle, they resemble federal arrangements. In Britain, for example, there are important elements of regional autonomy in the relationship between Northern Ireland, Wales, and Scotland and the national government in London; and the complex system of elected local governments, although in constitutional theory subject to abrogation by Parliament, is in practice a fixed and fairly formidable part of the apparatus of British government. In other unitary systems of this type, decentralization on a territorial basis is actually

provided for constitutionally, and the powers of locally elected officials are prescribed in detail. Thus, the Japanese constitution specifies certain autonomous functions to be performed by local administrative authorities.

A second type of unitary system makes substantially less provision for territorial decentralization of authority and employs rather strict procedures for the central supervision of locally elected governments. The classic example of this type is France. The French administrative system is built around 95 *départements*, each headed by a *préfet*, and 322 subdivisions of the *départements*, termed *arrondissements*, each headed by a *sous-préfet*. The *préfets* and *sous-préfets* are appointed by the government in Paris to serve as agents of the central government and also as the executives of the divisional governments or councils, which are composed of elected officials. The system thus combines central supervision of local affairs through appointed officers with territorial representation through locally elected governments.

A third type of unitary system provides for only token decentralization. In such cases, the officials responsible for managing the affairs of the territorial subdivisions are appointees of the central government, and the role of locally elected officers is either minimal or nonexistent. Examples of this kind of arrangement include Germany under Adolf Hitler and also several Communist countries. The Third Reich was divided into 42 *Gaue*, each headed by a *gauleiter* chosen for his personal loyalty to Hitler; in eastern Europe, the people's councils or people's committees are named by the centrally organized Communist parties; their appointment is confirmed by elections in which one slate of candidates is presented.

Federal systems. In federal systems, political authority is divided between two autonomous sets of governments, one national and the other subnational, both of which operate directly upon the people. Usually a constitutional division of power is established between the national government, which exercises authority over the whole national territory, and provincial governments that exercise independent authority within their own territories. Of the eight largest countries in the world, seven—Argentina, Australia, Brazil, Canada, India, the Soviet Union, and the United States—are organized on a federal basis. Federal states also include Austria, Cameroon, Czechoslovakia, Libya, Malaysia, Mexico, Nigeria, Switzerland, Tanzania, Venezuela, West Germany, and Yugoslavia.

The governmental structures and political processes found in these federal systems show great variety. One may distinguish, first, a number of systems in which federal arrangements reflect rather clear-cut cultural divisions. A classic case of this type is Switzerland, where the people speak four different languages—German, French, Italian, and Romansh—and the federal system unites 26 historically and culturally different entities, known as cantons and demicantons. The Swiss constitution of 1848, as modified in 1874, converted a confederation originally formed in the 13th century by the three forest cantons of Uri, Schwyz, and Unterwalden into the modern federal state. The principal agencies of federal government are a bicameral legislature, composed of a National Council representing the people directly and a Council of States representing the constituent members as entities; an executive branch (Bundesrat) elected by both houses of the legislature in joint session; and a supreme court that renders decisions on matters affecting cantonal and federal relations. The Soviet Union's federal arrangements, although of a markedly different kind, also reflect underlying cultural and linguistic differences among the 15 union republics. The member republics of the Union of Soviet Socialist Republics are constitutionally endowed with territorial autonomy, a "right to secession," and equal representation in the Supreme Soviet. Ethnic subdivisions within the 15 union republics are also granted territorial autonomy and direct representation in the upper chamber of the Supreme Soviet. These arrangements, however, are rather more important in Soviet constitutional theory than in practice, since, in addition to the virtual monopoly of military, economic, and social controls vested in the central government, more than half the population and

The Swiss and Soviet systems

Decentralization of power in unitary states

territory of the Soviet Union lies within one member republic, the Russian Socialist Federated Soviet Republic.

In other systems, federal arrangements are found in conjunction with a large measure of cultural homogeneity. The Constitution of the United States delegates certain activities that concern the whole people, such as the conduct of foreign relations and war and the regulation of interstate commerce and foreign trade to the federal government; certain other functions are shared between the federal government and the states; and the remainder are reserved to the states. Although these arrangements require two separate bodies of political officers, two judicial systems, and two systems of taxation, they also allow extensive interaction between the federal government and the states. Thus, the election of Congress and the President, the process of amending the Constitution, the levying of taxes, and innumerable other functions necessitate cooperation between the two levels of government and bring them into a tightly interlocking relationship.

SUBNATIONAL POLITICAL SYSTEMS

Although national government is the dominant form of political organization in the modern world, an extraordinary range of political forms exists below the national level—tribal communities, the intimate political associations of villages and towns, the governments of regions and provinces, the complex array of urban and suburban governments, and the great political and administrative systems of the cities and the metropolises. These subnational entities are, in a sense, the basic political communities—the foundation on which all national political systems are built.

Tribal communities. The typical organization of mankind in its early history was the tribe. Today, in many parts of the world, the tribal community is still a major form of human political organization. Even in advanced systems, traces can still be found of its influence. Some of the *Länder* of modern Germany, such as Bavaria, Saxony, or Westphalia, have maintained their identity since the days of the Germanic tribal settlements. In England, too, many county boundaries can be explained only by reference to the territorial divisions in the period after the end of the Roman occupation.

In many of the new states of Africa, the tribe is still the effective community and a principal vehicle of political consciousness. Most of these states are the successors to the administrative units established by colonial regimes and owe their present boundaries to the often arbitrary decisions of imperial bureaucracies or to the territorial accommodations of rival colonial powers. The result was often the splintering of the tribal communities or their aggregation in largely artificial entities. That the force of tribalism is far from exhausted is suggested by the experience of Nigeria and other new states where a resurgence of tribal rivalries has presented great obstacles to the process of nation building.

In its primary sense, the tribe is a community organized in terms of kinship, and its subdivisions are the intimate kindred groupings of moieties, gentes, and totem groups. Its territorial basis is rarely defined with any precision, and its institutions are typically the undifferentiated and intermittent structures of an omnifunctional social system. The leadership of the tribe is provided by the group of adult males, the lineage elders acting as tribal chiefs, the village headmen, or the shamans, or tribal magicians. These groups and individuals are the guardians of the tribal customs and of an oral tradition of law. Law is thus not made but rather invoked; its repository is the collective memory of the tribal council or chief men. This kind of customary law, sanctioned and hallowed by religious belief, nevertheless changes and develops, for each time it is declared something may be added or omitted to meet the needs of the occasion.

Rural communities. The village has traditionally been contrasted with the city: the village is the home of rural occupations and tied to the cycles of agricultural life, while the inhabitants of the city practice many trades, and its economy is founded on commerce and industry; the village is an intimate association of families, while the city

is the locus of a mass population; the culture of the village is simple and traditional, while the city is the centre of the arts and sciences and of a complex cultural development. The village and the city offer even sharper contrasts as political communities. Historically, the village has been ruled by the primitive democracy of face-to-face discussion in the village council or by a headman whose decisions are supported by village elders or by other cooperative modes of government; urban government has never been such a simple matter, and monarchical, tyrannical, aristocratic, and oligarchic forms of rule have all flourished in the city. In the village, the boundaries among political, economic, religious, and other forms of action have not been as clearly drawn as in cities.

The origins and development of the apparatus of government can be seen most clearly in the simple political society of the rural community. The transformation of kin-bound societies with their informal, folk-sustained systems of sociopolitical organization into differentiated, hierarchical societies with complex political structures began with the enlargement of the rural community—an increase in its population, the diversification of its economy, or its interaction with other communities. The rudimentary organs of communal government were then elaborated, the communal functions received more specialized direction, and leadership roles were institutionalized. This was sometimes a process that led by gradual stages to the growth of cities. Elsewhere, however, as in the case of ancient Attica, the city was established as the result of a process of *synoikismos*, or the uniting of a number of tribal or village communities. This was undoubtedly the origin of Athens, and, according to its legendary history, Rome also was established as a result of the forcible unification of the tribes that dwelt on the hills surrounding the Palatine Hill.

Even in the nation-states of today's world, the contrasts between the village or the town and the city as centres of human activity are readily apparent. In the country, life is more intimate, the human contacts more informal, the structure of society more stable. In the city, the individual becomes anonymous, the contacts between people are mainly formal, and the standing of the individual or the family in society is subject to rapid change. In many contemporary systems, however, the differences in the forms of government of rural and urban communities appear to be growing less pronounced. In the United States, for example, rural institutions have been seriously weakened by the movement of large numbers of people to the city. The township meeting of New England and other forms of direct citizen participation in the affairs of the community have declined in importance and have often been displaced by more formal structures and the growth of local governmental bureaucracies.

Cities. Cities first emerged as complex forms of social and political organization in the valleys of the Euphrates and the Tigris, the Nile, the Yellow River, and the Yangtze. These early cities broke dramatically with the patterns of primitive life and the rural societies from which they sprang. Kinship as the basis of society was replaced with status determined by class and occupation; the primitive magical leaders of the tribe were displaced by temple priesthoods presiding over highly developed religious institutions and functioning as important agencies of social control; earlier systems of rule by the tribal chieftains and the simple forms of communal leadership gave way to kingships endowed with magical powers and important religious functions; and specialized functionaries in the royal courts became responsible for supervising new kinds of governmental activity. Many other developments contributed to the growing centralization of power in these city civilizations. Barter was replaced by more effective systems of exchange, and the wealth generated in commerce and the specialized city trades became both an object of taxation and an instrument of power. Class distinctions emerged as the result of a division of labour and advances in technical development. A military order and a professional soldiery were created and trained in new techniques of warfare, and a slave class provided the work force for large-scale projects of irrigation, fortification, and royal architecture. As these developments proceeded, the

cities

The Greek polis

city was able to project its power even further into the surrounding countryside, to establish its rule over villages and other cities in its sphere, and finally to become the centre of such early empires as those of Sumeria, Egypt, China, Babylonia, Assyria, and Persia.

A very different form of city life emerged among the Greeks. The Greek polis also broke with the folkways of primitive society, but its political development was in striking contrast to the despotism of the Oriental city empires and their massive concentrations of power in the hands of king and priest. As the polis transcended its origins in village life, the powers of the tribal chief dwindled and passed into the hands of aristocratic families. The kingship of Homeric tradition vanished, the "kings" who remained became mere dignitaries in the religious and ceremonial life of the city, and new magistracies and other civic offices were founded. These offices became the focus of factional struggle among the aristocratic families and, later, with the weakening of aristocratic rule, the chief prizes in a contest of power between the nobility and the common citizens. Eventually, these developments issued in the characteristic form of Greek city government. A citizen body, always a much narrower group than the total population but often as numerous as the population of freeborn males, acquired power in the direction of the city government through the election of its officers and direct participation in the city councils. Although often interrupted by episodes of oligarchic or tyrannical rule and by periods of civic dissension and class rivalry, the main theme of governmental development in the Greek city was the elaboration of structures that permitted the control of political affairs by its citizens.

The medieval city

Autonomous cities also sprang up in Europe in the later Middle Ages. Medieval city life, although it differed from that of the polis and was coloured by the forms of feudal society, also emphasized the principle of cooperative association. Indeed, for the first time in the history of city civilization, the majority of the inhabitants of the city were free. The development of trades, the growth of commerce, and the mobilization of wealth emancipated the city from its feudal environment, and the merchant and craft guilds became the matrices of a new kind of city democracy. In time, the guilds were transformed into closed corporations and became a basis for oligarchic control; and the city's independence was threatened by the rise of the new nation-states. Tempting targets for the ambition of kings, Venice, Genoa, Florence, Milan, Cologne, Amsterdam, Hamburg, and other free cities of Europe eventually succumbed to monarchical control. Theirs was an important legacy, however, for the political order of the medieval city was a powerful influence in the development of the constitutional structures of the modern democratic state.

Modern cities

Although cities are no longer independent, the almost universal increase in urban population has made them more important than ever before as centres of human activity. The political organization of modern cities differs from country to country. Even within the same nation-state, there are often important contrasts in the structures of city government. In the United States, for example, three principal types of city government are usually distinguished: the council-manager form, the mayor-council form, and the commission form.

More than half of all American cities with populations of between 25,000 and 250,000 operate under council-manager governments. In council-manager systems the council is generally small, elected at large on a nonpartisan ballot for overlapping four-year terms; no other offices are directly elected, and the mayor, who presides at council meetings and performs mainly ceremonial functions, is chosen by the council from among its members. The manager, a professional city administrator, is selected by the council, serves at the council's pleasure, and is responsible for supervising the city departments and municipal programs, preparing the budget, and controlling expenditures.

Mayor-council governments are found in two basic forms, the "weak" mayor and the "strong" mayor. The former was typical of the 19th-century municipal organization and is now mainly confined to cities of less than 25,000 population; the latter is a common arrangement in

cities with populations of more than 5,000,000. In weak-mayor-council governments, a number of officials, elected or appointed for lengthy terms, wield important administrative powers; the council, typically elected by divisions of the city called wards, is responsible for the direction of the major city agencies; and the mayor's powers of appointment and removal and his control over the city budget are severely limited. In many cases, strong-mayor-council governments evolved from weak-mayor-council systems as an independently elected mayor won the power of veto over council ordinances, strengthened his control over appointment and removal, and established himself as the city's chief budgetary officer; at the same time, also, the elective administrative officers and the semi-autonomous appointive boards and commissions were often eliminated and the number of councilmen reduced.

The commission plan, which is now found in fewer than 200 cities of more than 10,000 population, concentrates legislative and executive powers in the hands of a small group of commissioners. The commissioners serve individually as the heads of administrative departments and choose one of their number to act as a ceremonial mayor without executive authority.

The variety in the governmental structures of American cities is paralleled in many other countries, for everywhere in the modern world the government of the city continues to challenge man's political invention. Although no longer sovereign, cities are the centres of modern civilization and, both in terms of the services demanded of them and the range and importance of the functions they exercise, the most important of contemporary subnational political systems. Moreover, it is in the cities that most of the problems of modern industrial society seem to have their focus. These problems are not only governmental but also technological, cultural, and economic. They are found in their most acute form in the great metropolitan centres and in that vast urban agglomeration known as the megapolis. In political terms, the issue that is posed appears to be whether these huge centres of population can continue as effective communities with democratically manageable governments.

Regions. In many contemporary national political systems the forces of history and administrative necessity have joined to produce regional communities at an intermediate level between the local and the national community. In some cases—the Swiss canton, the English county, the German *Land*, and the American state—these regional communities possess their own political institutions and exercise governmental functions. In other cases, however, the territorial community is a product of ethnic, cultural, linguistic, physiographic, or economic factors and maintains its identity without the support of political structures.

As subnational political systems, regional communities are sometimes based in tradition, even tracing their origin to a period prior to the founding of the nation; in other cases, they are modern administrative units created by national governments for their own purposes. Examples of both types may be found in the history of regionalism in France and its complex pattern of internal territorial divisions. Before the French Revolution, France was divided into ancient provinces—Burgundy, Gascony, Brittany, Normandy, Provence, Anjou, Poitou, and others. After the Revolution, in what seems to have been an effort to discourage regional patriotism and threats of separatism, the Napoleonic government superimposed a new regional structure of *départements* on the old provincial map. More than a century and a half later, in the era of rapid communications and national economic planning, the French national government announced a regrouping of the Napoleonic *départements* into much larger Gaullist *régions*. Recognizing, perhaps, the continuing strength of the provincial attachments of Gascon, Breton, Norman, and Provençal and the survival of old regional folk cultures with their distinctive patterns of speech, the new *régions* were given boundaries similar in many cases to the traditional provincial boundaries of pre-republican France.

The history of the French regional communities is not a special case, for political, administrative, economic, and technical forces have led many other national governments

Regional communities

to replace traditional territorial divisions with new regional units. In England, for example, the traditional structure of county governments (52 in number) was replaced by a system of administrative counties (61 plus London); and, in 1969, a royal commission proposed a further reform that would abolish 39 counties. Attempts have also been made to use older regional communities as the infrastructure for new systems of regional government. Thus, the Italian constitution provides for semi-autonomous government in five special regions—Valle d'Aosta, Sardinia, Sicily, Trentino-Alto Adige, and Friuli-Venezia Giulia—which, in different ways, are historically distinct from the rest of Italy. In yet other cases the fear of competition from regional governments or of separatist movements has led national governments to make various efforts to resist the development of regional political structures. Again, Italy provides a convenient example, for its constitution requires the establishment of 14 other autonomous regions, but Italian governments refused to implement this provision of the 1947 constitution until recently. It should be noted that the Italian republic of 1870–1922 and its Fascist successor state also made similar efforts to combat regional political development, the former by the creation of a large number of administrative provinces and the latter by establishing *corporazione* to represent occupations regardless of geographic location.

In several modern states the growth of vast conurbations and the rise of the megalopolis have prompted the development of new kinds of regional governmental structures. The Port of London Authority, the Port of New York Authority, and the San Francisco Bay Area Transit Authority are examples of regional systems designed to serve the needs of urban communities that have outgrown the boundaries of existing city governments. New regional structures have also resulted from the increased responsibility of national governments for the administration of comprehensive social and economic programs. The Tennessee Valley Authority, for example, is both a national agency and a regional government whose decisions affect the lives of the inhabitants of all the states and cities in its sphere. Other examples of new regional administrative structures include the zonal councils established in India for social and economic planning purposes, the districts of the Interstate Commerce Commission in the United States, and the governmental and economic units established in Britain to deal with the problems of industrially depressed areas.

ISSUES OF CLASSIFICATION

The almost infinite range of political systems has been barely suggested in this brief review. Confronted by the vast array of political forms, political scientists have attempted to classify and categorize, to develop typologies and models, or in some other way to bring analytic order to the bewildering variety of data. Many different schemes have been developed. There is, for example, the classical distinction between governments in terms of the number of rulers—government by one man (monarchy or tyranny), government by the few (aristocracy or oligarchy), and government by the many (democracy). There are schemes classifying governments in terms of their key institutions (for example, parliamentarism, cabinet government, presidentialism). There are classifications that group systems according to basic principles of political authority or the forms of legitimacy (charismatic, traditional, rational-legal, and others). Other schemes distinguish between different kinds of economic organization in the system (the laissez-faire state, the corporate state, and Socialist and Communist forms of state economic organization) or between the rule of different economic classes (feudal, bourgeois, and capitalist). And there are modern efforts to compare the functions of political systems (capabilities, conversion functions, and system maintenance and adaptation functions) and to classify them in terms of structure, function, and political culture.

Although none is comprehensive, each of these principles of analysis has some validity, and the classifying schemes that are based on them, although in some cases no longer relevant to modern forms of political organization, have

often been a major influence on the course of political development. The most influential of such classifying schemes is undoubtedly the attempt of Plato and Aristotle to define the basic forms of government in terms of the number of power holders and their use or abuse of power. Plato held that there was a natural succession of the forms of government: an aristocracy (the ideal form of government by the few) that abuses its power develops into a timocracy (in which the rule of the best men, who value wisdom as the highest political good, is succeeded by the rule of men who are primarily concerned with honour and martial virtue), which through greed develops into an oligarchy (the perverted form of government by the few), which in turn is succeeded by a democracy (rule by the many); through excess, the democracy becomes an anarchy (a lawless government), to which a tyrant is inevitably the successor. Abuse of power in the Platonic typology is defined by the rulers' neglect or rejection of the prevailing law or custom (*nomos*); the ideal forms are thus *nomos* observing (*ennomon*), and the perverted forms are *nomos* neglecting (*paranomon*). Although disputing the character of this implacable succession of the forms of government, Aristotle also based his classification on the number of rulers and distinguished between good and bad forms of government. In his typology it was the rulers' concern for the common good that distinguished the ideal from perverted forms of government. The ideal forms in the Aristotelian scheme are monarchy, aristocracy, and polity (a term conveying some of the meaning of the modern concept of "constitutional democracy"); when perverted by the selfish abuse of power, they are transformed respectively into tyranny, oligarchy, and ochlocracy (or the mob rule of lawless democracy). The concept of the polity, a "mixed" or blended constitutional order, fascinated political theorists for another millennium. To achieve its advantages, innumerable writers from Polybius to St. Thomas Aquinas experimented with the construction of models giving to each social class the control of appropriate institutions of government.

Another very influential classifying scheme was the distinction between monarchies and republics. In the writings of Machiavelli and others, the tripartism of classical typologies was replaced by the dichotomy of princely and republican rule. Sovereignty in the monarchy or the principality is in the hands of a single ruler; in republics, sovereignty is vested in a plurality or collectivity of power holders. Reducing aristocracy and democracy to the single category of republican rule, Machiavelli also laid the basis in his analysis of the exercise of princely power for a further distinction between despotic and nondespotic forms of government. In the work of Montesquieu, for example, despotism, or the lawless exercise of power by the single ruler, is contrasted with the constitutional forms of government of the monarchy and the republic. As a result of the decline of monarchies and the rise of new totalitarian states terming themselves republics, this traditional classification is now, of course, of little more than historical interest.

The usefulness of all the traditional classifications has been undermined by the momentous changes in the political organization of the modern world. Typologies based on the number of power holders or the formal structures of the state are rendered almost meaningless by the standardization of "democratic" forms, the deceptive similarities in the constitutional claims and governmental institutions of regimes that actually differ markedly in their political practices, and the rise of new political orders in the non-Western world. A number of modern writers have attempted to overcome this difficulty by constructing classifying schemes that give primary importance to social, cultural, economic, or psychological factors. The most influential of such schemes is the Marxist typology, which classifies types of rule on the basis of economic class divisions and defines the ruling class as that which controls the means of production in the state. A monistic typology that also emphasized the importance of a ruling class was developed by an Italian theorist of the early 20th century, Gaetano Mosca. In Mosca's writings all forms of government appear as mere facades for oligarchy

Approaches to the analysis of political systems

Modern classifying systems

or the rule of a political "elite" that centres power in its own hands. Another classification, which distinguishes between "legitimate" and "revolutionary" governments, was suggested by Mosca's contemporary Guglielmo Ferrero. Using a sociopsychological approach to the relations between rulers and ruled, Ferrero held that a legitimate government is one whose citizens voluntarily accept its rule and freely give it their loyalty; in revolutionary systems, the government fears the people and is feared by them. Legitimacy and leadership are also the basis of a typology developed by the German sociologist Max Weber. In Weber's scheme there are three basic types of rule: charismatic, in which the authority or legitimacy of the ruler rests upon some genuine sense of calling and in which the followers submit because of their faith or conviction in the ruler's exemplary character; traditional, in which, as in hereditary monarchy, leadership authority is historically or traditionally accepted; and rational-legal, in which leadership authority is the outgrowth of a legal order that has been effectively rationalized and where there is a prevailing belief in the legality of normative rules or commands. The Weberian typology has been elaborated by a number of recent writers who have found it particularly useful for comparing and classifying the emergent political orders of the non-Western world.

A serviceable classification of political systems must penetrate beneath formal appearances to underlying realities; these realities, however, do not consist only of the facts of social and economic organization. Important differences often exist between political systems having very similar socioeconomic structures. That is why some recent sociological classifications and schemes of analysis fail as tools of political inquiry: they cannot effectively distinguish between certain societies whose political orders are full of contrasts. The political system itself must be the primary focus of inquiry and the phenomena of politics the principal facts of investigation. Such an approach may involve many different kinds of analysis, but it must begin with an examination of the ways in which power is acquired and transferred, exercised, and controlled. This is important for comparing advanced political orders and also for drawing important distinctions between regimes in the underdeveloped areas of the world.

GOVERNMENTS CLASSIFIED BY MODE OF SUCCESSION

A key problem of all political orders is that of succession. "The king is dead; long live the king" was the answer, not always uncontested, of European hereditary monarchy to the question of who should rule after the death of the king. A second, closely related problem is in what manner and by whom a present ruler may be replaced or deprived of power. To this second question hereditary monarchy gave no definite answer, although the concept of *diffidatio*, or the severance of the bond of allegiance between king and feudal lord, was invoked more than once in the medieval period. Political systems, even those of primitive tribal societies, have approached both problems in a variety of ways. Anthropological records show that tribal chiefs or kings were sometimes selected as a result of ritual tests or the display of magical signs and proofs of divine origin, usually as determined by the tribal elders or magical leaders; in other cases, a principle of heredity, often diluted by a choice among heirs in terms of physique or warrior ability, was applied; in still other cases, the chief was elected, often from among the adult males of a select group of families. Techniques for the removal of tribal rulers were equally varied. Sometimes the ruler would be killed after a specified period or when his magical powers weakened or when his physical prowess or health failed; in other cases the chief was exposed to periodic tests of his magical powers or required to accept challenges to combat from other qualified candidates for rule; and in some cases the elders could remove him from office.

Techniques for assuring the succession are also varied in the modern world. Succession procedures range from the complex hieratic process of identifying a reincarnated Dalai Lama, which was practiced until quite recently in Tibet, to the subtle, informal procedures by which parliamentary majorities choose a successor to the office of

prime minister in Britain. In fact, however, the succession practices of modern political systems appear to be of four main types: (1) heredity, (2) constitutional prescription, (3) election, and (4) force.

Hereditary succession. Although dictators still occasionally seek to establish their sons as their heirs, they usually rely on force rather than the claims of heredity to achieve their object. Apart from a few states, mostly in the Arab world, where the dynastic ruler is the effective head of the government, the hereditary principle of succession is now almost exclusively confined to the constitutional monarchies of western Europe. There is some irony in the fact that the line of succession is more securely established in these monarchies now than at any point in their earlier history: intradynastic struggle, it appears, is much less likely when kingship is mainly ceremonial. Heredity may be reinforced or modified by constitutional prescription: this was the case, for example, of the famous Act of Settlement that secured the Hanoverian succession in Britain.

Succession by constitutional prescription. A leading example of succession by constitutional prescription is the United States. Article II, Section 1, of the Constitution of the U.S. provides:

In case of the removal of the President from office, or of his death, resignation, or inability to discharge the powers and duties of the said office, the same shall devolve on the Vice President, and the Congress may by law provide for the case of removal, death, resignation, or inability, both of the President and Vice President, declaring what officer shall then act as President, and such officer shall act accordingly, until the disability be removed, or a President shall be elected.

A constitutional amendment was ratified in 1967 elaborating these procedures to include further arrangements for dealing with the problem of presidential disability. The original language of the Constitution has been the basis for the peaceful succession of Vice Presidents John Tyler, Millard Fillmore, Andrew Johnson, Chester Arthur, Theodore Roosevelt, Calvin Coolidge, Harry S. Truman, and Lyndon Johnson. Constitutionally prescribed arrangements for assuring the succession are not always so successful, and many states whose constitutions contain very similar provisions have experienced succession crises that were resolved only by violence.

Succession by election. Election is a principle of succession also frequently combined with force. In cases of closely contested elections or where there is doubt as to the validity or proper form of the election, the result is often a disputed succession. The Great Schism in the papacy in the 14th century and the disputed succession to the elective kingship of Hungary in the 16th century are examples of the failure of elective systems to assure an orderly succession. Force is the effective basis of succession in several contemporary states in which *pro forma* electoral confirmation is given to a ruler who seizes power.

The problem of succession imposes great strains on any political order: the continuity of rule is broken, established patterns of action are interrupted, and the future suddenly becomes uncertain. This political crisis tests the character of regimes in ways that are of some importance for comparative political analysis. A number of interesting comparisons may be drawn from the study of succession practices, but perhaps the most important is the distinction between those systems in which the problem is resolved primarily by force and those systems in which heredity, constitutional prescription, or election assure a peaceful and orderly succession.

Political orders are subjected to another kind of strain when the rule of their present power holders is challenged and the question arises of depriving them of authority. This is the problem of the transfer of power: whether, in what way, and by whom a present ruler may be displaced. Like succession, it is a recurrent problem in all political systems, and, as in the case of succession practices, the ways in which political systems respond to the strains involved offer important clues to their character. It is, in a sense, the fundamental political crisis, for all systems are in some way shaken, often violently, sometimes to the point of destruction, by the struggles between established rulers and their rivals.

The transfer of power

Succession by force. Revolutions, which are the result of the crisis in its most extreme form, involve the overthrow not merely of the government but of the political order itself. Typically, a revolution is preceded by a series of strains within the system: challenges to the authority of the government mount, and its legitimacy is increasingly questioned; the exercise of power becomes coercive, and the challenge to rule assumes ever more violent forms; eventually, the struggle comes to a dramatic climax in the destruction of the old order. The coup d'état is another form of violent response to the crisis of rule, but it is distinguished from the revolution in that it involves the overthrow only of the government: the political order is not immediately affected, for the coup is managed by an individual or group within the government or within the ruling class. In some cases, however, the coup d'état is merely a preliminary stage to revolution. Sometimes this happens when the new ruler leads a governmentally imposed revolution: this was the role played by Napoleon I, Napoleon III, Mussolini, and Hitler. At other times, coups are actually prompted by fear of revolution but succeed only in further weakening the claims to legitimacy of the existing order: this has recently been the case in some countries in the non-Western world where conservative-led coups were quickly overthrown by revolutionary movements. In addition to revolutions and coups d'état, the crisis of rule may prompt other forms of violent political reaction, including civil war and secession, resistance movements and rebellions, guerrilla warfare and terrorism, class warfare, and peasant revolts.

Causes
of the
overthrow
of govern-
ments

The causes of internal conflict leading to the forcible overthrow of governments are extremely varied. They include tensions created by rapid social and economic development; the rise of new social classes and the refusal of established elites to share their power; problems of the distribution of wealth and the grievances of different economic groups and interests; the rise of corrosive social and political philosophies and the estrangement of intellectuals; conflict of opinions over the ends of government; factional struggles among power holders or within the ruling class; the rise of a charismatic leader; oppressive rule that alienates powerful groups; weak rule that tolerates antigovernmental or revolutionary movements; and many different combinations of these and other social, economic, and political factors. All political systems experience some of these conditions with some frequency. Yet there are a number of modern states that have avoided internal wars and the forcible overthrow of their governments for considerable periods.

It appears that rulers in the contemporary world are generally safe from violent challenges if they possess an effective monopoly of military, economic, and political power, linked with certain important social controls; or, alternatively, if they are obliged to exercise limited powers for specified periods and are required to yield office to rivals who meet certain qualifications. The first is the definition of a modern totalitarian regime, fully and efficiently organized; the second describes the governments of several contemporary constitutional democracies. In the first case, the government secures itself by force combined with social and psychological means of preventing the formation of opposition. In the second case, alternatives to internal war are provided by the opportunities for oppositions to influence the exercise of power and ultimately to replace the government. The great achievement of constitutional democracy has been to give reasonable security to governments from forcible overthrow by compelling them to accept limitations on their power, by requiring them to forgo the use of force against rivals who agree to accept the same limitations, and by establishing well-known legal procedures through which these rivals may themselves constitute the government.

Autocratic versus nonautocratic rule. The foregoing discussion has suggested a distinction among political systems in terms of the role played by force in the acquisition and transfer of power. The role of force is vital, also, in distinguishing among political systems in terms of the exercise and control of power. Here the contrast is essentially between "autocratic" and "nonautocratic" governments, for

Autocracy

totalitarianism is only a recent, although very successful, species of autocracy, to which constitutionalism is the principal contemporary antithesis. Autocracy is characterized by the concentration of power in a single centre, be it an individual dictator or a group of power holders such as a committee or a party leadership. This centre relies on force to suppress opposition and to limit social developments that might eventuate in opposition. The power of the centre is not subject to effective controls or limited by genuine sanctions: it is absolute power. In contrast, nonautocratic government is characterized by the existence of several centres, each of which shares in the exercise of power. Nonautocratic rule allows the development of social forces that generate a variety of interests and opinions. It also subjects the power holders to reciprocal controls and to effective sanctions of law.

In appearance, autocracy may sometimes be difficult to distinguish from nonautocratic rule. Often, autocracies attempt to borrow legitimacy by adopting the language of the constitutions of nonautocratic regimes or by establishing similar institutions. It is a common practice, for example, in many modern totalitarian states to establish institutions—parliaments or assemblies, elections and parties, courts and legal codes—that differ little in appearance from the institutional structures of constitutional democracies. Similarly, the language of totalitarian constitutions is often couched in terms of the doctrines of popular rule or democracy. The difference is that in totalitarian regimes neither the institutions nor the constitutional provisions act as effective checks on the power of the single centre: they are essentially facades for the exercise of power through hierarchical procedures that subject all the officials of the state to the commands of the ruling individual or group. The underlying realities of autocratic rule are always the concentration of power in a single centre and the mobilization of force to prevent the emergence of opposition.

Totalitarianism, as already noted, is the most successful of contemporary forms of autocratic rule; it is distinguished from previous forms in its use of state power to impose an official ideology on its citizens. Nonconformity of opinion is treated as the equivalent of resistance or opposition to the government, and a formidable apparatus of compulsion, including various kinds of state police or secret police, is kept in being to enforce the orthodoxy of the proclaimed doctrines of the state. A single party, centrally directed and composed exclusively of loyal supporters of the regime, is the other typical feature of totalitarianism. The party is at once an instrument of social control, a vehicle for ideological indoctrination, and the body from which the ruling group recruits its members.

In the modern world, constitutional democracy is the chief type of nonautocratic government. The minimal definition in institutional terms of a constitutional democracy is that it should provide for a regularized system of periodic elections with a free choice of candidates, the opportunity to organize competing political parties, adult suffrage, decisions by majority vote with protection of minority rights, an independent judiciary, constitutional safeguards for basic civil liberties, and the opportunity to change any aspect of the governmental system through agreed procedures. Two features of constitutional democracy require emphasis in contrasting it with modern totalitarian government: the constitution, or basic law, and the political party. A constitution, as the example of British constitutional democracy suggests, need not be a single written instrument; indeed, the essence of a constitution is that it formalizes a set of fundamental norms governing the political community and determining the relations between the rulers and the people and the interaction among the centres of power. In most modern constitutional democracies, however, there is a constitutional document providing for fixed limitations on the exercise of power. These provisions usually include three major elements: an assignment of certain specified state functions to different state organs or offices, the delimitation of the powers of each organ or office, and the establishment of arrangements for their cooperative interaction; a list of individual rights or liberties that are protected against the

Constitu-
tional
democracy

exercise of state power; and a statement of the methods by which the constitution may be amended. With these provisions a concentration of power in the hands of a single ruler is prevented, certain areas of political and social life are made immune to governmental intervention, and peaceable change in the political order is made possible. The political party is the other chief instrument of constitutional democracy, for it is the agency through which the electorate is involved in both the exercise and transfer of power. In contrast with the centralized, autocratic direction of the totalitarian single-party organization, with its emphasis on ideological conformity and restricted membership, the political parties of constitutional democracy are decentralized, concerned with the integration of many interests and beliefs, and open to public participation. In constitutional democracies there is usually some measure of competition among two or more parties, each of which, if it cannot hope to form a future government, has some ability to influence the course of state action. The party in a constitutional democracy is at once a means of representing a mass electorate in the exercise of power and also a device for allowing the peaceful replacement of one set of power holders with another.

The distinction between autocratic and nonautocratic rule should not conceal the existence of intermediate types that combine elements of both. In these cases, also, the best procedure for comparative purposes is to investigate the power configurations underlying the formal structures and to examine the extent to which power is concentrated in a single centre or the role that is played by force in the maintenance of the regime. It is a type of analysis that, by guiding attention to the relative weight of coercive and consensual power and the scope of individual freedom in the political order, allows comparisons between systems in terms of their most important attributes.

GOVERNMENTS CLASSIFIED BY STAGE OF DEVELOPMENT

Political life is shaped by a wide variety of factors, including social and cultural conditions, economic organization, intellectual and philosophical influences, geography or climate, and historical circumstance. Recurrent attempts have been made to reduce this range of variables to analytically manageable dimensions. This is partly the motive, for example, of Marxist and other efforts to relate specific types of political systems to stages of economic development or particular kinds of socioeconomic organization. Although interesting interrelations between political and economic development have been discovered, such monistic, or single-factor, approaches are inadequate to the task of explaining political change. The problem is not only that there are many factors that should be examined but also that they are found in different combinations from one society to another. All political orders are unique as products of history and creations of the peculiar forces and conditions of their environment. A second problem that confronts comparative analysis is the difficulty of devising measures of political development. The definition of what is modern or what constitutes an advanced or developed political system has troubled many recent writers. Clearly, the older notions of development toward the goals of constitutionalism or democracy must now be seriously questioned, and to judge the maturity of a political system in terms of the extent to which it adopts any particular set of institutions or techniques of rule is an equally doubtful procedure. Another difficulty is that political change is not simply a reaction to "objective" factors such as economic forces but also the product of conscious manipulation. In explaining the growth and development of political systems it is impossible to ignore the fact that men, having considered the advantages and disadvantages of different forms of government, often decide to adopt one form rather than another. A similar problem arises from the fact that the nature of the interaction between political systems and their environment is extremely complex. For example, to treat the political system as merely the outgrowth of particular patterns of social or economic organization is to ignore the fact that changes in social and economic structures are often the product, sometimes the intended product, of governmental action.

These difficulties of analysis have prevented the emergence of any satisfactory theory to explain the processes of political change or growth. In the absence of such a theory, however, several writers have recently attempted to identify certain basic phases in the development of national political systems. For example, five major steps in the emergence of the advanced nation-states of the modern world are often distinguished: (1) unification and independence or autonomy; (2) development and differentiation of political institutions and political roles; (3) transfer of power from traditional elites; (4) further institutional and political role differentiation accompanied by the development of a number of organized social interests and growth in governmental functions; and (5) use of state power in attempts to guide or control social and economic activity, extensive exploitation of resources as the result of technological development, and full participation in the international political system.

Other writers distinguish among "traditional," "transitional," and "modern" societies in an effort to identify differences and regularities in social, economic, cultural, and political development. The social structure of the traditional society is described as hierarchical, class bound, based on kinship, and divided into relatively few effectively organized social groupings; its economic basis is primarily agricultural, and industry and commerce are relatively undeveloped; its political institutions are those of sacred monarchy, rule by a nobility, and various forms of particularism. The social system of the transitional society is typified by the formation of new classes, especially a middle class and a proletariat, and conflict among ethnic, religious, and cultural groupings; its economic system experiences major tensions as the result of technological development, the growth of industry, urbanization, and the use of rapid communications; its political institutions are typically authoritarian, although constitutional forms also make their appearance. Modernity is seen as the age of high social mobility, equality, universal education, mass communications, increasing secularism, and sociocultural integration; in its economic system, the modern society experiences a further technological revolution, massive urbanization, and the development of a fully diversified economy; its political institutions are those of democracy and modified totalitarianism, and, in either case, a specialized bureaucracy is used to carry on the expanding functions of government.

These efforts to identify stages of "modernization" are poor substitutes for a general theory of political change, but they serve to emphasize the increasing complexity of all the structures—social, economic, and political—of the modern state. The elaboration of the institutions and procedures of modern government appears to be partly a reflection of the social and economic forces at work in the contemporary world and partly the result of efforts to control these forces through governmental action. The complex structures of advanced political orders are treated in the discussion that follows.

The structure of government

The study of governmental structures must be approached with great caution, for political systems having the same kind of legal arrangements and using the same type of governmental machinery often function very differently. A parliament, for example, may be an important and effective part of a political system; or it may be no more than an institutional facade of little practical significance. A constitution may provide the framework within which the political life of a state is conducted; or it may be no more than a piece of paper, its provisions bearing almost no relationship to the facts of political life. Political systems must never be classified in terms of their legal structures alone: the fact that two states have similar constitutions with similar institutional provisions and legal requirements should never, by itself, lead to the conclusion that they represent the same type of political system.

To be useful, the study of governmental structures must always proceed hand in hand with an investigation of the actual facts of the political process: the analyst must exer-

Steps in the emergence of advanced nation-states

The difficulties of analyzing political change

cise the greatest care in distinguishing between form and reality and between prescription and practice. Approached in this way, an examination of the organizational arrangements that governments use for making decisions and exercising power can be a valuable tool of political inquiry.

CONTEMPORARY FORMS OF GOVERNMENT

The
rapidity of
change

Few states in the modern world have constitutional arrangements that are more than a century old. Indeed, the vast majority of all the world's states have constitutions written in the 20th century. This is true of states, such as Germany, Italy, and Japan, that were defeated in World War II and of other states, such as the Soviet Union, Spain, and China, that have experienced civil war and revolutions in the course of the century. Great Britain and the United States are almost alone among major contemporary nation-states in possessing constitutional arrangements that predate the 20th century.

Even in Britain and the United States, the 20th century has seen much change in the governmental system. In the United States, for example, the relationship of legislature and executive at both the national and the state levels has been significantly altered by the growth of bureaucracies and the enlargement of the executive's budgetary powers. In Britain, even more far-reaching changes have occurred in the relationship between the prime minister and Parliament and in Parliament's role in supervising the executive establishment. In both countries, the appearance of the welfare state, the impact of modern technology on the economy, and international crises have resulted in major alterations in the ways in which the institutions of government function and interact.

The modern student of constitutional forms and institutional arrangements confronts an endlessly changing world. In many parts of the world, in countries as different as France, Pakistan, Argentina, Tanzania, and South Vietnam, there are continuing experiments with new constitutions. All systems, moreover, even without formal constitutional change, undergo a continual process of adjustment and mutation as their institutional arrangements respond to and reflect changes in the social order and the balance of political forces.

Decline of
traditional
monarchy

Monarchy. The ancient distinction among monarchies, tyrannies, oligarchies, and constitutional governments, like other traditional classifications of political systems, is no longer very descriptive of political life. A king may be a ceremonial dignitary in one of the parliamentary democracies of western Europe, or he may be an absolute ruler in one of the emerging states of North Africa, the Middle East, or Asia. In the first case his duties may be little different from those of an elected president in many republican parliamentary regimes; in the second his role may be much the same as that of countless dictators and strong men in autocratic regimes throughout the underdeveloped areas of the world.

It may be said of the reigning dynasties of modern Europe that they have survived only because they failed to retain or to acquire effective powers of government. Royal lines have been preserved only in those countries of Europe in which royal rule was severely limited prior to the 20th century or in which royal absolutism had never firmly established itself. More successful dynasties, such as the Hohenzollerns in Germany, the Habsburgs in Austria-Hungary, and the Romanovs in Russia, which continued to rule as well as to reign at the opening of the present century, have paid with the loss of their thrones. Today, in countries such as Great Britain or The Netherlands or Denmark, the monarch is the ceremonial head of state, an indispensable figure in all great official occasions and a symbol of national unity and of the authority of the state; but he is almost entirely lacking in power. Monarchy in the parliamentary democracies of modern Europe has been reduced to the status of a dignified institutional facade behind which the functioning mechanisms of government—cabinet, parliament, ministries, and parties—go about the tasks of ruling.

The 20th century has also seen the demise of most of the hereditary monarchies of the non-Western world. Thrones have toppled in Turkey, in China, in most of the

Arab countries, in the principates of India, in the tribal kingdoms of Africa, and in several countries of Southeast Asia. The kings who maintain their position do so less by the claim of legitimate blood descent than by their appeal as popular leaders responsible for well-publicized programs of national economic and social reform or as national military chieftains. In a sense, these kings are less monarchs than monarchs, and their regimes are little different from several other forms of one-man rule found in the modern world.

Dictatorship. While royal rule, as legitimized by blood descent, has almost vanished as an effective principle of government in the modern world, monarchy—a term that comprehends the rule of the remaining non-Western royal absolutists, of the generals and strongmen of Latin America and Asia, of the messianic leaders of postcolonial Africa, and of the totalitarian heads of Communist and Fascist states—still flourishes. Indeed, the 20th century, which has witnessed the careers of Kemal Atatürk, Benito Mussolini, Adolf Hitler, Joseph Stalin, Francisco Franco, Mao Tse-tung, Juan Perón, Tito, Gamal Abdel Nasser, Sukarno, Kwame Nkrumah, and Charles de Gaulle, could appear in history as the age of plebiscitary dictatorship.

The contemporary world provides examples of several types of monocratic or dictatorial rule. In many of the new states of Africa and Asia, for example, dictators quickly established themselves on the ruins of constitutional arrangements inherited from Western colonial powers. In some of these countries, presidents and prime ministers captured personal power by banning opposition parties and building primitive replicas of the authoritarian one-party systems of the Communist world. In other new countries the armies seized power, and military dictatorships were established. Whether as presidential dictatorships or as military dictatorships, the regimes that came into being appear to have had common roots in the social and economic problems of the new state. The constitutional systems inherited from the colonial powers proved unworkable in the absence of a strong middle class; local traditions of autocratic rule retained a powerful influence; the army, one of the few organized forces in society, was also often the only force capable of maintaining order; and a tiny intellectual class was impatient for economic progress, frustrated by the lack of opportunity, and deeply influenced by the example of authoritarianism in other countries. The dictatorships that resulted proved highly unstable, and few of the individual dictators were able to satisfy for long the demands of the different groups that supported their bids for power.

Monocratic
rule

Although similar in some respects to the dictatorships of the new nations, the caudillos of 19th- and 20th-century Latin America represent a very different type of monocratic rule. In its 19th-century form, *caudillismo* was the result of the breakdown of central authority. After a brief period of constitutional rule, each of the former Spanish colonies in the Americas experienced a collapse of effective national government. A self-proclaimed leader, usually an army officer, heading a private army typically formed from the peasantry with the support of provincial landowners, established his control over one or more provinces, and then marched upon the national capital. The famous 19th-century caudillos—Antonio López de Santa Anna of Mexico or Juan Manuel de Rosas of Argentina, for example—were thus essentially provincial leaders who seized control of the national government to maintain the social and economic power of provincial groups. The 20th-century dictatorships in Latin-American countries have had different aims. The modern caudillo is less a provincial than a national leader. The Perón regime, for example, was established by nationalistic army officers committed to a program of national reform and various ideological goals. Often, too, the dictators of contemporary Latin America have allied themselves with a particular social class, attempting either to maintain the interests of established economic groupings or to press far-reaching social reforms.

Dictatorship in the technologically advanced, totalitarian regimes of modern Communism or Fascism is distinctly different from the authoritarian regimes of either

Latin America or the new states of Africa and Asia. Nazi Germany under Hitler and the Soviet Union under Stalin are the leading examples of modern totalitarian dictatorships. The crucial elements of both were the identification of the state with the single mass party and of the party with its charismatic leader, the use of an official ideology to legitimize and maintain the regime, the employment of a terroristic police force and a controlled press, and the application of all the means of modern science and technology to control the economy and individual behaviour. The two systems, however, may be distinguished in several ways. Fascism, in its National Socialist form, was primarily a counterrevolutionary movement that mobilized middle and lower middle class groups to pursue nationalistic and militaristic goals and whose sole principle of organization was obedience to the Führer. By contrast, Soviet Communism grew out of a revolutionary theory of society, pursued the goal of revolutionary overthrow of capitalist systems internationally, and employed the complex bureaucratic structures of the Communist Party as mechanisms of governmental organization.

Western constitutional democracies have provided examples of another type of contemporary dictatorship. At various points in the 20th century, during periods of domestic or foreign crisis, most constitutional regimes have conferred emergency powers on the executive, suspending constitutional guarantees of individual rights or liberties, or declaring some form of martial law. Indeed, the constitutions of some Western democracies explicitly provide for the grant of emergency powers to the executive in a time of crisis in order to protect the constitutional order. In many cases, of course, such provisions have been the instruments by which dictators have overthrown the regime. Thus, the proclamation of emergency rule was the beginning of the dictatorships of Mussolini in Italy, of Kemal Atatürk in Turkey, of Józef Piłsudski in Poland, of António de Oliveira Salazar in Portugal, of Franz von Papen and Hitler in Germany, and of Engelbert Dollfuss and Kurt von Schuschnigg in Austria. In other democracies, however, constitutional arrangements have survived quite lengthy periods of crisis government. After World War II, for example, in both the United States and Britain, the use of extraordinary powers by the executive came to a halt with the end of the wartime emergency. Similarly, although the 1958 constitution of the Fifth Republic of France contained far-reaching emergency powers conferred on the president—"when the institutions of the Republic, the independence of the nation, the integrity of its territory or the fulfillment of its international obligations are threatened with immediate and grave danger, and when the regular functioning of the constitutional authority is interrupted"—their implicit threat to the constitutional order has not been realized.

Many forces at work in the 20th century appear to lend impetus to the rise of monocratic forms of rule. In nearly all political systems, the powers of chief executives have increased in response to the demanding social, economic, and military crises of the age. The complex decisions required of governments in a technological era, the perfectionist impulses of the great bureaucratic structures that have developed in all industrialized societies, and the imperatives of national survival in a nuclear world continue to add to the process of executive aggrandizement. The question for many constitutional regimes is whether the limitation and balance of power that are at the heart of constitutional government can survive the growing enlargement of executive power.

Oligarchy. In the Aristotelian classification of government there were two forms of rule by the few: aristocracy and its debased form, oligarchy. Although the term oligarchy is rarely used to refer to contemporary political systems, the phenomenon of irresponsible rule by small groups has not vanished from the world.

Many of the classical conditions of oligarchic rule were found until recently in those parts of Asia in which governing elites were recruited exclusively from a ruling caste—a hereditary social grouping set apart from the rest of society by religion, kinship, economic status, prestige, and even language. In the contemporary world, in some

countries that have not experienced the full impact of industrialization, governing elites are still often recruited from a ruling class—a stratum of society that monopolizes the chief social and economic functions in the system. Such elites exercise power in the interests of their class.

The simple forms of oligarchic rule associated with pre-industrial societies are, of course, rapidly disappearing. Industrialization produces new, differentiated elites that replace the small leadership groupings that once controlled social, economic, and political power in the society. The demands of industrialization compel recruitment on the basis of skill, merit, and achievement, rather than on the basis of inherited social position and wealth. New forms of oligarchic rule have also made their appearance in many advanced industrial societies. Although governing elites in these societies are no longer recruited from a single class, they are often not subjected to effective restraints on the exercise of their power. Indeed, in some circumstances, the new elites may use their power to convert themselves into a governing class whose interests are protected by every agency of the state. This is the criticism that is made, for example, of the Communist Party bureaucracy in the Soviet Union and in some eastern European states.

Oligarchic tendencies of a lesser degree have been detected in all the great bureaucratic structures of advanced political systems. The growing complexity of modern society and its government thrusts ever greater power into the hands of administrators and committees of experts. Even in constitutional regimes, no fully satisfactory answer has been found to the question of how these bureaucratic decision makers can be held accountable and their powers effectively restrained without, at the same time, jeopardizing the efficiency and rationality of the policy-making process.

Constitutional government. Constitutional government is defined by the existence of a constitution—which may be a legal instrument or merely a set of fixed norms or principles generally accepted as the fundamental law of the polity—that effectively controls the exercise of political power. The essence of constitutionalism is the control of power by its distribution among several state organs or offices in such a way that they are each subjected to reciprocal controls and forced to cooperate in formulating the will of the state. Although constitutional government in this sense flourished in England and in some other historical systems for a considerable period, it is only recently that it has been associated with forms of mass participation in politics. In England, for example, constitutional government was not harnessed to political democracy until after the Reform Act of 1832 and subsequent 19th-century extensions of the suffrage. In the contemporary world, however, constitutional governments are also generally democracies, and they are usually referred to as constitutional democracies or constitutional-democratic systems.

The contemporary political systems that combine constitutionalism and democracy share a common basis in the primacy they accord to the will of the majority of the people as expressed in free elections. In all such systems, political parties are key institutions, for they are the agencies by which majority opinion in a modern mass electorate is mobilized and expressed. Indeed, the history of the political party in its modern form is coincidental with the development of contemporary constitutional-democratic systems. In each case, the transition from the older forms of constitutionalism to modern constitutional democracy was accompanied by the institutionalization of parties and the development of techniques of party competition. The essential functions of political parties in a constitutional democracy are the integration of a multitude of interests, beliefs, and values into one or more programs or proposals for change and the nomination of party members for elective office in the government. In both functions, the party serves as a link between the rulers and the ruled: in the first case by allowing the electorate to register an opinion on policy and in the second by giving the people a chance to choose their rulers. Of course, the centralized, autocratically directed, and ideologically orthodox one-party systems of contemporary totalitarian regimes perform neither of these functions.

The British
and U.S.
systems
compared

The two major types of constitutional democracy in the modern world are exemplified by the United States and Great Britain. The United States is the leading example of the presidential system of constitutional democracy; Britain, although its system is sometimes referred to as a cabinet system, in recognition of the role of the Cabinet in the government, is the classic example of the parliamentary system. The U.S. presidential system is based on the doctrine of separation of powers and distinguishes sharply between the personnel, although not between the functions, of the legislature and the executive; the British parliamentary system provides for the integration or fusion of legislature and executive. In the U.S. system the separation of legislature and executive is reinforced by their separate election and by the doctrine of checks and balances that provides constitutional support for routine disagreements between the branches; in the British system the integration of legislature and executive is reinforced by the necessity for their constant agreement, or for a condition of "confidence" between the two, if the normal processes of government are to continue. In the U.S. system, reciprocal controls are provided by such devices as the presidential veto of legislation (which may be overridden by a two-thirds majority in Congress), the Senate's role in ratifying treaties and confirming executive nominations, congressional appropriation of funds, and judicial review of legislation; in the British system, the major control device is the vote of "no confidence" or the rejection of legislation that is considered vital.

The prestige of constitutional democracy was once so great that many thought all the countries of the world would eventually accede to the examples of the United States or Britain and establish similar arrangements. Recent history, however, has confounded this expectation. The collapse of the Weimar Constitution in Germany in the 1930s and the recurrent political crises of the Fourth Republic in France after World War II suggested that constitutional democracy, even in advanced systems, carries no guarantee of stability. The failure of both presidential and parliamentary systems to work as expected in less advanced countries that modelled their constitutions on those of the United States and Britain resulted in a further diminution in the prestige of both systems. Successful examples of established constitutional democracies are now limited to a dozen or so northwest European and North American countries, together with New Zealand and Australia in the Pacific. Systems in which experiments are being made in the use of constitutional-democratic arrangements with some degree of success include Mexico, Uruguay, Chile, the Philippines, India, and Malaya. In all these countries, constitutionalism and democracy have combined to produce political change under conditions of relative stability.

CONTEMPORARY LEVELS OF GOVERNMENT

Feudalism

Most national societies have passed through a stage in their social and political development, usually referred to as feudalism, in which a weak and ineffectively organized national government competes for territorial jurisdiction with local power holders. In medieval England and France, for example, the crown was perennially threatened by the power of the feudal nobles, and a protracted struggle was necessary before the national domain was subjected to full royal control. Elsewhere, innumerable societies continued to experience this kind of feudal conflict between local magnates and the central government well into the modern era. The warlords of 19th- and 20th-century China, for example, were just as much the products of feudal society as the warring barons of 13th-century England and presented the same kind of challenge to the central government's claim to exercise sovereign jurisdiction over the national territory. By the 1970s, feudalism was almost extinct. The social patterns that had formerly supported the power of local landowners were rapidly disappearing, and central governments had generally acquired a near monopoly of communications and military technology, enabling them to project their power into areas once controlled by local rulers.

In nearly all national political systems, central govern-

ments are better equipped than ever before to exercise effective jurisdiction over their territories. In much of the underdeveloped world, nationalist political movements and a variety of modern economic forces have swept away the traditional structures of local government, and the quasi-autonomous governments of village and tribe and province have been replaced by centrally directed systems of subnational administration. Even in the heavily industrialized states of the modern world, there has been an accelerating tendency toward greater centralization of power at the national level. In the United States, for example, the structure of relationships among the governments at the national, state, and local levels has changed in a number of ways to add to the power of the federal government in Washington. Even though the system of national grants-in-aid appears to have been designed as a means of decentralizing administration, the effect has been decidedly centralist, for the conditional character of the grants has allowed the federal government to exercise influence on state policies in fields that were once invulnerable to national intervention.

National government. The nation-state is the dominant type of political system in the contemporary world, and nationalism, or the creed that centres the supreme loyalty of the people upon the nation-state, is the dominating force in international politics. The national ideal triumphed as a result of the wars of the 19th and 20th centuries. The Napoleonic Wars, which spread the doctrines of the French Revolution, unleashed nationalism as a force in Europe and led to the Risorgimento in Italy and the emergence of Bismarck's Germany. The two world wars of the 20th century carried the principles of national self-determination and liberal democracy around the world and gave birth to the independence movements that resulted in the foundation of new states in eastern Europe in 1919 and the emergence from colonial status of countries in Asia and Africa after 1945.

All the major forces of world politics—war and the threat of war, the development of national economies, the demand for social services, and many others—have reinforced the national state as the primary focus of people's loyalties. Wars have played the major part in strengthening national governments and weakening political regionalism and localism. The attachments that people have to subnational political communities are loosened when they must depend for their security on the national power. Even in the new age of total war—which few nations are capable of waging and even fewer of surviving—people look for their security to national governments rather than to international organizations. In nearly all contemporary states, the national budget is dominated by expenditures for defense, the military employs the largest fraction of the work force, and questions of national security pervade the discussion of politics.

The lesson of the last three decades is that national sovereignty remains the most important obstacle to the emergence of new forms of supranational government and to effective international cooperation. Almost everywhere, attempts to achieve federation and other forms of multinational communication have foundered on the rocks of nationalism. The collapse of the Federation of Rhodesia and Nyasaland and the Federation of Malaya are paralleled by the failure of the Organization of American States and the Arab League: in all cases, nationalism has been the divisive force. National sovereignty has been successfully limited in only two major areas of the contemporary world: in eastern Europe, where, as a result of Soviet occupation, a number of formerly independent states were subjected to a form of centralized control from Moscow; and in western Europe, where several nation-states joined in a loose confederation (the European Economic Community) to achieve certain economic goals. Even in these cases, nationalism has been a major threat to continued unity. Several of the countries of eastern Europe have recently declared their independence of Moscow, and France under President de Gaulle made clear its hostility to any form of supranational union of the countries belonging to the European Economic Community.

At the international level, anarchy is the principal form

The
nation-
state

of contemporary rule, for the nation-state's freedom of action is limited only by its power. Some forces are at work, however, that may eventually lead to a lessening of the role of the nation-state and to the emergence of effective supranational governments. The first of these is industrial and commercial development. The development of national industries in the 19th and early 20th centuries played a major part in strengthening national as against regional and local political entities, but the scale of economic activity has now outgrown national markets. Industrial combines and commercial groupings have emerged that cross national frontiers and require international markets. This integrative influence of economic development may be assisted by the threat of nuclear war. Many national frontiers can no longer be adequately defended in the era of the intercontinental missile, and many states, even some that were until recently great powers, are incompetent to preserve themselves. Together these forces may assist the progress of efforts to develop new kinds of cooperative union among nation-states.

Although the failure of efforts to achieve world government and to develop an effective system of international law may be regretted, it should perhaps be remembered that the nation-state continues to function as an extremely effective system for maintaining order within its boundaries. In some cases, this is achieved with remarkably little coercion and in such a way that the progress of civilization is encouraged. In the conditions of our age, world government might well involve much higher levels of coercion and much less civilization.

Decline of
regional
and state
government

Regional and state government. The 18th-century political philosopher Montesquieu wrote that governments are likely to be tyrannical if they are responsible for administering large territories, for they must develop the organizational capacity characteristic of despotic states. It was partly this fear that led the American founding fathers to provide for a federal system and to divide governmental functions between the government in Washington and the state governments. Modern technology and mass communication are often said to have deprived Montesquieu's axiom of its force. Yet the technology that makes it possible for large areas to be governed democratically also holds out the spectre of an even greater tyranny than Montesquieu foresaw.

In all political systems the relationships between national and regional or state governments have been affected by technology and new means of communication. In the 18th century Thomas Jefferson, in arguing that local government, or the government closest to the people, was best, could claim that citizens knew most about their local governments, somewhat less about their state governments, and least about the national government. In the present-day United States, however, the concentration of the mass media on the issues and personalities of national government has made nonsense of this proposition. As several recent studies have demonstrated, people know much less about local government than national government and turn out to vote in much larger numbers in national elections. The necessity for employing systems for the devolution of political power is reduced when a central government can communicate directly with citizens in all parts of the national territory, and the vitality of subnational levels of government is sapped when public attention is focussed on national problems.

Another general development that has lessened the importance of regional or state government is the rise of efficient national bureaucracies. In nearly all political systems, there has been some tendency toward bureaucratic centralization, and in some cases national bureaucracies have almost completely replaced older systems of regional and provincial administration. In the United States, for example, complex programs of social security, veterans' benefits, income taxes, agricultural subsidies, and many others that bear directly on individuals are centrally administered; and great agencies of government, such as the Department of Health and Human Services, maintain regional and local offices for the supervision of other national activities.

Even in systems in which a division of functions between

national and subnational governments is constitutionally prescribed, the prevailing trend in intergovernmental relations is toward increasing involvement of the national government in areas once dominated by regional or state governments. Thus, the original constitutional arrangements prescribed by the Allied powers for the West German republic in 1949 won general acclaim at the time because they provided for greater decentralization than had the Weimar Constitution; but, as soon as Germany was free to amend its own constitution, several state functions were reassigned to the national government. In the United States, also, the collapse of the doctrine of "dual federalism," according to which the powers of the national government were restricted by the powers reserved to the states, signalled the end of an era in which the states could claim exclusive jurisdiction over a wide range of functions. Today, forms of cooperative federalism involving joint action by national and state governments are increasingly common. Such cooperative relationships in the United States include programs of public assistance, the interstate-highway system, agricultural extension programs, and aid to education. In some areas, such as school desegregation, the national government has used broad powers to compel states to conform to national standards.

Efforts made to halt the trend toward centralization and to re-invigorate regional or state governments have met with little success. In the U.S. a Commission on Intergovernmental Relations established by President Eisenhower in 1953 concluded that it could recommend no major reversion of functions to state governments. Similarly, efforts in France and Italy to decentralize parts of the national administrations have had few practical results. Political regionalism appears to be in steep decline almost everywhere, whether in China or in the American South. The attachments that bind people to localities and allow the growth of genuine subnational political communities have weakened under the impact of technology and the growth of national economies. Only where political regionalism has always been a cloak for movements of national independence—for example, in Scotland, Wales, Northern Ireland, Quebec, and Brittany—are there popular attempts to reverse the trend toward national centralization.

City and local government. Political scientists since Aristotle have recognized that the nature of political communities changes when their populations grow larger. One of the central problems of contemporary government is the vast increase in urban population and the progression from "polis to metro-polis to mega-polis." The catalog of ills that have resulted from urban growth includes political and administrative problems of extraordinary complexity.

The rise of great urban centres has had a major impact on the politics of all advanced industrial societies. In the United States, for example, the issues of metropolitan politics have become key political issues at the national level. Programs relating to urban renewal, mass-transit systems, school desegregation, and air and water pollution have become of pressing national importance, along with other social problems of the metropolis, such as urban crime, juvenile delinquency, the disorganization of the family, ghetto conditions, and unemployment. The growing involvement of the national government with such issues is in part a consequence of the impoverishment of the cities and the collapse of effective municipal government. The tax base of U.S. cities has dwindled with the flight of the middle classes to the suburbs and the relocation of industry; at the same time, although "bossism" and machine politics have almost vanished, newer forms of city governments have failed to establish effective systems of administration or to win support from stable majorities of city voters. In part, too, the national government gives priority to such issues because of the political power of the urban areas: cities have become the focuses of national politics, for they are rich in the votes that decide national campaigns. Aside from such fiscal and political pressures, the national government is inevitably concerned with the threat posed by racial conflict, ghetto violence, and other kinds of social chaos in the city.

The metropolis suffers from several acute governmental and administrative failures. Responsibility for the issues

The urban
metropolis

that transcend the boundaries of local governments has not been defined, for representative institutions have failed to develop at the metropolitan level. In most cases, there are no effective governmental structures for administering area-wide services or for dealing comprehensively with the common problems of the metropolitan community. The result has been the appearance of a new class of problems created by government itself, including uneven levels of service for metropolitan residents, inequities in financing government services and functions, and variations in the democratic responsiveness of the governments scattered through the metropolitan area. The tangled pattern of local governments, each operating in some independent sphere, does not allow the comprehensive planning necessary to deal with the escalating problems of urban life.

Efforts to create new governing structures for metropolitan communities are among the most interesting developments in contemporary government. In the United States these efforts include the creation of special districts to handle specific functions, area-wide planning agencies, interstate compacts, consolidated school and library systems, and various informal intergovernmental arrangements. Although annexation of outlying areas by the central city and city-county consolidations have been attempted in many cases, the reluctance of urban areas to surrender their political independence or to pay for central-city services has been an obstacle. The Los Angeles plan, by which the county has assumed responsibility for many area-wide functions, leaving the local communities with substantial political autonomy, may represent a partial solution to the problem of urban-suburban tensions. In other cases, "metropolitan federation" has been attempted. One of the earliest and most influential examples of a federated system of metropolitan government is the Greater London Area in Britain, which encompasses 32 London boroughs and places effective governing powers in the hands of an elected city council. In Canada the city of Toronto and its suburbs adopted a metropolitan "constitution" in 1953 under which mass transit, highways, planning, and several other functions are controlled by a council composed of elected officials from the central city and surrounding governments. In 1957 Miami and Dade counties in Florida chose "metro" government: Miami and 27 suburban cities retained control of local functions, while area-wide functions such as fire and police protection and transportation were allocated to the new federal structure. In 1962 Nashville, Tennessee, combined with Davidson County to form a single metropolitan government; and in 1968 Jacksonville, Florida, joined with Duval County in a similar arrangement. Other examples of various degrees of area-wide consolidation in the United States include Baton Rouge, Louisiana; Seattle, Washington; Portland, Oregon; and Indianapolis, Indiana.

Most of the major problems of contemporary politics seem to have found their focus in the metropolis, and there is almost universal agreement that new governing systems must be devised for the metropolitan community if the problems are ever to be resolved.

CONTEMPORARY DIVISIONS OF GOVERNMENT

In his *Politics*, Aristotle differentiated three categories of state activity—deliberations concerning common affairs; decisions of executive magistrates, and judicial rulings—and indicated that the most significant differences among constitutions concerned the arrangements made for these activities. This threefold classification is not precisely the same as the modern distinction among legislature, executive, and judiciary. Aristotle intended to make only a theoretical distinction among certain state functions and stopped short of recommending that they be assigned as powers to separate organs of government. Indeed, since Aristotle held that all power should be wielded by one man, pre-eminent in virtue, he never considered the concept of separated powers. In the 17th century the English political philosopher John Locke also distinguished the legislative from the executive function but, like Aristotle, failed to assign these to separate organs or institutions. Montesquieu was the first to make the modern division among legislative, executive, and judiciary. Arguing that the purpose

of political association is liberty, not virtue, and that the very definition of liberty's great antagonist, tyranny, is the accumulation of all power in the same hands, he urged the division of the three functions of government among three separate institutions. After Montesquieu, the concept of separation of powers became one of the principal doctrines of modern constitutionalism. Nearly all modern constitutions, from the document written at Philadelphia in 1787 through the French Declaration of the Rights of Man and of the Citizen of August 1789 up to the constitutions of the new states of Africa and Asia, provide for the separate establishment of legislative, executive, and judiciary. The functional division among the branches of government is never precise. In the American system, for example, the doctrine of checks and balances justifies several departures from the strict assignment of functions among the branches. Parliamentary forms of government depart even further from the concept of separation and integrate both the personnel and the functions of the legislature and the executive. Indeed, the principle of shared rather than separated powers is the true essence of constitutionalism. In the constitutional state, power is controlled because it is shared or distributed among the divisions of government in such a way that they are each subjected to reciprocal checks and forced to cooperate in the exercise of political power. In the nonconstitutional systems of totalitarianism or autocracy, although there may be separate institutions such as legislatures, executives, and judiciaries, power is not shared but rather concentrated in a single organ. Because this organ is not subjected to the checks of shared power, the exercise of political power is uncontrolled or absolute.

The legislature. The characteristic function of all legislatures is the making of law. In most systems, however, legislatures also have other tasks, such as selection and criticism of the government, supervision of administration, appropriation of funds, ratification of treaties, impeachment of executive and judicial officials, acceptance or refusal of executive nominations, determination of election procedures, and public hearings on petitions. Legislatures, then, are not simply lawmaking bodies. Neither do they monopolize the function of making law. In most systems the executive has a power of veto over legislation, and, even where this is lacking, the executive may exercise original or delegated powers of legislation. Judges, also, often share in the lawmaking process, through the interpretation and application of statutes or, as in the U.S. system, by means of judicial review of legislation. Similarly, administrative officials exercise quasi-legislative powers in making rules and deciding cases that come before administrative tribunals.

Legislatures differ strikingly in their size, the procedures they employ, the role of political parties in legislative action, and in their vitality as representative bodies. In size, the British House of Commons, with 630 members, is among the largest; the Icelandic lower house, with 40, the New Zealand House of Representatives, with 80, and the Senate of Nevada, with 17 members, are among the smallest. Most legislatures are bicameral, although New Zealand, Denmark, the state of Queensland, in Australia, and Nebraska, in the United States, have all abolished their second chambers. The procedures of the United States House of Representatives, which derive from a manual of procedure written by Thomas Jefferson, are among the most elaborate of parliamentary rules, requiring study and careful observation over a considerable period before members become proficient in their manipulation. Voting procedures range from the formal procession of the division or teller vote in the British House of Commons to the electric voting methods employed in the California legislature and in some other American states. Another point of difference among legislatures concerns their presiding officers. These are sometimes officials who stand above party and, like the speaker of the British House of Commons, exercise a neutral function as parliamentary umpires; sometimes they are the leaders of the majority party and, like the speaker of the United States House of Representatives, major political figures; and sometimes they are officials who, like the vice president of the United

and
judicial
functions

States in his role as presiding officer of the Senate, exercise a vote to break ties and otherwise perform mainly ceremonial functions.

Legislative parties are of various types and play a number of roles or functions. In the United States House of Representatives, for example, the party is responsible for assigning members to all standing committees; the party leadership fills the major parliamentary offices, and the party membership on committees reflects the proportion of seats held by the party in the House as a whole. The congressional party, however, is not disciplined to the degree found in British and some other European legislative parties, and there are relatively few "party line" votes in which all the members of one party vote against all the members of the other party. In the House of Commons, party-line voting is general; indeed, it is very unusual to find members voting against their party leadership, and, when they do, they must reckon with the possibility of penalties such as the "withdrawal of the whip" or the loss of their official status as party members.

It is often said that the 20th century has dealt harshly with legislatures and that this is an age of executive aggrandizement. Certainly, executives in most countries have assumed an increasingly large role in the making of law, through the initiation of the legislation that comes before parliaments, assemblies, and congresses, through the exercise of various rule-making functions, and as a result of the growth of different types of delegated legislation. It is also true that executives have come to predominate in the sphere of foreign affairs and, by such devices as executive agreements, which are frequently used in place of treaties, have freed themselves from dependence upon legislative approval of important foreign-policy initiatives. Moreover, devices such as the executive budget and the rise of specialized budgetary agencies in the executive division have threatened the traditional fiscal controls of legislatures. This decline in legislative power, however, is not universal. The United States Congress, for example, has preserved a substantial measure of its power. Indeed, congressional oversight of the bureaucracy is an area in which it has added to its power and has developed new techniques for controlling the executive. The difficulties of recent presidents with legislative programs of foreign aid and the insistent congressional criticism of executive policies in Southeast Asia also suggest that Congress continues to play a vital role in the governing process.

The executive. Political executives are government officials who participate in the determination and direction of government policy. They include heads of state and government leaders—presidents, prime ministers, premiers, chancellors, and other chief executives—and many secondary figures, such as cabinet members and ministers, councillors, and agency heads. By this definition, there are several thousand political executives in the U.S. national government, including the president, dozens of political appointees in the Cabinet departments, in the agencies, in the commissions, and in the White House staff, and hundreds of senior civil servants. The same is true of most advanced political systems, for the making and implementation of government policy require very large executive and administrative establishments.

The crucial element in the organization of a national executive is the role assigned to the chief executive. In presidential systems, such as in the United States, the president is both the political head of the government and also the ceremonial head of state. In parliamentary systems, such as in Great Britain, the prime minister is the national political leader, but another figure, a monarch or elected president, serves as the head of state. In mixed presidential-parliamentary systems, such as that established in France under the constitution of 1958, the president serves as head of state but also wields important political powers, including the appointment of a prime minister and Cabinet to serve as the government.

The manner in which the chief executive is elected or selected is often decisive in shaping his role in the political system. Thus, although he receives his seals of office from the monarch, the effective election of a British prime minister usually occurs in a private conclave of the leading

members of his party in Parliament. Elected to Parliament from only one of 630 constituencies, he is tied to the fortunes of the legislative majority that he leads. By contrast, the American president is elected by a nationwide electorate, and, although he leads his party's ticket, his fortunes are independent of his party. Even when the opposition party controls the Congress, his fixed term and his independent base of power allow him considerable freedom of manoeuvre. These contrasts explain many of the differences in the roles of the two chief executives. The British prime minister invariably has served for many years in Parliament and has developed skills in debate and in political negotiation. His major political tasks are the designation of the other members of the Cabinet, the direction of parliamentary strategy, and the retention of the loyalty of a substantial majority of his legislative party. The presidential chief executive, on the other hand, often lacks prior legislative and even national-governmental experience, and his main concern is with the cultivation of a majority in the electorate through the leadership of public opinion. Of course, since the president must have a legislative program and often cannot depend on the support of a congressional majority, he may also need the skills of a legislative strategist and negotiator.

Another important area of contrast between different national executives concerns their role in executing and administering the law. In the U.S. presidential system, the personnel of the executive branch are constitutionally separated from the personnel of Congress: no executive officeholder may seek election to either house of Congress, and no member of Congress may hold executive office. In parliamentary systems the political management of government ministries is placed in the hands of the party leadership in parliament. In the U.S. system the president often appoints to Cabinet positions persons who have had little prior experience in politics, and he may even appoint members of the opposition party. In the British system, Cabinet appointments are made to consolidate the prime minister's personal ascendancy within the parliamentary party or to placate its different factions. These differences extend even further into the character of the two systems of administration and the role played by civil servants. In the U.S. system a change in administration is accompanied by the exodus of a very large number of top government executives—the political appointees who play the vital part in shaping day-to-day policy in all the departments and agencies of the national government. In Britain, when political control of the House of Commons changes, only the ministers, their parliamentary secretaries, and one or two other top political aids are replaced. For all practical purposes, the ministries remain intact and continue under the supervision of permanent civil servants.

In nearly all political systems, even in constitutional democracies where executive responsibility is enforced through free elections, the 20th century has seen an alarming increase in the powers of chief executives. The U.S. presidency, like the office of prime minister in Britain, has greatly enlarged the scope of its authority. One of the future tasks of representative government is to develop more constitutional restraints on the abuse of executive powers while retaining their advantages for effective rule.

The judiciary. Like legislators and executives, judges are major participants in the policy-making process; and courts, like legislatures and administrative agencies, promulgate rules of behaviour having the nature of law. The process of judicial decision making, or adjudication, is distinctive, however, for it is concerned with specific cases in which an individual has come into conflict with society by violating its norms or in which individuals have come into conflict with one another, and it employs formal procedures that contrast with those of parliamentary or administrative bodies.

Established court systems are found in all advanced political systems. Usually there are two judicial hierarchies, one dealing with civil and the other with criminal cases, each with a large number of local courts, a lesser number at the level of the province or the region, and one or more courts at the national level. This is the pattern of judicial organization in Britain, for example. In some countries—

Varieties of executives

Varieties of court systems

for example, in France—although there is a double hierarchy, the distinction is not between courts dealing with criminal cases and other courts dealing with civil cases but rather between those that handle all civil and criminal cases and those that deal with administrative cases or challenges to the administrative authority of the state. Reflecting the federal organization of its government, the United States possesses two court systems: one set of national courts and 50 sets of state courts. By contrast, West Germany and the Soviet Union, both of which are federal in governmental organization, each possess only one, integrated court system.

Local courts are found in all systems and are usually of two types. The first type deals with petty offenses and may include a traffic court, a municipal court, a small-claims court, and a court presided over by a justice of the peace or a local magistrate. The second type, sometimes called trial courts, are courts of first instance in which most cases of major importance are begun. These are the state superior courts in the United States, the county courts and quarter sessions in Britain, the *tribunal de grande instance* in France, and the district courts, or *Landgerichte*, in Germany. In some systems there is a level above the local court, usually referred to as assize courts, in which exceptionally serious crimes, such as homicide, are tried. Courts of appeal review the procedures and the law in the lower court and either reverse or affirm its judgment or, in some cases, return the case for a new trial. In all systems there are national supreme courts that hear appeals and exercise original jurisdiction in cases of the greatest importance, such as those involving conflict between a state and a national government. Outside the regular court systems, there are sometimes found specialized judicial tribunals, such as administrative courts, or courts of claims that deal with special categories of cases.

The functions of government

In all modern states, governmental functions have greatly expanded with the emergence of government as an active force in guiding social and economic development. In Communist countries, government has a vast range of detailed controls over all types of social and economic behaviour. Even in the United States, where there remains a much greater attachment than in most societies to the idea that government should be only an umpire adjudicating the rules by which other forces in society compete, such governmental activities as the Tennessee Valley Authority or the use of credit controls to prevent economic fluctuations are now accepted with relatively little question. Government has thus become the major or even the dominant organizing power in all contemporary societies.

The historical stages by which governments have come to exercise their contemporary functions make an interesting study in themselves. The scope of government in the ancient polis involved the comprehensive regulation of the ends of human existence. As Aristotle expressed it, what was not commanded by government was forbidden. The extent of the functions of government in the ancient world was challenged by Christianity and its insistence on a division of those things that belong separately to Caesar and to God. When the feudal world succeeded the Roman Empire, however, the enforcement of the sanctions of religion became one of the first objects of political authority. The tendencies that began in the 18th century separated church from state and state from society, and the modern concept of government came into being. The American Colonies' Declaration of Independence expresses the classic modern understanding of those ends that governmental functions exist to secure. The first aim of government is to secure the right to life; this comprehends the safety of fellow citizens as regards one another and the self-preservation of the nation as regards foreign powers. Life exists for the exercise of liberty, in terms of both natural and civil rights, and these, along with other specific functions of government, provide those conditions upon which men may pursue happiness, an end that is finally entirely private and beyond the competence of government.

With the advent of the Marxist conception of the state,

the ends of human existence once again became the objects of comprehensive government regulation. Marxism sees the state as a product of class warfare that will pass out of existence in the future age of perfect freedom. Aristotle believed human perfection to be possible only within political society; Marx believed that the perfection of man would follow upon the abolition of political society. Before the final disposal of the state, however, many Marxists believe that forceful use of governmental power is justified in order to hasten mankind's progress toward the last stage of history.

THE TASKS

Self-preservation. The first right of men and nations is self-preservation. The task of maintaining the nation, however, is more complex than the individual's duty of self-preservation, for the nation must seek to command the attachment of a community of citizens as well as to preserve itself from external violence. As Thomas Hobbes insisted, civil war constitutes the greatest threat to governments, for it represents the dissolution of the "sovereign power." In modern terms, civil war signifies that the government has lost one of the basic attributes of political authority: its monopoly of force and its control over the use of violence. In a fundamental sense, political authority may be preserved from the threat of civil war only when there exists in the political community an agreement on the basic principles of the regime. Such a consensus is the result, among other things, of a shared "ideology" that gives fellow citizens a sense of communal belonging and recognizes interlocking values, interests, and beliefs. Ideology, in this sense, may be the product of many different forces. Sometimes it is associated with ancient customs, sometimes with religion, sometimes with severe dislocations or the sort of common need that has led to the formation of many nation-states, and sometimes with the fear of a common enemy. The ideological commitment that people call patriotism is typically the product of several of these forces.

Governments neglect at their peril the task of strengthening the ideological attachment of their citizens to the regime. In this sense, civic education should be counted among the essential functions of the state, for it is primarily through systems of education that citizens learn their duties. Indeed, as a number of recent sociological studies have shown, the process of political socialization that transforms men into citizens begins in kindergarten and grade school. Even more than this, education is the instrument by which governments further the cohesion of their societies and build the fundamental kinds of consensus that support their authority. It is not surprising, therefore, that national systems of education are often linked to central elements of the regimes. The educational system of the Soviet Union emphasizes political indoctrination; in France, public education is traditionally mixed with the teachings of the Roman Catholic Church; in Great Britain, until very recently, a private system of education supported the class divisions of society; and in the United States a primarily secular form of public education has traditionally used constitutional documents as the starting point of children's training in patriotism.

The preservation of the authority of the state also requires a governmental organization capable of imposing its jurisdiction on every part of the national territory. This involves the maintenance of means of communication, the use of administrative systems, and the employment of police forces capable of controlling domestic violence. The police function, like education, is often a key to the character of a regime. In Nazi Germany, Hitler's Brown-shirts took over the operation of local and regional police systems and often supervised the administration of law in the streets. In the Soviet Union, the security police acts to check any deviation from the policy of the party or state. In the United States the police powers are left in the hands of the 50 states and the local agencies of government. They serve to check civil and criminal offenses; with the exception of certain offenses created by the McCarran Act and some parallel statutes, political crimes as such are unknown. In addition, there are state militias that act,

The maintenance of authority

under the control of the governors of the various states, in moments of local emergency, such as riots or natural catastrophes. The Federal Bureau of Investigation (FBI), the only equivalent of a national police force, is an agency established to carry out specific assignments dealing with a limited but important class of crimes. Since there is no comprehensive federal criminal code, there is not, strictly speaking, a federal police.

Governments must preserve themselves against external as well as domestic threats. For this purpose they maintain armed forces and carry on intelligence activities. They also try to prevent the entry of aliens who may be spies or saboteurs, imprison or expel the agents of foreign powers, and embargo the export of materials that may aid a potential enemy. The ultimate means of preserving the state against external threats, of course, is war. In war, governments usually enlarge the scope of their domestic authority; they may raise conscript forces, imprison conscientious objectors, subject aliens to internment, sentence traitors to death, impose extraordinary controls on the economy, censor the press, compel settlement of labour disputes, impose internal-travel limitations, withhold passports, and provide for summary forms of arrest.

Many forces generate clashes between nations, including economic rivalry and disputes over trade, the desire to dominate strategic land or sea areas, religious or ideological conflict, and imperialistic ambition. All national governments develop organizations and policies to meet these and other situations. They have foreign ministries for the conduct of diplomatic relations with other states, for representing them in the United Nations and other international organizations, and for negotiating treaties. Some governments conduct programs such as foreign aid, cultural exchange, and other activities designed to win goodwill abroad.

In the 20th century, relationships among governments have been affected by a developing awareness that world peace depends upon multinational and international cooperation. The League of Nations and the United Nations, together with their associated agencies, represent major efforts to establish substitutes for traditional forms of diplomacy. Regional alliances and joint efforts, such as the Organization of American States, the North Atlantic Treaty Organization, the European Economic Community, and the Organization of African Unity, represent another type of cooperation among nations.

Supervision and resolution of conflicts. The conflict of private interest is the leading characteristic of the political process in constitutional democracies, and the supervision, mediation, arbitration, and adjudication of such conflicts are among the key functions of their governments. Representative institutions are themselves a device for the resolution of conflict. Elections in constitutional democracies provide opportunities for mass participation in a process of open debate and public decision; assemblies, congresses, and other parliamentary institutions provide for public hearings on major issues of policy and require formal deliberative procedures at different stages of the legislative process; and political parties integrate a variety of interests and effect compromises on policy that win acceptance from many different groups.

If the interests that compete in the political process are too narrow or restricted, efforts may be made to control or change the rules of competition. Thus, laws have been enacted that seek to prevent discrimination from locking racial and other minorities out of the democratic process; the franchise has been extended so as to permit all groups, including minorities such as women, blacks, and 18-year-olds, to have a voice in elections; and government bodies such as courts and administrative agencies enforce legislation against groups considered to be too large or monopolistic.

Judicial processes offer a means by which some disputes in society are settled according to rule and legal authority, rather than by political struggle. In all advanced societies, law is elaborated in complex codes governing rights and duties and procedural methods; and court systems are employed that adjudicate disputes in terms of the law. In constitutional systems such as the United States, the judi-

ciary is deeply involved in the process of public decision making; the courts actually produce much of the substantive law that bears on private individuals and economic groups in society.

Regulation of the economy. Government regulation of economic life is not a new development. The national mercantilist systems of the 18th century provided for regulation of the production, distribution, and export of goods by government ministries; even during the 19th century, governments continued to intervene in the economy. The government of the United States, for example, from its inception in 1789, allotted funds or subsidies for the support of agriculture, maintained a system of tariffs for its own revenue and the support of domestic manufacturers, patronized the arts and sciences, and engaged in various kinds of public works to advance commerce and promote the general welfare. In France, even more elaborate governmental schemes of economic regulation were practiced throughout the 19th century, including a variety of Socialist experiments such as the Public Workshops that Louis Blanc established in Paris in 1848. In Britain, the various factory acts of the 19th century represented an effort by government to control working conditions in industry.

After World War II the ability of a government to regulate or control the economy became one of the chief tests of its success, and regulatory agencies multiplied to the point at which they are now often referred to as "the fourth branch of government." The extent of the controls imposed on the economy is one of the principal distinctions among capitalist, Socialist, and Communist systems. In Communist countries it is a matter of doctrine that the means of production should be owned and therefore controlled by the state; in the 1960s and 1970s, however, some Communist countries experimented with various ways of decentralizing economic decision making in an effort to increase flexibility and reduce the weight of the central bureaucracy. In Britain the Labour governments nationalized some major industries, including coal, steel, and the railroads, prompted partly by Socialist doctrine and partly by the failure of British industry to remain competitive in international markets. In the United States the government has involved itself in the economy primarily through its regulatory powers. In France the government has gone further and has engaged in national economic planning in cooperation with private business organizations.

The regulation of industrial conditions and of labour-management relations has been a major concern of most Western governments. In the United States the first regulatory efforts in this field were made during the Progressive era at the turn of the 20th century, when the wages, hours, and working conditions of women and children in industry became a matter of public scandal. A little later, the conditions, hours, food, and wages of merchant seamen were brought under government regulation; an eight-hour day was set for railway crews; and workmen's compensation laws were instituted. With the Depression of the 1930s, minimum wages were introduced for workers in many industries, hours of work were set, and the right to collective bargaining was given legal sanction.

Regulation of transportation has been another major activity in most Western political systems, beginning with the railroads. In the United States their monopolistic practices attracted the criticism of agricultural interests and led eventually to the Interstate Commerce Act of 1887, which regulated railroad rates; subsequent legislation covered the hours, conditions, and wages of railroad employees, among other things. Other modes of land and air transportation have since been brought under regulatory controls implemented by government agencies.

In most European countries, facilities of communication—the telegraph, telephone, radio, and television—are owned and operated by the government. In the United States most of these facilities have remained in private ownership, although they are regulated by the Federal Communications Commission. The regulation by government of important instruments of public opinion such as radio, television, and newspapers has important implications for the freedoms of speech and press and other individual rights. In the United States and Great Britain,

government censorship of the press and other media has been restricted to matters of national security. This is also generally true of other Western constitutional democracies, although the celebrated *Der Spiegel* affair in Germany in 1962 and some extraordinary controls imposed on the media in France have been widely criticized. In Communist countries and in many of the new states of Africa and Asia, very extensive controls are imposed on the press, and government-owned newspapers are often the principal sources of political news.

Other forms of government regulation of the economy involve the use of taxes and tariffs, the regulation of weights and measures, and the issuance of money.

Protection of political and social rights. To some extent, all modern governments assume responsibility for protecting the political and social rights of their citizens. The protection of individual rights has taken two principal forms: first, the protection of liberty in the face of governmental oppression; second, the protection of individual rights against hostile majorities and minorities. Even Communist governments recognize certain rights of individuals and minorities in the ordinary spheres of life, if not in matters touching the interests of the state. Beginning in the 1960s there appeared to be a broadening of the sphere of private rights in the Soviet Union. Authors, artists, and scientists were able to engage in criticism of official policies, not with impunity but with much greater freedom than in the Stalin era; and there were some signs that the Soviet state had begun to recognize the rights of the Jewish minority and the claims of some other national groups. In the United States the Supreme Court expanded the rights of the criminally accused; and, after 1954, the national government acted to bar legal discrimination against ethnic minorities. Indeed, almost all the freedoms detailed in the first ten amendments to the Constitution have been extended since World War II.

Another type of government regulation bearing on the individual concerns the law of immigration and emigration. The great mass migrations of the 19th and early 20th centuries came to an abrupt halt after 1914 with the proliferation of government controls on the freedom of movement across national boundaries.

Provision of goods and services. All modern governments participate directly in the economy, purchasing goods, operating industries, providing services, and promoting various economic activities. One of the indispensable functions of government—national defense—has made governments the most important consumers of goods, and they have not hesitated to use their resulting pricing, purchasing, and contracting powers to achieve various economic aims. In efforts to avoid dependence on private sources of strategic goods and defense materials, some governments have taken a further step and established their own military production plants. In wartime, governments have assumed control over entire industries and have subjected the work force to military direction.

In nearly all political systems, certain functions are recognized as public, or belonging to the government. In addition to national defense, these include the maintenance of domestic peace, public education, fire protection, traffic control, aid to the indigent, conservation of natural resources, flood control, and postal services. But governments have assumed responsibility for many other commercial operations, even in non-Socialist countries. The sale of electric power, for example, is one of the established enterprising functions of national, state, and local governments in the United States and Canada. Municipally owned power utilities exist in about 2,000 cities in North America; 14 states of the U.S. have public power districts; and the U.S. government markets power through the Tennessee Valley Authority, the Bureau of Reclamation, the Bonneville Power Administration, and the Southwestern and Southeastern Power administrations. Another range of functions is performed by other national agencies, including the Rural Electrification Administration, which loans money to rural cooperatives to finance local power projects; the Export-Import Bank of Washington, which makes loans to finance export and import trade; the Maritime Administration, which holds mortgages on ships;

and the Veterans Administration, which makes loans for farm or home purchases to military veterans. The United States government, acting through agencies such as the Social Security Board, the Federal Deposit Insurance Corporation, and the Federal Housing Administration, is also the largest insurer in the nation. Through other agencies, such as the Housing and Home Finance Agency, the Urban Renewal Administration, and the Public Works Administration, the national government has also developed a major role in the construction and rental of residential housing for low-income persons.

Other miscellaneous enterprises in which governments are involved include the provision of health care, the operation of public transport facilities, the development of public works, airport and port maintenance, and water-supply systems. In Great Britain the government operates hospitals and provides medical care under the National Health Service. In the United States, many state and local governments operate hospitals on a commercial basis, although providing some charity care. At the local level in the United States, the Port of New York Authority constructs and operates bridges, terminals, and airports. The states in the Delaware Basin recently joined in a compact to establish an agency to control the use of water from the basin, institute programs to prevent pollution, provide recreation facilities, transmit and sell hydroelectric power, and provide watershed management. Cities in the United States and Canada operate more than 70 urban transit systems, 600 municipal gas utilities, and more than 4,000 water-supply systems. Cities are also generally responsible for garbage disposal and sometimes operate commercial slaughterhouses, coal yards, laundries, ice plants, and golf courses. Finally, packaged liquor sales are often made by the state governments, at either wholesale or retail or both.

PUBLIC ADMINISTRATION

While the functional objectives of government administration vary from system to system, all countries that are technologically developed have evolved systems of public administration. A number of common features may be detected in all such systems. The first is the hierarchical, or pyramidal, character of the organization by which a single chief executive oversees a few subordinates, who in turn oversee their chief subordinates, who are in turn responsible for overseeing other subordinates, and so on, until a great structure of personnel is integrated and focussed on the components of a particular program. A second common feature is the division of labour or specialization within the organization. Each individual in the hierarchy has specialized responsibilities and tasks. A third feature is the maintenance of detailed official records and the existence of precise paper procedures through which the personnel of the system communicate with each other and with the public. Finally, tenure of office is also characteristic of all public bureaucracies.

The various national civil services, despite their similarities, also show important differences, particularly in the way in which individuals are recruited and in the status accorded them in the political system. The British civil service, for example, has traditionally been composed of three classes, or grades—clerical, executive, and administrative. Administrative civil servants, the highest grade, are recruited by examination from among recent university graduates. The top managers of the different government ministries are drawn from this elite group. They remain in office despite changes in government and are accorded immense prestige. The U.S. civil service is organized into 18 grades. Although promotion from the lower grades is the typical means by which positions in the top grades are filled, there is also a flow of individuals into senior positions from private business and the professions. The U.S. equivalent of the administrative civil servant in Britain is usually a political appointee recruited by each new administration from private life or from a position in politics.

Development and change in political systems

The student of political systems grapples with a subject matter that is today in constant flux. He must deal not

Civil
service

only with the major processes of growth, decay, and breakdown but also with a ceaseless ferment of adaptation and adjustment. The magnitude and variety of the changes that occurred in the world's political systems between the second and eighth decades of the 20th century suggest the dimensions of the problem. Great empires disintegrated; nation-states emerged, flourished briefly, and then vanished; world wars twice transformed the international system; new ideologies swept the world and shook established groups from power; all but a few nations experienced at least one revolution and many nations two or more; domestic politics in every system were contorted by social strife and economic crisis; and everywhere the nature of political life was changed by novel forms of political activity, new means of mass communication, the enlargement of popular participation in politics, the rise of new political issues, the extension of the scope of governmental activity, the threat of nuclear war, and innumerable other social, economic, and technical developments.

CAUSES OF STABILITY AND INSTABILITY

Although it is possible to identify a number of factors that obviously have a great deal to do with contemporary development and change in the world's political systems—industrialization, population growth, the “revolution of rising expectations” in the less developed countries, and international tensions—there is no agreed theory to explain the causes of political change. Some social scientists have followed Aristotle's view that political instability is generally the result of a situation in which the distribution of wealth fails to correspond with the distribution of political power and have echoed his conclusion that the most stable type of political system is one based on a large middle class. Others have adopted Marxist theories of economic determinism that view all political change as the result of changes in the mode of production. Still others have focussed on governing elites and their composition and have seen in the alienation of the elite from the mass the prime cause of revolutions and other forms of violent political change.

In the discussion that follows, a distinction is drawn between unstable and stable political systems, and an attempt is made to suggest ways of understanding the processes of political development and change.

Unstable political systems. In modern times the great majority of the world's political systems have experienced one form or another of internal warfare leading to violent collapse of the governments in power. Certain crisis situations seem to increase the likelihood of this kind of breakdown. Wars and, more particularly, national military defeats have been decisive in prompting many revolutions. The Paris Commune of 1871, the Russian revolutions of 1905 and 1917, Hitler's overthrow of the Weimar Constitution in Germany, and the revolutions in China all occurred in the aftermath of national military disasters. Many factors in such a situation, including the cheapening of human life, the dislocation of population, the ready availability of arms, the disintegration of authority, the discrediting of the national leadership, material scarcities, and a sense of wounded national pride, contribute to the creation of an atmosphere in which radical political change and violent mass action are acceptable to large numbers of people. Economic crises are another common stimulus to revolutionary outbreaks, for they produce not only the obvious pressures of material scarcity and deprivation but also a threat to the individual's social position, a sense of insecurity and uncertainty as to the future, and an aggravation of the relationships among social classes. A severe national economic crisis works, in much the same way as a military disaster, to discredit the existent leadership and the present regime. Another triggering factor is the outbreak of revolutions in other political systems. Revolutions have a tendency to spread: the Spanish Revolution of 1820 had repercussions in Naples, Portugal, and Piedmont; the French Revolution of July 1830 provoked similar outbreaks in Poland and Belgium; the Russian Revolution of 1917 was followed by a dozen other revolutions; and the colonial liberation movements in Africa, Southeast Asia, and elsewhere after World

War II appear to have involved a similar chain reaction.

Crisis situations test the stability of political systems in extremely revealing ways, for they place extraordinary demands on the political leadership and the structure and processes of the system. Since the quality of the political leadership is often decisive, those systems that provide methods of selecting able leaders and replacing them possess important advantages. Although leadership ability is not guaranteed by any method of selection, it is more likely to be found where there is free competition for leadership positions. The availability of established methods of replacing leaders is equally, if not more, important, for the result of crises is often to disgrace the leaders in power, and, if they cannot be replaced easily, their continued incumbency may discredit the whole regime. The stamina and resolve of the ruling elite are also important. It is often said that a united elite, firmly believing in the justice of its own cause and determined to employ every measure to maintain its power, will not be overthrown. Most revolutions have gotten under way not when the oppression was greatest but only after the government had lost confidence in its own cause.

Other conditions of the survival of political systems relate to the effectiveness of the structures and processes of government in meeting the demands placed on them. Political systems suffer violent breakdown when channels of communication fail to function effectively, when institutional structures and processes fail to resolve conflicts among demands and to implement acceptable policies, and when the system ceases to be viewed as responsive by the individual and groups making demands on it. Usually, a system has failed over a period of some time to satisfy persistent and widespread demands; then, exposed to the additional strains of a crisis situation, it is unable to maintain itself. Revolutions and other forms of violent collapse are thus rarely sudden catastrophes but rather the result of a process of considerable duration that comes to its climax when the system is most vulnerable.

Unstable political systems are those that prove vulnerable to crisis pressures and that break down into various forms of internal warfare. The fundamental causes of such failures appear to be the lack of a widespread sense of the legitimacy of state authority and the absence of some general agreement on appropriate forms of political action. Governments suffer their gravest handicap when they must govern without consent or when the legitimacy of the regime is widely questioned. This is often the case in systems that have experienced prolonged civil war, that are torn by tensions among different national or ethnic groups, or in which there are divisions along sharply drawn ideological or class lines. The problem is often most acute where there is a pretender to the throne, a government in exile, a neighbouring state sympathetic to a rebel cause, or some other focus for the loyalty of dissidents. To some degree, also, the problem of legitimacy confronts all newly established regimes. Many of the new states of Africa and Asia, for example, have found it a source of great difficulty. Often they have emulated the form of Western institutions but failed to achieve their spirit: borrowing eclectically from Western political philosophies and systems of law, they have created constitutional frameworks and institutional structures that lack meaning to their citizens and that fail to generate loyalty or a sense that government exercises rightful powers.

Closely related to the problem of legitimacy as a cause of the breakdown of political systems is the absence of a fundamental consensus on what is appropriate political behaviour. A regime is fortunate if there are well-established, open channels of political action and settled procedures for resolving grievances. Although the importance of such “rules of the game” is that they allow change to occur in mainly peaceful ways, stable political systems often show surprising tolerance for potentially violent forms of political behaviour, such as strikes, boycotts, and mass demonstrations. Such forms of political behaviour are not permitted in systems where there are no agreed limits to the role of violence and where there is a high risk that violence may escalate to the point of actual warfare. If the government cannot count upon widespread support for

Crisis
situations

Causes
of the
breakdown
of political
systems

Managed
and
evolution-
ary systems

peaceful political procedures, it must restrict many kinds of political action. Such restriction, of course, inhibits still more the development of open methods of citizen participation in politics and adds to tension between the government and the people.

Stable political systems. The simplest definition of a stable political system is one that survives through crises without internal warfare. Several types of political systems have done so, including despotic monarchies, militarist regimes, and other authoritarian and totalitarian systems. After 1868, in the period of the restoration regime under the Meiji emperor, Japan succeeded, without major political breakdowns, in building an industrial state and developing commercial structures that transformed traditional Japanese society. This achievement was based on the development of centralized patterns of political control and the growth of a type of authoritarianism involving the rule of a military elite. Similarly, some of the totalitarian regimes of the contemporary world have demonstrated an impressive capability for survival. The key to their success is their ability to control social development, to manage and prevent change, and to bring under governmental direction all the forces that may result in innovations that are threatening to the system.

In some systems, survival does not depend on the detailed management of the society or close governmental control over social processes but is the result of sensitive political response to the forces of change, of flexible adjustment of the structures of the system to meet the pressures of innovation, and of open political processes that allow gradual and orderly development. Much of the Western democratic world has achieved peaceful progress in this way, despite new political philosophies, population increases, industrial and technological innovations, and many other social and economic stresses.

Such evolutionary change is possible when representative institutions provide effective channels for the communication of demands and criticisms to governments that rely upon majority support. The election of legislators and executive officials, competition between political parties, constitutional guarantees of freedom of speech and press, the right of petition, and many other structures and procedures perform this function in contemporary constitutional democracies. In such systems, social and economic problems are quickly transformed into issues in the open arenas of politics; governments are obliged to shape policies that reflect a variety of pressures and effect compromises among many conflicting demands.

The representative mechanisms that have produced evolutionary change in Western constitutional democracies are themselves subject to a continuous process of adjustment and mutation. Indeed, representative institutions must develop in ways that reflect social and economic developments in the society or they will lose their legitimacy in the minds of the people. In political systems such as the United States, for example, subtle shifts in the function and relative power of different institutions are continuously being made and, over time, produce entirely new structures and very different patterns of institutional behaviour. It is as a result of this process that the presidency has accumulated a range of new powers that have given it primacy among the branches of American government. This process also explains the growth of administrative agencies that perform both legislative and judicial functions. This process of dynamic adjustment is crucial, for institutions that remain static in a changing society are unable to serve as agencies of evolutionary change.

TYPES OF POLITICAL CHANGE

The study of political change is difficult, for change occurs in many different ways and at many different points in the political system. One may distinguish several major types of change.

Radical revolution. First are changes of the most fundamental type—transformations not only of the structure of government but of the whole polity. Such change is not limited to political life but transforms also the social order, the moral basis, and the values of the whole society. Drastic change of this kind occurred in the four great revolutions of the modern era—the English Revolution of the

17th century, the American Revolution, the French Revolution, and the Russian Revolution. These movements had the most profound effect on social and political life, permanently altering the beliefs by which men live. Their consequences were felt not only in the societies in which they occurred but also in many other political systems, in which, as a result of their example, revolutions of an equally fundamental character occurred.

Each of these major revolutions was something of a world revolution, for it resulted in a basic change in the ways in which men in all political systems viewed the nature of politics and the purpose of political life. The independence movements in the colonial empires after World War II, for example, were fuelled by those principles of individual liberty and representative government that were once the slogans of 18th-century American and French revolutionaries. Marxist revolutionary concepts emphasizing economic progress and radical social change have shaped the development of many of the new nations. The continuing impact of such ideas is an example of another way in which fundamental political change occurs. The nature of a political system may be transformed not suddenly or violently in the course of revolution but by the gradual, corrosive influence of ideas and by the accumulating impact of different political philosophies.

Structural revision. A second type of change involves alterations to the structure of the political system. Such change is not fundamental, in the sense of a basic transformation of the nature of the regime, but it may produce great shifts in policy and other political outcomes. Because the structure of a political system—that is, its formal and informal institutional arrangements—is a major determinant of policy outcomes, it is frequently the target of political action of various kinds. The political activist, the reformer, and the revolutionary share the recognition that the policies of a government may be effectively changed by adjusting the institutional forms through which the government acts. In some systems, structural change has been accomplished by legal means. In the United States, for example, such major institutional reforms as the direct election of the Senate and the limitation on presidential terms were made by constitutional amendment; and in Britain the various reforms of Parliament were accomplished by statute. In other systems, structural changes are often achieved by revolution and other violence.

Change of leaders. A third type of political change involves the replacement of leaders. Again, the recognition that to change the personnel of a government may be an effective way of changing government policy prompts many kinds of political action, ranging from election contests to political assassination and various forms of coup d'état. In some systems the existence of established means of changing political leaderships works to prevent violent types of political action. In the United States the quadrennial contests for the presidency afford a constitutional opportunity to throw the whole executive leadership out of office. At the other extreme, the coup d'état leads to the abrupt, often violent replacement of national executives. Although it is a type of revolution, the coup d'état usually does not involve prolonged struggle or popular participation; after seizing office, the principal aim of the leaders of the coup is usually the restoration of public order. The coup d'état occasionally develops into much more than the replacement of one set of governmental leaders by another and may prove to be the initial stage of a truly revolutionary process; e.g., the coups d'état that initiated Communist rule in Czechoslovakia in 1948 and ended King Farouk I's regime in Egypt in 1952.

Change of policies. Government policy itself may be an important agency of political change. The social and economic policies of Franklin D. Roosevelt's New Deal and the Socialist programs implemented by the British Labour Party after 1945 are examples. In both cases, government policies resulted in far-reaching modifications to the functioning of the political system: a vast expansion in the role of government in the economy, the use of taxes to redistribute wealth, an increase in the political influence of organized labour, and the implementation of

national programs of social welfare. Major policy change of this type, of course, is often a response to widespread pressures and demands that, if not satisfied by the system, may intensify and lead to various forms of violent political action. At other times, however, policy changes are imposed by a government to achieve the political, social, and economic goals of a single class, of an elite, or of the political leadership itself.

Many important questions remain as to the reasons for change, the ways in which change occurs, and the effects of change. Political scientists are still not completely certain, for example, why some systems have managed to avoid violent political change for considerable periods, while in other systems change is typically accomplished through coups d'état, revolutions, and other forms of internal warfare. As suggested above, the explanation may have much to do with the existence in countries such as the United States and Great Britain of well-established political institutions that permit peaceful change, the presence in the population of widely shared attitudes toward the government, and the existence of basic agreement on the legitimacy of state authority. Clearly, however, other factors are also involved. Perhaps one of the chief goals of the study of political systems should be to determine as exactly as possible the conditions and prerequisites of those forms of change that permit the peaceful and evolutionary development of human society. (D.A.He.)

ELECTORAL PROCESSES

Elections are means of making political choices by voting. They are used in the selection of leaders and in the determination of issues. This conception of elections implies that the voters are presented with alternatives, that they can choose among a number of proposals designed to settle an issue of public concern. The presence of alternatives is a necessary condition, for although electoral forms may be employed to demonstrate popular support for incumbent leaders and their policies, the absence of alternatives disqualifies such devices as genuine elections.

The widespread use of elections in the modern world is due largely to the gradual emergence of representative government from the 17th century on. For proper appraisal, however, it is important to distinguish between the form and substance of elections. Electoral forms may be present but the substance may be missing. The substance is, of course, that the voter has a free and genuine choice between at least two alternatives. In a purely formal sense, the great majority of the approximately 150 contemporary nations have what are called "elections," but probably only a third of these have more or less competitive elections; perhaps a fifth have one-party elections; and in some others the electoral situation is highly ambiguous.

The discovery of the individual as the unit to be counted was, from the 17th century on, the critical factor in the emergence of modern electoral processes. The counting of individuals, in turn, was a by-product of the change from the holistic conception of representation in the Middle Ages to an individualistic conception. The British Parliament, for instance, was no longer seen as representing estates, corporations, and vested interests, but as standing for actual human beings. The movement abolishing "rotten boroughs"—boroughs of small population controlled by one person or family—that culminated in the Reform Act of 1832 was a direct consequence of the individualistic conception of representation. Once governments were not only believed to derive their powers from the consent of the governed but were expected to seek consent, the only remaining problem was to decide who was to be included among the governed whose consent was to be sought. The democratic answer was, of course, universal adult suffrage.

Although it is common to equate representative government, elections, and democracy, and although competitive elections under universal suffrage are in many respects a defining characteristic of political democracy, universal suffrage is not a necessary condition of competitive electoral politics. An electorate may be limited by formal legal requirements—as was the case before universal adult suffrage—or it may be limited by citizens' failure to take advantage of the vote, as is often the case in American

municipal and other elections. Although such legal or self-imposed exclusion affects the democratic quality of elections and may ultimately affect the legitimacy of government, it does not impede decision-making by election, provided the voter is presented with alternatives among which to choose.

Access to the political arena during the 18th century depended largely on membership in some aristocracy, and participation in elections was regulated mainly by local customs and arrangements. With the American and French revolutions every citizen was declared formally equal to every other citizen, but the vote remained an instrument of political power possessed by very few.

Even with the arrival of universal suffrage, the ideal of one man, one vote was not achieved. Systems of plural voting were maintained in some countries giving certain social groups an electoral advantage. In Great Britain, for example, university graduates and owners of businesses in constituencies other than those in which they lived continued to have an extra vote until 1948. Before World War I, both Austria and Prussia had three classes of weighted votes that effectively kept electoral power in the hands of the upper social strata.

Whereas in the Western nations of the 19th and 20th centuries the increasing use of competitive mass elections in selecting governments had the purpose and the effect of institutionalizing the diversity of modern societies, in the Eastern, one-party, Communist regimes, mass elections came to have quite different purposes and consequences. Elections in these nations were not designed to offer choice of leadership or to influence policy formation. They differ from competitive elections in that only one team of candidates is presented, and the voter has only the choice of voting for the official candidate. They are in the nature of the 19th century Napoleonic plebiscites, intended to demonstrate the unity rather than the diversity of the people, and, above all, they do not make or unmake governments.

Although the Soviet Union's constitution of 1936 provided for elections on the Western model, the election mechanism is manipulated to produce almost universal turnout and unanimous support of the regime. Elections are dramatic occasions for Communist agitation and propaganda to strengthen the citizen's identification with the Soviet way of life.

Because voting is considered a pledge of loyalty, it is easier to vote against the official candidate than to abstain. Although nonparticipation is not a legal offense, it may be socially punished. Although an unmarked ballot is considered a "yes" vote, dissent may be registered by crossing out the name of the candidate on the ballot, as some 2,000,000 Soviet citizens do in each election. These voters are easily identified because they are likely to choose voting booths that make secret voting possible. Perhaps for this reason less than 5 percent of the voters risk public scrutiny by secret voting. It may well be that dissenting votes are cast not so much because of dislike of Communism, but because of grievances involving the conduct of minor officials who stand for election to one of the numerous village, town, republic, or oblast soviets.

Not all elections under authoritarian governments follow the Soviet model. In Poland, for instance, more names appear on the ballot than there are offices to fill, and some degree of electoral choice is possible. Electoral participation is usually over 90 percent, but effective dissent is minimal. It is difficult to appraise election results in the Eastern, one-party, Communist nations because published data are unreliable and cannot be easily compared.

In the non-Communist authoritarian regimes of the world a variety of means is employed to eliminate free electoral choice, ranging from suppression of the opposition to the physical intimidation of voters.

Functions of elections. Fundamental to the use of elections is the contribution that they make to democratic government. Where the members of the body politic cannot themselves govern and must entrust government to representatives, elections serve not only to select leaders acceptable to the voters but also to hold the leaders accountable for their performance in office. Accountability,

Elections
in
authoritarian
systems

Democratic
functions

however, is greatly jeopardized in electoral situations in which elected leaders, for want of ambition, do not care whether or not they are re-elected or in situations in which, for historical or other reasons, one party is so predominant as to preclude effective choice among alternate candidates or policies. Nevertheless, the possibility of controlling leaders by requiring them to submit to regular and periodic elections contributes to solving the problem of succession in leadership and, thereby, to the continuation of democracy. Moreover, where the electoral process is competitive and forces candidates or parties to expose their record of accomplishment and future intentions to popular scrutiny in election campaigns, elections serve as forums for the discussion of public issues, facilitate the expression of public opinion, and, more generally, permit an exchange of influence between governors and governed.

Elections also serve to reinforce the stability and legitimacy of the political community in which they take place. Like national holidays commemorating common experiences, elections serve to link the members of a body politic to each other and thereby confirm the viability of the political community. By mobilizing masses of voters in a common act of governance, elections lend authority and legitimacy to the acts of those who wield power in the name of the people.

Elections can also confirm the worth and dignity of the individual citizen as a human being. Whatever other needs he may have, participation in an election serves to gratify the voter's sense of self-esteem and self-respect. It gives him an opportunity to have his say, and he can, through expressing partisanship and even through nonvoting, satisfy his sense of belonging to or alienation from the political community. It is for just this reason that the age-long battle for the right to vote and the demand for equality in electoral participation can be seen as the manifestation of a profound human craving for personal fulfillment.

In all forms of government, from the most democratic to the most totalitarian alike, elections have a ritualistic aspect. Elections and the campaigns preceding them are dramatic events which, depending on cultural or historical circumstances, may exude the gay atmosphere of a circus or the sombre atmosphere of a funeral. Rallies, banners, posters, buttons, headlines, and television call attention to the importance of participation in the event. Candidates and parties, from right to left, in addition to propagating their policy objectives through rhetoric and slogans, invoke the symbols of nationalism or patriotism, reform or revolution, past glory or future promise. Whatever the peculiar national, regional, or local variations, elections are events that, by arousing emotions and channelling them toward collective symbols, break the monotony of daily life and focus attention on the common fate.

Systems of counting votes. Individual votes are totalled into collective decisions by rules of counting that voters and leaders have accepted as legitimate prior to the election. These decision rules may call for plurality voting, which requires that, among three or more alternatives, the winner need have only the highest number of votes; simple majority voting, which requires that the winner receive more than 50 percent of the vote; extraordinary majority voting, which requires some higher proportion for the winner, such as a two-thirds vote; or unanimity.

Plurality and majority decision. The simplest means of deciding an election is the plurality rule. To win, a candidate need only poll more votes than any other single opponent; he need not, as required by the majority formula, poll more votes than the combined opposition. The more candidates contesting a constituency seat, the greater the probability that the winning candidate will receive less than 50 percent of the vote. The plurality formula is used in the national elections of such countries as Great Britain, Canada, and New Zealand. One half of the West German Bundestag is elected according to the plurality system, while the other half is elected according to a proportional representation formula (see below).

Under the majority rule, the party or candidate winning over 50 percent of the vote in a constituency is awarded the contested seat. The winning party or candidate must poll more votes than the combined opposition. This sys-

tem thus ensures that the elected representative has the support of the majority of the voters. The majority formula is employed in the election of the Australian House of Representatives, and of the French National Assembly. It is usually applied only within single-member electoral constituencies.

Both the plurality and the majority-decision rules are employed in the election of U.S. presidents. The composition of the electoral college, which actually elects the president, is determined by a plurality vote taken within each state. Voters choose between the names of the presidential candidates, but they are in effect choosing the electors who will elect the president by means of a majority vote in the electoral college. All of a state's electoral votes (which are equal in number to its seats in Congress) are given to the presidential candidate who gains a plurality of the vote in the state election. It is thus possible for a president to be elected on the basis of a minority of the popular vote.

A critical difficulty with the majority formula is that in a multiparty political system, the formula may produce an electoral deadlock if no candidate secures 50 percent of the total vote. In order to break such deadlocks a second round of elections (second ballot) is required, if no candidate obtains a majority on the first round. In Australia, voters rank the candidates on an alternate preference ballot. If a majority is not achieved on the first round of elections, the weakest candidate is eliminated, and the votes he accrued are distributed to the other candidates according to the second preference on the ballot. This redistributive process is repeated until one candidate collects a majority of the votes. If no candidate secures a majority in the first round of the French National Assembly elections, another round of elections is required. In this second round, the candidate securing a plurality of the popular vote is declared winner.

Neither the majority nor the plurality formulas distribute legislative seats in proportion to the share of the popular vote won by the competing parties. Both formulas tend to award the strongest party disproportionately and to handicap the weaker parties. The latter is particularly true if small parties are rooted in ethnic, religious, or social minorities; small parties escape the inequities of the electoral system only if they have a regionally concentrated base. The plurality formula distorts the distribution of seats more than the majority system.

Proportional representation. Proportional representation requires that the distribution of offices be proportional to the distribution of the popular vote among competing political parties or candidates. It seeks to overcome the distribution imbalances that result from majority and plurality formulas, and to create a representative body that reflects the distribution of opinion within the electorate. Because of the use of multimember constituencies in proportional representation, parties with neither a majority nor plurality of the popular vote can still win legislative representation.

Proportional representation is an ideal that is sought after, but only approximated: the size of electoral districts is the critical factor; the larger the electoral district in terms of seats, the more proportional the representation will be. The number of seats assigned to a constituency is in fact a greater determinant of the proportionality of the outcome than is the specific type of proportional formula used. The different formulas of proportional representation are basically similar in their effect on the conversion of votes to political representation.

Developed in the 19th century in Denmark and in Britain, the single transferable vote formula—or Hare system (after one of its English developers, T. Hare)—employs a ballot that allows the voter to rank the competing candidates in order of preference. When the ballots are counted, any candidate receiving the necessary quota of first preference votes is awarded a seat. In the electoral calculations, votes received by a winning candidate in excess of the quota are transferred to other candidates according to the second preference marked on the ballot. Any candidate who then has the necessary quota is also awarded a seat. This process is repeated, with subsequent surpluses also being transferred, until all the remaining

Plurality
voting

seats have been awarded. Five-member constituencies are considered optimal for the working of the Hare system.

The single transferable vote formula, because it involves the aggregation of ranked preferences, necessitates complex electoral computations. This factor, plus the fact that the Hare system limits the influence of political parties, probably accounts for its infrequent use; at present it is used only in Eire and in the selection of the Australian and South African senates. The characteristic of the Hare formula, which distinguishes it from other proportional representation formulas, is its emphasis on candidates, not parties. The party affiliation of the candidates has no bearing on the computations.

The basic difference between the transferable vote formula and the list systems is that, in the latter, voters choose among party-compiled lists of candidates rather than among individual candidates. Although voters may have some limited choice among individual candidates, electoral computations are on the basis of party affiliation; seats are awarded in respect to party rather than candidate totals. The seats that a party wins are allocated to its candidates in the order in which they appear on the party list. Several types of electoral formulas are used, although they fall into two main categories; largest average formulas and greatest remainder formulas. All employ some type of electoral quota.

Largest
average
formula

In the largest average formula, the number of votes won by each party is divided by the number of seats held by the party, plus one. The first seat is awarded to the party with the highest number of votes, since, no seats yet having been allocated, the initial denominator is 1. When a party wins a seat, its formula denominator is increased by one and hence the party's chances of winning the next seat are reduced. The available seats are awarded one at a time to the party with the greatest average. Party totals, not candidate totals, are used in the calculations. No transfer of ballots takes place. Frequently named after its Belgian inventor, Victor d'Hondt, the largest average formula is used in Austria, Belgium, Finland, and Switzerland, and in the proportional representation half of the West German Bundestag elections.

The d'Hondt formula has a slight tendency to over reward large parties and to reduce the chance of small parties gaining legislative representation. The so-called Lague variation of the d'Hondt formula—used in Denmark, Norway, and Sweden—reduces the reward to large parties but increases further the handicap to small parties. By adjusting the denominator of the d'Hondt formula, the Lague formula increases the cost of both the initial seat of a party and that of additional seats. The Lague formula thus aids middle-size political parties and reduces the number of legislatively represented small parties.

The greatest remainder method establishes a vote quota for each seat in an electoral district by dividing the total vote in the district by the number of competing parties. The total popular vote won by each party is then divided by the quota, and a seat is awarded as many times as the party total contains the full quota. If all the seats are awarded in this manner, the election is complete. Such an outcome is unlikely, however. Seats that were not won by full quotas are subsequently awarded to the parties with the largest remainder of votes after the quota has been subtracted from each party's total vote for each seat it was awarded. Seats are awarded sequentially to the parties with the largest remainder until all the district's allocated seats have been awarded.

Of all the proportional representation formulas, the greatest remainder formula, given large enough constituencies, yields results closest to the proportional ideal. Small parties fare better when the greatest remainder formula is used than when the largest average formula is employed. The greatest remainder formula is used in Israel, Italy, and Luxembourg and in some elections in Denmark. Italy, however, uses a special variety of the formula, called the Imperiali formula, whereby the electoral quota is established by dividing the total popular vote by the number of parties plus two. This modification increases the legislative representation of small parties but leads to a greater distortion of the proportional ideal.

The choice of majority and plurality or proportional systems is, of course, not simply a matter of pure theory. Different methods of counting, just as different conceptions of representation, usually reflect cultural, social-structural, and political circumstances in a particular jurisdiction. Majority or plural methods of voting are most likely to be acceptable in relatively stable political cultures. In such cultures, fluctuations in electoral support, given to one party or another from one election to the next, reduce polarization and make for political centrism. Thus the "winner take all" implications of the majority or plurality formulas are not experienced as unduly deprivational or restrictive. Proportional representation, on the other hand, is more likely to be found in societies with traditional ethnic, linguistic, and religious cleavages or in societies experiencing pervasive class and ideological conflicts.

Types of elections. *Election of officeholders.* Rather than deciding public policy, election to public office bestows the right to decide on a small group of elected officials. The elections grant officials the authority to make public policy decisions, and thereby legitimize the decisions that are made. The policy voice of the electorate in these elections may be weak. An electoral mandate results not so much in the implementation of the abstract preferences of the majority of the citizens, but rather in the implementation of the policy of those leaders who come to power in elections.

Most officeholder elections are interpretable only in terms of the role of political parties in the political process. Parties are tied so closely to the democratic functions of elections that their competition for the electorate's support is considered the main criterion by which democratic elections are distinguished from nondemocratic elections. Because of the difficulty in fixing individual responsibility in the complexity and vastness of modern governments, political parties, rather than representatives, have become the vehicle of democratic accountability.

Political parties shape the nature of the electoral decision. The selection and nomination of candidates, a vital first stage of the electoral process, lies in the hands of the political parties; the election serves only as the final process in the recruitment to political office. The party system can thus be regarded in a true sense as an extension of the electoral process. Political parties provide the pool of talent from which candidates are drawn, and they simplify and direct the electoral choice and mobilize the electorate at the registration and election stage. Political parties have transformed elections from a choice of men to a choice of governments.

But the fusion of political parties with the electoral process has not gone unchallenged. In North America a number of modifications have been made in the electoral structure to limit the influence of political parties. Nonpartisan elections (elections in which party affiliations are not formally indicated on ballots) are the norm for some municipalities in the United States and Canada and represent an attempt to remove political parties from the electoral scene. Nonpartisanship started as a reform movement in the early part of the 20th century and was designed to put local government on a more businesslike basis and to isolate local politics from state and national politics. The exclusion of party labels from the ballot, however, does not guarantee that political parties will be inactive or without influence in nonpartisan elections.

Recall. The practice of recalling officeholders was, like most populist innovations, an attempt to minimize the influence of political parties on representatives. The recall was an electoral modification designed to ensure that an elected representative would act as a spokesman for his constituency rather than for his political party or the dictates of his own conscience or interests. It enabled constituents to recall their elected representative before the end of his term of office if, in their opinion, he was no longer acting in accord with the best interests of the constituency. The actual instrument of recall was often a letter of resignation signed by the elected representative before assuming office. During the term of office this letter could be evoked by a quorum of constituents if the representative's legislative performance failed to meet their

Role of
parties

expectations. In practice the recall is not often or widely used today, even where it is provided for constitutionally.

Referendum. A referendum is an election, held either at the initiative of the governors or the governed, in which the preferences of the community regarding a particular issue are assessed. The use of the referendum reflects a reluctance to entrust full decision-making power to elected representatives. Because of the small voting turnout for referendum elections, and the absence of affixed party labels to the referendum alternatives, voting in referendum elections is more open to leadership and interest group influence than is voting in officeholder elections.

Referenda usually concern the raising and spending of public money, although they are occasionally used to decide moral issues in which the elected bodies are deemed to possess no special competence. They may be legislatively binding, or merely consultative, but even consultative referenda are likely to be considered legislative mandates.

Plebiscite. Plebiscites are elections held to decide two paramount types of political issue: the form of government and the national boundaries adopted by the state. In the first case, the plebiscite is a means of establishing the legitimacy to rule, not a means of providing a choice among alternate governmental teams or legislative proposals. The incumbent government, seeking a popular mandate as a basis for legitimacy, employs a plebiscite to establish its right to speak for the nation. The incumbent rulers seek a single identity with the nation, and thus a vote for the nation is interpreted as a vote for the incumbent regime. Plebiscites of this nature are thought to establish a direct linkage between the rulers and the ruled; intermediaries such as political parties are bypassed in plebiscites, and in this respect they are antithetical to pluralism and competitive politics. Following the Revolution of 1789, the plebiscite had a great appeal in France, rooted as it was in the ideas of nationalism and popular sovereignty. In more recent times totalitarian regimes have employed plebiscites to legitimize their power.

Plebiscites have also been used as a device for establishing the boundaries of political units according to criteria of nationality. After World War I the plebiscite was employed as a means of fitting political boundaries to boundaries of nationality. Eleven plebiscites, based on universal suffrage, were proposed by the League of Nations, the most successful of which was held in 1935 in the Saar (which chose to remain a German territory rather than go to France). The potential of plebiscites for establishing or changing political boundaries is, however, severely limited, because they entail the prior agreement of two governments over what is usually a very contentious issue.

Constituencies: districting and apportionment. The drawing up of constituencies—those subdivisions of the total electorate that send representatives to the local or central assembly—is inextricably linked with questions concerning the nature of representation and methods of voting. Of these questions, that of representation is primary. The problem of electoral representation turns on the question of what is to be represented. In this connection the functions of constituencies and the problem of determining them (districting) become relevant. The central problem is that the constituency, as a geographical area, may contain within its boundaries diverse, and sometimes incompatible, social, economic, religious, or ethnic interests, all of which seek to be represented.

Districting The solution to this problem has been largely historically determined. Where the interests of electors have not been totally incompatible, and where ethnic, religious, social, and economic differences have been relatively free of passionate conflict, as in the Anglo-American countries, geographical areas (electoral districts) have usually been considered the constituency, and the method of counting has been some system of majority or plurality voting. The elected person represents the geographical unit as a whole, irrespective of internal divisions. In general, the district is a single-member constituency, although multimember constituencies are also possible.

On the other hand, where the electorate is composed of several minorities, none of which can hope to obtain a majority, or perhaps even a plurality sufficiently large to

obtain representation, the geographical district can only be regarded as an administrative unit for counting votes. The effective constituency is the group of electors that can be identified as having voted for a given candidate. In this case, election is usually by some method of proportional counting whereby any candidate, party, or group receiving a requisite number of votes is entitled to a proportionate number of representatives.

The drawing up, or delimitation, of electoral districts is inextricably linked with differing conceptions of representation; and conceptions of representation are inextricably linked with alternate methods of vote counting. The virtues and vices of different electoral arrangements are still debated by constitution makers, but the arguments advanced in favour of any one set of arrangements remain inconclusive. Although proportional systems treating electoral districts as merely administrative conveniences and providing for multiple representation are believed to approximate more closely the one man, one vote principle of democratic theory than do single-member geographic constituencies providing for majority or plurality voting, they are probably conducive to governmental instability, and they place an inordinately heavy burden of conflict resolution on representative bodies. This often makes for political stalemate or immobilism, as has been the case at times in France and Italy. But it is doubtful that in nations with many interests seeking representation any other method of electoral districting and vote counting would be satisfactory.

Representation of geographic constituencies with majority or plurality voting, on the other hand, disguises many differences in the electorate's composition and preferences. In single-member, majority-vote electoral districts, the minority losing at the polls may feel unrepresented. But it is often a precarious assumption that the majority itself is truly represented, since it is likely to be a loose coalition of diverse interests, and no single representative can usually do justice to the diversity of interests involved. In general, therefore, the representative, in so far as he is responsive, is more likely to play the role of broker among his district's diverse interests, rather than the role of spokesman for the district as a whole.

Whatever the role of representative, and however electoral units are conceived—as geographic areas with stable, compatible interests, or as purely administrative areas for the purpose of vote counting—districting must be distinguished from apportionment. In general, if the district is considered as only an administrative unit for counting votes, its boundaries can be drawn rather arbitrarily without injustice. The district as such has no stakes of its own to be represented. On the other hand, if the district is considered a true constituency, in the sense that it has unique interests that can be geographically and, as a result, socially defined, districting should not be arbitrary. The area involved should at least be contiguous and compact so that its presumed interests can be fairly recognized.

The difficulty in treating geographic areas as genuine constituencies is, of course, that internal transformations in their economy and social structure may make their historical boundaries obsolete. As a result, historical areas serving as electoral districts (such as provinces, states, or counties), which once served as genuine communities of interest to be represented, may no longer do so. As these districts become increasingly diverse, making it difficult to identify particular constituency interests, representatives find it increasingly impossible to be responsive to constituency wishes or needs.

Problems of apportionment, in contrast to problems of districting, stem from efforts to reconcile the territorial and population bases of representation. If geographic areas, for instance, are assumed to have an equal right to be represented because the area is considered to be a viable constituency, malapportionment in terms of population size is inevitable. New York with a population of nearly 20,000,000 has, in the U.S. Senate, the same number of representatives as Nevada with a population of less than 1,000,000. This kind of "constitutional malapportionment" must not be confused with the kind of "electoral malapportionment" that defies the one-man, one-vote

Apportionment

principle of equal representation. The latter is usually the result of population shifts. Under modern conditions of increasing urbanization, failure to reapportion the number of seats in representative bodies to take account of population changes has largely benefitted rural electoral districts. More recently, the shift of city people to the suburbs has led to possible underrepresentation of suburban vis-à-vis urban populations.

From a political rather than a legal perspective, malapportionment is usually considered "undemocratic" because it results in overrepresentation and underrepresentation of certain sectors of the population and, as a result, may culminate in public policies not acceptable to the true majority.

Apportionment is not a simple matter. In particular, the definition of the population among which a specified number of legislative seats is to be apportioned is not easy to arrive at. Any of several distinct quantities—total population, number of citizens of voting age, number of registered voters, or number of actual voters—may serve as bases of apportionment. If there were a constant relation between these groupings, apportionment would not be a problem, and any one of them could serve as a basis. In fact, however, the relation is not constant because of variations in registration and voting turnout.

Gerry-
mandering

Malapportionment, whether of the constitutional or electoral sort, must not be confused with gerrymandering—a form of arbitrary districting used to benefit the party that at a given time controls the apportionment process. Gerrymandering is named after governor of Massachusetts Elbridge Gerry (1744–1814), who recognized the possibility of influencing electoral outcomes by manipulating the boundaries of electoral districts. The practice involves concentrating large percentages of the opposite party's votes into a few districts, and drawing the boundaries of the other districts in such a way that the gerrymandering party wins in them all, even though the majority, or, in three-cornered elections, the plurality, is relatively small.

Gerrymandering comes to politicians easily. Party managers prefer "safe" districts to those that are competitive. By not contesting seriously in the other party's safe districts, by maintaining one's own safe districts, and by carving competitive districts up in such a way that one's own party is favoured, party managers use gerrymandering to create artificial district boundaries that, though advantageous to the parties, may harm other social, economic, and political interests that need representation.

Voting practices. There is a direct relation between the size of an electorate and the formalization and standardization of its voting practices. In very small voting groups, in which political encounters are face-to-face and the members are bound together by ties of friendship or common experience, voting is mostly informal and may not even require counting, because the "sense of the meeting" emerges from the group's deliberations. The consensus of the Quaker meeting is of this order. An issue is discussed until a solution emerges to which all participants can agree or, at least, from which any one participant will not dissent.

By way of contrast, in modern mass electorates, in which millions of individual votes are aggregated into the collective choice, formalization and standardization of voting practices and vote counting are the rule. This is necessary in order to guarantee that the outcome can be considered valid, reliable, and legitimate. Validity means that the collective choice in fact expresses the sense of the electorate. Reliability means that each vote is accurately recorded and effectively counted into the total. Legitimacy means that the criteria of validity and reliability have been met, so that the result of the voting is acceptable and provides authoritative guidelines in subsequent political conduct.

The development of routinized and standardized electoral practices in mass electorates is a surprisingly recent phenomenon, not much older than 100 years. It is as much a corollary of the growth of rapid communication through telephone and telegraph as of the growth of the electorate and rational insistence on making electoral processes fair and equitable. Nevertheless, even today electoral practices around the world differ a great deal, depending not just

on formal institutional arrangements, but even more on a country's political culture.

Secret voting. Once suffrage rights had been extended to masses of voters who, in theory, were assumed to be equal but who, in fact, were unequal (in order of birth, in intellectual endowment and educational accomplishment, in social status and the possession of property, and so on), open voting was no longer tolerable precisely because it could and often did involve undue influence, ranging from hidden persuasion and bribery to intimidation, coercion, and punishment. Equality, at least in voting, was not something given but something that had to be engineered; the secrecy of the vote was a first and necessary administrative step toward the one man, one vote principle. Equality in voting was possible only if each vote was formally independent of every other vote, and this suggested the need for strict secrecy.

The slow progress made in introducing secret voting, from the French Revolution well into the 20th century, attests to the fact that social engineering, no matter how desirable or lofty in purpose, depends on favourable conditions for success. One need not assume that the obstacles placed in the way of secret voting were the result of some conspiracy on the part of those who recognized, quite accurately, that the mobilization of large numbers of voters fundamentally changed the distribution of political power and who, through opposing the secret vote, hoped to maintain a stranglehold on the newly enfranchised electorates. Rather, the success of secret voting depended on the reduction of illiteracy and, at the cultural level, on the spread of the individualistic norms of privacy and anonymity to certain classes of the population, notably peasants and workers. Traditionally these groups took their cues from those accepted as superior in status, or from their peers. Secret voting required learning to free oneself as a citizen from one's customary associations and from pressures for conformity. The difficulty of introducing and practicing the secret vote in today's politically and economically less developed nations mirrors the tortuous advance of the secret ballot in the Western nations during the 19th and early 20th centuries.

Secret voting reduces drastically the possibility of undue influence on the voter. Without it, influence can range from outright purchase of votes to social chastisement or economic sanctions. This is not to say that bribery in voting is automatically eliminated by secret voting. Laws prohibiting and punishing the purchase of votes are on the statute books of many countries and undoubtedly contribute to discouraging the practice.

Although informal social pressures on the voter are probably unavoidable and, in some respects, useful in reducing political rootlessness and contributing to political stability, secrecy in voting permits voters to break away from their social moorings and gives them a considerable degree of independence if they wish to take advantage of this electoral freedom. As a result it becomes ever more difficult for interest groups, whether labour unions, farmers' organizations, commercial or industrial associations, ethnic leadership groups, or even criminal syndicates, to "deliver the vote." The extent to which "deviant voting" occurs depends partly on the degree of rigidity in the social structure. In countries where caste or class barriers are high or where traditional social, economic, religious, or regional cleavages remain strong, deviant voting is less likely than in countries where social mobility is possible and where political conflicts cut across traditional social cleavages. In Western nations the increasing difficulties of labour, farm, religious, or ethnic leaders in influencing the voter attests to the success that secret voting seems to have had on freeing the individual from electoral bondage to his traditional or economic affiliations.

Balloting. The ballot makes secret voting possible. Its initial use seems to have been a means to reduce irregularities and deception in elections. This objective, however, could be achieved only if the ballot was not supplied by the voter himself, as was the case in much early voting by secret ballot, or by political parties, as is still the case in some countries. Ballot procedures differ widely, ranging from marking the names of preferred candidates to

Benefits
of secret
voting

crossing out those not preferred or writing in the names of persons who are not formal candidates. Ballots also differ according to the type of voting system employed. Where plurality or majority voting is practiced, most elections employ classified ballots whereby the voter casts his vote for only one candidate or list of candidates. Where proportional methods are used, election is by ballots that enable the voter to rank the candidates according to his preferences.

Though evidence is hard to come by, it is commonly believed that the nature of the ballot influences the voter's choice. In jurisdictions where electors are called upon to vote not only for higher offices but also for a multitude of local positions and where, in addition, the election may include propositions in the nature of referenda, the length of the ballot seems to be a factor affecting vote outcomes. Overwhelmed by the length of the ballot, voters may be discouraged from expressing their preferences for candidates of whom they have not heard, or from deciding on propositions that they do not understand. Breaking up of the single ballot into separate short ballots helps overcome this problem but does not eliminate it. Election data show a rapid decline from votes cast for higher offices to those cast for lower offices and referendum-type propositions.

Ballot position also seems to have an effect on the votes cast for particular candidates, especially in the absence of cues as to party affiliation or other identifications. The first position on the ballot may be favoured, and in the case of a long ballot both first and last names may benefit, with candidates in the middle of the ballot suffering a slight handicap. Ballot position is likely to have its greatest impact in nonpartisan elections, primaries, and elections for minor offices.

Finally, the manner in which candidates are listed—by party column or office bloc—is likely to affect election outcomes. On party-column ballots it is possible to vote a “straight ticket” for all of a party's candidates by entering a single mark, although voting for individual candidates is usually possible. On the other hand, on the office-bloc ballot, voting is for individual candidates grouped by office rather than party. This discourages, though it does not eliminate, voting exclusively for members of one party. This can have important consequences for the structure of government, especially in systems with separated powers and federal territorial organization. If different offices are controlled by different parties, the governmental process may be marked by greater conflict than would otherwise be the case, and governmental decision-making often will be more difficult.

The introduction of voting machines has not substantially changed the balloting process, although it has made it faster, more accurate and economical, and virtually tamper-proof. The voting machine is not without some minor problems of its own, in that it may marginally depress the level of voting. In candidate elections the dampening effect is accounted for by improper use of the machine, a problem that is being overcome through improved machines and voter education.

Compulsory voting. In some nations, notably Australia and Belgium, electoral participation is legally required of all citizens, and nonvoters without legitimate excuses face money fines. The concept of compulsory voting reflects a strain in democratic theory in which voting is considered not merely a right but a duty. Its purpose is to ensure the electoral equality of all social groups.

Whether made compulsory in law or through social pressure, it is doubtful that high voter turnout as such is a good indication of an electorate's capability for intelligent social choice. On the other hand, high rates of abstention or differential rates of abstention by different social classes are not necessarily signs of satisfaction with governmental processes and policies and may in fact indicate the contrary.

Electoral abuses. Corruption of electoral practices is, of course, not limited to bribery or intimidation of the individual voter. The possibilities are endless, ranging from the dissemination of scurrilous rumours about candidates, and deliberately false campaign propaganda, to tampering with the election machinery by stuffing the ballot box

with fraudulent returns, dishonest counting or reporting of the vote, and total disregard of electoral outcomes by incumbent officeholders. The existence of these practices depends more on a population's adherence to political civility and the democratic ethos than on the prohibitions and sanctions written into the law.

The integrity of the electoral process is maintained by a variety of devices and practices. Permanent and up-to-date registries of voters are maintained to guarantee easy identification of those eligible to participate in elections, and procedures are designed to make the registration process as simple as possible. In most jurisdictions, elections are now held on a single day rather than staggered. Polling hours in all localities are the same, and opening and closing hours are fixed and announced, so that voters have an equal opportunity to participate. Polling stations are manned by presumably disinterested government officials or polling clerks under governmental supervision; and political party agents or party workers are given an opportunity to observe the polling process, enabling them to challenge irregularities and prevent abuses. Efforts are made to maintain order in polling stations, directly through police protection or indirectly through such practices as closing bars and liquor stores. The act of voting itself takes place in voting booths that protect privacy. Votes are counted and often recounted by tellers, watched by party workers to assure an honest count. The transmission of voting results from local polling stations to central election headquarters is safeguarded and checked.

Participation in elections. The rate at which individuals participate in the electoral process depends on many factors, including the type of electoral system, the social groupings to which voters belong, the voters' personality and beliefs, their place of residence, and a host of other idiosyncratic factors.

The level and type of election has a great impact on the rate of electoral participation. Electoral turnout is greater in national than in state or provincial elections, and greater in the latter than in local elections. Because of this, scheduling has an impact on the turnout for local elections. If local elections are held concurrently with provincial or national elections, a higher voter turnout is achieved than for nonconcurrent elections.

Whether an election is partisan or nonpartisan also affects voter turnout—lighter participation occurring in the nonpartisan elections. Participation is also greater in candidate elections than in noncandidate elections such as referenda. There is some evidence that elections based on proportional representation, in which in some cases every vote counts, have higher electoral turnouts than majority or plurality elections. Noncompetitive or safe electoral districts tend to depress the level of voter turnout, whereas marginal elections increase the turnout.

Technicalities in electoral law involuntarily disenfranchise many potential voters. As a result of moving, people may temporarily lose their vote because of residence requirements for voters in their new electoral district. Complicated voter registration procedures, combined with a high level of geographical mobility, significantly reduce the size of the active electorate in the United States, whereas in Canada and Great Britain the size of the electorate is maximized by government-initiated registration immediately prior to elections. Voter registration in the United States is left to the initiative of individuals and political parties.

Relatively low levels of electoral participation are associated with rural residence, and also with low levels of education, occupational status, and income. The groups in society that have been most recently enfranchised also tend to vote less. Hence women vote less than men, American blacks less than whites, and working class people less than those of the middle class. Young people who have just turned of age, and have therefore just been enfranchised, are less likely to vote than people who are middle-aged. It is important to note that the nonparticipation of certain groups in elections has important implications; if everyone were to vote, the balance of electoral power would shift toward the recently enfranchised and less privileged members of the society.

Effect of
level and
type of
election

Group
differences

Some people are conscientious nonvoters, although such people are rare. Others, perceiving the vote more as an instrument of censure than of support, may not vote because they are satisfied with the present government. This group of voluntary nonvoters is also small, however. In fact, nonvoters have been shown to be generally less satisfied with the political status quo than are voters. The vote is a rather blunt and ineffectual instrument for expressing dissatisfaction, and nonvoting is more likely to be symptomatic of alienation from, than of satisfaction with, the political system.

Supporters of political parties vote more frequently than nonsupporters; to party supporters the vote becomes a pledge of their party loyalty as well as a political instrument.

Those who feel that government policies have some direct relevance to their lives are more likely to vote than those who are disinterested or who sense the government as being more remote.

Finally, a great number of random factors may determine individual participation in specific elections. Election campaigns vary in their intensity. A crisis atmosphere may induce an unusually large number of people to vote, on one occasion, whereas on another the chance to vote for an extremist candidate may increase the participation of the normally disinterested. Even the weather has a substantial impact on election turnout.

Influences on the direction of voting. The electoral choice of voters is largely influenced by their membership in social groups or by the social groups with which they identify, and, to a much lesser extent, by campaign issues and party promises. The determinants of party membership or party identification are the most crucial factors behind the voting decision. Membership in social and occupational classes, regional, religious or ethnic groupings, and so on, are thus important influences on the direction of the vote.

Because the electoral choice appears to be largely determined by long-standing group and party identifications, the voting decision may appear to be irrational, in that it is not based on a careful calculation of the immediate benefits expected to accrue to the voter from each electoral outcome. Group-determined voting does not preclude rationality, however, for individual self-interest may well be tied to the destiny of the social groups to which the voter belongs.

Independent
voting

The independent voter, contrary to much common belief, is likely to be poorly informed politically and relatively uninterested and uninvolved in politics. Paradoxically, however, by switching their support, independent voters represent an important factor in democratic politics.

In most countries the relatively permanent party alignments are based on social and cultural cleavages. But if elections are to be competitive, and if control of the government is to alternate between parties or coalitions of parties, then some voters must switch party support from election to election. New voters and independent voters, therefore, provide a vital source of change in democratic politics.

(H.E./R.G./Ed.)

BIBLIOGRAPHY

General works: Perhaps the best single introduction to the subjects covered in this article is CARL J. FRIEDRICH, *Man and His Government: An Empirical Theory of Politics* (1963). Other excellent general works include KARL LOEWENSTEIN, *Political Power and the Governmental Process*, 2nd ed. (1965); and R.M. MACIVER, *The Modern State* (1926) and *The Web of Government* (1947). A good introductory text is JOHN C. WAHLKE and ALEX N. DRAGNICH (eds.), *Government and Politics* (1966); and some carefully selected readings are available in HARRY ECKSTEIN and DAVID E. APTER (eds.), *Comparative Politics* (1963). For many subjects, *The International Encyclopedia of the Social Sciences*, 17 vol. (1968), is an excellent reference.

Supranational political systems: The history of the empires of the ancient world may be studied in a number of monumental works, including ARNOLD J. TOYNBEE, *A Study of History*, 1st-2nd ed., 12 vol. (1948-61); OSWALD SPENGLER, *Der Untergang des Abendlandes*, 2 vol. (1918-23; Eng. trans., *The Decline of the West*, 2 vol., 1926-28); and EDUARD MEYER, *Geschichte des Altertums*, 5 vol. (1884-1902, reprinted 1910-39). Among other general works, S.N. EISENSTADT, *The Political Systems of*

Empires (1963), compares the ancient empires in terms of bureaucracy; and KARL WITTFÖGEL, *Oriental Despotism: A Comparative Study of Total Power* (1957), traces the origins of their political orders. Treatments of the major empires of the ancient world include JAMES H. BREASTED, *Development of Religion and Thought in Ancient Egypt* (1912); A.T. OLMSTEAD, *History of Assyria* (1923, reprinted 1960); JOHN A. WILSON, *The Culture of Ancient Egypt* (1956); WILLIAM C. HAYES, *The Scepter of Egypt* (1953); R.E.M. WHEELER, *The Indus Civilization* (1953); OTTO FRANKE, *Geschichte des chinesischen Reiches*, 5 vol. (1930-52); WOLFRAM EBERHARD, *Chinas Geschichte* (1948; Eng. trans., *A History of China*, 3rd ed. rev., 1969); ETIENNE BALAZS, *Chinese Civilization and Bureaucracy* (1964); MIKHAIL ROSTOVTSSEV, *The Social and Economic History of the Roman Empire* (1963); A.E.R. BOAK, *History of Rome to 565 A.D.* (1921); GEORGE OSTROGORSKI, *Geschichte des byzantinischen Staates* (1965; Eng. trans., *History of the Byzantine State*, 2nd ed., 1968). Histories of modern colonial empires are found in J. HOLLAND ROSE et al. (eds.), *The Cambridge History of the British Empire*, 9 vol. (1929-59; 2nd ed., 1963-); RICHARD KOEBNER and HELMUT D. SCHMIDT, *Imperialism: The Story and Significance of a Political World, 1840-1960* (1964); CHARLES DE LANNOY and HERMAN V. LINDEN, *Histoire de l'expansion coloniale des peuples européens*, 3 vol. (1907-21); STEPHEN H. ROBERTS, *The History of French Colonial Policy, 1870-1925* (1963); ROBERT L. SCHUYLER, *The Fall of the Old Colonial System* (1945); MARY E. TOWNSEND, *The Rise and Fall of Germany's Colonial Empire, 1884-1918* (1930); CLARENCE H. HARING, *The Spanish Empire in America* (1947). A discussion of the post-imperial era in Asia and Africa is provided by RUPERT EMERSON in *From Empire to Nation* (1960). An excellent discussion of modern supranational political institutions is available in INIS L. CLAUDE, *Swords into Ploughshares*, 4th ed. (1971); the same author discusses the conditions for the development of different types of international organization in his *Power and International Relations* (1962). GERARD J. MANGONE, *A Short History of International Organization* (1954), is a convenient reference for the development of most contemporary supranational political institutions. Standard treatments of the League of Nations and the United Nations are available in FRANCIS P. WALTERS, *A History of the League of Nations* (1960); ALFRED E. ZIMMERN, *The League of Nations and the Rule of Law, 1918-1935* (1938); and HERBERT G. NICHOLAS, *The United Nations As a Political Institution*, 2nd ed. (1962). More specialized works that may be consulted include THOMAS HOVET, *Bloc Politics in the United Nations* (1958); STEPHEN M. SCHWEBEL, *The Secretary-General of the United Nations* (1952); and ALEXANDER DALLIN, *The Soviet Union at the United Nations* (1962). The development of supranational institutions in Europe is discussed in ERNST B. HAAS, *The Uniting of Europe* (1958); MICHAEL CURTIS, *Western European Integration* (1965); WALTER HALLSTEIN, *United Europe: Challenge and Opportunity* (1962); and UWE W. KITZINGER, *The Politics and Economics of European Integration* (1963). Good discussions of the political and constitutional organization of the British Commonwealth are found in WILLIAM S. LIVINGSTON (ed.), *Federalism in the Commonwealth* (1963); J.D.B. MILLER, *The Commonwealth in the World* (1958); and K.C. WHEARE, *The Constitutional Structure of the Commonwealth* (1960). An extremely useful commentary on various forms of supranational political organization is provided in IVO D. DUCHACEK, *Comparative Federalism: The Territorial Dimension of Politics* (1970). A journal published since 1947 by the World Peace Foundation, *International Organization* (quarterly), contains articles on current developments in international organization and also provides selective bibliographies. J.D.B. MILLER, *The World of States* (1981), is a pessimistic discussion of the likelihood that an international political system could replace the national systems.

National political systems: The phenomenon of nationalism is treated in HANS KOHN, *The Idea of Nationalism* (1961); and EUGEN LEMBERG, *Nationalismus*, 2 vol. (1964); and a historical sketch of the emergence of the idea and its reality is provided in CARLTON J.H. HAYES, *The Historical Evolution of Modern Nationalism* (1931, reprinted 1968). Among the many works on federal and unitary systems that the student should consult are ARTHUR W. MACMAHON (ed.), *Federalism, Mature and Emergent* (1955); WILLIAM S. LIVINGSTON, *Federalism and Constitutional Change* (1956); VALERIE EARLE (ed.), *Federalism* (1968); CARL J. FRIEDRICH, *Trends of Federalism in Theory and Practice* (1968); PETER HAY, *Federalism, and Supranational Organizations* (1966); K.C. WHEARE, *Federal Government*, 4th ed. (1963); and GEORGE C.S. BENSON et al., *Essays in Federalism* (1961). IVO D. DUCHACEK (*op. cit.*) should also be consulted. Works on individual nation-states are so numerous that the student may wish to consult some standard texts that include selected bibliographies: HAROLD ZINK, *Modern Governments*, 2nd ed. (1962); HERMAN FINER, *The Major Governments of Modern Europe* (1960); and GWENDOLEN M. CARTER and JOHN H. HERZ, *Major Foreign*

Powers, 5th ed. (1967). Comparative studies of different aspects of contemporary national government are also numerous. The bureaucracies and administrative procedures of different modern governments are treated in BRIAN CHAPMAN, *The Profession of Government: The Public Service in Europe* (1959); JOSEPH G. LA PALOMBARA (ed.), *Bureaucracy and Political Development* (1963); FRITZ MORSTEIN MARX, *The Administrative State* (1957); WILLIAM J. SIFFIN (ed.), *Toward the Comparative Study of Public Administration* (1957); ERICH STRAUSS, *The Ruling Servants: Bureaucracy in Russia, France and—Britain?* (1960); and J.D. THOMPSON et al. (eds.), *Comparative Studies in Administration* (1959). Constitutions, courts, and other judicial institutions are comparatively treated in LESLIE WOLF-PHILLIPS (ed.), *Constitutions of Modern States* (1968); K.C. WHEARE, *Modern Constitutions*, 2nd ed. (1966); WILLIAM GEORGE ANDREWS (ed.), *Constitutions and Constitutionalism*, 3rd ed. (1968); HENRY J. ABRAHAM, *Courts and Judges* (1959) and *The Judicial Process: An Introductory Analysis of the Courts of the United States, England, and France*, 2nd ed. rev. (1968); FREDA CASTBERG, *Freedom of Speech in the West: A Comparative Study of Public Law in France, the United States, and Germany* (1960); RUSSELL F. MOORE (ed.), *Modern Constitutions* (1957); DOROTHY PEASLEE XYDIS, *Constitutions of Nations*, rev. 3rd ed., 4 vol. (1965–70); and CHARLES F. STRONG, *A History of Modern Political Constitutions* (1964). National legislatures are discussed in LORD CAMPION and D.W.S. LIDDERDALE, *European Parliamentary Procedure* (1953); PAUL EINZIG, *The Control of the Purse* (1959); JOHN E. KERSELL, *Parliamentary Supervision of Delegated Legislation* (1960); and K.C. WHEARE, *Legislatures* (1963). Political parties, elections, and interest groups are comparatively treated in ROBERT R. ALFORD, *Party and Society: The Anglo-American Democracies* (1963); DAVID E. BUTLER (ed.), *Elections Abroad* (1959); ROBERT A. DAHL (ed.), *Political Oppositions in Western Democracies* (1966); MAURICE DUVERGER, *Les Partis politiques*, 5th ed. (1964; Eng. trans., *Political Parties*, 2nd ed. rev., 1959); HENRY W. EHRLMANN (ed.), *Interest Groups on Four Continents* (1958); JOSEPH G. LA PALOMBARA and MYRON WEINER (eds.), *Political Parties and Political Development* (1966); W.J.M. MACKENZIE, *Free Elections* (1958); SIGMUND NEUMANN (ed.), *Modern Political Parties* (1956); and T.E. SMITH, *Elections in Developing Countries* (1960). General comparative studies of national political systems include GABRIEL ALMOND and SIDNEY VERBA, *The Civic Culture: Political Attitudes and Democracy in Five Nations* (1965); GABRIEL ALMOND and JAMES S. COLEMAN (eds.), *The Politics of the Developing Areas* (1960); GABRIEL ALMOND and G. BINGHAM POWELL, JR., *Comparative Politics: A Developmental Approach* (1966); ZBIGNIEW BRZEZINSKI and SAMUEL P. HUNTINGTON, *Political Power: USA/USSR* (1964); JAMES S. COLEMAN (ed.), *Education and Political Development* (1965); ROBERT C. FRIED, *Comparative Political Institutions* (1966); LUCIAN W. PYE (ed.), *Communications and Political Development* (1963); LUCIAN W. PYE and SIDNEY VERBA (eds.), *Political Culture and Political Development* (1965); and KENNETH H.F. DYSON, *The State Tradition in Western Europe* (1980).

Subnational political systems: Excellent general treatments of local and city government are found in WILLIAM A. ROBSON, *The Development of Local Government*, 3rd rev. ed. (1954); and (ed.), *Great Cities of the World: Their Government, Politics, and Planning*, 2nd ed. rev. (1957); and in LEWIS MUMFORD, *The City in History* (1961). On early forms of city government, the student should consult HENRI PIRENNE, *Les Villes du moyen âge* (1927; Eng. trans., *Medieval Cities*, 1956); and FUSTEL DE COULANGES, *La Cité antique* (1864; Eng. trans., *The Ancient City*, 1873, many reprints). A useful comparative study of local government is found in G.M. HARRIS, *Comparative Local Government* (1949). City and local governments in contemporary Western systems are treated in D.N. CHESTER, *Central and Local Government* (1951); HERMAN FINER, *English Local Government*, 4th ed. rev. (1950); and BRIAN CHAPMAN, *Introduction to French Local Government* (1953). Political and sociological analyses of the local community include ROBERT A. DAHL, *Who Governs?* (1961); DONALD J. BOGUE, *The Structure of the Metropolitan Community* (1949); FLOYD HUNTER, *Community Power Structure* (1953); ROBERT S. and HELEN M. LYNDE, *Middletown: A Study in Contemporary American Culture* (1929); and H.D. MALAVIYA, *Village Panchayats in India* (1966). For tribal forms of government, see J.A. NOON, *Law and Government of the Grand River Iroquois* (1949); and ISAAC SCHAPERA, *The Khoisan Peoples of South Africa* (1930) and *Government and Politics in Tribal Societies* (1956).

Types and models: The student of classical typologies of political systems will first refer to Book IV of Aristotle's *Politics* and then perhaps consult Book VIII of Plato's *Republic* together with a number of passages in *The Laws*. Leading modern efforts to develop types and models of political systems may be found in GAETANO MOSCA, *Elementi di scienza politica*, 2nd ed. (1923; Eng. trans., *The Ruling Class*, rev. ed., 1939);

GUGLIELMO FERRERO, *Pouvoir* (1942; Eng. trans., *The Principles of Power*, 1942); and MAX WEBER, *Wirtschaft und Gesellschaft* (1922; Eng. trans. of pt. 1, *The Theory of Social and Economic Organization*, 1947). The Marxist typology, of course, is set forth in the writings of KARL MARX, FRIEDRICH ENGELS, LENIN, and their disciples. Contemporary efforts to develop typologies may be studied in DAVID E. APTER, "A Comparative Method for the Study of Politics," *American Journal of Sociology*, 64:221–237 (1958); DAVID EASTON, *A Systems Analysis of Political Life* (1965); GABRIEL ALMOND and G. BINGHAM POWELL, JR. (op. cit.); and ALEXANDER J. GROTH, *Comparative Politics: A Distributive Approach* (1971).

Development and change: There is a large contemporary literature centering on the question of modernization and political development. In addition to works by Gabriel Almond noted above, the student should consult PETER H. MERKL, *Modern Comparative Politics* (1970), which includes an excellent bibliography; and DAVID E. APTER, *The Politics of Modernization* (1965). Other works are CYRIL E. BLACK, *The Dynamics of Modernization* (1966) and (ed.), *The Transformation of Russian Society: Aspects of Social Change Since 1861* (1960); S.N. EISENSTADT, *Modernization: Protest and Change* (1966); JASON FINKLE and RICHARD W. GABLE (eds.), *Political Development and Social Change* (1966); EVERETT E. HAGEN, *On the Theory of Social Change* (1962); ROBERT T. HOLT and JOHN E. TURNER, *The Political Basis of Economic Development* (1966); SAMUEL P. HUNTINGTON, *Political Order in Changing Societies* (1968); JOHN H. KAUTSKY (ed.), *Political Change in Underdeveloped Countries* (1962); DANIEL LERNER, *The Passing of Traditional Society* (1958); MAX F. MILLIKAN and DONALD L.M. BLACKMER (eds.), *The Emerging Nations* (1961); DANKWART RUSTOW, *A World of Nations: Problems of Political Modernization* (1967); EDWARD A. SHILS, *Political Development in the New States* (1962); I. ROBERT SINAI, *The Challenge of Modernisation* (1964); FRED VON DER MEHDEN, *Politics of the Developing Nations* (1964); IMMANUEL WALLERSTEIN, *Social Change: The Colonial Situation* (1966); BARBARA WARD, *The Rich Nations and the Poor Nations* (1961); and ARISTIDE R. ZOLBERG, *Creating Political Order: The Party-States of West Africa* (1966).

Forms, levels, and divisions of government: One of the best introductions to the study of different forms of government and an excellent review of the differences between constitutionalism and autocracy, democracy and totalitarianism, is KARL LOEWENSTEIN, *Political Power and the Governmental Process*, 2nd ed. (1965). Also excellent are CARL J. FRIEDRICH, *Constitutional Government and Politics* (1937); and with ZBIGNIEW BRZEZINSKI, *Totalitarian Dictatorship and Autocracy*, 2nd rev. ed. (1965). On totalitarianism, other books that should be consulted are ZBIGNIEW BRZEZINSKI, *The Soviet Bloc*, rev. ed. (1967), and *Ideology and Power in Soviet Politics*, rev. ed. (1967); MILOVAN DJILAS, *The New Class* (1957); MERLE FAINSDOD, *How Russia Is Ruled*, rev. ed. (1963); ALEX INKELES and R.A. BAUER, *The Soviet Citizen: Daily Life in a Totalitarian Society* (1959); ERNST NOLTE, *Der Faschismus in seiner Epoche* (1963; Eng. trans., *The Three Faces of Fascism*, 1966); J.L. TALMON, *The Rise of Totalitarian Democracy* (1952); ALEXANDER DALLIN and ALAN F. WESTIN (eds.), *Politics in the Soviet Union* (1966); and HERBERT MCCLOSKEY and JOHN E. TURNER, *The Soviet Dictatorship* (1960). On constitutional forms, the student should refer to WALTER BAGEHOT, *The English Constitution*, rev. ed. (1911, reprinted 1966); JAMES BRYCE, *The American Commonwealth*, rev. ed., 2 vol. (1931–33); D.L. KEIR, *The Constitutional History of Modern Britain, 1485–1951*, 9th ed. (1969); IVOR JENNINGS, *Cabinet Government*, 3rd ed. (1969), and *Parliament*, 2nd ed. (1957); C.W. CASSINELLI, *The Politics of Freedom* (1961); V.O. KEY, *Politics, Parties, and Pressure Groups*, 5th ed. (1964), and *Public Opinion and American Democracy* (1961); A.D. LINDSAY, *The Modern Democratic State* (1943); C.H. MCILWAIN, *Constitutionalism, Ancient and Modern*, rev. ed. (1947); HERBERT MORRISON, *Government and Parliament*, 3rd ed. (1964); CLINTON ROSSITER, *Constitutional Dictatorship* (1948); and HERBERT J. SPIRO, *Government by Constitution: The Political Systems of Democracy* (1959). A good general introduction to the major European forms of constitutional and totalitarian governments is available in SAMUEL H. BEER and ADAM B. ULAM (eds.), *Patterns of Government: The Major Political Systems of Europe*, 2nd ed. rev. (1962). CARL J. FRIEDRICH offers an excellent introduction to the problem of the relationship between different levels of government in *Man and His Government* (1963)—see especially pt. 5, "Ranges and Levels of Government." Other books to consult on this subject are CLAUDE AKE, *A Theory of Political Integration* (1967); HAROLD ALDERFER, *Local Government in Developing Countries* (1964); REINHARD BENDIX, *Nation-Building and Citizenship* (1964); BRIAN CHAPMAN, *Introduction to French Local Government* (1953); L.G. COWAN, *Local Government in West Africa* (1958); RICHARD COX, *Pan-Africanism in Practice* (1964); KARL W. DEUTSCH, *Nationalism and Social Communication* (1953) and *The Nerves of Government* (1963);

with new introd., 1966); RUPERT EMERSON, *From Empire to Nation* (1960); RICHARD R. FAGEN, *Politics and Communication* (1966); JAMES FESLER, *Area and Administration* (1949); HERMAN FINER, *English Local Government* (1933); J.A.G. GRIFFITH, *Central Departments and Local Authorities* (1966); LUCIAN W. PYE (ed.), *Communications and Political Development* (1963); WILLIAM A. ROBSON, *Local Government in Crisis* (1966); and MARC J. SWARTZ (ed.), *Local-Level Politics* (1968). Short introductions to the divisions of government, suitable for the beginning student, are available in ROBERT C. FRIED, *Comparative Political Institutions* (1966); and JOHN C. WAHLKE and ALEX N. DRAGNICH (op. cit.). On the legislative division of government, in addition to the books listed in an earlier section of this bibliography, the student should consult BERTRAM GROSS, *The Legislative Struggle* (1953); WILLIAM J. KEEFE and MORRIS S. OGUL, *The American Legislative Process*, 2nd ed. (1968); D.W.S. LIDDERDALE, *The Parliament of France* (1951); STEPHEN KING-HALL and R.K. ULLMANN *German Parliaments* (1954); JOHN C. WAHLKE and HEINZ EULAU (eds.), *Legislative Behaviour* (1959); and JOHN C. WAHLKE et al., *The Legislative System* (1962). Additional reading on executives should include C.G. BROWNE and T.S. COHN (eds.), *The Study of Leadership* (1958); EDWARD S. CORWIN, *The President: Office and Powers, 1787-1957*, 4th rev. ed. (1957); ALVIN W. GOULDNER (ed.), *Studies in Leadership* (1950); HOOVER INSTITUTE STUDIES, *Elites*, 5 vol. (1951-55); RICHARD E. NEUSTADT, *Presidential Power* (1960); and ERIC STRAUSS (op. cit.). Further reading on courts and systems of law is available in HAROLD J. BERMAN, *Justice in the U.S.S.R.* (1963); FELIX S. COHEN, *Ethical Systems and Legal Ideals* (1933); RENE DAVID and HENRY DE VRIES, *The French Legal System* (1957); JEROME FRANK, *Courts on Trial* (1949); RICHARD M. JACKSON, *The Machinery of Justice in England*, 3rd ed. (1960); HANS KELSEN, *The Communist Theory of Law* (1955); W.F. MURPHY and C.H. PRITCHETT, *Courts, Judges, and Politics* (1961); J.W. PELTASON, *Federal Courts in the Political Process* (1955); J.R. SCHMIDHAUSER, *The Supreme Court: Its Politics, Personalities, and Procedures* (1960); GLENDON SCHUBERT (ed.), *Judicial Decision-Making* (1963); and BERNARD SCHWARTZ, *French Administrative Law and the Common-Law World* (1954).

The functions of government: The functions of government may be studied in many works dealing with each of the world's advanced political systems. For the United States, the student should consult JAMES E. ANDERSON, *The Emergence of the Modern Regulatory State* (1962); MELVIN ANSHEN and FRANCIS D. WORMUTH, *Private Enterprise and Public Policy* (1954); MORROE BERGER, *Equality by Statute* (1952); RICHARD E. CAVES, *Air Transport and Its Regulators* (1962); ROBERT A. DAHL and CHARLES E. LINDBLOM, *Politics, Economics, and Welfare* (1953); KENNETH CULP DAVIS, *Administrative Law* (1951); ERNST FREUND, *Administrative Powers over Persons and Property* (1928); D.E. HATHAWAY, *Government and Agriculture: Public Policy in a Democratic Society* (1963); CARL KAYSEN and DONALD F. TURNER, *Antitrust Policy* (1959); JAMES M. LANDIS, *The Administrative Process* (1938); AVERY LEISERSON, *Administrative Regulation* (1942); JOHN H. LEEK, *Government and Labor in the United States* (1952); MICHAEL D. REAGAN, *The Managed Economy* (1963); EMMETTE S. REDFORD, *American Government and the Economy* (1965) and *Administration of National Economic Control* (1952); GEORGE A. STEINER, *Government's Role in Economic Life* (1953); GEORGE W. TAYLOR, *Government Regulation of Industrial Relations* (1948); and DONALD S. WATSON, *Economic Policy: Business and Government* (1960). For Great Britain, the student should consult PATRICK ABERCROMBIE, *Town and Country Planning*, 3rd ed. (1959); W.P. ALEXANDER, *Education in England: The National System—How It Works*, 2nd ed. (1964); MAX BELOFF, *New Dimensions in Foreign Policy* (1961); A.M. CARTTER, *The Redistribution of Income in Postwar Britain* (1955); HARRY ECKSTEIN, *The*

English Health Service (1958); PETER GOLDMAN, *The Welfare State* (1964); F.A. JOHNSON, *Defense by Committee* (1960); T.H. MARSHALL, *Social Policy* (1965); and HAROLD E. RAYNES, *Social Security in Britain*, 2nd ed. (1960). On France there are WARREN C. BAUM, *The French Economy and the State* (1958); JOHN S. HARLOW, *French Economic Planning* (1966); MARIO EINAUDI, MAURICE BYE, and ERNESTO ROSSI, *Nationalization in France and Italy* (1955); W.R. FRASER, *Education and Society in Modern France* (1963); JOHN and ANNE-MARIE HACKETT, *Economic Planning in France* (1963); WALLACE C. PETERSON, *The Welfare State in France* (1960); and JOHN B. SHEAHAN, *Promotion and Control of Industry in Postwar France* (1963).

The changing of government: Further reading on the politics of change should include DAVID E. APTER (ed.), *Ideology and Discontent* (1964); ROBERT N. BELLAH, *Religion and Progress in Modern Asia* (1965); CRANE BRINTON, *The Anatomy of Revolution*, rev. ed. (1952); HARRY ECKSTEIN (ed.), *Internal War* (1964); SAMUEL E. Population

Few aspects of human societies are as fundamental as the size, composition, and rate of change of their populations. Such factors affect economic prosperity, health, education, family structure, crime patterns, language, culture—indeed, virtually every aspect of human society is touched upon by population trends.

The study of human populations is called demography—a discipline with intellectual origins stretching back to the 18th century, when it was first recognized that human mortality could be examined as a phenomenon with statistical regularities. Demography casts a multidisciplinary net, drawing insights from economics, sociology, statistics, medicine, biology, anthropology, and history. Its chronological sweep is lengthy: limited demographic evidence for many centuries into the past, and reliable data for several hundred years are available for many regions. The present understanding of demography makes it possible to project (with caution) population changes several decades into the future.

THE BASIC COMPONENTS OF POPULATION CHANGE

At its most basic level, the components of population change are few indeed. A closed population (that is, one in which immigration and emigration do not occur) can change according to the following simple equation: the population (closed) at the end of an interval equals the population at the beginning of the interval, plus births during the interval, minus deaths during the interval. In other words, only addition by births and reduction by deaths can change a closed population. The notion of a closed population is not an abstraction; unless one believes that there has been substantial migration to and from this planet, the world population as a whole is closed.

Populations of nations, regions, continents, islands, or cities, however, are rarely closed in the same way. If the assumption of a closed population is relaxed, in- and out-migration can increase and decrease population size in the same way as do births and deaths; thus, the population (open) at the end of an interval equals the population at the beginning of the interval, plus births during the interval, minus deaths, plus in-migrants, minus out-migrants. Hence the study of demographic change requires knowledge of fertility (births), mortality (deaths), and migration. These, in turn, affect not only population size and growth

rates but also the composition of the population in terms of such attributes as sex, age, ethnic or racial composition, and geographic distribution.

Fertility. Demographers distinguish between fecundity, the underlying biological potential for reproduction, and fertility, the actual level of achieved reproduction. (Confusingly, these English terms have opposite meanings from their parallel terms in French, where *fertilité* is the potential and *fécondité* is the realized; similarly ambiguous usages also prevail in the biological sciences, thereby increasing the chance of misunderstanding.) The difference between biological potential and realized fertility is determined by several intervening factors, including the following: (1) most women do not begin reproducing immediately upon the onset of puberty, which itself does not occur at a fixed age; (2) some women with the potential to reproduce never do so; (3) some women become widowed and do not remarry; (4) various elements of social behaviour restrain fertility; and (5) many human couples choose consciously to restrict their fertility by means of sexual abstinence, contraception, abortion, or sterilization.

The magnitude of the gap between potential and realized fertility can be illustrated by comparing the highest known fertilities with those of typical European and North American women in the late 20th century. A well-studied high-fertility group is the Hutterites of North America, a religious sect that views fertility regulation as sinful and high fertility as a blessing. Hutterite women who married between 1921 and 1930 are known to have averaged 10 children per woman. Meanwhile, women in much of Europe and North America averaged about two children per woman during the 1970s and 1980s—a number 80 percent less than that achieved by the Hutterites. Even the highly fertile populations of developing countries in Africa, Asia, and Latin America produce children at rates far below that of the Hutterites.

The general message from such evidence is clear enough: in much of the world, human fertility is considerably lower than the biological potential. It is strongly constrained by cultural regulations, especially those concerning marriage and sexuality, and by conscious efforts on the part of married couples to limit their childbearing.

Dependable evidence on historical fertility patterns in Europe is available back to the 18th century, and estimates have been made for several earlier centuries. Such data for non-European societies and for earlier human populations are much more fragmentary. The European data indicate that even in the absence of widespread deliberate regulation there were significant variations in fertility among different societies. These differences were heavily affected by socially determined behaviours such as those concerning marriage patterns. Beginning in France and Hungary in the 18th century, a dramatic decline in fertility took shape in the more developed societies of Europe and North America, and in the ensuing two centuries fertility declines of fully 50 percent took place in nearly all of these countries. Since the 1960s fertility has been intentionally diminished in many developing countries, and remarkably rapid reductions have occurred in the most populous, the People's Republic of China.

There is no dispute as to the fact and magnitudes of such declines, but theoretical explanation of the phenomena has proved elusive. (See below *Population theories*.)

Biological factors affecting human fertility. Reproduction is a quintessentially biological process, and hence all fertility analyses must consider the effects of biology. Such factors, in rough chronological order, include:

- the age of onset of potential fertility (or fecundability in demographic terminology);
- the degree of fecundability—*i.e.*, the monthly probability of conceiving in the absence of contraception;

Potential
and
realized
fertility

Closed
and open
popula-
tions

the incidence of spontaneous abortion and stillbirth; the duration of temporary infecundability following the birth of a child; and the age of onset of permanent sterility.

The age at which women become fecund apparently declined significantly during the 20th century; as measured by the age of menarche (onset of menstruation), British data suggest a decline from 16–18 years in the mid-19th century to less than 13 years in the late 20th century. This decline is thought to be related to improving standards of nutrition and health. Since the average age of marriage in western Europe has long been far higher than the age of menarche, and since most children are born to married couples, this biological lengthening of the reproductive period is unlikely to have had major effects upon realized fertility in Europe. In settings where early marriage prevails, however, declining age at menarche could increase lifetime fertility.

Variations
in
fecund-
ability

Fecundability also varies among women past menarche. The monthly probabilities of conception among newlyweds are commonly in the range of 0.15 to 0.25; that is, there is a 15–25-percent chance of conception each month. This fact is understandable when account is taken of the short interval (about two days) within each menstrual cycle during which fertilization can take place. Moreover, there appear to be cycles during which ovulation does not occur. Finally, perhaps one-third or more of fertilized ova fail to implant in the uterus or, even if they do implant, spontaneously abort during the ensuing two weeks, before pregnancy would be recognized. As a result of such factors, women of reproductive age who are not using contraceptive methods can expect to conceive within five to 10 months of becoming sexually active. As is true of all biological phenomena, there is surely a distribution of fecundability around average levels, with some women experiencing conception more readily than others.

Spontaneous abortion of recognized pregnancies and stillbirth also are fairly common, but their incidence is difficult to quantify. Perhaps 20 percent of recognized pregnancies fail spontaneously, most in the earlier months of gestation.

Following the birth of a child, most women experience a period of temporary infecundability, or biological inability to conceive. The length of this period seems to be affected substantially by breast-feeding. In the absence of breast-feeding, the interruption lasts less than two months. With lengthy, frequent breast-feeding it can last one or two years. This effect is thought to be caused by a complex of neural and hormonal factors stimulated by suckling.

A woman's fecundability typically peaks in her 20s and declines during her 30s; by their early 40s as many as 50 percent of women are affected by their own or their husbands' sterility. After menopause, essentially all women are sterile. The average age at menopause is in the late 40s, although some women experience it before reaching 40 and others not until nearly 60.

Contraception. Contraceptive practices affect fertility by reducing the probability of conception. Contraceptive methods vary considerably in their theoretical effectiveness and in their actual effectiveness in use ("use-effectiveness"). Modern methods such as oral pills and intrauterine devices (IUDs) have use-effectiveness rates of more than 95 percent. Older methods such as the condom and diaphragm can be more than 90-percent effective when used regularly and correctly, but their average use-effectiveness is lower because of irregular or incorrect use.

The effect upon fertility of contraceptive measures can be dramatic: if fecundability is 0.20 (a 20-percent chance of pregnancy per month of exposure), then a 95-percent effective method will reduce this to 0.01 (a 1-percent chance).

Abortion. Induced abortion reduces fertility not by affecting fecundability but by terminating pregnancy. Abortion has long been practiced in human societies and is quite common in some settings. The officially registered fraction of pregnancies terminated by abortion exceeds one-third in some countries, and significant numbers of unregistered abortions probably occur even in countries reporting very low rates.

Sterilization. Complete elimination of fecundability can be brought about by sterilization. The surgical procedures of tubal ligation and vasectomy have become common in diverse nations and cultures. In the United States, for example, voluntary sterilization has become the most prevalent single means of terminating fertility, typically adopted by couples who have achieved their desired family size. In India, sterilization has been encouraged on occasion by various government incentive programs and, for a short period during the 1970s, by quasi-coercive measures.

Mortality. As noted above, the science of demography has its intellectual roots in the realization that human mortality, while consisting of unpredictable individual events, has a statistical regularity when aggregated across a large group. This recognition formed the basis of a wholly new industry—that of life assurance, or insurance. The basis of this industry is the life table, or mortality table, which summarizes the distribution of longevity—observed over a period of years—among members of a population. This statistical device allows the calculation of premiums—the prices to be charged the members of a group of living subscribers with specified characteristics, who by pooling their resources in this statistical sense provide their heirs with financial benefits.

Overall human mortality levels can best be compared by using the life-table measure life expectancy at birth (often abbreviated simply as life expectancy), the number of years of life expected of a newborn baby on the basis of current mortality levels for persons of all ages. Life expectancies of premodern populations, with their poor knowledge of sanitation and health care, may have been as low as 25–30 years. The largest toll of death was that exacted in infancy and childhood: perhaps 20 percent of newborn children died in their first 12 months of life and another 30 percent before they reached five years of age.

In the developing countries by the 1980s, average life expectancy lay in the range of 55 to 60 years, with the highest levels in Latin America and the lowest in Africa. In the same period, life expectancy in the developed countries of western Europe and North America approached 75 years, and fewer than 1 percent of newborn children died in their first 12 months.

For reasons that are not well understood, life expectancy of females usually exceeds that of males, and this female advantage has grown as overall life expectancy has increased. In the late 20th century this female advantage was seven years (78 years versus 71 years) in the industrial market economies (comprising western Europe, North America, Japan, Australia, and New Zealand). It was eight years (74 years versus 66 years) in the nonmarket economies of eastern Europe.

The epidemiologic transition. The epidemiologic transition is that process by which the pattern of mortality and disease is transformed from one of high mortality among infants and children and episodic famine and epidemic affecting all age groups to one of degenerative and man-made diseases (such as those attributed to smoking) affecting principally the elderly. It is generally believed that the epidemiologic transitions prior to the 20th century (*i.e.*, those in today's industrialized countries) were closely associated with rising standards of living, nutrition, and sanitation. In contrast, those occurring in developing countries have been more or less independent of such internal socioeconomic development and more closely tied to organized health care and disease control programs developed and financed internationally. There is no doubt that 20th-century declines in mortality in developing countries have been far more rapid than those that occurred in the 19th century in what are now the industrialized countries.

Infant mortality. Infant mortality is conventionally measured as the number of deaths in the first year of life per 1,000 live births during the same year. Roughly speaking, by this measure worldwide infant mortality approximates 80 per 1,000; that is, about 8 percent of newborn babies die within the first year of life.

This global average disguises great differences. In certain countries of Asia and Africa, infant mortality rates exceed 150 and sometimes approach 200 per 1,000 (that is, 15 or 20 percent of children die before reaching the age of

Life
table

Greater
longevity
of
females

Variations
in infant
mortality

one year). Meanwhile, in other countries, such as Japan and Sweden, the rates are well below 10 per 1,000, or 1 percent. Generally, infant mortality is somewhat higher among males than among females.

In developing countries substantial declines in infant mortality have been credited to improved sanitation and nutrition, increased access to modern health care, and improved birth spacing through the use of contraception. In industrialized countries in which infant mortality rates were already low the increased availability of advanced medical technology for newborn—in particular, prematurely born—infants provides a partial explanation.

Infanticide. The deliberate killing of newborn infants has long been practiced in human societies. It seems to have been common in the ancient cultures of Greece, Rome, and China, and it was practiced in Europe until the 19th century. In Europe, infanticide included the practice of “overlaying” (smothering) an infant sharing a bed with its parents and the abandonment of unwanted infants to the custody of foundling hospitals, in which one-third to four-fifths of incumbents failed to survive.

In many societies practicing infanticide, infants were not deemed to be fully human until they underwent a rite of initiation that took place from a few days to several years after birth, and therefore killing before such initiation was socially acceptable. The purposes of infanticide were various: child spacing or fertility control in the absence of effective contraception; elimination of illegitimate, deformed, orphaned, or twin children; or sex preferences.

With the development and spread of the means of effective fertility regulation, infanticide has come to be strongly disapproved in most societies, though it continues to be practiced in some isolated traditional cultures.

Mortality among the elderly. During the 1970s and 1980s in industrialized countries there were unexpectedly large declines in mortality among the elderly, resulting in larger-than-projected numbers of the very old. In the United States, for example, the so-called frail elderly group aged 85 years and older increased nearly fourfold between 1950 and 1980, from 590,000 to 2,461,000. Given the high incidence of health problems among the very old, such increases have important implications for the organization and financing of health care.

Marriage. One of the main factors affecting fertility, and an important contributor to the fertility differences among societies in which conscious fertility control is uncommon, is defined by the patterns of marriage and marital disruption. In many societies in Asia and Africa, for example, marriage occurs soon after the sexual maturation of the woman, around age 17. In contrast, delayed marriage has long been common in Europe, and in some European countries the average age of first marriage approaches 25 years. Another aspect of historical marriage patterns in Europe is the high incidence of permanent celibacy: as many as 10 percent of women never marry. In contrast, nearly all women marry in most traditional developing countries of Asia and Africa.

In the 20th century dramatic changes have taken place in the patterns of marital dissolution caused by widowhood and divorce. Widowhood has long been common in all societies, but the declines of mortality (as discussed above) have sharply reduced the effects of this source of marital dissolution on fertility. Meanwhile, divorce has been transformed from an uncommon exception to an experience terminating a large proportion (sometimes more than a third) of marriages in some countries. Taken together, these components of marriage patterns can account for the elimination of as little as 20 percent to as much as 50 percent of the potential reproductive years.

Many Western countries have experienced significant increases in the numbers of cohabiting unmarried couples. In the 1970s some 12 percent of all Swedish couples living together aged 16 to 70 were unmarried. When in the United States in 1976 the number of such arrangements approached 1,000,000, the Bureau of the Census formulated a new statistical category—POSSLQ—denoting persons of the opposite sex sharing living quarters. Extramarital fertility as a percentage of overall fertility accordingly has risen in many Western countries, accounting

for one in five births in the United States, one in five in Denmark, and one in three in Sweden.

Migration. Since any population that is not closed can be augmented or depleted by in-migration or out-migration, migration patterns must be considered carefully in analyzing population change. The common definition of human migration limits the term to permanent change of residence (conventionally, for at least one year), so as to distinguish it from commuting and other more frequent but temporary movements.

Human migrations have been fundamental to the broad sweep of human history and have themselves changed in basic ways over the epochs. Many of these historical migrations have by no means been the morally uplifting experiences depicted in mythologies of heroic conquerors, explorers, and pioneers; rather they frequently have been characterized by violence, destruction, bondage, mass mortality, and genocide—in other words, by human suffering of profound magnitudes.

Early human migrations. Early humans were almost surely hunters and gatherers who moved continually in search of food supplies. The superior technologies (tools, clothes, language, disciplined cooperation) of these hunting bands allowed them to spread farther and faster than had any other dominant species; humans are thought to have occupied all the continents except Antarctica within a span of about 50,000 years. As the species spread away from the tropical parasites and diseases of its African origins, mortality rates declined and population increased. This increase occurred at microscopically small rates by the standards of the past several centuries, but over thousands of years it resulted in a large absolute growth to a total that could no longer be supported by finding new hunting grounds. There ensued a transition from migratory hunting and gathering to migratory slash-and-burn agriculture. The consequence was the rapid geographical spread of crops, with wheat and barley moving east and west from the Middle East across the whole of Eurasia within only 5,000 years.

About 10,000 years ago a new and more productive way of life, involving sedentary agriculture, became predominant. This allowed greater investment of labour and technology in crop production, resulting in a more substantial and securer food source, but sporadic migrations persisted.

The next pulse of migration, beginning around 4000 to 3000 bc, was stimulated by the development of seagoing sailing vessels and of pastoral nomadry. The Mediterranean Basin was the centre of the maritime culture, which involved the settlement of offshore islands and led to the development of deep-sea fishing and long-distance trade. Other favoured regions were those of the Indian Ocean and South China Sea. Meanwhile, pastoral nomadry involved biological adaptations both in humans (allowing them to digest milk) and in species of birds and mammals that were domesticated. Once completed, these adaptations allowed humans to consume the meat of most male newborn animals and the maternal milk thereby made available.

Both seafarers and pastoralists were intrinsically migratory. The former were able to colonize previously uninhabited lands or to impose their rule by force over less mobile populations. The pastoralists were able to populate the extensive grassland of the Eurasian Steppe and the African and Middle Eastern savannas, and their superior nutrition and mobility gave them clear military advantages over the sedentary agriculturalists with whom they came into contact. Even as agriculture continued to improve with innovations such as the plow, these mobile elements persisted and provided important networks by which technological innovations could be spread widely and rapidly.

That complex of human organization and behaviour commonly termed Western civilization arose out of such developments. Around 4000 bc seafaring migrants from the south overwhelmed the local inhabitants of the Tigris-Euphrates floodplain and began to develop a social organization based upon the division of labour into highly skilled occupations, technologies such as irrigation, bronze metallurgy, and wheeled vehicles, and the growth of cities

Growth of
migratory
populations

Disruption
of

Urban
cultures

of 20,000–50,000 persons. Political differentiation into ruling classes and ruled masses provided a basis for imposition of taxes and rents that financed the development of professional soldiers and artisans, whose specialized skills far surpassed those of pastoralists and agriculturalists. The military and economic superiority that accompanied such skills allowed advanced communities to expand both by direct conquest and by the adoption of this social form by neighbouring peoples. Thus migration patterns played an important role in creating the early empires and cultures of the ancient world.

By about 2000 BC such specialized human civilizations occupied much of the then-known world—the Middle East, the eastern Mediterranean, South Asia, and the Far East. Under these circumstances human migration was transformed from unstructured movements across unoccupied territories by nomads and seafarers into quite new forms of interaction among the settled civilizations.

These new forms of human migration produced disorder, suffering, and much mortality. As one population conquered or infiltrated another, the vanquished were usually destroyed, enslaved, or forcibly absorbed. Large numbers of people were captured and transported by slave traders. Constant turmoil accompanied the ebb and flow of populations across the regions of settled agriculture and the Eurasian and African grasslands. Important examples include the Dorian incursions in ancient Greece in the 11th century BC, the Germanic migrations southward from the Baltic to the Roman Empire in the 4th to 6th centuries AD, the Norman raids and conquests of Britain between the 8th and 12th centuries AD, and the Bantu migrations in Africa throughout the Christian Era.

Modern mass migrations. Mass migrations over long distances were among the new phenomena produced by the population increase and improved transportation that accompanied the Industrial Revolution. The largest of these was the so-called Great Atlantic Migration from Europe to North America, the first major wave of which began in the late 1840s with mass movements from Ireland and Germany. These were caused by the failure of the potato crop in Ireland and in the lower Rhineland, where millions had become dependent upon this single source of nutrition. These flows eventually subsided, but in the 1880s a second and even larger wave of mass migration developed from eastern and southern Europe, again stimulated in part by agricultural crises and facilitated by improvements in transportation and communication. Between 1880 and 1910 some 17,000,000 Europeans entered the United States; overall, the total amounted to 37,000,000 between 1820 and 1980.

Since World War II equally large long-distance migrations have occurred. In most cases groups from developing countries have moved into the industrialized countries of the West. Some 13,000,000 migrants have become permanent residents of western Europe since the 1960s. More than 10,000,000 permanent immigrants have been admitted legally to the United States since the 1960s, and illegal immigration has almost surely added several millions more.

Forced migrations. Slave migrations and mass expulsions have been part of human history for millennia. The largest slave migrations were probably those compelled by European slave traders operating in Africa from the 16th to the 19th century. During that period perhaps 20,000,000 slaves were consigned to American markets, though substantial numbers died in the appalling conditions of the Atlantic passage.

The largest mass expulsion is probably that imposed by the Nazi government of Germany, which deported 7,000,000–8,000,000 persons, including some 5,000,000 Jews later exterminated in concentration camps. After World War II, 9,000,000–10,000,000 ethnic Germans were more or less forcibly transported into Germany, and perhaps 1,000,000 members of minority groups deemed politically unreliable by the Soviet government were forcibly exiled to Central Asia. Earlier deportations of this type included the movement of 150,000 British convicts to Australia between 1788 and 1867 and the 19th-century exile of 1,000,000 Russians to Siberia.

Forced migrations since World War II have been large indeed. Some 14,000,000 persons fled in one direction or the other at the partition of British India into India and Pakistan. Nearly 10,000,000 left East Pakistan (now Bangladesh) during the fighting in 1971; many of them stayed on in India. An estimated 3,000,000–4,000,000 persons fled from the war in Afghanistan during the early 1980s. More than 1,000,000 refugees have departed Vietnam, Cuba, Israel, and Ethiopia since World War II. Estimates during the 1980s suggested that approximately 10,000,000 refugees had not been resettled and were in need of assistance.

Internal migrations. The largest human migrations today are internal to nation-states; these can be sizable in rapidly increasing populations with large rural-to-urban migratory flows.

Early human movements toward urban areas were devastating in terms of mortality. Cities were loci of intense infection; indeed, many human viral diseases are not propagated unless the population density is far greater than that common under sedentary agriculture or pastoral nomadism. Moreover, cities had to import food and raw materials from the hinterlands, but transport and political disruptions led to erratic patterns of scarcity, famine, and epidemic. The result was that cities until quite recently (the mid-19th century) were demographic sinkholes, incapable of sustaining their own populations.

Urban growth since World War II has been very rapid in much of the world. In developing countries with high overall population growth rates the populations of some cities have been doubling every 10 years or less (see below *Population composition*).

Natural increase and population growth. *Natural increase.* Put simply, natural increase is the difference between the numbers of births and deaths in a population; the rate of natural increase is the difference between the birthrate and the death rate (see Figure 1). Given the fertility and mortality characteristics of the human species (excluding incidents of catastrophic mortality), the range of possible rates of natural increase is rather narrow. For a nation, it has rarely exceeded 4 percent per year; the highest known rate for a national population—arising from the conjunction of a very high birthrate and a quite low death rate—is that experienced in Kenya during the 1980s, in which the natural increase of the population approximated 4.1 percent per annum. Rates of natural increase in other developing countries generally are lower; these countries averaged about 2.5 percent per annum during the same period. Meanwhile the rates of natural increase in industrialized countries are very low: the highest is approximately 1 percent, most are in the neighbourhood of several tenths of 1 percent, and some are slightly negative (that is, their populations are slowly decreasing).

Population growth. The rate of population growth is the rate of natural increase combined with the effects of migration. Thus a high rate of natural increase can be offset by a large net out-migration, and a low rate of natural increase can be countered by a high level of net in-migration. Generally speaking, however, these migration effects on population growth rates are far smaller than the effects of changes in fertility and mortality.

Population "momentum." An important and often misunderstood characteristic of human populations is the tendency of a highly fertile population that has been increasing rapidly in size to continue to do so for decades after the onset of even a substantial decline in fertility. This results from the youthful age structure of such a population, as discussed below. These populations contain large numbers of children who have still to grow into adulthood and the years of reproduction. Thus even a dramatic decline in fertility, which affects only the numbers at age zero, cannot prevent the continuing growth of the number of adults of childbearing age for at least two or three decades.

Eventually, of course, as these large groups pass through the childbearing years to middle and older age, the smaller numbers of children resulting from the fertility decline lead to a moderation in the rate of population growth. But the delays are lengthy, allowing very substantial additional

Political
refugees

European
settlement
of
America

population growth after fertility has declined. This phenomenon gives rise to the term population momentum, which is of great significance to developing countries with rapid population growth and limited natural resources. The nature of population growth means that the metaphor of a "population bomb" used by some lay analysts of population trends in the 1960s was really quite inaccurate. Bombs explode with tremendous force, but such force is rapidly spent. A more appropriate metaphor for rapid population growth is that of a glacier, since a glacier moves at a slow pace but with enormous effects wherever it goes and with a long-term momentum that is unstoppable.

Figure 1: Population growth through natural increase in the less developed and more developed countries, 1775–1985.

POPULATION COMPOSITION

The most important characteristics of a population—in addition to its size and the rate at which it is expanding or contracting—are the ways in which its members are distributed according to age, sex, ethnic or racial category, and residential status (urban or rural).

Age distribution. Perhaps the most fundamental of these characteristics is the age distribution of a population. Demographers commonly use population pyramids to describe both age and sex distributions of populations. A population pyramid is a bar chart or graph in which the length of each horizontal bar represents the number (or percentage) of persons in an age group; for example, the base of such a chart consists of a bar representing the youngest segment of the population, those persons less than, say, five years old. Each bar is divided into segments corresponding to the numbers (or proportions) of males and females. In most populations the proportion of older persons is much smaller than that of the younger, so the chart narrows toward the top and is more or less triangular, like the cross section of a pyramid; hence the name. Youthful populations are represented by pyramids with a broad base of young children and a narrow apex of older

people, while older populations are characterized by more uniform numbers of people in the age categories. Figure 2 presents population pyramids for three nations that have markedly different characteristics: high fertility and rapid population growth (Mexico), low fertility and slow growth (United States), and very low fertility and negative growth (West Germany).

Contrary to a common belief, the principal factor tending to change the age distribution of a population—and, hence, the general shape of the corresponding pyramid—is not the death or mortality rates, but rather the rate of fertility. A rise or decline in mortality generally affects all age groups in some measure, and hence has only limited effects on the proportion in each age group. A change in fertility, however, affects the number of people in only a single age group—the group of age zero, the newly born. Hence a decline or increase in fertility has a highly concentrated effect at one end of the age distribution and thereby can have a major influence on the overall age structure. This means that youthful age structures correspond to highly fertile populations, typical of developing countries. The older age structures are those of low-fertility populations, such as are common in the industrialized world.

Sex ratio. A second important structural aspect of populations is the relative numbers of males and females who compose it. Generally, slightly more males are born than females (a typical ratio would be 105 or 106 males for every 100 females). On the other hand, it is quite common for males to experience higher mortality at virtually all ages after birth. This difference is apparently of biological origin. Exceptions occur in countries such as India, where the mortality of females may be higher than that of males in childhood and at the ages of childbearing because of unequal allocation of resources within the family and the poor quality of maternal health care.

The general rules that more males are born but that females experience lower mortality mean that during childhood males outnumber females of the same age, the difference decreases as the age increases, at some point in the adult life span the numbers of males and females become equal, and as higher ages are reached the number of females becomes disproportionately large. For example, in Europe and North America, among persons more than 70 years of age in 1985, the number of males for every 100 females was only about 61 to 63. (According to the Population Division of the United Nations, the figure for the Soviet Union was only 40, which may be attributable to high male mortality during World War II as well as to possible increases in male mortality during the 1980s.)

The sex ratio within a population has significant implications for marriage patterns. A scarcity of males of a given age depresses the marriage rates of females in the same age group or usually those somewhat younger, and this in turn is likely to reduce their fertility. In many countries, social convention dictates a pattern in which males at marriage are slightly older than their spouses. Thus if there is a dramatic rise in fertility, such as that called the "baby boom" in the period following World War II, a "marriage squeeze" can eventually result; that is, the number of males of the socially correct age for marriage is insufficient for the number of somewhat younger females. This may lead to deferment of marriage of these women, a contraction of the age differential of marrying couples, or both. Similarly, a dramatic fertility decline in such a society is likely to lead eventually to an insufficiency of eligible females for marriage, which may lead to earlier marriage of these women, an expansion of the age gap at marriage, or both. All of these effects are slow to develop; it takes at least 20 to 25 years for even a dramatic fall or rise in fertility to affect marriage patterns in this way.

Ethnic or racial composition. The populations of all nations of the world are more or less diverse with respect to ethnicity or race. (Ethnicity here includes national, cultural, religious, linguistic, or other attributes that are perceived as characteristic of distinct groups.) Such divisions in populations often are regarded as socially important, and statistics by race and ethnic group are therefore commonly available. The categories used for such groups differ from nation to nation, however; for example, a person

Sex differences in natality and mortality

Population pyramids

Figure 2: Population pyramids, showing age and sex distributions of the populations of Mexico, the United States, and West Germany in 1980.

of Pakistani origin is considered "black" or "coloured" in the United Kingdom but would probably be classified as "white" or "Asian" in the United States. For this reason, international comparisons of ethnic and racial groups are imprecise, and this component of population structure is far less objective as a measure than are the categories of age and sex discussed above.

Geographical distribution and urbanization. It goes without saying that populations are scattered across space. The typical measure of population in relation to land area, that of population density, is often a meaningless one, since different areas vary considerably in their value for agricultural or other human purposes. Moreover, a high population density in an agrarian society, dependent upon agriculture for its sustenance, is likely to be a severer constraint upon human welfare than would the same density in a highly industrialized society, in which the bulk of national product is not of agricultural origin.

Also of significance in terms of geographical distribution is the division between rural and urban areas. For many decades there has been a nearly universal flow of populations from rural into urban areas. While definitions of urban areas differ from country to country and region to region, the most highly urbanized societies in the world are those of western and northern Europe, Australia, New Zealand, temperate South America, and North America; in all of these the fraction of the population living in urban areas exceeds 75 percent, and it has reached 85 percent in West Germany. An intermediate stage of urbanization exists in the countries making up much of tropical Latin America, where 50 to 65 percent of the population lives in cities. Finally, in many of the developing countries of Asia and Africa the urbanization process has only recently begun, and it is not uncommon to find less than one-third of the population living in urban areas.

The rapidity of urbanization in some countries is quite astonishing. The population of Mexico City in 1960 was around 5,000,000; it was estimated to be about 17,000,000 in 1985 and was projected to reach 26,000,000 to 31,000,000 by 2000. A rule of thumb for much of the developing world is that the rate of growth of urban areas is twice that of the population as a whole. Thus in a population growing 3 percent annually (doubling in about 23.1 years), it is likely that the urban growth rate is at least 6 percent annually (doubling in about 11.6 years).

POPULATION THEORIES

Population size and change play such a fundamental role in human societies that they have been the subject of theorizing for millennia. Most religious traditions have had something to say on these matters, as did many of the leading figures of the ancient world.

In modern times the subject of demographic change has played a central role in the development of the politico-economic theory of mercantilism; the classical economics of Adam Smith, David Ricardo, and others; the cornucopian images of utopians such as the Marquis de Condorcet; the contrasting views of Malthus as to the natural limits imposed on human population; the sociopolitical theories of Marx, Engels, and their followers; the scientific revolutions engendered by Darwin and his followers; and so on through the pantheon of human thought. Most of these theoretical viewpoints have incorporated demographic components as elements of far grander schemes. Only in a few cases have demographic concepts played a central role, as in the case of the theory of the demographic transition that evolved during the 1930s as a counter to biological explanations of fertility declines that were then current.

Population theories in antiquity. The survival of ancient human societies despite high and unpredictable mortality implies that all societies that persisted were successful in maintaining high fertility. They did so in part by stressing the duties of marriage and procreation and by stigmatizing persons who failed to produce children. Many of these pronatalist motives were incorporated into religious dogma and mythology, as in the biblical injunction to "be fruitful and multiply, and populate the earth," the Hindu laws of Manu, and the writings of Zoroaster.

The ancient Greeks were interested in population size, and Plato's *Republic* incorporated the concept of an optimal population size of 5,040 citizens, among whom fertility was restrained by conscious birth control. The leaders of imperial Rome, however, advocated maximizing population size in the interest of power, and explicitly pronatalist laws were adopted during the reign of Augustus to encourage marriage and fertility.

The traditions of Christianity on this topic are mixed. The pronatalism of the Old Testament and the Roman Empire was embraced with some ambivalence by a church that sanctified celibacy among the priesthood. Later, during the time of Thomas Aquinas, the church moved toward more forceful support of high fertility and opposition to birth control.

Islāmic writings on fertility were equally mixed. The 14th-century Arab historian Ibn Khaldūn incorporated demographic factors into his grand theory of the rise and fall of empires. According to his analysis, the decline of an empire's population necessitates the importation of foreign mercenaries to administer and defend its territories, resulting in rising taxes, political intrigue, and general decadence. The hold of the empire on its hinterland and on its own populace weakens, making it a tempting target for a vigorous challenger. Thus Ibn Khaldūn saw the growth of dense human populations as generally favourable to the maintenance and increase of imperial power.

On the other hand, contraception was acceptable practice in Islām from the days of the Prophet, and extensive attention was given to contraceptive methods by the great physicians of the Islāmic world during the Middle Ages. Moreover, under Islāmic law the fetus is not considered a human being until its form is distinctly human, and hence early abortion was not forbidden.

Mercantilism and the idea of progress. The wholesale mortality caused by the Black Death during the 14th century contributed in fundamental ways to the development of mercantilism, the school of thought that dominated Europe from the 16th through the 18th century. Mercantilists and the absolute rulers who dominated many states of Europe saw each nation's population as a form of national wealth: the larger the population, the richer the nation. Large populations provided a larger labour supply, larger markets, and larger (and hence more powerful) armies for defense and for foreign expansion. Moreover, since growth in the number of wage earners tended to depress wages, the wealth of the monarch could be increased by capturing this surplus. In the words of Frederick II the Great of Prussia, "the number of the people makes the wealth of states." Similar views were held by mercantilists in Germany, France, Italy, and Spain. For the mercantilists, accelerating the growth of the population by encouraging fertility and discouraging emigration was consistent with increasing the power of the nation or the king. Most mercantilists, confident that any number of people would be able to produce their own subsistence, had no worries about harmful effects of population growth. (To this day similar optimism continues to be expressed by diverse schools of thought, from traditional Marxists on the left to "cornucopians" on the right.)

Physiocrats and the origins of demography. By the 18th century the Physiocrats were challenging the intensive state intervention that characterized the mercantilist system, urging instead the policy of laissez-faire. Their targets included the pronatalist strategies of governments; Physiocrats such as François Quesnay argued that human multiplication should not be encouraged to a point beyond that sustainable without widespread poverty. For the Physiocrats, economic surplus was attributable to land, and population growth could therefore not increase wealth. In their analysis of this subject matter the Physiocrats drew upon the techniques developed in England by John Graunt, Edmond Halley, Sir William Petty, and Gregory King, which for the first time made possible the quantitative assessment of population size, the rate of growth, and rates of mortality.

The Physiocrats had broad and important effects upon the thinking of the classical economists such as Adam Smith, especially with respect to the role of free markets

of
cities

Laissez-
faire
economics

unregulated by the state. As a group, however, the classical economists expressed little interest in the issue of population growth, and when they did they tended to see it as an effect rather than as a cause of economic prosperity.

Utopian views. In another 18th-century development, the optimism of mercantilists was incorporated into a very different set of ideas, those of the so-called utopians. Their views, based upon the idea of human progress and perfectibility, led to the conclusion that once perfected, mankind would have no need of coercive institutions such as police, criminal law, property ownership, and the family. In a properly organized society, in their view, progress was consistent with any level of population, since population size was the principal factor determining the amount of resources. Such resources should be held in common by all persons, and if there were any limits on population growth, they would be established automatically by the normal functioning of the perfected human society. Principal proponents of such views included Condorcet, William Godwin, and Daniel Malthus, the father of the Reverend Thomas Robert Malthus. Through his father the younger Malthus was introduced to such ideas relating human welfare to population dynamics, which stimulated him to undertake his own collection and analysis of data; these eventually made him the central figure in the population debates of the 19th and 20th centuries.

Malthus and his successors. In 1798 Malthus published *An Essay on the Principle of Population as It Affects the Future Improvement of Society, with Remarks on the Speculations of Mr. Godwin, M. Condorcet, and Other Writers*. This hastily written pamphlet had as its principal object the refutation of the views of the utopians. In Malthus' view, the perfection of a human society free of coercive restraints was a mirage, because the capacity for the threat of population growth would always be present. In this, Malthus echoed the much earlier arguments of Robert Wallace in his *Various Prospects of Mankind, Nature, and Providence* (1761), which posited that the perfection of society carried with it the seeds of its own destruction, in the stimulation of population growth such that "the earth would at last be overstocked, and become unable to support its numerous inhabitants."

Not many copies of Malthus' essay, his first, were published, but it nonetheless became the subject of discussion and attack. The essay was cryptic and poorly supported by empirical evidence. Malthus' arguments were easy to misrepresent, and his critics did so routinely.

The criticism had the salutary effect of stimulating Malthus to pursue the data and other evidence lacking in his first essay. He collected information on one country that had plentiful land (the United States) and estimated that its population was doubling in less than 25 years. He attributed the far lower rates of European population growth to "preventive checks," giving special emphasis to the characteristic late marriage pattern of western Europe, which he called "moral restraint." The other preventive checks to which he alluded were birth control, abortion, adultery, and homosexuality, all of which as an Anglican minister he considered immoral.

In one sense, Malthus reversed the arguments of the mercantilists that the number of people determined the nation's resources, adopting the contrary argument of the Physiocrats that the resource base determined the numbers of people. From this he derived an entire theory of society and human history, leading inevitably to a set of provocative prescriptions for public policy. Those societies that ignored the imperative for moral restraint—delayed marriage and celibacy for adults until they were economically able to support their children—would suffer the deplorable "positive checks" of war, famine, and epidemic, the avoidance of which should be every society's goal. From this humane concern about the sufferings from positive checks arose Malthus' admonition that poor laws (*i.e.*, legal measures that provided relief to the poor) and charity must not cause their beneficiaries to relax their moral restraint or increase their fertility, lest such humanitarian gestures become perversely counterproductive.

Having stated his position, Malthus was denounced as a reactionary, although he favoured free medical assistance

for the poor, universal education at a time that this was a radical idea, and democratic institutions at a time of elitist alarms about the French Revolution. Malthus was accused of blasphemy by the conventionally religious. The strongest denunciations of all came from Marx and his followers (see below). Meanwhile, the ideas of Malthus had important effects upon public policy (such as reforms in the English Poor Laws) and upon the ideas of the classical and neoclassical economists, demographers, and evolutionary biologists, led by Charles Darwin. Moreover, the evidence and analyses produced by Malthus dominated scientific discussion of population during his lifetime; indeed, he was the invited author of the article "Population" for the supplement (1824) to the fourth, fifth, and sixth editions of the *Encyclopædia Britannica*. Though many of Malthus' gloomy predictions have proved to be misdirected, that article introduced analytical methods that clearly anticipated demographic techniques developed more than 100 years later.

The latter-day followers of Malthusian analysis deviated significantly from the prescriptions offered by Malthus. While these "neo-Malthusians" accepted Malthus' core propositions regarding the links between unrestrained fertility and poverty, they rejected his advocacy of delayed marriage and his opposition to birth control. Moreover, leading neo-Malthusians such as Charles Bradlaugh and Annie Besant could hardly be described as reactionary defenders of the established church and social order. To the contrary, they were political and religious radicals who saw the extension of knowledge of birth control to the lower classes as an important instrument favouring social equality. Their efforts were opposed by the full force of the establishment, and both spent considerable time on trial and in jail for their efforts to publish materials—condemned as obscene—about contraception.

Marx, Lenin, and their followers. While both Karl Marx and Malthus accepted many of the views of the classical economists, Marx was harshly and implacably critical of Malthus and his ideas. The vehemence of the assault was remarkable. Marx reviled Malthus as a "miserable parson" guilty of spreading a "vile and infamous doctrine, this repulsive blasphemy against man and nature." For Marx, only under capitalism does Malthus' dilemma of resource limits arise. Though differing in many respects from the utopians who had provoked Malthus' rejoinder, Marx shared with them the view that any number of people could be supported by a properly organized society. Under the socialism favoured by Marx, the surplus product of labour, previously appropriated by the capitalists, would be returned to its rightful owners, the workers, thereby eliminating the cause of poverty. Thus Malthus and Marx shared a strong concern about the plight of the poor, but they differed sharply as to how it should be improved. For Malthus the solution was individual responsibility as to marriage and childbearing; for Marx the solution was a revolutionary assault upon the organization of society, leading to a collective structure called socialism.

The strident nature of Marx's attack upon Malthus' ideas may have arisen from his realization that they constituted a potentially fatal critique of his own analysis. "If [Malthus'] theory of population is correct," Marx wrote in 1875 in his *Critique of the Gotha Programme* (published by Engels in 1891), "then I cannot abolish this [iron law of wages] even if I abolish wage-labor a hundred times, because this law is not only paramount over the system of wage-labor but also over every social system."

The anti-Malthusian views of Marx were continued and extended by Marxians who followed him. For example, although in 1920 Lenin legalized abortion in the revolutionary Soviet Union as the right of every woman "to control her own body," he opposed the practice of contraception or abortion for purposes of regulating population growth. Lenin's successor, Joseph Stalin, adopted a pronatalist argument verging on the mercantilist, in which population growth was seen as a stimulant to economic progress. As the threat of war intensified in Europe in the 1930s, Stalin promulgated coercive measures to increase Soviet population growth, including the banning of abortion despite its status as a woman's basic right. Although contraception

Neo-Malthusians

Critics of Malthus

Stalin's pronatalism

is now accepted and practiced widely in most Marxist-Leninist states, some traditional ideologists continue to characterize its encouragement in Third-World countries as shabby Malthusianism.

The Darwinian tradition. Charles Darwin, whose scientific insights revolutionized 19th-century biology, acknowledged an important intellectual debt to Malthus in the development of his theory of natural selection. Darwin himself was not much involved in debates about human populations, but many who followed in his name as "social Darwinists" and "eugenicists" expressed a passionate if narrowly defined interest in the subject.

In Darwinian theory the engine of evolution is differential reproduction of different genetic stocks. The concern of many social Darwinists and eugenicists was that fertility among those they considered the superior human stocks was far lower than among the poorer—and, in their view, biologically inferior—groups, resulting in a gradual but inexorable decline in the quality of the overall population. While some attributed this lower fertility to deliberate efforts of people who needed to be informed of the dysgenic effects of their behaviour, others saw the fertility decline itself as evidence of biological deterioration of the superior stocks. Such simplistic biological explanations attracted attention to the socioeconomic and cultural factors that might explain the phenomenon and contributed to the development of the theory of the demographic transition.

Theory of the demographic transition. The classic explanation of European fertility declines arose in the period following World War I and came to be known as demographic transition theory. (Formally, transition theory is a historical generalization and not truly a scientific theory offering predictive and testable hypotheses.) The theory arose in part as a reaction to crude biological explanations of fertility declines; it rationalized them in solely socioeconomic terms, as consequences of widespread desire for fewer children caused by industrialization, urbanization, increased literacy, and declining infant mortality.

Changing
role of
the
family

The factory system and urbanization led to a diminution in the role of the family in industrial production and a reduction of the economic value of children. Meanwhile, the costs of raising children rose, especially in urban settings, and universal primary education postponed their entry into the work force. Finally, the lessening of infant mortality reduced the number of births needed to achieve a given family size. In some versions of transition theory, a fertility decline is triggered when one or more of these socioeconomic factors reach certain threshold values.

Until the 1970s transition theory was widely accepted as an explanation of European fertility declines, although conclusions based on it had never been tested empirically. More recently careful research on the European historical experience has forced reappraisal and refinement of demographic transition theory. In particular, distinctions based upon cultural attributes such as language and religion, coupled with the spread of ideas such as those of the nuclear family and the social acceptability of deliberate fertility control, appear to have played more important roles than were recognized by transition theorists.

TRENDS IN WORLD POPULATION

Before considering modern population trends separately for developing and industrialized countries, it is useful to present an overview of older trends. It is generally agreed that only 5,000,000–10,000,000 humans (*i.e.*, one one-thousandth of the present world population) were supportable before the agricultural revolution of about 10,000 years ago. By the beginning of the Christian era, 8,000 years later, the human population approximated 300,000,000, and there was apparently little increase in the ensuing millennium up to the year AD 1000. Subsequent population growth was slow and fitful, especially given the plague epidemics and other catastrophes of the Middle Ages. By 1750, conventionally the beginning of the Industrial Revolution in Britain, world population may have been as high as 800,000,000. This means that in the 750 years from 1000 to 1750, the annual population growth rate averaged only about one-tenth of 1 percent.

The reasons for such slow growth are well known. In

the absence of what is now considered basic knowledge of sanitation and health (the role of bacteria in disease, for example, was unknown until the 19th century), mortality rates were very high, especially for infants and children. Only about half of newborn babies survived to the age of five years. Fertility was also very high, as it had to be to sustain the existence of any population under such conditions of mortality. Modest population growth might occur for a time in these circumstances, but recurring famines, epidemics, and wars kept long-term growth close to zero.

From 1750 onward population growth accelerated. In some measure this was a consequence of rising standards of living, coupled with improved transport and communication, which mitigated the effects of localized crop failures that previously would have resulted in catastrophic mortality. Occasional famines did occur, however, and it was not until the 19th century that a sustained decline in mortality took place, stimulated by the improving economic conditions of the Industrial Revolution and the growing understanding of the need for sanitation and public health measures.

The world population, which did not reach its first 1,000,000,000 until about 1800, added another 1,000,000,000 persons by 1930. (To anticipate further discussion below, the third was added by 1960, the fourth by 1974, and the fifth before 1990; see Figure 3.) The most rapid growth in the 19th century occurred in Europe and North America, which experienced gradual but eventually dramatic declines in mortality. Meanwhile, mortality and fertility remained high in Asia, Africa, and Latin America.

Modern
increase
in world
population

Figure 3: World population growth since 8000 BC.

Beginning in the 1930s and accelerating rapidly after World War II, mortality went into decline in much of Asia and Latin America, giving rise to a new spurt of population growth that reached rates far higher than any previously experienced in Europe. The rapidity of this growth, which some described as the "population explosion," was due to the sharpness in the falls in mortality that in turn were the result of improvements in public health, sanitation, and nutrition that were mostly imported from the developed countries. The external origins and the speed of the declines in mortality meant that there was little chance that they would be accompanied by the onset of a decline in fertility. In addition, the marriage patterns of Asia and Latin America were (and continue to be) quite different from those of Europe; marriage in Asia and Latin America is early and nearly universal, while that in Europe is usually late and significant percentages of people never marry.

These high growth rates occurred in populations already of very large size, meaning that global population growth became very rapid both in absolute and in relative terms. The peak rate of increase was reached in the early 1960s, when each year the world population grew by about 2 percent, or about 68,000,000 people. Since that time both mortality and fertility rates have decreased, and the annual growth rate has fallen moderately, to about 1.7 percent. But even this lower rate, because it applies to a larger population base, means that the number of people added each year has risen from about 68,000,000 to 80,000,000.

The developing countries since 1950. After World War

If there was a rapid decline in mortality in much of the developing world. In part this resulted from wartime efforts to maintain the health of armed forces from industrialized countries fighting in tropical areas. Since all people and governments welcome proven techniques to reduce the incidence of disease and death, these efforts were readily accepted in much of the developing world, but they were not accompanied by the kinds of social and cultural changes that had occurred earlier and had led to fertility declines in industrialized countries.

The reduction in mortality, unaccompanied by a reduction in fertility, had a simple and predictable outcome: accelerating population growth. By 1960 many developing countries had rates of increase as high as 3 percent a year, exceeding by two- or threefold the highest rates ever experienced by European populations. Since a population increasing at this rate will double in only 23 years, the populations of such countries expanded dramatically. In the 25 years between 1950 and 1975, the population of Mexico increased from 27,000,000 to 60,000,000; Iran from 14,000,000 to 33,000,000; Brazil from 53,000,000 to 108,000,000; and China from 554,000,000 to 933,000,000.

The greatest population growth rates were reached in Latin America and in Asia during the mid- to late 1960s. Since then, these regions have experienced variable but sometimes substantial fertility declines along with continuing mortality declines, resulting in usually moderate and occasionally large declines in population growth. The most dramatic declines have been those of the People's Republic of China, where the growth rate was estimated to have declined from well over 2 percent per year in the 1960s to about half that in the 1980s, following official adoption of a concerted policy to delay marriage and limit childbearing within marriage. The predominance of the Chinese population in East Asia means that this region has experienced the most dramatic declines in population growth of any of the developing regions.

Over the same period population growth rates have declined only modestly, and in some cases have actually risen, in other developing regions. In South Asia the rate has declined only from 2.4 to 2.0 percent; in Latin America, from about 2.7 to about 2.3 percent. Meanwhile, in Africa population growth has accelerated from 2.6 percent to more than 3 percent over the same period, following belated significant declines in mortality not accompanied by similar reductions in fertility.

The industrialized countries since 1950. For many industrialized countries, the period after World War II was marked by a "baby boom." One group of four countries in particular—the United States, Canada, Australia, and New Zealand—experienced sustained and substantial rises in fertility from the depressed levels of the prewar period. In the United States, for example, fertility rose by two-thirds, reaching levels in the 1950s not seen since 1910.

A second group of industrialized countries, including most of western Europe and some eastern European countries (notably Czechoslovakia and what is now East Germany), experienced what might be termed "baby boomlets." For a few years after the war, fertility increased as a result of marriages and births deferred during wartime. These increases were modest and relatively short-lived, however, when compared to those of the true baby-boom countries mentioned above. In many of these European countries fertility had been very low in the 1930s; their postwar baby boomlets appeared as three- to four-year "spikes" in the graph of their fertility rates, followed by two full decades of stable fertility levels. Beginning in the mid-1960s, fertility levels in these countries began to move lower again and, in many cases, fell to levels comparable to or lower than those of the 1930s.

A third group of industrialized countries, consisting of most of eastern Europe along with Japan, showed quite different fertility patterns. Most did not register low fertility in the 1930s but underwent substantial declines in the 1950s after a short-lived baby boomlet. In many of these countries the decline persisted into the 1960s, but in some it was reversed in response to governmental incentives.

By the 1980s the fertility levels in most industrialized countries were very low, at or below those needed to

maintain stable populations. There are two reasons for this phenomenon: the postponement of marriage and child-bearing by many younger women who entered the labour force, and a reduction in the numbers of children born to married women.

POPULATION PROJECTIONS

Demographic change is inherently a long-term phenomenon. Unlike populations of insects, human populations have rarely been subject to "explosion" or "collapse" in numbers. Moreover, the powerful long-term momentum that is built into the human age structure means that the effects of fertility changes become apparent only in the far future. For these and other reasons, it is by now conventional practice to employ the technology of population projection as a means of better understanding the implications of trends.

Population projections represent simply the playing out into the future of a set of assumptions about future fertility, mortality, and migration rates. It cannot be stated too strongly that such projections are not predictions, though they are misinterpreted as such frequently enough. A projection is a "what-if" exercise based on explicit assumptions that may or may not themselves be correct. As long as the arithmetic of a projection is done correctly, its utility is determined by the plausibility of its central assumptions. If the assumptions embody plausible future trends, then the projection's outputs may be plausible and useful. If the assumptions are implausible, then so is the projection. Because the course of demographic trends is hard to anticipate very far into the future, most demographers calculate a set of alternative projections that, taken together, are expected to define a range of plausible futures, rather than to predict or forecast any single future. Because demographic trends sometimes change in unexpected ways, it is important that all demographic projections be updated on a regular basis to incorporate new trends and newly developed data.

A standard set of projections for the world and for its constituent countries is prepared every two years by the Population Division of the United Nations. These projections include a low, medium, and high variant for each country and region. To illustrate the nature of such projected futures, Figure 4 presents these alternatives for the world as a whole and for its developed and developing regions.

Figure 4: Projected population of the world, less developed countries, and more developed countries (high, medium, and low variants, AD 1985–2025).

General works: ROLAND PRESSAT, *The Dictionary of Demography* (1985; originally published in French, 1979); JOHN A. ROSS (ed.), *International Encyclopedia of Population*, 2 vol. (1982), a comprehensive reference work that contains articles on topics ranging from classic demography to current problems and that provides coverage of world regions and countries as well as organizations and agencies active in the field; PETER R. COX, *Demography*, 5th ed. (1976), an examination of methods used in the study of population; DENNIS H. WRONG, *Population and Society*, 4th ed. (1977), an introduction to the main aspects of the population dilemma; and WARREN S. THOMPSON and DAVID T. LEWIS, *Population Problems*, 5th ed. (1965), a comprehensive sociological study.

Population change: ARTHUR A. CAMPBELL, *Manual of Fertility Analysis* (1983), a methodological study; GERRY E. HENDERSHOT and PAUL J. PLACEK (eds.), *Predicting Fertility: Demographic Studies of Birth Expectations* (1981), a survey of the concepts, knowledge, and methods of fertility; NORMAN E. HIMES, *Medical History of Contraception* (1936, reissued 1970), a classic historical treatise; JOHN BONGAARTS and ROBERT G. POTTER, *Fertility, Biology, and Behavior: An Analysis of the Proximate Determinants* (1983), a scholarly examination of such aspects of the population problem as family planning, family size, birth intervals, and fertility; ANSLEY J. COALE and SUSAN COTTS WATKINS (eds.), *The Decline of Fertility in Europe* (1985), a summary of studies of fertility transition in Europe during the 1970s; MICHAEL S. TEITELBAUM and JAY M. WINTER, *The Fear of Population Decline* (1985), the history and bases of past and current concerns about low fertility, with special emphasis on major Western countries; PRANAY GUPTA, *The Crowded Earth: People and the Politics of Population* (1984), a study of the effects of Western development programs on overpopulation; SAMUEL H. PRESTON, *Mortality Patterns in National Populations: With Special Reference to Recorded Causes of Death* (1976), a discussion of the determinants and consequences of national mortality patterns, with attention to the role of standards of living, sex differences, and major causes of death; ALAN A. BROWN and EGON NEUBERGER (eds.), *Internal Migration: A Comparative Perspective* (1977), a collection of scholarly articles; *International Migration Policies and Programmes: A World Survey* (1982), a study of immigration and refugee programs, one of the series of population studies conducted by the United Nations; DAVID GRIGG, *Population Growth and Agrarian Change: An Historical Perspective* (1980), a study of the relationship between demography and economics; ELI S. MARKS, WILLIAM SELTZER, and KAROL J. KRÓTKI, *Population Growth Estimation: A Handbook of Vital Statistics Measurement* (1974), an examination of methods for demographic estimates; and NATHAN KEYFITZ, *Population Change and Social Policy* (1982), a compendium of insightful essays. The 1984 issue of the annual *World Development Report* of the World Bank focuses on population changes in underdeveloped countries.

Population composition: COLIN MCEVEDY and RICHARD JONES, *Atlas of World Population History* (1978), comparisons of population statistics; NATHAN KEYFITZ and WILHELM FLIEGER, *World Population: An Analysis of Vital Data* (1968), a statistical analysis of demographic data for different countries; NATHAN KEYFITZ (ed.), *Population and Biology: Bridge Between Disciplines* (1984), a collection of papers on biological aspects of demography; DOROTHY L. NORTMAN, *Population and Family Planning Programs: Compendium of Data Through 1983*, 12th ed. (1985), including an analysis of demographic and social characteristics; DAVID M. HEER, *Society and Population*, 2nd ed. (1975), a brief study of the population of nation-states; PHILIP M. HAUSER et al., *Population and the Urban Future* (1982), which examines various demographic topics, including the quality of life of urbanized populations; RAYMOND F. DASMANN, *Environmental Conservation*, 5th ed. (1984), a study of the human influence on nature and its consequences for human population; and COLIN CLARK, *Population Growth and Land Use*, 2nd ed. (1977), an analysis of specific problems.

Population theories: RONALD FREEDMAN (ed.), *Population: The Vital Revolution* (1964), is a collection of authoritative essays on major aspects of contemporary demographic analysis. The history of population theory is presented in CHARLES EMIL STANGELAND, *Pre-Malthusian Doctrines of Population: A Study in the History of Economic Theory* (1904, reprinted 1967); JOSEPH J. SPENGLER, *French Predecessors of Malthus: A Study in Eighteenth-Century Wage and Population Theory* (1942, reprinted 1980); WILLIAM PETERSEN, *Malthus* (1979); PATRICIA JAMES, *Population Malthus, His Life and Times* (1979); E.P. HUTCHINSON, *The Population Debate: The Development of Conflicting Theories up to 1900* (1967); and J. DUPÂQUIER, A. FAUVE-CHAMOUX, and E. GREBENIK (eds.), *Malthus Past and Present* (1983). Other works include ALFRED SAUVY, *General Theory of Population* (1969; originally published in French, 1952-54), a study of the relationship between the demographic-biological characteristics of societies and their economic and social circumstances; PHILIP M. HAUSER (ed.), *The Population*

Dilemma, 2nd rev. ed. (1969), a collection of papers by leading theoreticians; GARRETT HARDIN, *Population, Evolution, and Birth Control: A Collage of Controversial Ideas*, 2nd ed. (1969), a survey of the history of views and opinions; JONAS SALK and JONATHAN SALK, *World Population and Human Values: A New Reality* (1981), which traces changes in attitudes to developments in population; and JULIAN L. SIMON, *The Ultimate Resource* (1981), an optimistic perspective for the world's population.

Development trends: The spatial distribution of population characteristics is studied in GLENN T. TREWARTHA, *The Less Developed Realm: A Geography of Its Population* (1972), and GLENN T. TREWARTHA (ed.), *The More Developed Realm: A Geography of Its Population* (1978). ALFRED SAUVY, *Fertility and Survival: Population Problems from Malthus to Mao Tse-Tung* (1961; originally published in French, 1959), presents an analysis of problems and proposes solutions. Other works include *The Determinants and Consequences of Population Trends: New Summary of Findings of Interaction of Demographic, Economic, and Social Factors*, 2 vol. (1973-78), a monumental compendium of theory and evidence on population trends compiled by the United Nations; the *Demographic Yearbook*, published by the Statistical Office of the United Nations, a basic source for more than 200 countries and territories; and BERNARD BERELSON (ed.), *Family Planning Programs: An International Survey* (1969), and *Family Planning and Population Programs: A Review of World Developments* (1966), comprehensive assessments of data. Later sources on trends in population development include ESTER BOSERUP, *Population and Technological Change* (1981); GAVIN W. JONES, *Population Growth and Educational Planning in Developing Nations* (1975); JOHN CLELAND and JOHN HOBcraft (eds.), *Reproductive Change in Developing Countries: Insights from the World Fertility Survey* (1985); GAVIN W. JONES (ed.), *Demographic Transition in Asia* (1984); C. ALISON MCINTOSH, *Population Policy in Western Europe: Responses to Low Fertility in France, Sweden, and West Germany* (1983); DONALD J. BOGUE, *The Population of the United States: Historical Trends and Future Projections* (1985); JOHN L. ANDRIOT (ed.), *Population Abstracts of the United States* (1980); RICHARD L. RUBENSTEIN, *The Age of Triage: Fear and Hope in an Overcrowded World* (1983); JANE MENKEN (ed.), *World Population & U.S. Policy: The Choices Ahead* (1986), papers by leading experts prepared for the second American Assembly on population issues; and NATIONAL RESEARCH COUNCIL, COMMITTEE ON POPULATION, *Population Growth and Economic Development: Policy Questions* (1986).

Population projections: *World Population Prospects: Estimates and Projections as Assessed in 1982* (1985), and *Patterns of Urban and Rural Population Growth* (1980), are publications of the United Nations Department of International Economic and Social Affairs. See also JUST FAALAND (ed.), *Population and the World Economy in the 21st Century* (1982), a collection of papers with economic and demographic forecasts; and MICHAEL D. BAYLES, *Morality and Population Policy* (1980), and *Reproductive Ethics* (1984), which discuss the moral aspects of long-term population policies.

For current discussions of relevant topics and reports of recent research the following periodicals may be recommended: *Contraception* (monthly); *Demography* (quarterly); *Economic Development and Cultural Change* (quarterly); *Economic History Review* (quarterly); *Family Planning Perspectives* (bimonthly); *Human Biology* (quarterly); *International Labour Review* (bimonthly); *International Migration Review* (quarterly); *Journal of Biosocial Science* (quarterly); *Journal of Economic History* (quarterly); *Journal of Interdisciplinary History* (quarterly); *Monthly Labor Review*; *Population and Development Review* (quarterly); *Population Bulletin* (quarterly); *Population Index* (quarterly); *Population Studies* (three times a year); *Science* (weekly); and *Social Biology* (quarterly). Many non-English periodicals in the field appear with systematic summaries in English: *Annales: Économies, Sociétés, Civilisations* (France, bimonthly); *Demografia* (Hungary, quarterly); *Demografia y economía* (Mexico, quarterly); *Demografie* (Czechoslovakia, quarterly); *Genus* (Italy, weekly); *Journal of Population Problems* (Japan, quarterly); and *Population* (France, bimonthly).

(M.S.T.)

Portugal

One of the oldest countries in Europe, with established frontiers since 1297, Portugal lies on the extreme western rim of the European continent. It is bordered on the east and north by Spain and on the west and south by the Atlantic Ocean. Occupying about 15 percent of the Iberian Peninsula, Portugal has a total area of 34,170 square miles (88,500 square kilometres). Despite its small size, the country displays a great diversity of geographical features; the land rises to 6,539 feet (1,993 metres) at its highest point in the Serra da Estrela. To the west and southwest lie the Atlantic islands of the Azores and Madeira, which are part of metropolitan Portugal.

Until the 1970s, Portuguese overseas territories included the Cape Verde Islands, São Tomé and Príncipe, Portuguese Guinea, Angola, and Mozambique, all in Africa; Macau in Asia; and Timor in Oceania. Of these, by the late 20th century only Macau (Macao) remained a Portuguese dependency.

As a member of the European Free Trade Association (EFTA) and the North Atlantic Treaty Organization (NATO), Portugal plays a greater role in both European and world affairs than its size would suggest. Nonetheless, it is one of the poorest countries in western Europe.

Physical and human geography

THE LAND

Relief. Most of Portugal consists of lowlands, only 11.6 percent of its area lying above 2,300 feet and most of that north of the Tagus River (Rio Tejo), which, flowing northeast to southwest, cuts the country in two. Southern Portugal is a region of plains and low tablelands, broad river basins, and gently undulating country, with few hills and only one mountain range rising higher than 3,280 feet. In the north, however, more than 90 percent of the land rises above 1,300 feet. Only 30 miles from the sea are mountains more than 3,280 feet high, and large plateaus are cut by deep valleys.

Minho and Douro Litoral. In the northwest, the mountains of Minho province, surmounted by the Serra do Larouco, 5,003 feet (1,525 metres) high, form an amphitheatre facing the Atlantic Ocean. The area is composed of metamorphic rocks (crystalline schists, slates, and quartzites) and intrusive or granitic rocks, marked by fault lines and hot springs. Parallel to the mountainous ridges, rivers such as the Lima and Cávado flow through deep gorges and flat-floored valleys. Along the coast a narrow beach rises gradually to meet the low hills, which lie just a few miles inland.

Trás-os-Montes e Alto Douro. Behind the mountains of Minho is the province of Trás-os-Montes e Alto Douro, bordered on two sides by Spain. It is an extension of the Spanish Meseta, a high, partly fractured plateau (from 2,000 to 2,600 feet high) composed largely of ancient Precambrian rock, such as granites, schists, and slates, marked by rivers that have carved canyons as deep as 1,600 feet. The plateau is surmounted by the Serra de Nogueira

(4,324 feet [1,318 metres] high), one of the remnants of the ancient mountains.

The Beira provinces. The rocks and landscape of Minho extend southward beyond the Rio Douro into the Beira Litoral, to a point north of Coimbra on the Rio Mondego. Most of central Portugal is included in the Beira provinces. The heart of Beira Alta is an elevated peneplain, partly dissected by the Mondego and Vouga river systems. Like Trás-os-Montes e Alto Douro, this high plain is an extension of the Meseta of Spain. The low, protected valleys, which are subject to climatic conditions very different from those of the high plateau directly above them, are called the *terra quente* ("hot country"). The high plain of the Beira is bounded on the northwest by the Serra do Caramulo (3,514 feet [1,071 metres]) and the Serra de Montemuro (4,534 feet [1,382 metres]) and their foothills. To the south and southeast it is bordered by the great escarpment of the Serra da Estrela, a granite and schist block that acts as a barrier between the northern and southern parts of Portugal. To the southwest, the mountain chain extends to the Serra de Açor (4,623 feet [1,409 metres]) and the Serra da Lousã (3,950 feet [1,204 metres]). To the south of Beira Alta and to the east of the Serra da Estrela lies the plateau of Guarda, which has an average height of 3,000 feet. Farther south the eroded plateau of Beira Baixa drops from an altitude of 1,600 feet to 700 feet, sloping toward the Tagus River in the south and merging almost imperceptibly into the highlands of Alto Alentejo.

Beira Litoral and Estremadura. North of Lisbon, the western provinces of Estremadura and Beira Litoral form a region totally without crystalline rocks. A narrow band of Triassic sandstones runs north and south from Coimbra to Tomar. To the west and southwest of the sandstones

The
Serra da
Estrela

lies a broad band of Jurassic limestones, interspersed with large areas of Cretaceous sandstones and conglomerates. Erosion has produced a landscape of rolling, sandy hills, plateaus of basalt, steep escarpments, and arid slopes.

Alto Alentejo. The south of Portugal is characterized by the rolling countryside of the Alentejo, formed from ancient schistose, granitic, and marble rocks. With an average height of between 700 and 1,600 feet, Alto Alentejo slopes downward toward the west and south.

Ribatejo. Between Beira Baixa, Estremadura, and Alentejo lies the Ribatejo, part of a large sedimentary basin forming the lower section of both the Tagus and Sado river systems.

Baixo Alentejo and the Algarve. The southern edge of the plain of Baixo Alentejo rises into the schistose mountains of the Serra do Caldeirão (1,893 feet [577 metres]) in the east. To the west lie the more extensive scarps and hills of the Algarve, composed of Mesozoic limestones and sandstones. The Serra de Monchique is a dissected massif of syenite, an igneous rock; its highest peak, at 2,959 feet (902 metres), is Foia.

Madeira. Composed of the islands of Madeira and Porto Santo, along with six uninhabited islets, Madeira lies in the Atlantic about 600 miles (1,000 kilometres) southeast of continental Portugal. It has an area of 307 square miles (796 square kilometres). Mountainous Madeira island rises to 6,109 feet (1,862 metres) in the interior, dropping steeply to the north coast, more gently to the south. Porto Santo is flat, formed basically of basalt and trachyte.

The Azores. The nine islands that compose the Azores archipelago lie in the Atlantic, in three widely separated groups, the island nearest to Portugal, São Miguel, being 740 miles (1,190 kilometres) from Cabo da Roca. With a total area of 902 square miles (2,305 square kilometres), they range in size from the 288 square miles of São Miguel to the 6.6 square miles of Corvo. They are characterized by great beauty, variety, and contrasts of landscape, with many lakes lying in craters of extinct volcanoes and constant volcanic activity.

Drainage and harbours. All the main rivers of Portugal flow from Spain over the edge of the Meseta in a series of defiles and gorges. Consequently none of them is navigable between the two countries (with the possible exception of the lower Minho and Guadiana). The longest river crossing Portugal is the Douro (200 miles, or 320 kilometres), whereas the longest river solely in the country is the Mondego (137 miles), rising in the Serra da Estrela. The principal exclusively Portuguese rivers, all of which are partly navigable, include the Vouga (85 miles), the Mondego, the Sado, and the Zêzere (a tributary of the Tagus). North of the Tagus, most of the rivers flow from the northeast to the southwest, whereas most of those in the south flow from the southeast to the northwest.

The coast has only a few natural harbours, the most important at the mouths of rivers: Lisbon, at the mouth of the Tagus; and Setúbal, on the Sado. Other harbours depend on the protection of headlands. North of the mouth of the Douro the artificial harbour of Leixões was built, and another is being constructed at Sines, south of Setúbal. Sandbars at the entrances of many rivers block passage of ships. Lisbon, with its fine harbour, was the only obvious choice for a large port.

Climate. The extreme southwesterly position of Portugal on the continent of Europe accounts for its mild, humid winters and relatively equable, dry summers. The effect of the ocean and the contrasts of relief offer an extremely varied climate marked by transitional features between Marine West Coast and Mediterranean conditions. In winter the northern half of Portugal is dominated by the North Atlantic cyclones, and in summer the Azores high-pressure system advances northward.

In January the average temperatures range from 52° F (11° C) in the southwest to about 45° F (7° C) in the northeast. Severe cold is usually associated with the incursion of high-pressure conditions from the Spanish Meseta or from Siberian anticyclones. The highest areas of the Serra da Estrela and of the region of Bragança (in the northeastern part of Trás-os-Montes e Alto Douro) regis-

ter temperatures of less than 32° F (0° C), and snow lies on the mountain summits for several months. Evening breezes off the sea cool the coastal zones in summer. August is usually the hottest month, with an average temperature of 68° F (20° C).

Northern Portugal receives considerable rainfall, and everywhere on the coast humidity is relatively high for the latitude. In the northwest, annual rainfall is more than 40 inches (1,000 millimetres), and a large part of Minho receives between 40 and 80 inches, with up to 100 inches recorded on mountain slopes. Near the northwestern frontier, the summer drought is not pronounced, but toward the northeast and south of the Tagus it is marked.

The climate of Madeira, influenced by the trade winds, is mild, of the Mediterranean type, with relatively high temperatures. Precipitation, rare in summer, seldom exceeds 25 inches (640 millimetres). The Azores also have a mild climate, moderated by the Gulf Stream. Precipitation in the archipelago averages 45 inches annually.

Plant life. Portugal exhibits a mixture of Atlantic deciduous flora and Mediterranean and African evergreens. About two-thirds are species common to Europe and about one-third Iberian and African.

Two species of pine (*Pinus pinaster* and *P. pinea*) and three species of oak (*Quercus robur*, or English oak; *Q. toza*, or Pyrenean oak; and *Q. lusitanica*, or Portuguese oak) predominate in the northern half of Portugal, with notable concentrations of maritime pine (*P. pinaster*) on the predominantly siliceous coastal soils. The chestnut, linden, elm, and poplar, like the olive, are widespread. South of the Tagus is a quite different vegetation region. Maritime pine is replaced in the western Alentejo by the European stone pine (*P. pinea*). The dominant trees, however, are the cork (*Q. suber*) and holm (*Q. ilex*) oaks. Both cultivated and wild olives grow well.

The far southern Algarve is renowned for its groves of carob (locust, or St. John's bread), almond, and fig, but there are also figs near Tomar and almonds in the upper valley of the Douro in the north. The olive, once concentrated in the south, is now widespread, especially in the Algarve, central Portugal, and the Douro Valley. The eucalyptus flourishes in the poorly drained valleys of the Tagus and Sado systems. Notable specialized flora include the aquatic plants of the Ria de Aveiro lagoons, the beautiful woodlands of the Serra da Arrábida, Serra de Sintra, and Serra do Buçaco, and the alpine flora of the Serra da Estrela.

The vegetation of Madeira has a distinctly south European character. There are about 100 plants that are peculiarly Madeiran, either as distinct species or as strongly marked varieties. Much of the indigenous vegetation has been crowded out by plants of foreign origin and now may be found only in virtually inaccessible areas.

The general character of the flora of the Azores is decidedly European, and vegetation in most of the islands is remarkably rich, especially in grasses, mosses, ferns, heath, juniper, and a variety of shrubs. There are almost no tall-growing trees native to the Azores.

Animal life. The fauna of Portugal is largely a mixture of central European and North African types, but there are some species that are indigenous to the Iberian Peninsula. Of the larger wild animals, only wild goat, wild pig, and deer are found in the mountains, the wolf in the remote parts of the Serra da Estrela, and the lynx in Alentejo. The fox, rabbit, and Iberian hare are ubiquitous.

Fish are plentiful in the Atlantic waters, especially the European sardine. Crustaceans are common on the northern rocky coasts, and oyster beds are found in the Ria de Aveiro and the estuaries of the Tagus and Sado. Birdlife is rich, since the peninsula lies on the winter migration routes of western and central European species.

The mammals of the Azores are limited to the rabbit, weasel, ferret, rat (brown and black), mouse, and bat. Game birds include woodcock, red partridge, quail, and snipe. There are valuable tunny, mullet, and bonito fisheries, and the porpoise, dolphin, and whale are common.

No species of land mammal is indigenous to Madeira, but monk seals (*Monachus albiventer*) are native and may still be seen on some of the islands. Among the 40 species

of birds that breed in the islands, only one, a wren, is endemic. Many kinds of fish are found in the surrounding waters, but the only freshwater fish is the eel. Beetles are the major form of indigenous Madeiran wildlife, an astonishing 695 species, a large proportion of them endemic, having been identified. Of the more than 100 species of moth collected, about a fourth are peculiar to Madeira.

THE PEOPLE

Although western Iberia has been occupied for a long time, relatively few human remains of the Paleolithic Period have been found. Neolithic and Bronze Age discoveries are commoner, among them many dolmens. Some of the earliest permanent settlements were the northern *citánias*, or *castros*, hill villages first built by Neolithic farmers who began clearing the forests. Incoming peoples, Phoenicians, Greeks, and Celts, intermingled with the settled inhabitants, and Celticized natives occupied the fortified *citánias*. For 200 years these were centres of resistance to the Roman legions. Subsequently the Romans, Suebi, Visigoths, Moors, and Jews exerted influence on the territory. Portugal's situation at the western extremity of Europe made it a gathering place for invaders by land, and its long coastline invited settlement by seafarers.

Although formed of such different elements, the population of Portugal is one of the most homogeneous in Europe, having physical characteristics common to circum-Mediterranean peoples. Most Portuguese are of slightly lower than average stature, with brown eyes, dark wavy hair, and a pallid or brunet skin.

Most Portuguese are Roman Catholic. Though freedom of worship is permitted, followers of other creeds are few. The church is separated from the state, and a concordat regulates the relations of Portugal with the Holy See.

Population density of Portugal.

Population distributions within Portugal reveal striking contrasts between the more densely populated north and the more sparsely populated south. A number of rural areas have suffered considerable population losses, resulting in economic and social depression, particularly in parts of the north, the central east, and the southern coastal areas. The coastal zones between Braga and Setúbal, with their low-lying plains and urban development, have attracted a large proportion of the population. Only the industrial areas of Lisbon and Porto are able to absorb their own working populations. Other areas that are currently going through the process of industrialization are Aveiro, Coimbra, Setúbal, and Faro. Areas such as Minho, the central plains, and the coastal areas of the Algarve are seriously overpopulated.

In the main, rural settlement is dispersed, the inhabitants living in small villages under a system of open-field farming. The Beira Litoral and Estremadura have settlements varying between dispersed and clustered farmsteads. In the region of Aveiro, clusters of farmsteads and other dwellings are strung along roads in strips, often of considerable length and density. Fishing, one of the earliest occupations of the Portuguese, still plays an important role in coastal settlements.

The decolonization process that took place after the revolution of April 25, 1974, inevitably had demographic repercussions on metropolitan Portugal because of the large number of people (mostly Portuguese) who left the former overseas provinces. According to official figures, incoming refugees totalled about 700,000, most of whom (approximately 90 percent) came from Angola because of the civil war between the liberation movements. The majority of the repatriates crowded into Portuguese cities and towns.

Incoming
refugees

Portugal has one of the highest rates of emigration in Europe. Before 1960, most of its émigrés went to Brazil and a few other Latin-American countries. In the late 20th century, however, the industrialized countries of western Europe became the major destination of emigrants whenever work was to be found there. Clandestine emigration, once much greater than legal, was basically channelled to France after the mid-1950s. It is said that, after Lisbon, Paris is the city with the largest Portuguese population.

THE ECONOMY

Even before the revolution of 1974, the economic situation in Portugal was considered to be poor, because of structural deficiencies that were felt in everyday life and that were bringing about increased inflation. After the revolution, the economy was very badly affected by such moves as the nationalization of banks, insurance companies, and heavy and basic industries, which led to the retraction of private initiative and investment; by a drop in emigrants' remittances, in part because of the decrease in the number of emigrants; and by the worsening of the economic situation of enterprises, both nationalized and public, and the small and medium-sized firms of the private sector.

Agriculture, forestry, and fishing. Portuguese agriculture is in persistent decline, chiefly because of the predominance of antiquated techniques. The main crops are cereals, including wheat, barley, maize (corn), and rice; potatoes; grapes; and olives. The country has to import wheat, maize, and meat.

Small farms predominate, particularly in the north, where they are too small and made up of too many dispersed holdings to allow integrated farming and rational crop rotation. In the south (except Algarve) the system of latifundios, or large estates, before 1975 prevented intensive cultivation because the latifundios were owned by absentee landlords who had no interest in making capital investment in machinery, fertilizers, and other items that would increase productivity. After the revolution (from March 1975) an agrarian reform got under way south of the Tagus, where about 3,200,000 acres (1,300,000 hectares) of land in large holdings was expropriated (with compensation) and nationalized. The policy adopted was aimed, among other things, at destroying the latifundio system, changing the tenancy system, handing uncultivated land back to the people, abolishing quitrent, increasing the irri-

Types of
farms

gated area, introducing new crops, intensifying the output of fodder and cereals, and developing livestock. A large part of the nationalized land was turned over to collective and cooperative production units. To help these and the owners of small and medium-sized farms, agricultural credit was expanded.

The ownership structure was thus profoundly changed. The process took place hastily, however, and accumulated errors, allied to the disturbance typical of such an undertaking, caused political tension, instability, and crisis.

Forestry

One-third of Portugal is wooded. Most of the mountainous areas are well suited to forestry, and forest products (cork, resins, and pine and eucalyptus timber), the market value of which has increased, find a growing demand in industry. For this reason, considerable reforestation has been conducted since the last quarter of the 19th century in areas where crop yields are low and erosion severe.

Portugal's long coastline and the abundance of fish in the surrounding waters have favoured the development of the fishing industry. Sardines, anchovies, and tuna caught near the coasts, together with other species such as codfish from the North Atlantic, make a large contribution to food supplies. The fishing industry has prospered, and its products are exported all over the world. Matosinhos in the north, Setúbal, and Portimão and Olhão and other ports in the Algarve are among the main fishery centres. But even the fishing industry is not able to feed the population; a quarter of the fish consumed in Portugal must be imported, mainly from Iceland (stockfish), Norway (dried cod), and the Soviet Union (sardines).

Mining and industry. Mineral production in Portugal is negligible. Portugal has to import coal, petroleum, and petroleum products.

In its level of industrial development, Portugal had an intermediate but fairly favourable position among southern European countries. Three main groups of industries—foodstuffs and beverages, textiles and footwear, and metals—together accounted for more than half of the country's total industrial product and employed more than half of the industrial labour force. Capital intensity varied widely among the industries included in these broad groups. Industrial centres are unevenly distributed, the more prosperous and rapidly growing industries being concentrated around the larger towns, especially Lisbon and Porto.

Nationalization of industry

In the wake of the revolution, deep alterations have occurred. There were basic labour questions, chiefly claims for better wages, which in many sectors were very low indeed; strikes and occupations took place. After the political crisis of March 1975, heavy industry, basic industries (cement, petrochemical, shipbuilding, electricity, etc.), and even some light industries were nationalized. One of the sectors that was most seriously affected by the unrest was the construction industry, in which activity was almost stopped; the government tried to revitalize it through public housing schemes.

Manufacturing could make a large contribution to equilibrium in the balance of payments. But to do so, Portuguese manufacturing would have to become more export-oriented, since the possibilities for import substitution are limited by the relatively small size of the domestic market. Access to the markets of the European Economic Community (EEC) and the European Free Trade Association (EFTA) augments Portugal's possibilities for increasing exports of manufactured goods, but larger exports would require improvement in the competitiveness of Portuguese industry.

Most electricity in Portugal is produced by hydroelectric plants, despite the relatively low and unevenly distributed rainfall, which constitutes a serious obstacle.

Trade deficits

Trade. Portugal has a large foreign trade relative to its population, and its composition changed considerably after about 1960. The trade balance reflects to a certain extent the deficiencies of the Portuguese economic structure: total imports (the most important being food products, raw materials, and equipment) have been greater than exports, which show little diversification. Until 1973, foreign trade (both imports and exports) was largely distributed among the European countries of the Organization for Economic Co-operation and Development (OECD), especially those

belonging to the EEC and the EFTA, and the United States. Transactions with the eastern European countries were very restricted under the system of compensation agreements, since Portugal had no diplomatic relations with those nations.

Portuguese products are insufficiently competitive in foreign markets, mostly because of their higher costs when compared to those of similar products from the OECD countries. Since the revolution of 1974, small and medium-sized firms have experienced rapid increase in production costs brought about by wage increases. In addition there was decreased demand for imports in the OECD countries, which are the destination of 80 percent of Portuguese exports.

Transportation. Although transport and communications were seriously neglected in the past, there has been a strong effort to improve the transport situation.

Several of the country's main roads date back to ancient times, but now main roads connect the largest towns and extend to the border and ports. Secondary roads link the towns with almost every part of the interior, and the total road network is being extended.

The Portuguese railroad network consists of some 3,000 miles (4,800 kilometres) of track; the main Lisbon-Porto line was electrified in 1965. The merchant fleet is of considerable size.

The Portela de Sacavém airport at Lisbon, an important junction for intercontinental flights, is the base of the Portuguese airline, Transportes Aéreos Portugueses (TAP), which provides regular services. The loss of the overseas territories of course caused difficulties for TAP. Other important airports are at Porto and Faro. (I.M.P. do A./Ed.)

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. Portugal has been a republic since the overthrow of the monarchy in 1910, and its status as a democratic state began with the so-called Captains' Revolution of April 25, 1974, which overthrew the conservative regime of Marcelo Caetano. According to the postrevolution constitution of 1976, the chief of state is the president of the republic, elected by universal suffrage for a five-year term. He is president of the Council of the Revolution and supreme commander of the armed forces. The president appoints the chairman of the Council of Ministers (the prime minister), fixes election dates, represents the nation and directs foreign policy, makes and adjusts international treaties, and promulgates the laws and resolutions of the Assembly of the Republic. In addition, he presides over the Council of the Revolution and, on the advice of the council, convokes and dissolves the Assembly of the Republic and regional organs. He appoints one of the members of the Constitutional Commission and also the chairman of the Advisory Commission on the autonomous regions (the Azores and Madeira) and appoints and dismisses other members of the government at the proposal of the prime minister.

The president of the republic is advised when necessary by the Council of the Revolution, which is composed of the president (both in his civilian capacity and that of supreme commander of the armed forces), the prime minister (if he is a military officer), and 14 officers (eight from the army, three from the air force, and three from the navy), all appointed by the respective services. A Constitutional Commission, operating in conjunction with the Council of the Revolution, pronounces upon the constitutional worth of acts submitted to the consideration of the Council of the Revolution. It reports any violation of the constitutional norm and gives its opinion on questions of unconstitutionality.

The prime minister forms the Council of Ministers (Cabinet) with the president's approval. The duties of the Council of Ministers consist of defining the general lines of government policy, approving decree laws, approving the budget and government acts involving increase or decrease in public revenue or expenditure, and deliberating upon government affairs submitted to it.

The parliamentary body is the Assembly of the Republic, with a minimum of 240 and maximum of 250 deputies, elected every four years under a system of pro-

Council
of the
Revolution

portional representation. Its duties include discussing and voting upon basic legislation, authorizing the government to raise loans, approving treaties concerning Portugal's membership in international organizations, and approving the politico-administrative statutes of the Azores and Madeira. It may also confer legislative authority upon the government.

Portugal is divided into 22 administrative districts (*distritos*; 18 on the mainland, three in the Azores, and one in Madeira), each with a civil governor who is appointed by and responsible to the central government through the Ministry of the Interior. He is assisted by a board. The country is also divided traditionally (though not officially since 1959) into provinces: Minho, Trás-os-Montes e Alto Douro, Douro Litoral, Beira Alta, Beira Baixa, Beira Litoral, Estremadura, Ribatejo, Alto Alentejo, Baixa Alentejo, and Algarve.

The districts are divided into municipalities (*concelhos*) and parishes (*freguesias*). Local government is in the hands of parish assemblies, municipal assemblies, municipal chambers, and municipal councils. There are about 4,000 parishes, whose assemblies are elected by the local citizens. The assembly elects an executive body, the parish committee. The municipal assemblies consist of the chairmen of the parish committees and at least an equal number of members elected by the voters in the municipal areas. The municipal chambers are the corporate executive organs, and the municipal councils are advisory.

The Portuguese police are under the control of the Ministry of Internal Administration and are divided into two main categories: the Public Security Police (Policia de Seguranca Pública, or PSP) and the National Republican Guard (Guarda Nacional Republicana, or GNR). The GNR includes the road police and is also responsible for rural armed police, who patrol the countryside and have outposts in the larger towns and villages. The duties of the PSP are the general maintenance of public order, direction of city traffic, and prevention of crime. The naval police are in charge of the ports.

Education. Private schools supplement the state schools that provide free education for the majority of people. There are five long-established universities: the University of Coimbra, one of the oldest in Europe; the University of Lisbon and the Technical University of Lisbon; the University of Oporto; and the Portuguese Catholic University (Universidade Católica Portuguesa), founded in 1968 in Lisbon.

Welfare services. The Portuguese welfare system is composed of several types of institutions that insure workers against sickness, disablement, and old age and provide for the payment of pensions and family allowances. Compulsory insurance by employers is in force in most sectors of business and industry, the employee paying into the fund as well. Trade-union provident funds and welfare funds for other employees take care of most categories of workers, and there are voluntary mutual assistance associations and provident institutions for the military forces and civil servants. Many big companies conduct their own welfare and sick benefit schemes and pensions for their employees.

Workers have the choice of belonging to one of two trade-union federations. One is the Intersindical, which is Communist-controlled. The other is the União Geral de Trabalhadores (UGT; General Union of Workers), which is democratic.

Portugal has both public and private hospitals. Regional hospitals are located in the main provincial centres and subregional hospitals in smaller centres. Charity hospitals (the *santas casas da misericórdia*) give free treatment to the underprivileged. The civil hospitals, mainly run by the municipalities with state support and funds from welfare and social organizations, charge according to the means of the patient. There are dispensaries and clinics all over the country to deal with mothers and infants. Special institutions include a cancer hospital and research unit in Lisbon, a school of tropical medicine, a sanatorium in the northern mountains, and a modern rehabilitation centre for the disabled near Lisbon.

CULTURAL LIFE

Portuguese culture is based on a past that dates from prehistoric times into the eras of Roman and Moorish invasion. All have left their traces in a rich patrimony of archaeological remains, including prehistoric cave paintings at Escoural, the Roman township of Conimbriga, the Temple of Diana in Évora, and the typical Moorish architecture of such southern towns as Olhão and Tavira. Throughout the centuries Portugal's arts have been enriched by foreign influences, including Flemish, French, and Italian. The voyages of the Portuguese discoverers opened the country to Oriental influences, and the revelation of Brazil's wealth of gold and jewels fed the Baroque flame in decoration.

Folk and popular culture. Folk traditions still survive, and old songs and dances grace local religious festivals. Much has been done to preserve them as a tourist attraction. Some of the best examples of the regional dances are the *vira*, *chula*, *corridinho*, *tirana*, and *fandango*, many of which express the courting and matrimonial traditions of the area. National dress is still seen in the northern Minho province at weddings and other festivals. Traditional garments such as the red and green stocking cap of the Alentejo cattleman still exist, and the *samarra* (a short jacket with a collar of fox fur) and *cifões* ("chaps") survive. In Trás-os-Montes e Alto Douro the shepherd wears a straw cloak.

Regional fairs abound throughout the year, many of them combined with religious festivals. Religious customs in this Catholic country include the burning of the yule log in the atrium of the village church at Christmas, so that the poor may warm themselves; and the fight between St. George and the Dragon in the streets of Monção at Corpus Christi.

Architecture. Romanesque and Gothic influences have given the country some of its greatest cathedrals, and in the late 16th century a national style (Arte Manuelina) was synthesized by adapting several forms into a luxuriantly ornamented whole. Outstanding examples of Portuguese architecture include the Jerónimos monastery in Lisbon, in ornate Manueline style; the Sé (cathedral) of Lisbon, in part of the facade of which the remains of Roman construction may still be seen; the Palace of Justice in Lisbon, a fine, soaring example of austere modern architecture; the castle and church of the Order of Christ (Ordem de Cristo) in Tomar; the late Portuguese Gothic abbey of Santa Maria da Vitória in Batalha; the granite Torre dos Clérigos (Tower of the Clerics) in Porto; and Braga's Romanesque cathedral.

Visual and decorative arts. Sculpture found rich expression in the magnificent tombs of the 12th and 13th centuries, and late 18th-century Baroque wood sculptures, of which the Christmas cribs of Joaquim Machado de Castro are the finest, also are outstanding. A school of primitive painters headed by Nuno Gonçalves was prominent in the 15th century, and subsequently Flemish artists influenced the native style, decorating palaces and convents and leaving a rich heritage of religious art. The 19th century saw another rebirth of national art with a late Romantic period. An era of naturalist realism that followed gave way to the experimental 20th century. Maria Helena Vieira da Silva is the country's finest contemporary abstract painter, and Carlos Botelho is noted for his street scenes of Lisbon.

Among the decorative arts, the Portuguese glazed tiles (*azulejos*) are outstanding. Many 16th- and 17th-century buildings are faced with tiles, and the rooms and halls of palaces and mansions exhibit blue and white tiled panels or motifs in other soft colours. Exceptionally fine examples are found in the Pátio da Carranca (*pátio*, "courtyard") of the Paço do Sintra (*paço*, "palace") at Sintra, São Roque church in Lisbon, and the Quinta da Bacalhoa at Vila Fresca de Azeitão near Setúbal.

Music. Portuguese music reached a peak of achievement during the Renaissance. Its modern revival was primarily the work of Luís de Freitas Branco, whose Neoclassic tradition has been perpetuated by Joly Braga Santos. Early Portuguese music was shaped by liturgical music, but it was accompanied by fine development of the troubadour art. Polyphonic music was developed in

Regional
dances

Literacy

Hospitals

Gul-
benkian
Founda-
tion

the 15th century, with an upsurge of the art of music following in the 17th. The Calouste Gulbenkian Foundation (founded by the oil magnate) continues to inspire the country's musical life. A group of young composers is acquiring prestige both at home and in international competitions, among them Filipe Pires, A. Vitorino de Almeida, Alvaro Cassuto, and Jorge Peixinho. There is an active National Broadcasting Symphony Orchestra, and Porto has had its own symphony orchestra since 1962, the year in which the Chamber Orchestra was set up by the Gulbenkian foundation. In 1971 the Lisbon Municipal Orchestra was created, and the Teatro São Carlos also has its own orchestra and ballet company. Folk music and dancing and the traditional *fado*, a song form that expresses the sad, romantic mood of the nation, remain the country's fundamental forms of musical expression.

Literature. The Portuguese language became synthesized in the 12th century, when a lyrical quality was outstanding in both poetry and prose. A soldier-poet, Luis de Camões, gave expression to the nation's epic genius in the 15th century, as the poet Fernando Pessoa expressed its decadence in the 19th. Lyric poetry still flourishes. The tendency of fiction has been away from the Romanticism of the 19th and early 20th centuries and toward Realism. José Maria Eça de Queirós was the outstanding Realist novelist, his works including *Os Maias* (1888; *The Maias*, 1965) and *A Cidade e as Serras* (1901; *The City and the Mountains*, 1955). In the 20th century Aquilino Ribeiro was the outstanding regional novelist, whose works include *Jardim dos Tormentos* (1913; "Garden of Torments") and *O Homem que Matou o Diabo* (1930; "The Man Who Killed the Devil"), while José Maria Ferreira de Castro has been the outstanding Realist, with *A Selva* (1930; *The Jungle*, 1934) and *Os Emigrantes* (1928; "The Emigrants"). The novelist, essayist, and poet Vitorino Nemésio was outstanding with his novel *Mau Tempo no Canal* (1944; "Bad Weather in the Channel").

Theatre and motion pictures. While the theatre is rapidly picking up after a period of stagnation, the Portuguese film industry is still inactive. With the rebuilding of the classic drama theatre, the National Theatre of Dona Maria II in Lisbon (guttled by fire), there is a revival of the serious play. State and Gulbenkian foundation aid has given new life to the "little theatre" not only in Lisbon but in the provinces. International opera, theatre, and ballet are prominent in regular seasons in the Teatro Nacional São Carlos, in Lisbon, and other theatres.

Museums, libraries, and art galleries. In Lisbon, in addition to the Calouste Gulbenkian Foundation, which houses Gulbenkian's collections, the most outstanding are the National Art Museum, the National Museum of Coaches, with Europe's finest collection of ancient vehicles; the National Museum of Contemporary Art; and the Museum School of Decorative Arts, which trains craftsmen in furniture restoration, bookbinding, repair of ancient tapestries, and other fine handicrafts. Provincial museums include the Soares dos Reis National Museum in Porto, Machado de Castro National Museum in Coimbra, and the Regional Museum of Aveiro. The Biblioteca Nacional (National Library) and Biblioteca da Ajuda (Ajuda Library) in Lisbon have fine collections, while the National Archives of Torre do Tombo contain valuable national documents. Outside Lisbon, the library of the Convento de Mafra in Mafra and that of the University of Coimbra have historical importance. For statistical data, see the "Britannica World Data" section in the current *Britannica Book of the Year*. (J.Sh./Ed.)

History

Portugal became an independent monarchy in the 12th century AD. Its name derives from Portus Cale, a pre-Roman or Roman settlement near the mouth of the Douro River. The southern part of the Roman province of Gallaecia was occupied by the Germanic Suebi in AD 411, and Portucale (Porto) was held by them. They were subdued by the Visigoths, whose state was overthrown by the Muslim invasions in the 8th century. A Christian territory of Portugal was constituted in 868; it later became a

county and was extended to Coimbra. Afonso Henriques assumed the title of king (1139) and annexed Lisbon. His successors took Alentejo and Algarve from the Muslims (by 1252). Portugal now includes the "adjacent islands" of Madeira and the Azores, first settled in the 15th century.

PRE-ROMAN, ROMAN, GERMANIC, AND MUSLIM PERIODS

The earliest human remains found in Portugal are Neanderthal-type bones from Furninhas. Most peninsular Paleolithic industries are represented, but a distinct culture first emerges in the Mesolithic middens of the lower Tagus Valley, dated c. 5500 BC. Neolithic cultures entered from Andalusia. There are varied types of beehive huts and passage graves: agriculture, pottery, and the working of soft metals followed by the same route. In the first millennium BC, Celtic peoples entered the peninsula by the Pyrenees, and many groups were projected westward by natural pressure. Hallstatt cultures brought ironworking to the Tagus Valley. Phoenician and later Carthaginian influence reached southern Portugal in the same period. By 500 BC, Iron Age cultures predominated in the north. Celtic hilltop settlements (*castros*, *citânias*) retained their vitality after the Roman conquest.

After the Second Punic War (218–201 BC), Rome dominated the eastern and southern seaboard of the peninsula, and Celtic peoples who had partially absorbed the indigenous population occupied the west. A Celtic federation, the Lusitani, resisted Roman penetration under the brilliant leadership of Viriathus; but after his assassination (c. 140 BC), Decius Junius Brutus was able to march northward through central Portugal, cross the Douro River, and subdue the Gallaeci. Julius Caesar governed the territory for a time. In 25 BC Augustus founded Augusta Emerita (Mérida) as capital of Lusitania, which incorporated the present central Portugal. Gallaecia, to the north of the Douro, became a separate province under the Antonines. In Roman times the region of Beja and Évora was a wheat belt. The valley of the Tagus was famous for its horses and farms, and there were important mines in Alentejo. Notable Roman remains include the "Temple of Diana" at Évora and the site of Conimbriga (Condeixa). Christianity reached Lusitania in the 3rd century and in the 4th Gallaecia, where the heretical and ascetic teaching of Priscillian long held sway.

With the collapse of the Rhine frontier (AD 406), barbarian peoples forced their way into Gaul and crossed the Pyrenees. A Germanic tribe, the Suebi, was settled in southern Gallaecia, their rulers residing at or near Bracara Augusta (Braga) and Portucale. They annexed Lusitania and for a time overran the rest of the peninsula, but the Visigoths were sent to subdue them and extinguished their monarchy (AD 469). The records are silent until c. 550, when the Suebic monarchy had been restored and was reconverted to Catholicism by St. Martin of Braga. The Visigoth Leovigild again overthrew the Suebic monarchy and annexed the territory, but it remained distinct from Gothic Spain. St. Martin's church grouped together the bishoprics of the Suebic territory until c. 660, when the ecclesiastical divisions were adjusted to the old Roman provincial system and the region to the south of the Douro was restored to Lusitania. With the Muslim invasion of 711, the only serious Gothic resistance was made at Mérida; on its fall the northwest submitted. Berber troops were placed in central Portugal and Galicia, but with the revolt of the Berbers and famine (740–750) the latter was evacuated. Braga was abandoned, but the rural population remained or was restored. When 'Abd ar-Rahmān I set up the Umayyad monarchy at Córdoba (756), there was some resistance in the west, and he perhaps stationed Berber allies at Mérida and Coimbra. Lisbon was independent for a few years (c. 805). The restoration of the Christian sees of Galicia, the discovery of the supposed tomb of St. James, and the erection of his shrine at Santiago de Compostela were followed by the organization of the frontier territory of Portucale (868) by Vimara Peres; Coimbra was annexed by the Christians but later lost again.

THE COUNTY AND KINGDOM OF PORTUGAL (TO 1383)

By the 10th century the county of Portugal (north of the Douro) was held by Mumadona Dias and her husband

Hermenegildo Gonçalves and their descendants, one of whom was tutor and father-in-law to the Leonese ruler, Alfonso V. But when this dynasty was overthrown by the Navarrese-Castilian house of Sancho III the Great, the western county lost its autonomy. Sancho's son, Ferdinand I of Castile, reconquered Coimbra in 1064 but entrusted it to a Mozarabic governor. When the African Almoravids annexed Muslim Spain, Alfonso VI of León (1065–1109) and Castile (1072–1109) provided for the defense of the west by calling on Henry, brother of Duke Eudes (Odo) of Burgundy, whom he married to his illegitimate daughter Teresa and made count of Portugal. From 1095, therefore, Henry and Teresa (who used the title of queen) ruled Portugal and Coimbra. On the death of Alfonso VI, his realms passed to his legitimate daughter Urraca and her little son Alfonso (VII). Henry of Portugal sought power but had achieved little when he died in 1112, leaving Teresa with an infant son, Afonso Henriques. Teresa's intrigues with her Galician favourite, Fernando Peres of Trava, lost her the support of the Portuguese barons, and in 1128 followers of her son defeated and drove her into exile. Thus Afonso Henriques became count of Portugal. Though at first obliged to submit to his cousin Alfonso VII, he began to use the title of king, traditionally because of a victory over the Muslims at Ourique (July 25, 1139; but perhaps a symbolic legend). In 1143 his cousin accepted his autonomy, but the title of king was formally conceded only in 1179, when Afonso Henriques placed Portugal under the direct protection of the Holy See, promising an annual tribute. He had captured Santarém (March 1147) and Lisbon (October 1147), the latter with the aid of English, French, German, and Flemish crusaders bound for Palestine. An English priest, Gilbert of Hastings, became first bishop of the restored see of Lisbon. Although the new Moroccan dynasty of the Almohads struck back (1179–84), when Afonso I died (December 6, 1185) the Portuguese frontier was firmly established on the Tagus. The new military orders, the Templars, those of Calatrava (from c. 1156), and of Santiago (from c. 1170), etc., governed castles and territory on the frontier, and the Cistercians were responsible for the introduction of agriculture and architecture in central Portugal (Alcobaca).

The kingdom and the Reconquista. Although Afonso Henriques began to grant charters to new settlements, it was his son Sancho I (1185–1211) who enfranchised many municipalities (*concelhos*), especially in eastern and central Portugal. The privileges of these communities were embodied in charters (*forais*), which attracted settlers from the more feudal north. Even Muslims were enfranchised, though on the other hand many of them were enslaved. Assisted by passing crusaders, Sancho captured Silves in Algarve (1189); but in 1190 an al-Muwāhhidūn army from Africa advanced to the Tagus and, although Lisbon, Santarém, and Tomar stood firm, the Muslims recovered Silves in 1191, together with most of the land south of the Tagus. In his later years Sancho was involved in a quarrel with Pope Innocent III over the payment of tribute due to the Holy See and with the bishop of Porto, who received Innocent's support. But peace was made before his death, and it was left to his son Afonso II, the Fat (1211–23), to endeavour to strengthen the power of the throne at the expense of the church.

Though Afonso II was an unwarlike king, his followers were beside the Castilians at the great Christian victory of Las Navas de Tolosa in 1212 and, again assisted by crusaders, recovered Alcácer do Sal in 1217. Meanwhile Afonso repudiated the bequests of large estates made by his father to his brothers and accepted those to his sisters only after a war with León and in a form, settled by the pope, that recognized Afonso's sovereignty. In the first year of his reign, Afonso called a meeting of the Cortes at Coimbra, to which the nobility and prelates were summoned (representatives of the commoners were not to appear until 1254). Both estates obtained important concessions; in fact, the position of the church and the orders was now so strong that Afonso II and his successors were involved in recurrent conflicts with Rome. Afonso himself instituted (from 1220) *inquirições*, or royal commissions, to investigate the nature of holdings and recover whatever

Portugal in the 12th and 13th centuries.

had been illegally taken from the crown. In his last years, Afonso quarrelled with the archbishop of Braga, who was supported by Pope Honorius III, defied the papacy, and was excommunicated.

Little is known of the reign of his son Sancho II (1223–c. 1246), but the reconquest of Alentejo was now completed and much of Algarve was reduced. On his accession, Sancho found the church in full ascendancy as a result of the agreement made before his father's death. Conflicting reports exist of Sancho's own government, but in his later years the kingdom seems to have slipped into anarchy. At all events, his younger brother Afonso, who had become count of Boulogne by his marriage (1238) with Matilde, daughter of Count Raynald I of Dammartin, was granted a papal commission (1245) to take over the government, and Sancho was ordered to be deposed by papal bull. When Afonso reached Lisbon (late 1245 or early 1246), he received the support of the church and of the inhabitants of Lisbon and other towns. After a civil war lasting two years, Sancho II retired to Toledo, dying there in January 1248.

On his arrival, the count of Boulogne had already declared himself king as Afonso III, and the death of Sancho without issue gave his usurpation the mantle of legality. He brought together the divided kingdom, completed the reconquest of Algarve, transferred the capital from Coimbra to Lisbon, and, fortified by the support of the towns, summoned the Cortes at Leiria at which for the first time commoners representing the municipalities made their appearance (1254). His conquest of Algarve aroused the jealousy of Castile. Two campaigns were fought (1250 and 1252), Afonso probably being worsted, and peace was made by means of a marriage pact. Although still the husband of Matilde of Boulogne, Afonso married Beatriz, illegitimate daughter of Alfonso X of Castile, holding the disputed territory of Algarve as a fief of Castile until such time as the eldest son of the marriage should reach the age of seven, when Algarve was to return to Portugal. This

The Cortes

marriage led to a dispute with the Holy See, in which Afonso was placed under an interdict. Despite his early connection with Rome, Afonso refused to give way; and in 1263 the bigamous marriage was legalized and his eldest son, Dinis, legitimized. Shortly afterward, Afonso launched *inquirições*, as a result of which the church was deprived of much property. The prelates protested these actions of the royal commissions, and most of them subsequently left the country. Although Afonso was excommunicated and threatened with deposition, he continued to defy the church until shortly before his death early in 1279.

The achievements of Afonso's reign—the completion of the reconquest, the assertion of royal power before the church, and the incorporation of the commoners in the Cortes—indicate important institutional advances. Under his son Dinis (1279–1325), Portugal was to come into closer touch with western Europe and to acquire a university, the elements of a national literature, and a navy. The chartering of fairs and the increased use of minted money bear witness to the growth of commerce, and the planting of pine forests to hold back the sand dunes near Leiria illustrates Dinis' concern for shipbuilding and agriculture. In 1317 Dinis engaged a Genoese admiral, Emmanuele Pessagno, to build up his navy, having already adopted various measures to stimulate foreign trade. He founded the University of Coimbra (at first in Lisbon) in 1290 and was both a poet and patron of literature. Yet he was especially famed as the “farmer king” (*rei lavrador*) for his interest in the land.

Despite Dinis' attachment to the arts of peace, Portugal was several times involved in strife during his reign. In 1297 the Treaty of Alcañices with Castile confirmed Portugal's possession of Algarve and provided for an alliance between Portugal and Castile. In the later years of Dinis' reign, his son, the future Afonso IV, rebelled more than once, being persuaded to submit by the influence of his mother Isabel, daughter of Peter III of Aragon. This remarkable woman, later canonized as St. Elizabeth of Portugal and popularly known as the Rainha-Santa (the Holy Queen), successfully exercised her influence in favour of peace on several occasions.

Disputes with Castile. Afonso IV (1325–57) was also involved in various disputes with Castile. Isabel, who had retired to the Convent of Santa Clara at Coimbra, continued to intervene in favour of peace; but on her death in 1336 war broke out, and terms were not made till 1340, when Afonso himself with a Portuguese army joined Alfonso XI of Castile in the great victory over the Muslims on the Salado River in Andalusia. Afonso's son Peter (Pedro) was married (1336) to Constança (died 1345), daughter of the Castilian infante Juan Manuel; but soon after the marriage he fell in love with one of her ladies, Inês de Castro, by whom he had several children. Afonso was persuaded to countenance the assassination of Inês in 1355, and one of Peter I's earliest acts on his accession was to take vengeance on her murderers. During his short reign (1357–67), Peter devoted himself to the dispensation of justice; his judgments, which he executed himself, were severe and often violent, and his iron rule was tempered only by fits of revelling.

Peter's son by Constança, Ferdinand (1367–83), inherited a wealthy throne almost free of external entanglements; but the dispute between Peter the Cruel and Henry of Trastámara (later Henry II) for the Castilian throne was raging; and, on the murder (1369) of the former, several Castilian towns offered Ferdinand their allegiance, which he was unwise enough to accept. Henry II duly invaded Portugal in 1369, and by the Peace of Alcoutim (1371) Ferdinand was constrained to renounce his claim and to promise to marry Henry's daughter; however, he instead took a Portuguese, Leonor Teles, although she was already married and in spite of the protests of the commoners of Lisbon. He also made alliance (1372) with the English in the person of John of Gaunt, duke of Lancaster, who had married the elder daughter of Peter the Cruel and claimed the Castilian throne. In 1372 Ferdinand provoked Henry II, who invaded Portugal and besieged Lisbon. Unable to resist, Ferdinand was forced to repudiate his alliance with John of Gaunt and to act as an ally of Castile, surrender-

ing various castles and persons as hostages. It was only on the death (1379) of Henry that Ferdinand dared openly to challenge Castile again. In 1380 the English connection was resumed, and in the following year John of Gaunt's brother, Edmund of Langley, earl of Cambridge (afterward duke of York), took a force to Portugal for the invasion of Castile and betrothed his son Edward to Ferdinand's only legitimate child, Beatriz. In mid-campaign, Ferdinand came to terms with the enemy (August 1382), agreeing to marry Beatriz to a Castilian prince. She did, in effect, become the wife of John I of Castile; and when Ferdinand died, prematurely decrepit, Leonor Teles became regent and Castile claimed the Portuguese crown.

Leonor had long been the paramour of the Galician João Fernandes Andeiro, count of Ourém, who had intrigued with both England and Castile and whose influence was much resented by Portuguese patriots. Opponents of Castile chose as their leader an illegitimate son of Peter I, John, master of Aviz, who killed Ourém (December 1383) and, being assured of the support of the populace of Lisbon, assumed the title of defender of the realm. The regent fled to Alenquer and thence to Santarém, and the king of Castile came to her aid, soon however, relegating her to a Spanish convent. Lisbon was besieged for five months (1384), but an outbreak of plague obliged the Castilians to retire.

THE HOUSE OF AVIZ, 1383–1580

The legitimate male line of Henry of Burgundy ended at Ferdinand's death, and when the Cortes met at Coimbra (March–April 1385), John was declared king and became the founder of a new dynasty. This result was not unopposed, for many of the nobility and clergy still considered the queen of Castile the rightful heiress; but popular feeling was strong, and John I had valuable and trusted allies in Nuno Álvares Pereira, “the Holy Constable,” his military champion, and in João das Regras, his chancellor and jurist.

Independence assured. A number of towns and castles still held out for Castile when in August 1385 John I of Castile and a considerable army made their appearance in central Portugal. Although much outnumbered, the Portuguese won the great Battle of Aljubarrota (August 14, 1385), in which the Castilian chivalry was dispersed and John of Castile himself barely escaped. The victory, followed by secondary successes won by Nuno Álvares, assured John I of his kingdom and made him a desirable ally. A small force of English archers had been present at Aljubarrota. Now the Treaty of Windsor (May 9, 1386) raised the Anglo-Portuguese connection to the status of a firm, binding, and permanent alliance between the two crowns. John of Gaunt duly went to the Peninsula (July 1386) and attempted an invasion of Castile in conjunction with John I. This was not successful, but the Portuguese king married Gaunt's daughter Philippa of Lancaster (1387), who introduced various English usages into Portugal. The truce arranged with Castile in 1387 was prolonged at intervals until peace was finally concluded in 1411.

The victory of John of Aviz may be regarded as a victory of the national spirit against the feudal attachment to established order. As much of the older nobility had adhered to Castile, John rewarded his followers at their and at the crown's expense. Meanwhile, commerce prospered, and the marriage of John's daughter Isabella to Philip the Good of Burgundy was to be followed by the growth of close trading relations between Portugal and Philip's County of Flanders. With the conclusion of peace with Castile, John found an outlet for the activities of his frontiersmen and of his own sons in the conquest of Ceuta (1415), from which may be dated the great age of Portuguese expansion.

During the short reign of John's eldest son, Edward (Duarte; 1433–38), an unsuccessful attempt was made to conquer Tangier in 1437 by John's third son, Prince Henry the Navigator, and his younger brother Ferdinand, who was captured by the Moors and died, still unransomed, in 1443. On Edward's death, his son Afonso V was still a child, and his brother Pedro, duke of Coimbra, had himself made regent (1440) instead of the widow, Leonor

of Aragon. But Pedro's own regency was later challenged by the powerful Bragança family, descended from Afonso, illegitimate son of John of Aviz and Beatriz, daughter of Nuno Álvares Pereira. This family continued to set the young king against his uncle, who was forced to resign the regency, driven to take up arms, and killed at Alfarrobeira (May 1449). Afonso V (1438–81) proved unable to resist the demands of the Braganças, who now became the wealthiest family in Portugal. Having married Joan, daughter of Henry IV of Castile, Afonso laid claim to the Castilian throne and became involved in a lengthy struggle with Ferdinand and Isabella in the region of Zamora and Toro, where he was defeated in 1476. He then sailed to France to entreat the aid of Louis XI, in which he failed, and on his return concluded with Castile the Treaty of Alcáçovas (1479), abandoning the claims of his wife Joan. Afonso never recovered from his reverse, and during his last years his son John administered the kingdom.

Consolidation of the monarchy. John II (1481–95) was as cautious, firm, and jealous of the royal power as his father had been openhanded and negligent. At the first Cortes of his reign, he exacted a detailed oath of homage that displeased his greatest vassals. A suspicion of conspiracy enabled him to arrest Fernando II, duke of Bragança, and many of his followers; the duke was sentenced to death and executed (1484) at Évora, and John himself stabbed James (Diogo), duke of Viseu (1484). As well as attacking the power of the nobility, John lessened the effects of the unfavourable treaty with Castile. Calculating and resolute, he later received the epithet "the Perfect Prince."

John II was predeceased by his legitimate son and therefore succeeded by his cousin, the duke of Beja, as Manuel I (1495–1521), known as "the Fortunate." Manuel, who assumed the title of "lord of the conquest, navigation, and commerce of India, Ethiopia, Arabia, and Persia," inherited, because of the work of John II, a firmly established autocratic monarchy and a rapidly expanding overseas empire. Drawn toward Spain by the common need to defend their overseas interests as defined by the Treaty of Tordesillas (1494), Manuel nourished the hope of joining the whole peninsula under the house of Aviz; he married Isabella, eldest daughter of Ferdinand and Isabella, who, however, died (1498) in giving birth to a son, Miguel da Paz. This child was recognized as heir to Portugal, Castile, and Aragon but died in infancy. Manuel then married Isabella's sister Maria (died 1517) and thirdly Eleanor, sister of the emperor Charles V.

As a condition of the marriage with Isabella, Manuel was required to "purify" Portugal of Jews. John II had admitted many Jewish refugees expelled from Spain (1492) and had taxed them heavily but was also to supply ships for them to leave Portugal. This was not done, and Manuel now ordered all Jews to leave within 10 months, by October 1497. On their assembly in Lisbon, every effort was made to secure their conversion by promises or by force. Some who resisted were allowed to go, but the rest were "converted" under promise that no inquiry should be made into their beliefs for 20 years. As "Christians" they could not be forced to emigrate, and they were indeed prohibited from leaving Portugal. In April 1506 a large number of these "new Christians," or *marranos*, were massacred in Lisbon during a riot, but Manuel afterward protected them and allowed many to emigrate to Holland, where their experience of Portuguese trade was put at the service of the Dutch.

If Manuel failed to realize his dream of ruling Spain, his son John III (1521–57) lacked the power to resist Castilian influence. A pious, retiring man, he was ruled by his wife, Catherine, sister of the emperor Charles V, and encouraged the installation of the Inquisition (1536); the first auto-da-fé was held in 1540. The Society of Jesus, established in 1540, soon controlled education in Portugal. In 1529 the settlement by the Treaty of Saragossa (Zaragoza) of a dispute over the possession of the Moluccas removed an obstacle to Portuguese-Spanish understanding, and the line of Tordesillas was matched by a similar line in the Pacific; all the territories of the New World were in theory divided between Spain and Portugal, while the Reformation (as well as the discoveries) had come between the latter and its English ally.

John III was succeeded by his grandson Sebastian (1557–78), then a child of three. As a boy, Sebastian became obsessed with the idea of a crusade against Morocco. Fanatically religious, he had no doubts of his own powers and listened only to flatterers. He visited Ceuta and Tangier in 1574 and began in 1576 to prepare a large expedition against Larache: this departed in June 1578 and on August 4 was utterly destroyed by the Moors in the Battle of the Three Kings near Alcazarquivir (Ksar el-Kebir). Sebastian himself was killed, 8,000 of his men are said to have died, and 15,000 were captured. Only a handful escaped.

Sebastian was succeeded by his great-uncle, Cardinal Henry (1578–80), a brother of John III. His age and celibacy made it certain that the Portuguese throne would soon pass from the direct line of Aviz. Philip II of Spain, nephew of John III and husband (by his first marriage) of John's daughter Maria, had already made his preparations and, on the death of the cardinal-king (January 31, 1580), summoned the authorities to obey him. An army under the great duke of Alba entered Portugal in 1580; the resistance of António the prior of Crato (illegitimate son of John III's brother Luís), acclaimed António I at Santarém, collapsed; and Philip II of Spain became Philip I of Portugal (1580–98). The claims of the duchess of Bragança (Catherine, daughter of John's brother Edward) were disregarded.

MEDIEVAL SOCIAL AND ECONOMIC DEVELOPMENT

Medieval Portugal comprised regions of considerable diversity. In the north, the old aristocracy of Leonese descent owned large estates worked mainly by serfs. In the southern territory that had been reconquered from Muslim rule, there were many towns, often separated by districts almost barren and depopulated. The initiative in settling these areas was taken by Cistercian monks, who had reached Portugal by 1143; later kings such as Sancho I and Afonso III established *concelhos* (municipalities), granting to them by the issue of *forais* (charters) many privileges designed to attract population. Tax concessions were often given, and freedom was promised to serfs or to Christian captives after a year's residence. But in the south, the *concelhos* were burdened with defense duties, the *cavaleiros-vilãos* (villein knights) being obliged to horse and arm themselves, and the *peões*, or less substantial men, being obliged to serve as foot soldiers in defense of the country and perhaps also on a *fossado* (raid) into Muslim territory.

At court, the king was advised by his *curia regis* (court or council), comprising the *major domus curiae*, the head of the administration, the military chief or *signifer*, the *dapifer curiae* (steward of the household), the chancellor (an official whose origins in Portugal were Burgundian rather than Visigothic), and any members of the greater aristocracy, the *ricos-homens*, who might be at court. This class also comprised the bishops and abbots and masters of the orders of knighthood; many held private civil or military authority. The lesser nobility were without such rights. Below them came various classes of free commoners, such as the *cavaleiros-vilãos* and the *malados*, men who had commended themselves to protectors. There were numerous serfs and slaves.

By the end of the medieval period several shifts in the social structure had occurred. Many of the old aristocracy lost their position at the advent of the House of Aviz, and the new nobility, exemplified in the House of Bragança, was often of bureaucratic or ministerial origin. The privileges granted to *concelhos* forced landlords to compete for labour, and by the time of Afonso III money payments had largely replaced labour services on the estates. Representatives of the commoners, first attending the Cortes in 1254 on behalf of the *concelhos*, took an increasing part in politics. The Cortes were very frequently called in the reigns of John I, Edward, and Afonso V; but the avenues of power had become wider by the 16th century, and John III's proposal (1525) to call them only every 10 years aroused no opposition. Although the trade guilds were slow in developing, they took some part in determining local taxation in the 13th century. Trade increased, Portuguese merchants having had connections with the Low Countries from the time of Afonso Henriques and with England

from the early 13th century. The political crisis of 1385 was followed by intense inflation and many debasements: there was thereafter no national gold currency until 1435, when West African sources began to be tapped.

THE DISCOVERIES AND THE EMPIRE

The idea of expansion into Africa was a logical result of the completion of the reconquest in the peninsula, and the conquest of Ceuta in North Africa (1415) probably provided the impulse toward further expansion. The simple idea of fighting the Muslims on their own soil was linked with more complicated motives: the desire to explore in a scientific sense, the hope of finding a way to the rich spice trade of the Indies, and the impulse to spread the Christian faith. These purposes were gradually molded together into a national enterprise, though at first they represented the hopes and aspirations of one man, Prince Henry. The third son of John I and Philippa of Lancaster, known rather inaccurately as "the Navigator" (he himself never went farther afield than Tangier), Henry became (1420) master of the Order of Christ, which King Dinis had founded (1319). The resources of the Order were used to draw together skilled geographers and navigators and to equip a series of expeditions that only gradually began to bear fruit.

The date of Prince Henry's earliest expedition is not exactly known but appears to have been about 1418, when the island of Porto Santo was visited; the first call at Madeira probably dates from 1419. An attempt was made to settle in the Canaries, and between 1427 and 1431 the Azores were visited by Portuguese seamen. Both the Azores and Madeira were then uninhabited, and their colonization proceeded fairly rapidly from c. 1445. Sugar was exported to Europe and gave the islands great economic importance. Meanwhile, Prince Henry's ships were probing the African coast, passing Cape Bojador in 1434 and Rio de Oro in 1436. The unsuccessful expedition against Tangier (1437) was followed by a break in the discoveries, but in 1439 Prince Henry was authorized to colonize the Azores; and from 1440 further expeditions equipped with a new and lighter ship, the caravel, reached the Bay of Arguin (1443), Cape Verde (1444), and by Henry's death (1460) had explored the coast as far south as Sierra Leone.

Under Afonso V, three military expeditions were sent against Morocco (1458, 1463, and 1471); by the last of them, Tangier and Arzila were captured. The African explorations were not entirely neglected, but it remained for John II, with his sharp sense of the national interest, to found a fortress and trading post in the Gulf of Guinea at Elmina (São Jorge da Mina, 1481–82). Diogo Cão (Cam) discovered the mouth of the Congo in 1482 and then advanced to Cape Cross, 200 leagues southward (1486). A native monarchy, the Manikongo, sought conversion and alliance with the Portuguese: its first Christian king, Afonso I (c. 1506–43), made Mbanza a centre of Portuguese influence, but the Kongo kingdom fell into internal strife and Portuguese interests were transferred to the neighbouring kingdom of Angola. Paulo Dias de Novais founded Luanda, the first city in West Africa south of the Equator, in 1576. In 1488, Bartolomeu Dias at length rounded the Cape of Good Hope and reached the East African coast, and the seaway to India lay open. His return was followed in 1493 with the news that Christopher Columbus had, as he thought, discovered the "Indies" by sailing across the Atlantic. Much as this news must have perturbed the Portuguese, Columbus brought no news of the spices or the cities of the East; and John II ordered the preparation of an expedition to India by way of the Cape of Good Hope, though this sailed only after his death. John also contested the Spanish claim to all lands discovered west of the Atlantic, and by the Treaty of Tordesillas (June 7, 1494), Spain's rights were limited to what lay more than 370 leagues west of the Cape Verde Islands. Thus the territory that was to become Brazil was reserved for Portugal.

The Treaty of Tordesillas had confirmed Portugal's rights to the exploration of Africa and the seaway to India. In July 1497 Vasco da Gama set sail with four ships on the first expedition to India. They reached Calicut (Ko-

zhikode) the following spring, and the survivors put into Lisbon in the autumn of 1499 with specimens of Oriental merchandise. A second fleet was prepared under Pedro Álvares Cabral, who touched the Brazilian coast (April 22, 1500) and claimed it for Portugal. One of Cabral's ships, under Diogo Dias, discovered Madagascar in 1500; João da Nova discovered Ascension in the following year and St. Helena in 1502. Tristão da Cunha sighted the island named after him in 1506 and went on to explore Madagascar. Meanwhile, trading posts in India had been established by Cabral at Cochin and Calicut (1501) and by João da Nova at Cannanore. In 1502 Vasco da Gama made tributary to Portugal the ruler of Kilwa (Quilwa) in East Africa.

In 1505 Francisco de Almeida arrived as viceroy of India, strengthening the African station at Kilwa and supporting the ruler of Cochin against the *zamorin* of Calicut. The control of sea trade now instituted became the chief source of Portuguese wealth in the East. It was assured by the defeat of Muslim naval forces off Diu in 1509. Almeida's successor, Afonso de Albuquerque, conquered Goa (1510), which he made the seat of Portuguese power, and Malacca (1511); sent two expeditions to the Moluccas (1512 and 1514); and captured Hormuz in the Persian Gulf (1515). Soon after, Fernão Peres de Andrade reached Canton in China; in 1542 Portuguese merchants were permitted to settle at Liampo (Ning-po), and in 1557 they founded the colony of Macao (Macau).

Albuquerque was responsible for this conception of a system of strong points that secured the trade of the Orient to Portugal for nearly a century. Goa soon became the chief port of western India; Hormuz controlled the Persian Gulf, and Malacca the gateway from the Indian Ocean to the South China Sea, while a string of fortified trading posts secured the coast of East Africa and the gulf and shores of India and Ceylon. Farther east, less fortified settlements were set up with the consent of the native rulers from Bengal to China, and the trade of the principal spice islands was in Portuguese hands. The preservation of the whole system was entrusted to a governor, who sometimes held the rank of viceroy, at Goa; and although Portuguese arms had both triumphs and reverses, their control of the Oriental trade remained substantial, if never complete, until the 17th century, when the Dutch, at war with the joint crown of Portugal and Spain and deprived of their traditional trade with Lisbon, began to seek spices from their source and effectively demolished the Portuguese monopoly.

UNION OF SPAIN AND PORTUGAL, 1580–1640

After Philip II of Spain had occupied Portugal in 1580, the island of Terceira in the Azores held out for António of Crato, who himself sought alliances in England and France. In 1582 a French expedition to establish him in the Azores was defeated, and in 1589 an English attempt upon Lisbon, led by Sir Francis Drake and Sir John Norris, failed dismally. But although António died in Paris in 1595, the true symbol of Portuguese independence was not the prior of Crato but King Sebastian himself. The Portuguese people refused to believe that he was dead and nourished a messianic faith in his reappearance, of which four pretenders sought to avail themselves, the last as late as 1600 and as far afield as Venice.

Meanwhile, Philip arrived in Portugal and was accepted as King Philip I (1580–98) by the Cortes held at Tomar (1581). He undertook to preserve Portuguese autonomy, to consider the union as a personal one like that of Aragon and Castile under Ferdinand and Isabella, to appoint only Portuguese to the administration, to summon Cortes frequently, and to be accompanied by a Portuguese council in Madrid. These undertakings were, however, neglected by Philip II (III of Spain, 1598–1621) and completely violated by Philip III (IV of Spain, 1621–40).

Portuguese resentment against Spanish rule was increased by the failure of these kings to visit Portugal, the appointment of Spaniards to Portuguese offices, the loss of trade consequent on Spain's foreign wars, and the levying of taxation to sustain these wars. In 1624 the Dutch seized Bahia in Brazil, only to be expelled by a joint Spanish and

Portuguese expedition (1625). But in 1630 they occupied Pernambuco and the adjoining sugar estates, which they held for a generation. The final straw was the conde-duque de Olivares' plan (1640) of using Portuguese troops against the equally discontented Catalans. Two Portuguese insurrections, in 1634 and 1637, had failed to attain dangerous proportions, but in 1640 Spain's powers were extended to the utmost by war with France and revolt in Catalonia. The French minister, Cardinal de Richelieu, already had agents in Lisbon, and a leader was found in John, duke of Bragança, a grandson of the duchess Catherine (niece of John III) whose claims had been overridden in 1580 by Philip II of Spain. Taking advantage of the unpopularity of the governor, Margaret of Savoy, duchess of Mantua, and her secretary of state Miguel de Vasconcelos, the leaders of the party of independence carried through a nationalist revolution on December 1, 1640. Vasconcelos was almost the only victim; the Spanish garrisons were driven out; and on December 15 the Duke of Bragança was crowned as John IV (1640–56).

THE HOUSE OF BRAGANÇA, 1640–1910

Although the Cortes confirmed the accession of the dynasty of Bragança and John's coronation on January 28, 1641, the success of the new regime was not finally assured until 1668, when Spain at last recognized Portuguese independence. Faced with the threat of a Spanish invasion, John had sent missions to the courts of Europe in quest of alliances. France now refused a formal treaty. The Dutch, having seized northern Brazil, accepted a truce in Europe and proceeded to capture Angola from Portugal. John made a treaty (1642) with Charles I of England, which was made void by Charles's execution (1649). Meanwhile, the Portuguese defeated the Spaniards at Montijo (May 26, 1644) and warded off several invasions. In 1654 they negotiated a treaty with the English Commonwealth, obtaining aid in return for commercial concessions. The Dutch were now finally expelled from Pernambuco in northern Brazil. By a secret article of the Treaty of the Pyrenees (1659), France promised Spain to give no further aid to Portugal, but in 1661 Portugal signed a treaty of alliance with the restored English monarchy. In 1662 Charles II of England married John's daughter Catherine of Bragança and, in return for a large dowry, including the cession of Bombay and Tangier, provided arms and men for the war with Spain. Portuguese defense was organized by the German soldier Friedrich Hermann von Schönberg (later duke of Schomberg); in June 1663 Sancho Manuel, count of Vila Flor, defeated Don John of Austria at Ameixial, and in June 1665 von Schönberg won the important victory of Montes Claros. Peace was finally made by the Treaty of Lisbon early in 1668.

On the death of John IV, his second son Afonso VI (1656–83) was 13 years of age. Afonso's mother, Luísa de Gusmão, acted as regent until, in June 1662, he began to rule. Afonso himself was feeble-minded, but the country was capably governed by Luiz de Vasconcelos e Sousa, conde de Castelo Melhor, until 1667. The French princess, Maria Francesca of Savoy, who married Afonso in the previous year, now entered into an intrigue with his more personable brother Pedro (afterward Peter, or Pedro, II). They contrived to dismiss Castelo Melhor and to have Maria Francesca's marriage annulled. She at once married Pedro (1668), who was declared regent. Afonso was imprisoned until his death. During the reign of Peter II (1683–1706), Portugal recovered from the strain of the Spanish wars and began to benefit from the discovery of gold and precious stones in Brazil. The first strike of gold in Minas Gerais took place in 1693, and in the last years of the 17th century, considerable wealth was being extracted; however, it was not until 1728 that diamonds were discovered: the mineral wealth of Brazil then formed a very substantial part of the revenue of the Portuguese crown.

The 18th century. The War of the Spanish Succession (1701–13) saw Portugal's recent friends, England and France, on opposing sides; and although Pedro sought at first to remain neutral, Portugal joined the Anglo-Austrian Grand Alliance in 1703, by which it afforded a base for the archduke Charles (later the emperor Charles VI) to

conduct his war for the Spanish throne. In the same year (December 27) the English envoy, John Methuen, also concluded the treaty that bears his name, by which the exchange of port wine for English woollens became the basis for Anglo-Portuguese trade. Although the treaty of 1654 had secured great privileges for English merchants in Lisbon, neither it nor the treaties of 1642 and 1661, by which the traditional alliance was restored, had created trade. This was now done, and by reason of the wealth that soon poured into Lisbon from Brazil, the English merchants gained a commanding position in the trade of Portugal. The political treaties of 1703 proved less fruitful. The Portuguese general António Luís de Sousa, marquess of Minas, entered Madrid in 1706; but French and Spanish forces were victorious at Almansa (1707), and in 1711 the French admiral René Duguay-Trouin sacked Rio de Janeiro. At the conclusion of the war Portugal negotiated a peace treaty with France (April 1713) but did not conclude peace with Spain until 1715.

Under Peter's son John V (1706–50), Portugal attained a degree of prosperity unknown since the restoration. The tax of a royal fifth levied on the precious metals and stones of Brazil gave the monarchy an independent source of wealth. The Cortes, which had met irregularly since 1640, was no longer summoned, and government was carried out by ministers appointed by the king. John V desired the absolute authority enjoyed by Louis XIV. He did not fail to convert his wealth into papal and other dignities: the archbishop of Lisbon became a patriarch (1716), and Pope Benedict XIV in 1749 gave John the title "his most faithful majesty"; and royal academies, palaces, and libraries were inaugurated. But in his later years his ministers proved inadequate and the kingdom sank into stagnation. On John's death, his son Joseph (1750–77) appointed as minister Sebastião José de Carvalho e Melo, later conde de Oeiras and marquês de Pombal, who soon gained a complete ascendancy over the king and endeavoured to replace the stagnant absolutism with a more active type of despotism that, with some qualifications, deserves the epithet enlightened. His full powers date from his efficient handling of the crisis caused by the disastrous Lisbon earthquake of November 1755; but even before this he had reformed the sugar and diamond trades, set up a national silk industry (1750), and formed one chartered company to control the sardine and tunny-fishing industry of Algarve and another to trade with northern Brazil. In 1756 he founded the Junta do Comércio, a board of trade with powers to limit the privileges enjoyed by the English merchants under the treaties of 1654 and 1661, and set up the General Company for Wines of Alto Douro (Companhia dos Vinhos do Alto Douro) to control the port wine trade. Industries for the manufacture of hats (1759), cutlery (1764), and other articles were set up with varying success.

Pombal's methods were arbitrary and his enemies numerous. His reform of the wine industry provoked a riot in Porto (1757) that was savagely repressed; but his principal victims were the Jesuits, expelled in 1759 from all the Portuguese dominions, and the nobility, in particular José Mascarenhas, duque de Aveiro, and the Távara family, who were accused of an attack on the King (September 3, 1758), condemned, and executed (January 12, 1759). Having eliminated the Jesuits from the educational system, Pombal applied regalist principles in the reform of the University of Coimbra (1772) and the royal board of censorship (1768), which supervised the system of lower education from 1771.

While Pombal succeeded in modifying the ascendancy of the British merchants in Portugal, he invoked the English alliance in 1762 when Spain, prompted by the renewal of the Bourbon Family Compact alliance with France, invaded Portugal. The Portuguese Army was reformed by Wilhelm von Schaumburg-Lippe, and an English force was led by James O'Hara, 2nd Baron Tyrawley, and John Campbell, 4th earl of Loudoun. Peace was signed in February 1763 at Fontainebleau. On the death of Joseph (February 24, 1777), his daughter Maria I (1777–1816), who had married his brother, her uncle (Peter III), acceded; Pombal was dismissed (1777) and eventually found

guilty on several charges. His successors made peace with Spain by the Treaty of San Ildefonso (1777).

The French Revolutionary and Napoleonic Wars. Maria I suffered from melancholia after the loss of her consort (1786) and eldest son John (1788). In 1792 her mental balance was further disturbed, probably by the news of the French Revolution, and she ceased to reign. Her son, who on her death became John VI (1816–26), then ruled in her name and in 1799 became prince regent. In 1793 Portugal joined England and Spain against France, sending a naval division to assist the English Mediterranean fleet and an army to the Catalan front. The Peace of Basel (July 1795), by which Spain abandoned its allies, left Portugal still at war. Although subjected to pressure from the French Directory and from the Spanish minister, Manuel de Godoy, Portugal remained unmolested until 1801, when Godoy sent an ultimatum and invaded Alentejo. By the Peace of Badajoz (June 1801), Portugal lost the town of Olivenza and paid an indemnity.

From the Peace of Amiens (1802) until 1807, Portugal was once more immune from attack, though subjected to continuous pressure to break off the English connection. By the Berlin decree of November 21, 1806, Napoleon sought to close all continental ports to British ships. Portugal endeavoured to maintain neutrality, but the secret Franco-Spanish Treaty of Fontainebleau (October 1807) provided for its eventual dismemberment by Napoleon I and Godoy. Already Gen. Andoche Junot was hastening across Spain with a French army, and on November 27, the prince regent and the royal family and court embarked on a fleet lying in the Tagus River and were escorted by British vessels to Brazil; the court remained 14 years at Rio de Janeiro. Junot declared the Braganças deposed, but his occupation of Portugal was challenged in August 1808 by the arrival of Sir Arthur Wellesley (later duke of Wellington) and 13,500 British troops in Mondego Bay. Winning the victories of Roliça (August 17) and Vimeiro (August 21), Wellesley enabled his superiors to negotiate the Convention of Sintra (August 31), by which Junot was allowed to evacuate Portugal with his army. A second French invasion (1808–09) led to Sir John Moore's death at La Coruña (January 1809) and the reembarkation of the British forces. In February, William Carr (later Viscount) Beresford was placed in command of the Portuguese Army, and in March Marshal N.J. de Dieu Soult advanced from Galicia and occupied Porto. Wellesley returned to Portugal in April, drove Soult from the north, and after his victory of Talavera de la Reina in Spain (July), withdrew to Portugal. The third French invasion followed in August 1810 when Marshal André Masséna with Marshal Michel Ney and Junot entered Beira province. Defeated by Wellington at Bussaco (September 27) near Coimbra, the French found themselves facing the prepared lines of Torres Vedras, north of Lisbon, where they wintered amid great privations. By the spring of 1811 they could only retreat and, on March 5, began the evacuation of Portugal, harassed all the way by English and Portuguese attacks and crossing the frontier after a defeat at Sabugal (April 3).

Portugal made peace with France on May 30, 1814. It was represented at the Congress of Vienna but played little part in the settlement. The series of Anglo-Portuguese treaties concluded between the years 1809 and 1817, however, was important insofar as it extended many of the conditions of the Anglo-Portuguese alliance to Brazil and had an influence on the future of Africa. England's efforts to get Portuguese collaboration in suppressing the slave trade resulted in the treaty of January 22, 1815, and in the additional convention of 1817, by reason of which Portugal's claims to a considerable part of Africa were formally recognized.

Constitutionalism. The Napoleonic campaigns had caused great devastation in Portugal, and the absence of the royal family and the presence of a foreign commander (Beresford) combined with revolutionary agitation and the influence of Spanish liberalism to produce an atmosphere of discontent and restlessness. On December 16, 1815, Brazil was raised to the rank of a kingdom united with Portugal, and John VI, who succeeded in March 1816, showed no desire to return to Portugal. In 1817 Beres-

ford suppressed a conspiracy in Lisbon, and the Masonic leader Gen. Gomes Freire de Andrade was executed. Unrest increased, and when Beresford himself went to Brazil (March 1820) to press John to return, a constitutionalist revolution began in Porto (August 24, 1820), spread over the country, and led to the formation of a junta in Lisbon (October 4). On Beresford's return (October 10) he was not allowed to land, and British officers were expelled from the army. A constituent assembly was summoned that drew up a very liberal constitution, thus confronting John VI with an accomplished fact.

John's reluctance to return was at last overcome, and he left his elder son Pedro to govern Brazil, landing at Lisbon on July 3, 1821. He swore to uphold the constitution, but his wife, Carlota Joaquina, and their second son, Dom Miguel, refused to take the oath and were sentenced to banishment, though this was not carried out. The Portuguese constitutionalists, not appreciating the determination of Brazil not to yield up its status as a kingdom, sought to compel Pedro to return; but he, rather than sacrifice the rule of the Braganças in Brazil, declared for Brazilian independence (September 7, 1822) and became emperor of Brazil as Pedro I. This enabled his brother Miguel (Michael) to appeal to absolutist forces in Portugal to overthrow the constitutionalists, and an insurrection led by Miguel almost succeeded (April 30, 1824); but through the action of the foreign ministers, John VI was restored and Miguel went into exile in Vienna (June 1824).

War of the Two Brothers. John VI acknowledged the independence of Brazil in 1825, assuming *pro forma* the imperial title and then yielding it to Pedro; but when John died (March 10, 1826), no provision had been made for the succession except that his daughter Maria Isabel was now named regent. Pedro, as Pedro, or Peter, IV of Portugal, issued from Brazil a charter providing for a parliamentary regime by the authorization of the monarchy and not based on the sovereignty of the people. He then made a conditional abdication (May 1826) of the Portuguese throne in favour of his daughter Maria da Glória, aged seven, provided that she should marry her uncle Miguel and that he should swear to accept the charter. This compromise could not be effective. The absolutists had hoped that Pedro would resign all rights to the Portuguese crown, and the council of regency hesitated to publish the charter until Gen. João Carlos de Saldanha (later duke de Saldanha) forced their hand. In 1827 Miguel took the oath and was appointed regent, landing in Lisbon in February 1828. His supporters at once began to persecute the liberals. A form of Cortes met in Lisbon, and in July 1828 repudiated Pedro's claims and declared Miguel rightful king.

Only the island of Terceira in the Azores sustained the liberal cause. In June 1829, however, a regency on behalf of Maria da Glória was set up in Terceira; and in 1831 Pedro, having abdicated the Brazilian throne, went to Europe and began to raise money and men for the conquest of Portugal. In February 1832 the expedition sailed to Terceira, and in July the liberals, led by Pedro, disembarked at Mindelo near Porto, which city they soon occupied. The rest of the country, however, stood by Miguel, who besieged the liberals in Porto for a year (July 1832–July 1833). By now, Miguelite enthusiasm had waned; and António José de Sousa Manuel, duque de Terceira, and Capt. (later Sir) Charles Napier, who had taken command of the liberal navy, made a successful landing in Algarve (June 1833). Terceira advanced on Lisbon, which fell in July 1833, and Miguel capitulated at Evora-Monte in May 1834.

Further political strife. The War of the Two Brothers ended with the exile of Miguel (June) and the death of Pedro (September 24, 1834). Maria da Glória became queen as Maria II (1834–53) at the age of 15. While Maria necessarily came under the influence of the successful generals of the civil war, her principal aim was to defend her father's charter (which had been granted by the crown) from those who demanded a "democratic" constitution like that of 1822, asserting the ultimate sovereignty of the nation.

In September 1836 the latter, thenceforth called Septembrists, seized power. The chartist leaders rebelled and were

chartists

exiled, but by 1842 the Septembrist front was no longer united, and António Bernardo da Costa Cabral restored the charter. In 1846 the movement of Maria da Fonte, a popular rising against higher taxation to improve roads and reforms in public health in which almost all parties joined, put an end to Costa Cabral's government but left Portugal divided between the Septembrists, who held Porto, and Saldanha, now in Queen Maria's confidence, in Lisbon. Saldanha negotiated for the intervention of other members of the Quadruple Alliance (formed in April 1834 by England, France, Spain, and Portugal), and a combined British and Spanish force received the surrender of the Porto junta in June 1847 and ended the war with the Convention of Gramido (June 29, 1847). Saldanha governed until 1849, when Costa Cabral resumed office only to be overthrown in April 1851. Saldanha then held office for five years (1851–56), and the period of peace at length permitted the country to settle down. The "Regeneration" ended civil strife and established party government.

Maria II was succeeded by her eldest son by her second husband, Ferdinand of Saxe-Coburg, Peter, or Pedro, V (1853–61), who married Stephanie of Hohenzollern-Sigmaringen in 1858. He gave promise of being a capable and conscientious monarch but died of typhoid fever on November 11, 1861. His brother Louis (Luís; 1861–89) seemed to have inherited a country that had recovered from the Napoleonic invasions and from civil wars, political strife, and *pronunciamentos*. But although the main parties were now defined as Historicals (*i.e.*, radicals) and Regenerators (or moderates), the alternation of governments gradually ceased to reflect any semblance of popular feeling, and in the last years of Luís' reign republicanism was already beginning to gain ground.

Colonial policies. With the accession of Charles (Carlos; 1889–1908), a serious dispute with Great Britain occurred. Portugal's possessions in Africa had been recognized by Great Britain in the treaty of 1815, but more recently Germany and Belgium had entered the colonial field; and at the Conference of Berlin (1885), the definition of "effective occupation" was adopted as the basis for possession of colonial territories. A colonial movement had gained momentum in Lisbon, and a Portuguese scheme, known as the "Rose-Coloured Map," which laid claim to a colony stretching across Africa from Angola to Mozambique, was recognized by France and Germany (1886). Although the Marquess of Salisbury registered a protest (1888), the Portuguese foreign minister Henrique de Barros Gomes sent Maj. Alexandre Alberto da Rocha de Serpa Pinto to the Shire Highlands (modern Malawi), with a view to their annexation. He became involved in a fight with the Makololos, who were under British protection, and a series of communications between London and Lisbon ended in the dispatch of the British ultimatum of January 11, 1890, demanding the withdrawal of all Portuguese from the Shire. Amid great popular excitement, Barros Gomes had no alternative but to comply, and the government resigned. The incident caused the deepest resentment in Portugal, not only against the ancient ally but also against the monarchy, which was menaced by an attempted republican revolution in Porto (January 31, 1891).

During the following years, the Portuguese African colonies were defined as a result of the Anglo-Portuguese treaty of July 1891, but the financial position of the country was so bad that it seemed unlikely that the efforts to consolidate the African colonies would succeed. In 1897 it became clear that Portugal would require a considerable loan, and Germany demanded to partake in any assistance that was offered. On August 30, 1898, A.J. (later the earl of) Balfour, temporarily in charge of the British Foreign Office, concluded a secret Anglo-German convention assigning spheres of influence in the Portuguese colonies to Great Britain and Germany in the event of such a loan. This was, however, denounced by the prime minister, Lord Salisbury, and in 1899, when the Germans endeavoured to persuade the Portuguese to accept a loan, Salisbury's action and the imminent danger of a conflict in the Transvaal caused an Anglo-Portuguese approximation. On October 14, 1899, the ancient treaties of alliance

were reaffirmed in a secret declaration, later made public (the so-called Windsor Treaty).

Meanwhile, the financial situation showed little improvement, and the republicans continued to progress. In 1906 João Franco, formerly a Regenerator, came to power as champion of the failing monarchist cause. Unable to obtain the support of the other monarchists, he began to govern by decree. Although Franco bravely undertook to reform the finances and administration, he was accused of illegally advancing money to the King. These scandals were followed by rumours of plots, and on February 1, 1908, Charles and his heir, Luís Filipe, were assassinated as they rode in an open carriage in Lisbon. Whether or not the regicides were isolated fanatics or agents of a hidden organization such as the Carbonária, a republican secret society, the deed was applauded by the republicans, who immediately began their preparations for a final attack on the monarchy.

King Manuel II (1908–10) found no unity among the monarchist politicians. The general election of August 1910 showed republican majorities in Lisbon and Porto, and on October 3 the murder by a madman of one of the republican leaders, the distinguished physician Miguel Bombarda, offered the pretext for a rising that was already organized. Armed civilians, soldiers, and the men aboard some ships in the Tagus began the republican revolution on October 4 and, after faltering, their movement, in which António Machado Santos played the predominant part, succeeded on October 5. Manuel escaped to Ericeira and thence by sea to Gibraltar and to England. On his death in 1932 his body was returned to Portugal.

Social and economic conditions. From the time of the Portuguese overseas conquests, the flow of wealth from the new territories and trading posts, if it sustained the court and capital, did little to improve the domestic economy, still largely rural. The favourable financial position of the late 15th century, derived from trade in slaves, gold, and spices, did not long survive into the 16th century, when the expenses of maintaining far-flung and unproductive foreign stations and the depredations of pirates quickly absorbed any surpluses. There were few native industries. Not only were manufactured goods such as cloth, tapestry, and metalware imported but also basic foodstuffs, salt meat, cured fish, and dairy produce. Agriculture was little regarded, and insufficient land was available for small holdings. During the years of Spanish domination, the ports were closed to English merchants; and by the time they were reopened after 1640 the flow of trade had found new channels, and the Dutch and English had outstripped Portugal as colonial powers. The discovery of gold in Brazil at the end of the 17th century brought about a revival in the country's economy, but gold production was in decline by 1750, while the diamond market was saturated. The later 18th century saw a series of protectionist measures, many introduced by Pombal. The Methuen Treaty with England (1703) had strengthened the port wine trade at the expense of Portuguese cloth; later further attempts were made to improve the export value of port wine. Support was also given for the production of woollen goods, linen, paper, porcelain, and cutlery and to the tunny and sardine fisheries. Pombal attempted to create an educated bourgeoisie, but the Portuguese textile industry could not withstand mechanized competition. After 1850 public works, railways, and ports were given priority, but Portugal had to wait until the 20th century for any sustained attack upon its economic difficulties.

Map"

THE REPUBLIC (FROM 1910)

The new regime formed a provisional government under the presidency of Teófilo Braga, a well-known writer. This in turn issued a new electoral law giving the vote to adult Portuguese males and presided over the election of a constituent assembly, which opened on June 19, 1911. The constitution was passed by the assembly on August 20, and the provisional government surrendered its authority a few days later (August 24) to the new president, Manuel José de Arriaga.

Evolutionists, Unionists, and Democrats. Although a monarchist invasion was unsuccessfully attempted by

Roman
Catholic
Church
disestab-
lished

Henrique de Paiva Couceiro in October 1911, the main danger to the new regime came from its internal divisions. For the moment, it was fairly united in denouncing monarchism and persecuting the church. The religious orders were expelled (October 8, 1910) and their property confiscated. The teaching of religion in primary schools was abolished and the Roman Catholic Church disestablished. The conditions under which Catholics and monarchists were imprisoned attracted attention abroad, and it was only gradually that this legislation was modified. New universities were founded at Lisbon and Porto; but the task of destruction proved easier than that of construction, and before long the republicans were divided into Evolutionists (moderates), led by António José de Almeida; Unionists (centre party), led by Manuel de Brito Camacho; and Democrats (the left wing), led by Afonso Augusto da Costa. A number of prominent republicans had no specific party. The whirligig of republican political life offered little improvement on the monarchist regime, and in 1915 the army showed signs of restlessness. Gen. Pimenta de Castro formed a military government and permitted the monarchists to reorganize, but a Democratic revolution (May 14) led to his arrest and consignment to the Azores. President Arriaga resigned and was succeeded by Braga and then by Bernardino Machado (August 5, 1915–December 8, 1917). The Democratic regime, in which Costa was paramount, was ended by the revolution (December 1917) of Maj. Sidónio Pais, who established a "New Republic" of a right-wing tendency, supported at first by the Unionists. On their withdrawal (March 1918), a new National Republican Party gained control. Sidónio Pais' "presidentialist" regime was abruptly ended with his assassination on December 14, 1918, when, after the provisional presidency of Adm. João do Canto e Castro, power passed gradually back to the Democrats.

Fighting
during
World
War I

Meanwhile, on the outbreak of World War I, Portugal had proclaimed its adhesion to the English alliance (August 7, 1914) and on November 23 committed itself to military operations against Germany. On September 11 a first expedition left to reinforce the African colonies, and there was fighting in northern Mozambique, on the Tanganyika frontier, and in southern Angola, on the frontier of German South West Africa. In February 1916 Portugal seized German ships lying in Portuguese ports, and Germany declared war (March 9). A Portuguese expeditionary force went to the western front in 1917, under Gen. Fernando Tamagnini de Abreu; on April 9, 1918, they were under heavy German attack in the Battle of Lys. By the Treaty of Versailles (1919) Portugal received 0.75 percent of the indemnity payable by Germany and the Quionga (Kionga) area of Mozambique captured by Portuguese forces in East Africa.

Almeida completed his term as president (October 5, 1919–October 5, 1923), but, with economic confusion reigning, ministers followed one another in rapid succession. In the violence of 1921, the founder of the republic, Machado Santos, and others were murdered. The Democratic Party, led by António Maria da Silva, governed for 21 months, but da Silva's fall in November 1923 was followed by short-lived ministries. In 1925 the Democrats won a clear majority. Pres. Manuel Teixeira Gomes (1923–25) was succeeded by Bernardino Machado. A military revolt on February 2, 1926, was quelled, but on May 28 a successful revolution was launched at Braga. Machado was deposed, and a provisional military government was formed by Commander José Mendes Cabeçadas and Gen. Manuel de Oliveira Gomes da Costa.

The "New State." The provisional government was shortly (July 9, 1926) taken over by Gen. (later Marshal) António Oscar de Fragoso Carmona, who favoured sweeping changes. He was elected president in March 1928 and re-elected until his death in April 1951. The military leaders attempted to overcome the financial crisis with a loan from the League of Nations, but the conditions included fiscal supervision, which was rejected, and Carmona called on António de Oliveira Salazar to take over the Ministry of Finance with full powers over expenditure.

Salazar's
first years

Salazar, then professor of economics at the University of Coimbra, controlled expenditures from 1928 to 1948,

producing budgetary surpluses (the hallmark of his regime) and devoting the proceeds to development plans. Becoming prime minister in 1932, he promulgated the new constitution of 1933; as minister of colonies in 1930, he prepared the Colonial Act, assimilating the administration of the overseas territories to his system; and as minister for foreign affairs (1936–47), he guided Portugal through the difficulties caused by the Spanish Civil War and World War II. He maintained neutrality until Britain invoked the Anglo-Portuguese alliance to obtain bases in the Azores.

On the death of Carmona (April 18, 1951), Salazar assumed the attributes of the presidency until Gen. Francisco Craveiro Lopes was elected (August). Craveiro Lopes was not re-elected in 1958 but was succeeded by Rear Adm. Américo de Deus Tomás, elected by a large majority on a limited franchise. Salazar's New State (Estado Novo) provided for a National Assembly, with deputies elected quadrennially as a bloc and meeting for at least three months annually, and a Corporative Chamber. All seats in the assembly went to government supporters. The Corporative Chamber did not come into being until employers' and workers' syndicates were formed. Collective contracts were negotiated under government supervision, and strikes were forbidden.

Under the development plans, electrification, afforestation, and industrialization were pressed ahead. In the postwar period the railways were re-equipped, roads were improved, and the national airline was developed. Steel manufacture was introduced, as were the assembly of motor vehicles and repair of tankers. The economies of Angola and Mozambique were integrated.

The determination of the Indian government to annex Portuguese India led to India's severing of diplomatic relations (August 1955) and to mass invasions of the Portuguese possessions by Indian passive resisters. Portugal effectively lost Dadrá and Nagar Haveli to India (despite a ruling by the International Court of Justice in April 1960 favouring Portugal), and on December 19, 1961, India took over Goa, Diu, and Damão.

Salazar had made it plain that decolonization was not part of his plan for Portugal, and when Angola was the scene of disturbances in which a number of lives were lost, he reinforced the troops in the African territories and took over the Ministry of Defense. In 1964 there was a recrudescence of independence movements.

In September 1968 Salazar was incapacitated by a stroke, and on July 27, 1970, he died. After his stroke, President Tomás invited Marcelo Caetano, one of the architects of the New State, to form a government. Caetano pledged himself to continuity and also to "evolution," which included the admission of an opposition to the National Assembly and the relaxation of economic controls in favour of expansionism. Under the Third Development Plan, large enterprises were undertaken, but the general economic crisis led to inflation, and emigration from the countryside to the cities and to other parts of Europe was accelerated. Caetano's moderate liberalization divided his supporters and stimulated the Socialist and Communist opposition.

After
Salazar

Portugal after 1974. *The Captains' Revolution.* The African policy entrenched in the constitution became a bone of contention, and oppositionist decolonization policies were conveyed to discontented younger military officers. Gen. António de Spínola, who had forged a reputation in Guinea while attempting a negotiated settlement there, entered the government as assistant chief of staff and precipitated a crisis with his book *Portugal e o Futuro* ("Portugal and the Future"), which argued that the wars in Africa could not be settled by force of arms and advocated negotiated autonomy for the colonies. On April 25, 1974, Tomás and Caetano were removed by a military coup, which became known as the Captains' Revolution because it was brought about by a group of some 200 service captains who had grown dissatisfied, especially with long, drawn-out wars to maintain Portuguese control of the African colonies. These captains constituted the Armed Forces Movement (Movimento das Forças Armadas, or MFA), led by the chiefs of staff, Francisco da Costa Gomes and Spínola. The latter became head of a figurehead junta.

The institutions of the New State were abolished, and the MFA, dominated by Marxists, obtained control of the press, radio, and education. Then the hitherto small Portuguese Communist Party seized control of organized labour and took possession of land, especially in the Alentejo. The armed and civil services were purged, and Spínola was driven from office and replaced by Costa Gomes, who appointed Col. Vasco Gonçalves to form a government, supported by the Marxist wing of the MFA. Elections for a constituent assembly (April 25, 1975) showed that this regime had little support, but Gonçalves attempted to impose a Marxist program.

Independence was granted to Portuguese Guinea (as Guinea-Bissau) almost immediately after the revolution, and in 1975 both Mozambique and Angola became sovereign states, as did the other Portuguese territories in Africa. Thus ended a Portuguese colonial involvement in that continent that had begun in 1415. From the former African colonies, nearly a million people fled to Portugal, adding a refugee problem to the serious political and economic crisis. (H.V.L./Ed.)

In April 1976 a new constitution was approved, which committed Portugal to making a transition to socialism. A transitional government under Adm. José Pinheiro de Azevedo held general elections in which the Socialists obtained 107 seats, the popular Democrats 73, the Social Democratic Centre Party (conservative) 41, and the Communists 40. The leader of the Socialists, Mário Soares, formed a minority government. The chief of staff (since November 1975, after he had put down a left-wing rebellion in the armed forces), Gen. António Ramalho Eanes, was elected president of the republic with 61.5 percent of valid votes in June 1976. (H.V.L./Ed.)

Soares' minority government resigned in December 1977, primarily because it was unable to enact an effective austerity program. In January 1978 Soares formed a new coalition government with the Social Democratic Centre Party, which, however, collapsed after only six months. A number of short-lived centre-left governments followed, until in 1980, in the general election scheduled by the constitution, a centre-right alliance, the Aliança Democrática, swept into power. It was headed first by Francisco Sá Carneiro and, after his death in an airplane crash in December 1980, by Francisco Pinto Balsemão. It was this government that succeeded in revising the character of the 1976 constitution. The Assembly of the Republic approved a series of reforms that included abolishing the Council of the Revolution and reducing the powers of the president. These constitutional reforms completed Portugal's transition to full civilian rule.

The alliance faltered in 1982, propelling the country into yet another crisis. President Eanes called an early general election for April 1983, in which the Socialists, headed by Soares, scored an inconclusive victory. Because Portugal urgently needed a stable, broadly based government to tackle its severe economic problems, Soares formed a coalition government with the Social Democrats (formerly the Democrats). It successfully implemented an 18-month emergency program and a four-year modernization program as a means of gaining admittance to the EEC, a goal Portugal was to achieve on January 1, 1986.

The coalition, although precarious, lasted until June 13, 1985. It survived several internal crises caused predominantly by a division within the Social Democrats between a left wing favouring the coalition and a right wing disagreeing with the coalition's economic policies. In 1985 Aníbal Cavaço Silva, leader of the right wing, became head of the party. He called into question the viability of the coalition, voicing doubts especially on subjects of labour and agrarian reform.

This crisis, which ended the coalition, had been intensified by nationwide strikes in the industrial and transport sectors, led by Communist unions, and by demonstrations from parties on both the left and the right of the political spectrum calling for an end to the coalition government. Soares resigned, and in the elections held in October 1985 the Social Democrats, campaigning on a platform advocating a free-market economy, became the largest single party, able to form a minority government with Cavaço

Silva as prime minister. In the election of February 16, 1986, Soares became Portugal's first civilian president in 60 years.

For later developments in the political history of Portugal, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL. (Ed.)

Portuguese Literature

The literature of Portugal is distinguished by a wealth and variety of lyric poetry, which has characterized it from the beginning; by its medieval lack of and later achievement in the national epic; by its wealth of historical writing; and by its relative slightness in drama, biography, and the essay. The early *cancioneiros* ("song-books") evidence a school of love poetry that spread, with the language, to Spain at a time when Spanish was as yet undeveloped for lyrical purposes. The *romanceiro*, or balladry, on the other hand, was much influenced by that of Spain, though not sharing the latter's predilection for the heroic. In its primitive version *Amadis de Gaula* (14th century; *Amadis of Gaul*), prototype of the romance of chivalry, probably was written in Portuguese, as was, later, *La Diana* (1559) of Jorge de Montemor (Montemayor), the masterpiece of the pastoral novel. *Os Lusíadas* (1572; *The Lusíads*), a history of the Portuguese (the name Lusíads deriving from the ancient Lusitania), by Luís de Camões, may be at once the most successful of the many Renaissance epics cast in the classical mold and the most national of great poems in any modern literature, and many works of history and travel of the 16th and 17th centuries are outstanding. Though Gil Vicente, in the early 16th century, was a dramatist of great gifts, no other appeared until João Baptista de Almeida Garrett in the 19th, and Portugal never developed a national drama.

This literature, which until the 19th century lay largely unstudied and unknown, has from the beginning been exposed to foreign influences. The earliest was Provençal, and Provençal taste ruled for more than a century. Then came Castilian, with a court poetry that provided models until the Renaissance saw the triumph of that form in Italy and in the classics of antiquity. In the 17th century with political domination Spain again imposed its literary standards, followed in the 18th century by France. The Romantic movement reached Portugal from both France and England, two countries whose influence, joined in a lesser degree by that of Germany, persisted long after. The closeness of contacts with Spain, reinforced by dynastic marriages that often brought to the court at Lisbon a predominantly Spanish atmosphere, explains why for two centuries and more after 1450 nearly every Portuguese writer of note was bilingual and wrote also in Spanish, so that some, like Montemor and Francisco Manuel de Melo, are numbered among the classics too of Spanish letters. Portuguese literature retains, nonetheless, a distinct individuality that contrasts strikingly with that of Spain. The medieval lyric, the plays of Gil Vicente, the bucolic verse and prose of the 16th century, and, above all, *Os Lusíadas*, are expressions of a clearly defined national temperament.

WRITINGS OF THE EARLY PERIOD

Poetry. Though no literary documents belonging to the first century of Portugal's history as a nation have survived, there is evidence of the existence of an indigenous popular poetry. A few compositions from before 1200 survive; one, attributed to Sancho I, is the earliest extant parallelistic song, a brief, repetitive lyrical poem marked by a wistful sadness that is never wholly absent from Portuguese literature. Of the many later poems that survive, most belong to the major categories of *cantigas de amor* ("songs of love"; sung by a man to the woman he loves in vain), *cantigas de amigo* ("songs of the lover"; sung by a woman to express her yearning for her lover), and *cantigas de escárnio e maldizer* (satirical songs). This body of lyrics, represented in three great *cancioneiros*, shows the vitality of a school of poetry in Galician-Portuguese (the dialect of northern Portugal) that, while essentially inspired by the sophisticated French and Provençal songs of the troubadours, is also anchored in the popular tradition.

This poetry reached the peak of its creativity in the first half of the 13th century, coinciding with the reign of Afonso III (1248–79). His son, Dinis, had a deep interest in literature and was considered to be the best poet of his age in the Iberian Peninsula. Dinis founded his country's first university at Lisbon in 1290 (it later was moved to Coimbra) and encouraged translation into Portuguese of outstanding works from Spanish, Latin, and Arabic. To his court came troubadours from Leon, Castile, and Aragon to enjoy the last of a cult dying elsewhere, and about 2,000 poems by its 200 poets were preserved in the three great repositories of verse, *Cancioneiros da Ajuda*, *Cancioneiros da Vaticana*, and *Cancioneiros Colocci-Brancuti* (or *da Biblioteca Nacional de Lisboa*).

In contrast with the restricted horizons of courtly verse, themes of adventure, war, and chivalry mingled with love, religion, and the sea in a collection of ballad poetry known as the *romanceiro*. Few of these ballads can be dated earlier than the 15th century; they belonged to an anonymous poetry kept alive by oral transmission, with a late artificial flowering from known poets in the 16th and 17th centuries.

Prose. Prose literature in Portugal took much longer than verse to perfect. Religious writings, brief annals of the early kings, and books of descent formed the earliest texts. The *Livro de Linhagens* ("Book of Genealogy") of Pedro Afonso, count of Barcelos (the natural son of Dinis), constituted a landmark by going beyond genealogy to history and legend. The work contains short epic narratives, romances, and tales of adventure and fantasy. Pedro was also responsible for the compilation in 1344 of the *Crónica Geral de Espanha* ("General Chronicle of Spain"), interesting, within the peninsular tradition of the general chronicle genre, for its original version of well-known episodes.

The early popularity of subject matter based on Celtic tradition is attested in the five songs based on Breton lays with which the *Cancioneiro Colocci-Brancuti* opens. The ideals of chivalry and the spirit of sentimental adventure associated with the knights of the Round Table made strong appeal to the Portuguese imagination: a *História dos Cavaleiros da Távola Redonda* ("History of the Knights of the Round Table") and the *Demanda do Santo Graal* ("Search for the Holy Grail"), adapted from the French, are the chief relics of considerable activity in this field.

DEVELOPMENTS OF THE 15TH AND 16TH CENTURIES

Literature of the 15th century. Under King John (João) I, founder of the new dynasty of Avis, the Portuguese court became once again a literary centre. The King himself wrote a treatise on hunting. His son Duarte (Edward) collected a rich library of the ancients and of medieval poems

Dinis' encouragement of literature

The influence of the Avis dynasty

and histories and composed a moral treatise, *Leal Conselheiro* (1437/38; "Loyal Counselor"), which revealed a conscious stylist. But the historical chronicle distinguished the age, with credit to King Edward, who in 1434 created the office of *cronista mor do reino*, or "chief chronicler of the realm," and appointed Fernão Lopes, author of chronicles of the first 10 kings of Portugal. The *Crónica dos Sete Primeiros Reis do Portugal*, a chronicle of the first seven kings, discovered in 1947 and published in 1952–53, is almost certainly the first part of that work. Until its discovery only the chronicles of Pedro I, Ferdinand I, and John I were known. Vividness of style combined with serious documentation to produce in Lopes the finest writer of medieval Portuguese prose.

His successor in office, Gomes Eanes de Zurara, continued the chronicle on a lower level of artistry. His chief works are the *Crónica da Tomada de Ceuta* (*Conquests and Discoveries of Henry the Navigator*) and the *Crónica do Descobrimento e Conquista da Guiné* (*The Chronicle of the Discovery and Conquest of Guinea*).

Poetry was cultivated in the mid-15th century after a long eclipse, but much had changed. The dominant influence came now from Spain, and Portuguese poets initiated the long chapter of allegiance to Spain. Apart from the ballads, popular poetry had disappeared along with that of the troubadours. The constable Dom Pedro de Portugal initiated the fashion of writing in Castilian. As one of the first to adopt the new Spanish trend toward allegory and the cult of classical antiquity derived from Italy, his influence on his compatriots was doubly important. His own poems were inspired by deep feeling and much reflection on life, and he was one of almost 200 poets represented in an anthology of poetry, the *Cancioneiro Geral* (1516; "General Songbook"), of the chronicler Garcia de Resende, covering the preceding three-quarters of a century. The main subjects of these 1,000-odd poems, in Portuguese and Castilian, were love, satire, and epigram. Resende was a better poet than most of his contributors.

Gil Vicente and early drama. The emergence of the modern play may be traced in the works of the court dramatist Gil Vicente. Eleven of his 44 plays were written wholly, and another 17 partly, in Spanish. The *Barcas* (1517–19), a group of *autos*, or religious plays, revealed his dramatic power and a fondness for comic relief; in this lay his strength, and in construction lay his weakness. The phenomenon of a potential national theatre, however, died with its founder, and his real influence was felt in Spain. The Inquisition, introduced into Portugal in 1536, early declared war on the popular theatre on the charge of grossness. Vicente's own plays, which figured on the Spanish Index of 1559, were reduced in number to 35 and were sadly mutilated in the second edition of 1586.

The Renaissance in Portugal. The Renaissance reached Portugal both indirectly through Spain and directly from Italy, with which country there had been close cultural relations through the 15th century. In the following century many famous humanists took up residence in Portugal. In 1532 the historian and humanist João de Barros published the *Rópica Pnema* ("Spiritual Merchandise"), the most important philosophical dialogue of the time in Portugal.

In 1547 John III reformed the University of Coimbra, and distinguished Portuguese teachers returned from abroad to assist the King in his task. At home Portugal produced scholars of note, including André de Resende, author of *De antiquitatibus Lusitaniae* (1593; "Of the Antiquities of Portugal"), and Francisco de Holanda, painter, architect, and author of the *Diálogos da Pintura Antiga* ("Dialogues on Ancient Painting").

The Italianate school of poetry and drama. The return in 1526 of the poet Francisco de Sá de Miranda after a six years' stay in Italy initiated a literary reform of far-reaching effect. Like his contemporary Garcilaso de la Vega in Spain, he introduced the new poetic forms of sonnet, canzone, ode, and epistle, and he gave fresh vigour to the national verse forms, mainly through his *Saíres*. His chief disciple, António Ferreira, a convinced classicist, wrote sonnets superior in form and style. Other poets continued the erudite school, which triumphed with Luís de Camões, author of *Os Lusíadas*. In Camões, a profound

classical education combined with perfect mastery of his instrument and a lifetime of varied experience to produce in sonnets, eclogues, odes, elegies, and *canções* the greatest poetry in the language.

In the drama Sá de Miranda and his followers substituted prose for verse. Taking the Roman dramatist Terence as their model, they produced not Portuguese characters but Romano-Italian types. This revived classical comedy was to be short-lived. Sá de Miranda, avowedly to combat the school of Vicente, wrote *Os Estrangeiros* (c. 1528; "The Strangers"), the first prose comedy, and *Os Vilhalpandos* (c. 1528), both actions being set in Italy. Ferreira, a greater dramatist, likewise attempted both kinds: *O Cioso*, Italian even to the names of the personages, came nearer to being a comedy of character, but his fame rests chiefly on *Castro* (c. 1557; *Igneis de Castro*), which treated one of the most moving tragic themes in the nation's history—the execution of Inês de Castro—by reference to the ancient Greek dramatists Sophocles and Euripides. From the comic playwright Jorge Ferreira de Vasconcelos came a "new invention" of another kind with *Comédia Eufrosina* (1555), written under the influence of the Spanish novel *La Celestina*. This and his other plays, *Comédia Ulissipo* (1618) and *Comédia Aulegrafia* (1619; "Life at Court"), resembled novels in dialogue and contained a treasury of popular lore and wise and witty sayings introduced with a moral purpose.

The 16th-century history. Discovery and conquest in Africa, Asia, America, and on the ocean inspired historians as well as poets. Their records gained in vividness what they might have lost in scientific detachment. In the three "Decades" of his *Décadas da Ásia* (1552–63), João de Barros told in vigorous language the deeds of compatriots overseas down to 1526. His first "Decade" undoubtedly influenced Camões, and together, one by his prose and the other by his verse, these two fixed the written language. This work, continued by the more critical and inclusive Diogo do Couto, can rank as the noblest historical monument of the century. In his *Soldado Prático* (written before 1578, published in 1790; "Experienced Soldier"), Diogo do Couto added acute observations on the causes of Portuguese decadence in the East. Ten years of investigation in India underlay the *História do Descobrimento e Conquista da Índia Pelos Portugueses* (1551–61; "History of the Discovery and Conquest of India by the Portuguese") of the chronicler and notary Fernão Lopes de Castanheda, a work that ranks close to those of Barros and do Couto.

From this spate of writing on expansion overseas, attention returned, by way of chronicles of the monarchs who presided over the work, to the history of Portugal itself. Damião de Góis, diplomat, traveler, humanist, and intimate friend of Erasmus, possessed an encyclopaedic mind and was one of the most critical spirits of the age: his *Chronica do Felicissimo Rey Dom Emanuel* (1566–67; "Chronicle of the Most Happy King, Dom Emanuel") was most valuable where the author's own feelings of experience came into play.

Works of travel abounded, and their authors were often the first Europeans to visit the countries in question. Among the more noteworthy was a much-translated classic, *História da Vida do Padre Francisco Xavier* (1600; "History of the Life of Father Francis Xavier"), by Padre João de Lucena. Important both as history and as human documents were the *cartas*, or "letters," written home by Jesuits in China and Japan. An anonymous *Descobrimento da Florida* ("Discovery of Florida") and a *Tratado Descritivo do Brasil em 1587* ("Descriptive Treatise of Brazil in 1587") of Gabriel Soares de Sousa were reminders that Portugal was also present and active in the New World to the west. A work notable for its curious interest is the *Peregrinacam* (1614; *The Voyages and Adventures of Ferdinand Mendez Pinto, of Portugal*), which Fernão Mendes Pinto, prince of adventurers throughout the East, composed in his old age, and another, known for tragic pathos, is the *História Trágico-Marítima* ("Tragic Maritime History"), a collection of contemporary narratives, told by survivors or based on their accounts, of the more notable disasters that befell Portuguese ships between 1552 and 1604.

Luís de
Camões

The novel and other prose. The poet Bernardim Ribeiro, whose five eclogues introduced pastoral poetry to Portugal, was equally an innovator in the pastoral novel with his *Hystoria de Menina e Moça* (1554; "The Story of Menina and Moça"). This tale of rustic love and melancholy with chivalric elements adopted themes and emotions previously found only in poetry. From it a musician and poet, Jorge de Montemor, drew some part of his inspiration for *La Diana*, which, written in Spanish, started a fashion subscribed to by Cervantes and Lope de Vega among many others and represented one of the outstanding contributions of Portugal to the neighbouring literature. The first romance of chivalry in Portuguese was João de Barros' *Crônica do Imperador Clarimundo* (1520; "Chronicle of the Emperor Clarimundo"), concerning the adventures of a fictitious progenitor of the kings of Portugal.

Among moralists and theologians, three ranked as masters of prose style: Frei Heitor Pinto, for his *Imagem da Vida Cristã* (part I, 1563, part II, 1572; "Image of the Christian Life"); Bishop Amador Arrais for 10 *Diálogos* (1589; "Dialogues") on religious and other topics; and Frei Tomé de Jesus for a mystic and devotional treatise, *Trabalhos de Jesus* (1602-09; "Works of Jesus"). The work of scientists included that of a cosmographer and mathematician, Pedro Nunes, and of a botanist, Garcia de Orta, whose *Colóquios dos Simples e Drogas* (1563; *Colloquies on the Simples and Drugs of India*) was the first Portuguese book to be printed in the East (at Goa in India).

THE 17TH CENTURY

From a literary and political point of view, the 17th century found Portugal in a state of decadence. Before the loss of independence to Spain in 1580, Spanish influence had introduced the Inquisition and, with it, censorship of books and the preparation of an Index of Forbidden Books. Between 1552 and 1555 the Jesuits gained control of higher education. The cult of classical Latin was already present, in the work of Camões and others, before the example of the Spanish poet Luis de Góngora y Argote was felt; but with the exhaustion of the national spirit that underlay political eclipse the influence of Góngora penetrated deeply. Its extent may be seen in the five volumes of the *Fénix Renascida* (1716-28; "Phoenix Reborn"), which anthologizes the poetry of the preceding century and reveals the futilities to which good talents could devote themselves. The trend survived the throwing-off of the Spanish yoke in 1640; Portuguese editions of Góngora continued to appear.

The foremost literary figure of the age was the encyclopaedic Francisco Manuel de Melo, a classic of Spanish and—with his series of historical episodes, *Epanáforas de Vária História Portuguesa* (1660; "Anaphoras of Diverse Portuguese History"), and dialogues on literary and social topics, *Apólogos Dialogais* (1721)—of Portuguese literature who strove, more successfully in prose than in verse, to free himself from subservience to Spanish form and style. Most lyricists of the period remained steeped in Gongorism. Epic poets continued active, but few of their productions were more than rhymed chronicles.

Frei Luís de Sousa, a monastic chronicler, won fame as a stylist with his *Vida do Arcebispo D. Frei Bartolomeu dos Mártires* (1619; "Life of Archbishop D. Frei Bartolomeu dos Mártires") and the *História de São Domingos* (three parts, 1623, 1662, 1678; "History of São Domingos"). A Jesuit, António Vieira, missionary and diplomatist, was highly regarded for his *Cartas* (1925-28; "Letters") and *Sermões* (1679-1748; "Sermons").

The popular theatre lived on obscurely with mostly anonymous plays that were never printed. Those that survived were mainly religious and showed the common Gongoristic abuse of metaphor and simile. All through the century most dramatists who aspired to be heard wrote in Spanish. The court after 1640 preferred Italian opera, French plays, and Spanish operettas—to the detriment of native drama and of acting.

THE 18TH CENTURY

The 18th century, in Portugal as in Spain, was predominantly prosaic, even in poetry. Yet signs gradually appeared

of a literary revolution that developed eventually into the Romantic movement. Luís António Verney poured scorn on prevailing methods of education in *Verdadeiro Método de Estudar* (1746; "True Method of Studying"). Men of liberal ideas traveled to France and England, and to their example were largely due the reforms that invaded every branch of letters. Among the most influential were Alexandre de Gusmão, Francisco Xavier de Oliveira, António Ribeiro Sanches, José Correia da Serra, Avelar Brotero, and Francisco Manuel do Nascimento. New literary societies called *arcádias* cooperated in the task of reform. In 1720 King John V established the Academia Real da História Portuguesa, which counted among its members such men as Manuel Caetano de Sousa, author of a colossal *História Genealógica de Casa Real Portuguesa* (1735-49; "Genealogical History of the Portuguese Royal House"). The Academia Real das Ciências (Royal Academy of Sciences), founded in 1779, initiated research into the study of Portuguese literary history. In its ranks were found nearly all the scholars of note at the end of the century, such as the ecclesiastical historian Frei Manuel do Cenáculo; a scientist, António Ribeiro dos Santos; João Pedro Ribeiro, perhaps his country's first modern historian; and critics Francisco Alexandre Lobo and Frei Fortunato de São Boaventura.

In 1756 António Dinis da Cruz e Silva established the Arcádia Lusitana (or Uliissiponense), its first aim being the uprooting of Spanish influence. The bucolic verse of Dómingos dos Reis Quita signified a return to the native tradition of two centuries earlier. Sincerity and suffering spoke in the justly more famous *Marília de Dirceu* (1792), love lyrics in a pastoral setting, by Tomás António Gonzaga. In 1790, a Brazilian Nova Arcádia came into being, its two most distinguished members being the rival poets Manuel Maria Barbosa du Bocage and José Agostinho de Macedo.

Outside the Arcádias stood the "Dissidents," among whom were at least two writers of distinction. These were the satirist Nicolau Tolentino de Almeida, who painted the customs and follies of his day with devastating accuracy, and Francisco Manuel do Nascimento (pseudonym Filinto Elísio), who addressed himself perseveringly to purifying the language and to restoring the cult of the 16th-century poets.

Early in the century popular authors attempted a revival of the drama in Lisbon. The *Operas Portuguesas* (1733-41) of António José da Silva owe their name to the interspersing of the prose dialogue with arias, minuets, and *modinhas* (popular light songs).

THE 19TH CENTURY

Romanticism and after. The 19th century witnessed a general revival of Portuguese letters. The chief exponents of Romanticism were, in poetry and drama, João Baptista de Almeida Garrett and, in prose, Alexandre Herculano; both lived for some years in exile, the price of their political liberalism. Almeida Garrett read literature in English and French and introduced Portugal to nationalistic Romanticism through two epics, *Camões* (1825) and *Dona Branca* (1826). António Feliciano de Castilho, half-Romantic, half-Classicist, exercised much influence over a younger generation of poets: João de Lemos, Soares de Passos, Tomás Ribeiro (who won fame with the ardently patriotic *Dom Jaime*, 1862). In 1865 Antero de Quental, a student of German philosophy and poetry, and Teófilo Braga, disciple of Auguste Comte, led a revolt against the primacy of Castilho, much to the benefit of literature, and of poetry in particular. The *Campo de Flores* (1893; "Field of Flowers") of João de Deus contained some of the finest short poems in the language, marked by a spontaneous simplicity. Abílio Manuel Guerra Junqueiro, heir to Victor Hugo, was a would-be social revolutionary excessively prone to grandiloquence. In *Os Simples* (1892) he turned to the portrayal of peasant life, and this work constituted his finest poetry. Akin to him was António Duarte Gomes Leal, author of *Claridades do Sul* (1875; "Clarities of the South") and *O Anti-Cristo* (1884; "The Anti-Christ"), who could likewise achieve quiet sincerity when dealing with humble themes.

Establishment of the Portuguese academies

The attempted revival of drama in Lisbon

The influence of the Spanish poet Góngora

Antônio Cândido Gonçalves Crespo stood out as the first of his country's Parnassians. By contrast Cesário Verde, considered to be the greatest poet of the century, addressed himself to the poetic essence of common realities. The *Só* (1892; "Alone") of Antônio Nobre was intensely Portuguese in themes, mood, and rhythms; he and Teixeira de Pascoais developed a cult of *saudosismo* ("yearning," "nostalgia") that inspired a whole school of poets. French Symbolism found an enthusiastic adept in Eugénio de Castro.

Drama, the novel, and history. Almeida Garrett, seeking to reinvigorate drama, found he had to create alike theatre, plays, actors, and audience. In *Um Auto de Gil Vicente* (1838; "An Auto of Gil Vicente"), *O Alfageme de Santarém* (1841; "The Swordsmith of Santarém"), and especially in *Frei Luís de Sousa* (1843; *Brother Luiz de Sousa*), he proved himself to be, after Vicente, his country's most notable dramatist. João da Câmara was the outstanding dramatist of his day, and his works include *Afonso VI* (1890), *Rosa Enfeitada* (1901; "Rose Abandoned"), and *Os Velhos* (1893; "The Old Ones"). Herculano, returning from exile with an enthusiasm for Sir Walter Scott, launched the historical romance with *O Monasticon: Eurico, o presbítero* (1844; "The Monastic: Eurico, the Presbyter") and *Lendas e Narrativas* (1851; "Legends and Narratives"). Many followed suit, including Oliveira Marreca, Arnaldo da Gama, and Pinheiro Chagas, popular successes being *A Mocidade de D. João V* (1852; "The Youth of D. João V"), by Luís Antônio Rebelo da Silva, and João de Andrade Corvo's *Um Ano na Corte* (1850–51; "A Year in the Court"). This was the great age of the novel: Camilo Castelo Branco, Joaquim Gomes Coelho (better known as Júlio Dinis), and especially José Maria Eça de Queirós were names that would stand high in any country. The first was a master of the language and of dramatic, or melodramatic, plot; Júlio Dinis depicted country life, as in *As Pupilas do Senhor Reitor* (1867; "The Pupils of the Dean"); while Eça de Queirós introduced Realism with a powerful novel, *O Crime do Padre Amaro* (1876; *The Sin of Father Amaro*).

With his magnum opus, the *História de Portugal* (1846–53; "History of Portugal"), and the *História da Origem e Estabelecimento da Inquisição em Portugal* (1854–59; *History of the Origin and Establishment of the Inquisition in Portugal*), Herculano established himself as a leader of modern Spanish and Portuguese historians. Historiography flourished with the Visconde de Santarém, historian of the Cortes; José Simão da Luz Soriano (of constitutionalism); Rebelo da Silva (of the period of Spanish rule under the Philips); and José Maria Latino Coelho (of the dictatorship of Pombal). Henrique da Gama Barros and Antônio da Costa Lobo followed in the footsteps of Herculano. The works of Joaquim Pedro de Oliveira Martins gave proof of psychological imagination, a notable capacity for general ideas, and a gift of picturesque narration. He left in his numerous writings a vast portrait gallery of great figures of his country, particularly in the *Portugal Contemporâneo* (1881; "History of Contemporary Portugal").

THE 20TH CENTURY

The passage from monarchy to republic in Portugal in 1910 saw a revisionary urge in literature associated chiefly with Oporto and the Renascença Portuguesa ("Portuguese Renaissance"). Leonardo Coimbra was its philosopher, and Antônio Sérgio its critic and historian. Its poets—Mário Beirão, Augusto Casimiro, and João de Barros—adopted the *saudosismo* of Teixeira de Pascoais as the key to the nation's recovery of greatness, though the inadequacy of this nostalgia was soon realized. The "Integralist" school reacted from 1913 onward in favour of the Roman Catholic monarchist tradition, led by Antônio Sardinha, a historian and poet. Fernando Pessoa, author of *Mensagem* (1934; "Message"), was posthumously regarded as the most brilliant poet of his generation.

Among novelists of the first half of the century, Aquilino Ribeiro was a prolific writer whose themes often were centred on his native Beira; his delight in life was combined with awareness of decay and death. Miguel Torga, a poet, storyteller, and author of autobiography, showed a

radical individualism that took its strength from his peasant roots. The psychological novel, which had attained a sophisticated form with José Régio, also an outstanding dramatist and a religious poet, took new directions with Carlos de Oliveira. *Casa na Duna* (1943; "A House on a Sandhill"), his first novel, combines an acute perception of human motivation with social awareness, leading up to *Finisterra* (1978), his last book and a masterpiece. Vergílio Ferreira added a metaphysical dimension to the novel of social concern in *Alegria Breve* (1965; "Brief Joy") and explored the evanescent moods of the past and the idea of death in *Para Sempre* (1983; "Forever").

After the overthrow of the Salazar regime on April 25, 1974, poetry and fiction found a new freedom of expression. Jorge de Sena, a poet and novelist of outstanding quality, published *Sinais de Fogo* (1978; "Signs of Fire"), an impressive novel about the effects in Portugal of the Spanish Civil War. J. Cardoso Pires wrote his best novel, *Balada da Praia dos Cães* (1983; "Ballad of the Beach of the Dogs") based on the account of a political assassination. Women novelists have also brought a new voice to fiction. Agustina Bessa Luís, a most prolific writer, first came to notice in 1955. She extended the psychological insight evident in her drawing of fictional characters to enhance her portraits of historical figures, as in her work *Fanny Owen* (1979). Maria Velho da Costa, one of the authors of *Novas Cartas Portuguesas* (1971; *The Three Marias: New Portuguese Letters*)—a book that became a cause célèbre because its authors were put on trial by the state—explored with great subtlety the condition of women in a repressive society in *Lúcia Lima* (1983; "Lemon Verbena"). José Saramago came to the fore in the 1980s. His novels combine an acute observation of reality with flights of poetic fancy. In *Memorial do Convento* (1982; "Memorial of the Convent") the story of the building of a magnificent convent is also the allegory of human suffering in history, told in the form of an epic tale.

Notable work also came out in history and literary criticism, and through this Portugal's history and literature have become more adequately known.

Postal Systems

In the modern world, the term "postal system" may be defined as the institution—almost invariably under the control of a government agency—that makes it possible for any person to send a letter, packet, or parcel to any addressee, in his own country or abroad, in the expectation that it will be conveyed according to certain established standards of regularity, speed, and security. The service is paid for in advance by the sender according to a relatively simple scale of fees based on weight and, in some countries, on speed of service required. Prepayment is ordinarily made by means of postage stamps, franking machine impression, or printed indication of postage paid; payment is not usually required of the addressee.

It may seem tedious to catalog at such length characteristics that are familiar to everyone. Their very familiarity, however, and the consequent unthinking acceptance of them make it important to emphasize that until recently postal systems lacked many of these features. Though the basic need for a system to exchange written communications has been felt by all human societies and has been met in many ways, the evolution of varied postal systems adopted by different societies through the centuries into the basically similar pattern of today's state monopoly service has been a long and difficult process.

Today the governments of many countries use their postal systems to provide a range of services that often have no direct connection with the traditional function of exchanging letters. To provide for the collection, transport, and delivery of letters throughout a country, it has been necessary to establish a network of post offices extending into the remotest areas. Such a network of offices, staffed by agents of the state, provides an efficient banking service in areas in which it would be uneconomic for a commercial or state bank to establish a branch office. Many governments also pay various social security benefits—such as pensions and family allowances—through vouchers that can be cashed at post offices. In some countries post offices also collect certain taxes, normally through the sale of licenses and revenue or tax stamps. In fact, a wide range of ancillary services is provided through the postal system. In some African and Asian countries, for instance, the postal system helps distribute antimalarial drugs. While the variety of such services significantly indicates the ever-increasing use made of postal systems throughout the modern world, they lie outside the scope of this article, which concentrates on the traditional postal or mail services.

POSTAL OPERATIONS AND MANAGEMENT

The raw material of the postal services, always a single object that demands individual treatment, is something sent by one person or entity to another who may be anywhere else in the world. Letters and parcels go in all shapes and sizes, subject only to the limits of weight and dimensions prescribed by postal legislation. Yet if postal services are to be efficient and economical, these items must be mass-processed, as far as is possible. Thus, the basic function of postal organization is to convert the individual item as rapidly as possible into something that can be handled on a bulk basis, ensuring, however, that it finally regains its individual status.

The collection and sorting of individual items by the most economic method, concentrating together all items that are going to the same place or in the same direction, involves the use of local transport, usually operated by the postal services themselves, and sorting offices. The size of the sorting office depends on local requirements, but some are, in fact, large centres that handle several million items a day and employ thousands of personnel. Certain ancillary operations are involved, such as the canceling (by machine in all except the smallest offices) of stamps that have served to prepay the postal charge.

The next stage is to transport the grouped items to different destinations that may be intermediate sorting offices, perhaps a railway sorting car. Items are combined by further sorting with mail from other sources to permit grouping the mails for final destinations.

The third stage is the arrival of the mail at the sorting office of the final destination, where it is sorted systematically. The items finally recover their identity and are grouped for delivery to the individual address. In most countries, delivery is on a house-to-house basis, although boxes at a local post office are sometimes used.

All stages have to be planned and dovetailed to meet an overall standard of performance. The transport of mail between sorting offices is normally by services not necessarily directly operated by the post office—i.e., by truck, bus, train, marine shipping, or air services. In some countries, however, the administration operates its own air service, usually by night, to supplement the public services. Post-office counter services (i.e., the public offices that existed originally as depots where the public could buy stamps, make inquiries, and post and collect correspondence) have in many countries gone beyond the role of accessory to the postal service proper and pose their own problems of organization.

Postal services require extensive manpower. Many countries are striving to mechanize or even automate sorting, transport, and counter processes. Postal organization depends largely on geography; large agglomerations of population present the greatest problems. Furthermore, geography usually determines the routing of mails and the intermediate steps between the posting and destination offices. Traffic problems have forced postal managers, through the years, to develop their own approach to the operational aspects of postal organization. They developed

 sorting
 process

Problems
of postal
manage-
ment

their own work-study methods and operational research techniques long before these terms were invented. Apart from postal operations as such, postal management is concerned with the efficient administration and deployment of large bodies of manpower, the organization of large transport fleets, many aspects of property management, and financial and economic problems, particularly in an increasing number of countries where the postal services are expected to depend on their postal revenue in order to meet all of their costs (including those related to capital expenditure). Computer technology is increasingly exploited as a management aid.

Express
mail

In this connection, many of the developed and developing countries have come to realize that postal services often operate within a commercial market where competition can be fierce and efficiency is the watchword. With the adoption of marketing and sales techniques, new services emphasizing speed, convenience, and reliability have been introduced. One such service is express mail, known under different service names according to the country (Express Mail in the United States, Datapost in Great Britain and Germany). At additional cost, this service, in which about half the UPU membership participates, provides expedited conveyance and individualized priority handling of correspondence and goods.

HISTORY

Message-relay systems of the ancient world. Since good communications were clearly essential for governing the extensive empires of the ancient world, it is not surprising that among the earliest historical references to postal systems were those concerning Egypt about 2000 BC and China under the Chou dynasty 1,000 years later. It was probably in China that a posthouse relay system was first developed and was brought to a high state of development under the Mongol emperors. The great Persian Empire of Cyrus in the 6th century BC also employed relays of mounted messengers, served by posthouses. The system was favourably described by the Greek historians Herodotus and Xenophon. The admiration of the Greeks was natural since their political divisions inhibited the growth of a coherent postal system, although each city-state possessed its corps of messengers.

The *cursus
publicus*

The development of Rome from a small city-state into a vast empire embracing most of the known world brought with it the necessity for reliable and speedy communications with the governors of distant provinces. This need was met by the *cursus publicus*, the most highly developed postal system of the ancient world. The relay stages of the *cursus publicus*, established at convenient intervals along the great roads of the empire, formed an integral part of its complex military and administrative system. The speed with which messengers were able to travel during the peak of the administration was not to be rivaled in Europe until the 19th century: it has been claimed that more than 170 miles (270 kilometres) could be covered in a day and a night. The maintenance of the *cursus publicus* required a high degree of organization; an inspectorial system existed to control its operation and prevent abuse for private ends.

The fall of the Roman Empire in the west during the 5th century did not completely destroy the *cursus publicus*. Its advantages were evident to the new barbarian rulers; some, such as Theodoric, king of the Ostrogoths, who ruled Italy from AD 493 to 526, are known to have maintained the essentials of the Roman postal system within their own domains. Even in the early 9th century, under the Carolingian Empire, the vestiges of the *cursus publicus* appear to have persisted, and posthouses were maintained. While the service did not follow a regularly organized pattern, it was at least reasonably frequent. The continued decay of the Roman roads, the increasing unwillingness of communities bordering the roads to support the expenses of the system, and the progressive political fragmentation of Europe, however, caused all traces of the Roman postal system to disappear.

The *cursus publicus* fared better in the Byzantine Empire because its provinces were eventually absorbed into the Islamic Empire. The substitution of one centralized imperial regime for another meant that the *cursus publicus*

could be incorporated into a similar Arabian postal system based in Baghdad.

The pre-Columbian civilizations of America, responding to the same needs as the imperial states of Asia and Europe, also evolved relay systems, limited to foot messengers. In the Inca Empire, posthouses were maintained at frequent intervals along the remarkable road network, and a like system probably served the Mayan civilization for more than 1,000 years.

Growth of business correspondence in the Middle Ages. The end of the reign of the last Carolingian king in 987 marked the beginning of several centuries of confusion in Europe, in which it is difficult to trace any postal system worthy of the title. Since the kings of the period were constantly struggling to assert their authority over their unruly feudal vassals, the strong central authority that sustained most postal systems was lacking. The uncertain political situation did not favour the creation of a regulated postal service, though it necessitated frequent contact between the kings and vassals and among the great princes. They, along with other powerful institutions—the municipalities, the religious orders, and the universities (notably in Paris)—started to maintain corps of messengers to serve their particular needs.

One of the more significant trends of the later Middle Ages was the development of international commerce and, with it, the growth of business correspondence. Many corporations or guilds established messenger systems to allow their members to maintain contacts with customers. Notable among these was the so-called Butcher Post (Metzger Post), which was able to combine the carrying of letters with the constant traveling that the trade required.

The mercantile corporations of Italy provided the most extensive and regular postal system of this period. Of particular importance were the links maintained from the mid-13th century between the great Italian commercial centres, such as Florence, Genoa, and Siena, and six important annual fairs held in the Champagne area of northern France. Two fixed dispatches were made to each of these fairs: the first to carry orders and commissions and the second to effect settlements. The service was carefully regulated. Conditions of acceptance, scales of payment, and timetables were laid down; the route was fixed, and hostels were maintained along the route. Since the Champagne fairs were attended by merchants from all over Europe, the postal system provided a valuable international link.

Early
postal
links
between
Italy and
France

Italian business interests were also responsible for the only regular extra-European postal link of this period, between Venice and Constantinople. The extent and importance of Venetian business correspondence may be gauged from the fact that in 1320 the king of Persia accorded its couriers the right of free passage throughout his domains.

Russia shared in the general European trend toward the development of postal services in the 13th century. Horses and drivers for the transport of couriers were kept at regular staging posts to provide the so-called carriage express, which gradually developed into an organized system for the exchange of letters.

Growth of the post as a government monopoly. Institutional postal systems that developed during the later Middle Ages also conveyed letters between private persons, with or without official sanction and for a substantial fee in either case. Initially, such letters were relatively few. Outside the institutions with their own postal services, the number of literate people having interests that ranged beyond their own neighbourhoods was small.

In the late 15th century, however, the trend toward improved postal services was reinforced by Gutenberg's printing press (c. 1450) and the expansion of education. The growth of demand made letter carrying a profitable business, leading to the rise of private undertakings—the majority, like the Swiss Stumpelbotten, purely local in scope. Some, like the Paar family in Austria, developed postal organizations on a national scale. By far the most famous and extensive of such systems was that built up by the Thurn and Taxis family, who originally came from Bergamo near Milan, Italy. Under the patronage of the Habsburg emperors, they became the organizers of an

The Thurn
and Taxis
postal
operation

extensive network of postal routes linking the imperial possessions. Their system developed throughout the 16th century until it covered most of Europe, using 20,000 couriers to operate a relay system that was speedy, efficient, and highly profitable.

Although the remnants of the Thurn and Taxis postal system survived in Germany up to 1867, it was essentially out of keeping—like the empire and the petty German states it served—with the main trend of development in Europe, the rise of nation-states with strong central governments. The first reflection of this trend in the postal sphere was the establishment of efficient national systems of relay posts under the control of the state. In France, Louis XI set up a Royal Postal Service in 1477 employing 230 mounted couriers. In England, a Master of the Posts was appointed by Henry VIII in 1516 to maintain a regular postal service along the main roads radiating from London. Neither of these systems was comprehensive, nor were they intended to serve the public. The security and regularity of the service along certain routes, however, inevitably resulted in an increasing amount of unofficial correspondence being carried. After initial attempts to prevent this practice in France, its fiscal advantages were realized, and the carrying of private mails was legalized about 1600. The basis of a real public service was not created until 1627, when fees and timetables were fixed and post offices established in the larger cities. In Britain, a separate public service was set up in 1635 by a royal proclamation “for the settling of the letter-office of England and Scotland.” Thomas Witherings, a London merchant, was given the task of organizing regular services to run by day and night along the great post roads.

In both countries, these state systems naturally began to develop into monopolies since such an evolution was seen by rulers as advantageous both to the security and to the revenues of the state. In England, the establishment of state posts along the principal roads was accompanied by the suppression, under the royal monopoly, of private and municipal posts, although “common carriers” were still permitted to convey letters on routes not covered by the royal system.

In 1672 France declared postal services to be a state monopoly under which operating rights were sold. Private undertakings that had established legal rights in this field were allowed to continue, but private messenger systems were eventually forced out of business by state competition or were bought out. In 1719 the University of Paris, the most important private competitor, gave up its last postal privileges in return for substantial compensation.

There was still opportunity for private enterprise to succeed by introducing services that were not at that time provided by the state systems. It was in this way that an important step in postal history, the establishment of local collection and delivery services in the great cities of London and Paris, was taken. London was the first city to benefit from an urban service when one William Dockwra set up his Penny Post in 1680. Striking features of the scheme were that letters were prepaid and stamped to indicate place of posting and the time they had been sent out for delivery. Deliveries were made almost hourly. Dockwra's scheme was so successful that he was prosecuted for infringing the state monopoly, and his service was closed down in November 1682, only to be reopened by the government. Not until 1759 was a similar local service introduced in Paris. It too was quickly absorbed by the state postal system; but its originator, Claude-Humbert Piarron de Chamousset, was paid compensation. Thus, the state monopolies expanded their scope, happily combining an improved service to the public with greater profitability.

The pace of postal progress in England during the later 18th century was accelerated by remarkable economic growth and a consequent demand for better mail services to the growing commercial and manufacturing centres. The most striking improvements came as the result of an extensive program of road building that began about 1765, paving the way for the era of the stagecoach. These were first used by the post office in 1784 and rapidly superseded the mounted postboys on the main routes. They began by

averaging six or seven miles an hour, but continuing improvements in the roads and in the design of the vehicles pushed this up to 10 miles an hour in the 1830s. With the stagecoaches making possible a general reorganization of the entire system of mail circulation, letters could be delivered the morning after posting in towns more than 120 miles from London. A carefully regulated postal service—unprecedented for its standards of speed, frequency, and security—was evolved during this period.

Despite the disruptive effects of the Revolutionary and Napoleonic wars, great progress was made throughout Europe in the late 18th and early 19th centuries in improving the speed and regularity of postal service and in providing internal delivery services for most of the larger cities. In the United States, too, postal services expanded at a remarkable rate: in 1789 only 75 post offices existed, but 40 years later there were more than 8,000.

Rowland Hill's reforms. The publication in 1837 of *Post Office Reform: Its Importance and Practicability*, by Rowland Hill (later Sir Rowland Hill), a British educator and tax reformer, is justly regarded as one of the most important milestones in postal progress. Based on an exhaustive study of the cost structure of postal operations, it demonstrated conclusively that conveyance charges were an insignificant factor in the total cost of handling a letter. The then current intricate charging scales based on distance were shown to be irrelevant: they inflated operating costs by requiring a host of clerks to apply them and to prepare complicated interoffice accounts. He also realized that another major item in the current cost structure—the collection of money payments on delivery—was easily avoidable. Hill's solution was a uniform rate of postage, regardless of distance, and prepayment of postage by means of adhesive stamps sold by the post office. Hill proposed a basic rate of one penny for each half ounce, calculating the “natural cost of distribution” to be slightly less than this. The cheapest current rate of postage was fourpence, and the average charge 6¼ pence (11.56 cents).

Not surprisingly, Hill's proposals rapidly gained strong support: popular agitation for the “penny post” overcame initial political disinterest, and the uniform rate and a system of prepayment by stamps were introduced in 1840. The originality of Hill's proposal for an adhesive postage stamp has been questioned but is irrelevant in considering the overall merits of his work. The significance of his reforms lies not only in the fact that they brought the post within the means of the mass of the people but also in the less obvious way in which they gave the postal system the technical capacity to deal with the vastly increased demand for postal service that ensued. The radical simplification of postal organization and methods characterizing Hill's reforms are the key to the speed and economy with which modern postal systems in many countries handle tens of millions of letters daily.

The chief features of Hill's system were gradually adopted in varying degrees by other countries throughout the world, first among which were Switzerland and Brazil in 1843.

The introduction of uniform cheap rates of postage for letters was accompanied by the establishment of even lower tariffs for newspapers (carried free in some countries) and for printed matter (e.g., the British “Book Post” of 1848). These reduced rates were perhaps originally intended to favour the spread of education but quickly expanded, under the vigorous pressure of vested interests, to cover all sorts of commercial documents, advertising matter, magazines, etc. An inexpensive form of correspondence, the postcard, first introduced by Austria in 1869, was soon adopted by most other countries.

The general postal reforms of the mid-19th century ensured maximum benefit from the technological progress in transport in the great age of the railway and the steamship. These new modes of conveyance permitted a far speedier, more regular, and more reliable mail service, both internally and internationally. Railways in particular had a marked effect on the organization of postal work: instead of merely using trains to carry mailbags more speedily, postal administrations soon introduced the practice of sorting the letters in transit, using specially adapted railway cars. This greatly multiplied the advantages of railway

Effect of
railways

conveyance. The first traveling, or railway, post offices ran in 1838 between Birmingham and Liverpool and London and Preston. By the end of the century, Britain, many continental European countries, the United States, and India had built up a complex network of such services, allowing the delivery of letters the day after mailing at distances three or four times as great as had been possible with the stagecoach, exceeding 400 miles in some cases.

International postal reform: the Universal Postal Union. The advent of the steamship and the railway had provided the opportunity for speedier international postal services, and the expansion of commerce ensured a growing demand for such facilities. Unfortunately, serious obstacles to the free exchange of international mails existed. Postal relations between states were the subject of bilateral postal treaties that had multiplied alarmingly during the 19th century. Most large European states were party to at least a dozen treaties by the 1860s. Such treaties necessitated the maintenance of detailed accounts between the countries concerned. Owing to the bewildering variety of currencies and units of weight and measurement then in use, the accounts attained a complexity described by a contemporary postmaster general of the United States as "almost beyond belief." Understandably, the users of the post suffered from this chaotic situation and from the high international postage rates that were its natural result.

The Paris
Postal
Conference

The first practical step toward reform did not come until May 1863, when the delegates of 15 European and American postal administrations met at the Paris Postal Conference, convening at the suggestion of the U.S. postmaster general. The conference established important general principles for the simplification of procedures, which were adopted as a model for subsequent bilateral treaties by the countries concerned.

The final step required the embodiment of these principles in a formal international treaty and the creation of an organization to administer them. An example was set by another conference at Paris two years later, which established the International Telegraph Union. Similar developments in the postal field were delayed by the advent of the American Civil War and the Franco-German War.

In 1868, however, a plan for a general postal union was put forward by the director of posts of the North German Confederation. Eventually, an international postal congress met, on Sept. 15, 1874, in Bern. It was attended by representatives of 22 states, all European except for Egypt and the United States. On October 9 a "Treaty concerning the Establishment of a General Postal Union" was signed. It was implemented on July 1, 1875, when the General Postal Union came into being. This title was changed in 1878 to the Universal Postal Union (UPU), and the basic treaty was renamed the Universal Postal Convention. The treaty provides a uniform framework of rules and procedures for the exchange of international mails. The union grew rapidly, increasing its membership to 55 within 10 years. By 1914, when China was admitted, it included almost all independent countries. The scope of the union's activities also expanded. In addition to its primary role, it gradually extended its functions to cover other international services provided by postal administrations, such as money orders (1878), parcel post (1885), postal checks (1920), cash on delivery (1947), and savings banks (1957). The UPU has been a specialized agency of the United Nations since 1948.

Activities
of
the UPU

Development of airmail. Balloon posts, apart from those organized during the sieges of Paris (1870) and Przemyśl (1915), for the most part only carried souvenir mail, owing to the balloons' uncontrollability. Airships overcame this problem but, again, did not establish themselves as a regular means of mail transport. It was only through the development of the airplane in the early decades of the 20th century that airmail truly came into its own. Certain experiments had been undertaken before World War I, such as airmail service between Hendon, on the northwestern outskirts of London, and Windsor in 1911 to mark the coronation of George V and flights between Paris and Bordeaux in 1913. Regular flights did not begin in the United States until 1918, and it was not until 1919, when the reliability of airplanes had considerably improved, that the

first regular international service was introduced—between London and Paris. Other European links soon followed. On the long-distance continental and intercontinental routes airmail demonstrated its clear superiority over all surface transport. Technical factors delayed progress in opening up longer routes. The first American transcontinental airmail flight took place in 1920, but regular service did not begin until 1924. In 1926 a service between Egypt and Karachi began and was linked to London in 1929. It was extended to Singapore by 1933 and to Australia in 1934. It was not until 1939 that a regular air service across the North Atlantic was launched with the takeoff of the *Yankee Clipper*, an American seaplane, on May 20.

While the growing availability of air flight did not affect basic postal organization as profoundly as the railways, its advantages of speed and operational reliability have been exploited in different ways since the 1920s. Prior to World War II, a number of European countries adopted the practice of forwarding letters to distant destinations at no extra cost to the sender (such as British mails sent to most parts of the British Empire). The consistently high costs of airmail curtailed this trend after the war. During the mid-1960s the UPU, in response to the continuing increase of aircraft capacity, adopted the policy of maximizing air conveyance of mail. In the mid-1970s, the concept of "surface air-lifted" (SAL) mails was developed in conjunction with the International Air Transport Association (IATA). This arrangement allows some mails to receive, for little or no surcharge, speedier transmission than by surface, but without the priority of fully surcharged mails. Use of SAL varies from country to country.

For individual correspondence, the most practical and inexpensive form of airmail remains the compact aerogram, which was introduced in Britain during World War II as a convenient way of writing to overseas military personnel. It consists of a sheet of lightweight paper suitably folded and gummed on all sides. Recognized by the UPU, the aerogram is available in most countries.

The
aerogram

Advanced communications technology. Rapidly advancing computer and data transmission technologies of the late 20th century are being felt far more widely within the postal sector than were previous advances, such as improved roads, the railway, and the airplane. Although the latter enabled postal services to reform or enhance existing services, today's technologies go further by providing alternatives to the letter in the form of electronic messaging networks and electronic data-processing techniques to improve administrative efficiency.

NATIONAL POSTAL SYSTEMS

United States. Although the first official reference to overseas mail arrangements (concerning the receipt of overseas mail at Fairbanks' Tavern in Boston) dates to 1639, little real progress was made in building a postal system in colonial America until the appointment of Benjamin Franklin, formerly postmaster at Philadelphia, as deputy postmaster general for the American Colonies in 1753. Through diligent personal survey and inspection, he provided a more extensive, frequent, and speedier mail service, both within the Colonies and to England. Franklin built a sound foundation for the postal service in the United States, and, fittingly, he became its first postmaster general in 1775.

Postal service expanded rapidly after independence: annual revenue increased from \$37,935 in 1790 to \$1,707,000 by 1829, when the postmaster general first became a member of the Cabinet. The heavy cost of establishing a postal structure to keep pace with the remarkable economic progress of the country and the accelerating extension of its settled area caused expenditure to rise even faster than revenue. The trend toward annual postal deficits, which began in the 1820s, often exceeded an annual figure of \$5,000,000 later in the 19th century.

By 1901, however, this expenditure had produced remarkable results. The accessibility, quality, and range of services provided had improved immeasurably. The number of post offices stood at a peak of 76,945. Postage rates had been considerably reduced with the gradual adoption of the principles of Rowland Hill: a single uniform

Growth of services

rate regardless of distance was adopted in 1863 (after an interim period with two rates since 1845), and postage stamps were introduced in 1847. Free collection services came with the provision of street letter boxes in 1858. A free delivery service was established in 1863, covering 49 cities and employing 440 letter carriers. By 1900 the service was provided at 796 offices by 15,322 carriers. The rural free delivery (RFD) service was introduced in 1896 and town delivery in 1912. These delivery services have greatly expanded their scope. The vast majority of mail is delivered by carriers, about one-tenth through post-office boxes, and only a small fraction at windows or counters.

Division of mail into four classes

The range of services available to the public has also grown steadily since the first supplementary postal service, registered mail, was introduced in 1855. The major milestones in this progress were postal money order service (1864); international money orders (1867); special delivery (1885); parcel post, with its accessory collect on delivery (COD) and insurances services (1913); and certified mail (1955), which provides proof of posting for items without intrinsic value. In 1911 a postal savings system was inaugurated, reaching a peak of more than 4,000,000 accounts in 1947. A decline to less than 1,000,000 depositors caused the service to be discontinued in 1966. Mail was formally divided into three classes in 1863, and a fourth was added in 1879. First-class, or letter, mail (called letter post in the United Kingdom) is the basis of the postal service monopoly and, as the class of mail most commonly used by the public, has generally had a simplified rate structure. The other classes were established according to mail content: second-class consists of newspapers and magazines, third-class encompasses other printed matter and merchandise weighing less than one pound, and fourth-class mail is either merchandise or printed matter that weighs one pound or more. The addition of these classes allowed the post office to adopt more complicated rate structures that would take into account factors affecting handling costs—such as the weight of the piece and the distance it would be conveyed. Second-class mail receives preferential rates because the dissemination of information through newspapers and other publications is considered to serve the public interest.

The post office has played a vital role as a pioneer and major user of all systems of transport as each was developed: the stagecoach, steamboat, canals, and railroads; the short-lived pony express; and airlines and motor vehicles. It also helped subsidize their development. A traveling post-office system, in which mail could be sorted in transit, was introduced experimentally in 1862, and it made railway mail service the dominant form of mail conveyance well into the 20th century. The gradual reduction of passenger train services during the 1930s led to the birth of a highway post-office service in 1941. Both of these services declined rapidly in the 1950s and 1960s. Railway post-office mileage was reduced from 96,400,000 in 1965 to 10,100,000 in 1969, and the number of highway post offices in operation during that period fell from 163 to none. Conversely, annual ton-miles of airmail flown grew from 188,103,000 in 1965 to more than 1,000,000,000 by the 1980s, indicating the significant trend toward air transportation of regular mail without surcharge.

Postal Reorganization Act of 1970

The United States maintains the largest postal system in the world, handling almost half the world's volume of postal traffic. To deal with the problem of increasing deficits and to improve the overall management and efficiency of the post office, the U.S. Congress approved the Postal Reorganization Act of 1970, signed into law Aug. 12, 1970. The act transformed the Post Office Department into a government-owned corporation, called the United States Postal Service. Congress no longer retains power to fix postal tariffs (although changes may be vetoed) or to control employees' salaries, and political patronage has been virtually eliminated. Government subsidies continued on a declining basis until 1982, after which the U.S. Postal Service itself no longer received a direct subsidy from Congress. An indirect subsidy is still paid for certain mailers, however. These mailers, primarily nonprofit organizations or small publishers, pay lower rates than others, with Congress making up the difference in cost. The cor-

poration has authority to raise capital to modernize its equipment and buildings. It is also subject to competition from private companies, a situation that in 1977 led to the introduction of Express Mail, which guaranteed overnight delivery.

The availability of adequate funds for its mechanization and automation program has allowed the post office to benefit considerably from its sustained effort in research and development. More than half of all letter mail is handled by preparation and sorting machines, a trend greatly assisted by the ZIP (Zone Improvement Plan) Code program, which has come to be almost universally used.

Great Britain. The development of the British Post Office up to the reforms introduced by Rowland Hill has already been described. After 1840 the volume of postal traffic increased enormously and by 1870 had reached 10 times its prereform level. The growth was fostered by the introduction of new facilities, such as registration and postcards, and of preferential rates for books, printed papers, and samples. Financial services were also expanded: a savings bank was established in 1861, and postal orders were introduced in 1881 to supplement the money order service taken over from private interests in 1838. In 1883 a parcel post service was established.

The sweeping social reforms of the 20th century have given the post office an additional role as the chief payment agency for social security benefits, beginning with old-age pensions in 1908. This has been expanded to provide a variety of payments and also to collect large sums for state insurance schemes. The scale and range of financial transactions have been further boosted by the establishment in 1968 of the post office's banking arm, National Girobank, which provides an improved money transfer arrangement for the settlement of bills, as well as an account banking system and loan facilities.

Another important 20th-century trend has been the gradual recognition of the post office's role as a commercial enterprise rather than as a government revenue department. The process of achieving full commercial status took an important step forward in October 1969, when the post office became a public corporation. The British Telecommunications Act of 1981 divided the post office into two corporations, one for postal and banking operations and the other for telecommunications. This law also has provisions for the suspension of the post office's monopoly in certain categories of mail, allowing private companies to compete with it.

To maintain quality of service economically by removing the need to handle nonpriority mail at peak periods, a change to a two-tier system of letter classification was started in September 1968. The system abolished the complex preferential rate structure for printed papers and similar material—based on the contents of correspondence—and substituted the more relevant criterion of priority. The sender indicates the urgency of the item as being high (first-class) or lower (second-class) and pays on this basis, which simplifies the work of accepting the mail.

As in a number of other postal administrations, the sorting of mail has been gradually mechanized since the mid-1960s, with some 80 mechanized offices replacing more than 600 offices. The key to mechanization is an alphanumeric postal code that provides for sorting by machine at every stage of handling, including the carrier's delivery route. The coding equipment translates the postal code into a pattern of dots by means of which machines can sort mail at eight times the speed of manual sorting.

The post office transports mail by road, rail, and increasingly by air. More than half still travels by rail, using an extensive network of railway traveling post offices. To improve service and to enable next-day delivery for remote areas, letters are flown each night either by scheduled or chartered aircraft. New services based on communications and computer technology have been introduced. The Intelpost facsimile service operates nationally and with many other countries. An electronic mail system enables data for large mailings to be transmitted to local centres for enveloping and delivery.

France. The chief stages in the pre-Revolutionary development of postal services in France have already been

British Post Office social services

described. With the Revolution the system of farming, or selling the right to operate a postal service, was abolished. In the years following the 1789 Revolution, the postal and stagecoach services were reorganized into a Directorate of Posts, which became a national monopoly organization on June 16, 1801. After a brief return to the farming system a general Directorate of Posts attached to the Ministry of Finance was created in 1804. During the 19th century, the service developed to keep pace with the Industrial Revolution, notably through improvements in administration and transportation. The first French postage stamp was issued on Jan. 1, 1849, thereby introducing the principle of prepayment as well as simplifying the rate structure. The scope and range of the postal administration's activities widened in the 19th century to include postal money orders (1817), registered letters (1829), parcel post (1881), the savings bank (1881), and postal checks (*giro*; 1918). During these years the post also took advantage of the newly developing methods of transport. Rail transport, for example, introduced in 1841, was so successful that by 1892 it had become an established means of conveyance; postal steamships served more than 100 ports; and bicycles and, later, motor vehicles were provided for postmen's collection rounds. In the early 1900s a full motor vehicle service was set up for the conveyance of mails in Paris.

airmail
service

The knack of turning technological innovation to good account was repeated with the airplane. The first airmail flights within France began in 1918, and in 1919 an irregular route was established between Avignon and Nice; by 1935 a network of routes linked the main French cities. During that period, the exploits of Antoine de Saint-Exupéry, Juan Mermoz, and other pilots of the *Aéropostale* airline, founded by Pierre Latécoère, served to establish an overseas network with French West Africa and Latin America.

World War II severely disrupted the postal service, and the German occupation forces exerted strict control over mail conveyed within a homeland that had been divided into virtually separate zones. The reinstatement of night airmail service in 1945 marked the beginning of a period of rapid reorganization for the postwar French postal service. Eventually the propeller-driven aircraft was replaced by relatively quiet turbojets, carrying 20 times the amount of airmail dispatched in 1948. Additionally, the postal service acquired its own custom-built rolling stock, which is used on the high-speed train run between Paris and Lyon. Daily mail traffic has grown by some two and a half times since the early postwar years, and, to cope with the increased volume, work began in the late 1970s on a network of mechanized sorting centres.

To speed up and reduce the cost of processing this huge quantity of mail traffic, the French postal service introduced a two-tier system in January 1969, thus enabling the customer to choose the priority of service desired by paying an appropriate charge. The postal service also entered the express mail market with the *Postadex* service, which operates with more than 50 other countries, and a national and international facsimile transmission service (*Postéclair*) has been established. An electronic mail printing and delivery service is being developed. The banking and savings service has also embarked upon a comprehensive program involving the microcomputerization of virtually every aspect of local office operation, as well as actively exploiting memory-card technology.

West Germany. Postal organization in Germany remained on a relatively small scale until the latter half of the 19th century because of the numerous and fragmented sovereign states. The need for a more widely based postal system had been met, to a certain degree, since the 16th century, when the Thurn and Taxis postal service was begun. The fragmented political state of Germany, in fact, allowed the Thurn and Taxis organization to survive until 1867, when its last privileges were acquired by the postal service of the North German Confederation.

Establish-
ment of
the
German
postal
service

The unification of Germany under Prussia during the second half of the 19th century, culminating in the establishment of the German Empire in January 1871, was followed by the creation of a German postal service in the same year, under a law establishing a state monopoly for conveying letters and newspapers. In 1924 the postal

administration was accorded a considerable degree of financial autonomy, which allowed it to conduct business in a semicommercial manner, while still taking account of national economic and social factors in determining rate structure and pattern of service. The post office has developed a complete range of normal postal and financial services and an extensive postal passenger transport network and carries out various social security, revenue, and other agency functions.

Mail is transported chiefly by rail, but there is also an extensive complementary postal road network and an important night airmail service. The air service, inaugurated in 1961, carries letters and postcards without surcharge.

The present-day operation of the West German post office has been affected by two major factors. The first of these has been increased competition, which has brought about the adoption of customer-oriented business policies, along with appropriate reorganization. As a result, the post office entered the express mail market with overseas (*Datapost*) and inland services and introduced the surface air-lifted (*SAL*) parcel service to overseas destinations. The second factor has been the rapid technological development that has taken place over the same period. This has been an agent of change in a number of ways: a new general messaging service, incorporating different forms of electronic mail and the traditional letter mail, is under development; entirely new services such as cash dispensing, interactive videotext, and money services based on memory cards have been introduced; and the post office has exploited modern technology to increase its administrative efficiency and ability to compete.

Introduc-
tion of
new mail
services

Italy. A long history of organized postal systems in Italy began with the *cursus publicus* of the Romans, but a modern national postal system was not established until 1862, when the long process of unifying the former small sovereign states into the new Kingdom of Italy had been completed. The new state postal service was given a monopoly for the collection, conveyance, and delivery of letters, printed papers, and newspapers, and a uniform tariff was established. The monopoly was surrendered for printed papers and newspapers in 1873 but was extended to cover parcels up to 20 kilograms in 1923. A registration service also began in 1862, and postal orders were introduced, extending on a national scale a service that had been made available to the public in the former Kingdom of Sardinia as early as 1845. The Post Office Savings Bank, set up in 1875, and the postal check service, founded in 1917, are other important aspects of the postal service. The post office also acts as an agency for the payment of such social security benefits as state pensions and various other grants.

Railways are the chief means of mail transport, although their use has declined since 1965, while road and particularly air transport have increased significantly, with the need for next-day service between major cities, such as Milan and Palermo. The Italian postal mechanization program moved forward significantly after the late 1970s. In the larger cities mechanized centres have been constructed in which electronic address-reading equipment processes mail for delivery, provided certain physical specifications are met.

Soviet Union. Following the October Revolution of 1917, postal services in the Soviet Union underwent important development, particularly in what are now the Central Asian republics of Kazakh, Kirgiz, Tadzhik, Turkmen, and Uzbek, where the number of post offices is now 30 to 40 times that of the 1913 figure. Today, state enterprises and individual customers alike are served by a network of some 90,000 post offices, about three-fourths of which are located in rural areas that prior to 1917 had little or no service.

For a country with an area of 8,600,400 square miles (22,000,000 square kilometres), air transport is singularly significant among the available types of transport. It accounts for about 60 percent of all postal traffic, which totals some 54,500,000,000 items annually, about 80 percent of which consists of newspapers and magazines. Prompt delivery of central press publications is now achieved by facsimile transmission of text, in some cases by satellite,

for decentralized printing. These facilities contributed, in the early 1980s, to a significant increase in the volume of periodicals handled.

All types of mail can be processed by a national network of large sorting centres, which is constantly being improved. Work in public offices is being mechanized in various ways, an example being the national automation of postal order operations. Increasing use is being made of computers at all levels of administration, particularly on mail handling and transport. Postal research efforts aim toward improving productivity, staff working conditions, and service to the public.

China. The first use of a postal system in China was under the Chou dynasty (c. 1111–255 BC). A reference by Confucius in the late 6th century demonstrates that it was already renowned for its efficiency: "The influence of the righteous travels faster than a royal edict by post-station service."

Improve-
ments
under
the Han
dynasty

By the late 3rd century BC the postal network consisted of relays of couriers, who changed their mounts at staging posts about nine miles apart. This network was considerably enlarged following the opening of new territories in Central Asia under the Han dynasty (206 BC–AD 220), during which time contacts were made with the Romans, who, it was observed, maintained a postal system similar to that of the Han. Further improvements were made under the T'ang dynasty (618–907). During this period the number of staging posts increased, and correspondence could be conveyed by road or by river. Administered centrally by the secretary for transport under the Ministry of War, the postal service underwent periodic checks for quality of service. It was possible for urgent documents to be conveyed up to 93 miles in a day. The Sung dynasty (960–1279) instituted a parallel express service for military correspondence, its couriers regularly traveling as far as 124 miles in a day and even more in cases of extreme urgency. The postal network that had evolved under the T'ang and the Sung was to prove a valuable base for organizing the posts under later dynasties. In the late 13th century Marco Polo revealed to Europe the quality of the Chinese postal system under the Yüan, or Mongol, dynasty (1206–1368). Nothing comparable existed in Europe at the time.

The
Imperial
Post

Until the end of the 14th century the post was used purely for the conveyance of official documents. At the beginning of the 15th century private post offices for the use of traders appeared, conveying private correspondence and arranging payment transfers. During the middle years of the Ch'ing dynasty (1644–1911/12) there were several thousand of these private post offices. In 1896 the Imperial Post was created and organized along European lines, and the old staging points that had functioned for more than 3,000 years were phased out. The new state system gradually absorbed the business of the private companies, although the last one did not close its doors until 1935. The last of the foreign post offices (maintained by Britain, the United States, France, Germany, and the Soviet Union) was withdrawn by the end of 1922.

When the Republic was proclaimed after the 1911 Revolution had overthrown the Ch'ing dynasty, the service was renamed the Chinese Post. In 1914 China joined the UPU. Development of services was extremely slow, however, because of internal strife and eight years of resistance to the Japanese invasion. Thus, on the eve of the founding of the People's Republic, there were only 4,868 postal establishments throughout the whole of China, of which 463 alone were in country areas. Postal transport was minimal by present-day standards.

One month after the proclamation of the People's Republic of China on Oct. 1, 1949, the Ministry of Posts and Telecommunications was established. On the mainland this administration reorganized the postal service, known thereafter as the People's Post of China. Much was accomplished in the years that followed. The mainland postal network grew to more than 3,000,000 miles of roads, railways, and air routes centred upon the capital, Peking. It reached into every corner of the land to serve remote towns and villages where prior to 1949 the postal service was hardly known. Letter mail has increased fourfold since the late 1940s.

Postal research centres set up during the 1950s have actively exploited new technology in the design and manufacture of specialized equipment for the postal service. Notable examples include sorting machines using optical character or bar recognition (OCR or OBR) and computer- and microprocessor-controlled sorting machines.

India. The earliest reference to an official postal system in India was made in the 14th century by the Arab traveler and historian Ibn Baṭṭūṭah, remarking upon the organized official service of mounted couriers and runners. The system was brought to its height during the 16th century under the great Mughal emperor Akbar, with a network of 2,000 miles of post roads. Two centuries of political turmoil, without a strong central authority, destroyed this courier system. It was not until 1766 that an official post was reestablished to serve a new ruling power. It was made available for public use in 1774.

In 1837 the Imperial Post was established and granted a monopoly to provide efficient postal communications between the seat of government at Calcutta and the principal provincial towns. Within the provincial districts a complementary local service was maintained. In 1854 the basis of the modern Indian Post Office was established when these parallel systems were merged under a director general. A uniform postage rate was then introduced, a step of particular significance in so vast a country.

Establish-
ment of
the Indian
Post
Office

International postal relations developed rapidly after the establishment of a weekly steamer service between Bombay and England in 1867, with India becoming a member of the UPU by 1876. At the same time, the post office began to expand the range of services provided to the public: COD in 1877, an insured service in 1878, and money orders in 1880.

Internal communications were improved to keep pace with the progress made in these other fields. The "bullet train"—the Indian equivalent of the mail coach—gave way to the growing network of railways. A regular traveling post-office service was introduced in 1870. Although experiments with airmail conveyance started in 1911, a regular inland service did not begin until 1932. Rapid expansion followed in 1949. A complex night airmail network connects all major cities, carrying a growing percentage of the mail. Railways have retained much of the traffic as a result of speedier train services, although motor vehicles have become the dominant carrier of mail.

More traditional forms of transport—the foot runner, horse, mule, camel, bullock cart, and bicycle—still help distribute mail to many of India's villages. More than one-half of these now have daily delivery of letters, and almost all have at least weekly delivery.

Pakistan. Although Pakistan did not exist as an independent sovereign state until 1947, its postal history extends to the official postal systems established by Muslim emperors. Particularly noteworthy was the network of post relays at caravansaries (inns) established by the emperor Shēr Shāh of Sūr in the early 16th century. Under British rule in 1852, the province of Sind had the distinction of being the first region in the subcontinent to adopt a uniform letter postage rate.

On becoming independent, Pakistan was faced with a particularly difficult problem of postal communications because its eastern and western regions were separated by 1,000 miles of Indian territory. The growth of civil aviation services and maritime links overcame the initial difficulty. In 1952 an airmail service was introduced between East and West Pakistan in which letters and postcards were carried without payment of surcharge. This concessionary airmail system was extended to cover the internal mail service of both regions in 1959. The post office made use of the entire network of the national airline to connect 29 key points throughout the country. The service for printed paper and parcel mail was improved in 1962 by the introduction of direct sea-mail links between Karachi and Chittagong.

Pakistan
airmail
service

The creation of Bangladesh out of East Pakistan in 1971 allowed Pakistan to improve its internal mail services, especially in rural areas, where three-fourths of the post offices are located. Postal facilities were greatly expanded throughout the country.

The post office is run on a commercial accounting basis but with strong emphasis on its function as a public utility. Postal traffic has grown rapidly. To improve its capacity to deal efficiently with the continuing growth, the postal administration has pursued a carefully considered and moderate policy of mechanization. At some of the busiest offices, machines designed to facilitate the acceptance of registered mail have been introduced. To speed up the handling of mail in sorting offices, electromechanical sorting machines have been installed at Karāchi and Lahore. All major post offices now use electrically operated stamp-canceling machines, as well as franking machines.

Japan. Although official and private systems of communications had existed in Japan from ancient times, it was not until 1870 that the creation of a comprehensive government-operated postal service was proposed. The idea was put forward by Hisoka Maejima, often called "the Father of the Post" in Japan. It was rapidly accepted by the government, which set up a service between Tokyo and Ōsaka on April 20, 1871, and extended it throughout the country in July 1872. In 1873 the postal service was proclaimed a monopoly and private courier systems were prohibited, a uniform postal tariff scale was adopted, and postage stamps and postcards were introduced. The first official overseas mail service was established in 1875 with the United States. International postal relations expanded rapidly, and in 1877 Japan became a member of the UPU.

Other landmarks include the introduction of a parcel post service in 1892, express delivery in 1911, airmail in 1929, and the achievement of a special accounting status on semicommercial lines in 1934.

A distinctive feature of the postal scene in Japan is the special New Year's Mail Service, introduced in 1900. Operating partly for the benefit of charities, this provides for the timely delivery of billions of New Year greetings.

The shortage of manual labour and the growth in postal business resulting from the country's rapid economic development have also led to the adoption of an extensive mechanization policy. To facilitate this process, a postal code address system was introduced in July 1968. Japanese-produced segregating and sorting equipment, including automatic postal code reader-sorters, has been installed at major post offices throughout the country.

POSTAL SERVICES IN THE DEVELOPING COUNTRIES

The establishment of efficient and comprehensive postal systems in the developing countries is important internationally as well as from the purely domestic viewpoint. Successful maintenance and progressive improvement of international postal service require the effective cooperation of all member countries of the UPU.

The internal need for a good postal service is sufficient in itself, however, to justify a high priority. A country-wide network of post offices provides government with many points of contact with its people for implementing administrative programs in such fields as social security, taxation, and public information. When its operation is properly developed, the post office may also become one of the principal employers in a country; it may help to promote economic growth through its need for buildings, vehicles, and equipment; and it has the potential to become a major user of transport services. The employment potential of a postal system is evident from the fact that the percentage of the working population engaged in providing postal services is generally several times higher in developed than in developing countries.

An efficient postal service, in addition to promoting national cohesion, provides an essential infrastructure for the expansion of industry and commerce. Postal money transfer and savings services are particularly valuable in developing economies, where banking facilities are limited. They may generate large resources that can be used for public investment.

Postal administrations in developed countries have long appreciated the importance of collaborating in the improvement of postal services throughout the world, and this participation in postal technical assistance is an aim embodied in the constitution of the Universal Postal Union. In addition to fostering bilateral assistance between

Importance
to national
economies

members, the UPU itself has, since 1964, taken part as a specialized agency in the United Nations Development Programme (UNDP). UPU activities in this field are monitored and realigned as necessary at each postal congress.

In view of the rapid expansion of postal business in most developing countries, the training of staff is a most urgent need. The UPU's initial activity has, therefore, been largely devoted to this field. The needs of individual countries are evaluated by traveling postal experts attached to the International Bureau in Bern. In addition, expert aid is provided for the establishment of national training schools for postal workers and regional centres for middle and higher management staff, such as those set up in Abidjan, Ivory Coast, and in Bangkok and Damascus. Special instructor-training courses are conducted in Britain and France, as well as in multinational schools in Africa, Asia, and Latin America, where seminars are also held for higher grade officials. Specialist aid is also provided to evaluate operational and organizational needs and subsequently to enlist UNDP assistance in meeting them. The missions of experts are thus directed either to the postal services in general or to a certain sector of postal activity. Some larger projects may include overall postal organization as well as postal training; such projects have been undertaken in Ethiopia and Niger. Fellowships are awarded for overseas study of specialized subjects, such as international mails, philately, and, in particular, instructor training. Although the UNDP provides the major share of technical assistance funds, the UPU has increasingly supplemented these from its own resources to meet the increasing demand for assistance from its members. Moreover, a considerable amount of aid is given directly by developed countries within the framework of their own bilateral technical assistance arrangements.

Many developing countries are not able to provide even the minimum scale of postal facilities. To underline the pressing need for improvement and to provide a yardstick for future progress, the UPU has adopted, for the Second and Third United Nations Development Decades, certain key planning objectives, covering management, quality of service, promotion of its financial services, and improved public information. These are to be carried out to favour, in particular, the least developed countries.

UPU
planning
objectives

THE INTERNATIONAL SYSTEM

International mail is a key means of furthering economic, social, and cultural links between nations. The international postal system is in itself an outstanding example of worldwide organization and mutual trust. A postal administration relies completely upon the postal authorities of other countries to play their parts in ensuring that its foreign mails reach their destination.

International cooperation in this field has been greatly facilitated by the Universal Postal Union since 1875. It has built a comprehensive international organization, with a membership composed of numerous sovereign states and several dependent territories. The postal administrations that are not represented generally follow the rules of the UPU.

These fundamental rules of the international postal service are to be found in the Universal Postal Convention and General Regulations and have been little changed since adoption of the Bern Treaty. The first basic principle is that all member countries form "a single postal territory for the reciprocal exchange of correspondence." From it is derived the principle of freedom of transit: every member country guaranteeing to respect the inviolability of transit mails and to forward them by the most rapid transport used for its own mails.

Another important principle is that the charges for letter-post items are not shared. Since 1875 each country has retained the postage it collects on international mail. Although intermediate countries are paid for transit service, the country in which the mail is delivered receives no payment. This principle was adopted in order to minimize the need for complex international accounts and was justified on the supposition that a letter normally generates a reply. Certain developing countries, however, have found themselves at a considerable disadvantage under this rule,

Provisions
of the
Universal
Postal
Conven-
tion

due to an excessive imbalance between incoming and outgoing mail. To remedy this, the 1969 Congress of Tokyo provided for compensatory payments in such cases.

As a further measure of simplification, the convention prescribes international postal charges, as well as agreed tolerances, and specifies weight steps, limits of size, and conditions of acceptance for letter-post items. Disputes between postal administrations, which usually concern allocation of liability for the loss of registered or insured items, are to be settled by arbitration. The convention is completed by two other basic documents: the Final Protocol, which allows member countries to register certain general and specific reservations to the provisions of the convention; and the Detailed Regulations for implementing the convention. Apart from these obligatory documents, there are a number of optional agreements concerning services, such as parcel post and cash on delivery. The provision of a registration service is compulsory under the convention.

Mention should also be made of the constitutive acts of the union that prescribe its general aims, its organization, its financial structure, and the rules of membership, namely, the constitution and its general regulations.

This comprehensive framework of international regulations is regularly revised to take account of changing circumstances and technical advances. This is the chief function of the union's quinquennial congress. Between congresses, the continuity of the union's work is ensured by its elected Executive Council and its permanent office in Bern, the International Bureau. The bureau acts as a clearinghouse for the settlement of international accounts and for the exchange of information between members, especially notifications of important operational and organizational changes. Problems arising in the technical, operational, and economic fields are studied by another permanent organ, the Consultative Council for Postal Studies (CCPS). Regular contact is also maintained with other international bodies, such as the International Telecommunications Union and the International Standards Organisation.

The UPU Constitution authorizes member countries to establish restricted unions, a provision that enables regional groups such as the Arab, African, and Asian-Pacific postal unions to conclude agreements aimed at improving postal services between their members by such means as reduced rates of postage or the elimination of transit fees. These agreements are more easily achieved on a limited regional basis than on a worldwide scale, and the restricted unions have a valuable role in the task of the UPU, which is, basically, to improve international postal service by simplifying its organization and reducing its cost.

POSTAL TECHNOLOGY

Technological progress in postal transport. Postal administrations have been among the first to utilize new forms of transport. They have often applied considerable technical skill in maximizing the benefits to be derived from progress in this field, particularly in originating the traveling post-office concept and apparatus enabling express trains to pick up and discharge mails without slowing. They have also developed their own transport systems to combat traffic congestion in certain busy cities, such as the pneumatic tubes of Paris, New York, and other cities and the automatic underground railway, opened in 1927, that links London's chief mail centres to railway terminals.

The advent of aerospace and telecommunications technology in the mid-20th century gave rise to research aimed at adapting this technology to postal systems. Experiments have been conducted using ballistic missiles to transport mail, but this remains a novelty because of costs and the problems of reusability and accuracy. Advances in computer and message transmission technologies are, however, being utilized by postal administrations.

Since 1980 public facsimile services have been available in a number of advanced postal administrations in various parts of the world. The United States, Great Britain, France, and Sweden were among the first countries to introduce tele-impression services, whereby bulk correspondence in electronic form is transmitted to regional postal printing centres for enveloping and delivery.

Experi-
ments with
missilery

Automation of mail handling. Since the 1950s there has been a marked intensification of research and development efforts to apply technology to the handling of mails, especially in countries faced by manpower problems and higher labour costs. The wide variety of projects undertaken in many countries and the progress made have been summarized in CCPS studies.

Actual implementation has generally been slower than expected. There have been good reasons for this. Primarily, most postal administrations, being government agencies, are subject to strict control of their capital investment programs. Second, mail traffic patterns—with marked peaks of work—make economic utilization of machines difficult: the introduction of measures to counteract this problem takes considerable time. Similarly, the introduction of postal address codes and the standardization of sizes of envelopes and cards, which are prerequisites for mechanical handling, are relatively slow because of difficulties inherent in the change of procedures.

Materials-handling equipment. Postal systems continue to rely heavily on human labour for bulk materials handling and distribution, both at loading bays and between work processes within sorting centres. New mail centres, however, are normally built in the style of factories and include all appropriate materials-handling equipment.

Equipment used for loading and unloading sacks of mail, rigid containers, and loose parcels includes mobile belt conveyors, roller conveyors, forklift trucks, mobile and fixed cranes, and table lifts. Handling equipment within buildings includes chain conveyors; horizontal and rising belt conveyors of all types, for the transport of loose letters, packets, and trays of letters (notably used for continuous clearance of public posting boxes); tow conveyors, which allow wheeled containers to be hooked onto a fixed-path underfloor traction system; bucket or pan elevators; and chutes and other gravity devices.

The use of a wide range of equipment is necessitated by the varied handling characteristics of different types of mail at particular stages. Buffer-storage facilities, in the form of ramps, hoppers, and moving belts, have to be incorporated to compensate for normal postal traffic fluctuations. The smooth distribution of traffic through the system is often monitored by closed-circuit television, which allows effective centralized control. Automatic regulation and recording, using a variety of sensing and counting devices linked to a computer, are the ideal. Modern systems-engineering techniques are thus able to ensure a carefully planned continuous mechanized mail flow with maximum productivity benefits.

Buffer-
storage
facilities

Segregating machines. Mail collected from branch post offices and street mailboxes, although for the most part made up of ordinary letters and cards, also contains small parcels, newspapers, magazines, and large envelopes. These items, because of their size or shape, cannot be handled on machinery designed for the normal-sized letter and have to be segregated from the majority of standard "machinable" letters. Owing to its varied characteristics, most packet mail has to be manually stamped and sorted, although its movement between work processes may be fully mechanized. So-called packet sorting machines are, in fact, essentially conveyor systems for distributing manually sorted mail.

A commonly adopted type of segregator consists of a laterally inclined rotating drum, into the upper end of which a regulated flow of "mixed" mail is fed from a storage conveyor. Letters within a thickness standard, but of excessive length or breadth, are picked out by various simple mechanical devices installed on the conveyor belt that eventually delivers machinable letters to the storage stacks of the facer-canceler equipment.

Facing and canceling equipment. Facing is the process of aligning letters so that all will have the address side facing the canceler, with stamps in a uniform position. The process is normally combined with a separation of the mail into at least two streams, letter and printed-paper rate or first- and second-class, to allow priority handling for one of the streams.

Facer-canceler machines perform these processes by passing letters through sensing or stamp-detecting units,

which identify the presence or absence of a stamp on the side of the envelope facing them, and, when present, its position. Sensing units are also designed to separate mail in the priority class from nonpriority mail by identifying the stamp or commonly used combination of stamps representing the basic postage rate and manipulating selector gates accordingly. This identification is usually achieved by printing distinctive indexes on the stamps in normally invisible, phosphorescent or luminescent inks that are sensitive to ultraviolet radiation emitted by the sensing unit.

Coding and sorting machines. For manual sorting of letters, each operator normally uses a device with between 40 and 50 pigeonholes. This has been found by most administrations to be the optimum arrangement in view of the limited arm span and "memory" of the sorter. The development of various types of postal codes was aimed at making the sorting of a coded letter a mechanical process for the operator by dispensing with the need to memorize a sorting plan. To be totally effective these schemes need complete public cooperation, a requirement that has been difficult to achieve.

Postal administrations have responded to this dilemma by concentrating research on using an operator only to impress the postal code on each letter, employing phosphorescent or magnetic ink patterns that can be read by a sensing unit attached to a sorting machine. After the code has been impressed, the letter can be sorted at any subsequent stage by high-speed automatic machines, which are no longer utilized at the pace of a single operator and indeed can take the output of several operators. Furthermore, any second sortation required—even at an intermediate office or where the code includes the necessary information to letter carriers' routes at the delivery office—does not need further manual operations. Another potential advantage of this method is that letters may be directly encoded by the mail-processing machines used by large-volume mailers.

Optical character recognition. The ultimate aim in automated sorting has been to perfect a machine that can read some or all elements of the address on letters. Research in this field has been conducted in most of the industrial nations with sophisticated postal services. The immediate aims of these national research programs vary insofar as the type of character to be recognized is concerned: printed, typewritten, or addressing-machine characters; stylized handwritten scripts; and even ordinary handwriting. Some administrations require the machine to read a purely numeric code, others an alphanumeric code, and others the names of towns or regions. Several different techniques are used for the basic task of pattern matching in identifying the characters. For example, the observed character as a whole may be compared with matrices registered in the memory of the machine. Or the different traits of the character observed—vertical or horizontal strokes, curves, etc.—may be analyzed and their combination successively compared with a series of models registered by the computer.

An optical character reader (OCR) can be designed to either directly sort mail or mark it with a machine-readable code so that sorting at subsequent stages can be carried out by high-speed automatic machines. In 1965 the U.S. Postal Service began experimenting with an alphanumeric OCR. By the early 1980s the service had developed a machine capable of scanning up to three lines of an address, verifying the postal code, and imprinting the letter with a routing code.

Research in the United States subsequently has concentrated on various systems that print a machine-readable bar code to allow for high-speed automatic processing to individual carrier routes or blocks of addresses within carrier routes. In 1983 the U.S. Postal Service began deploying OCR's with this capability to major post offices throughout the country. The postal service regards this application of automation, combined with the use of ZIP+4

(a nine-digit postal code) by business mailers, as a major means of keeping postal costs under control as mail volumes expand.

Numerical speech translator. Another line of research being pursued in the United States is the development of equipment that translates five- and nine-digit ZIP codes and sorting-code numbers spoken by an operator into instructions for a sorting machine. Since this system obviates the need for a keyboard, it leaves the operator's hands free, making it particularly valuable in the operation of parcel- and sack-sorting machines. It also eliminates the need for keyboard training of operators. The testing of the equipment includes determination of the effects of regional speech variations, background noise, and operator speech fatigue.

BIBLIOGRAPHY. Postal services are treated in official publications, such as legislative texts, manuals, working instructions, postal guides, annual reports, and commission reports; much of this material is available to the public. Many postal administrations publish periodical reviews or bulletins informing employees and users of recent events and trends. ROWLAND HILL, *Post Office Reform: Its Importance and Practicability*, 4th ed. (1838), is a work by an expert whose reforms affected subsequent worldwide postal development; ROWLAND HILL and GEORGE BIRKBECK HILL, *The Life of Sir Rowland Hill and the History of Penny Postage*, 2 vol. (1880), provides a fuller account of Sir Rowland's innovations. Detailed studies of specific postal service aspects are A.D. SMITH, *The Development of Rates of Postage* (1917); A.D. LITTLE, *The Market for Postal Services* (1968); and MICHAEL E. CORBY, *The Postal Business 1969-79: A Study in Public Sector Management* (1979). International mail services are treated in GEORGE A. CODDING, JR., *The Universal Postal Union* (1964); and L. ZILLIACUS, *Mail for the World: From the Carrier to the Universal Postal Union* (1953), a popular treatment; both F. STAFF, *Transatlantic Mail* (1956, reissued 1980); and HOWARD ROBINSON, *Carrying British Mails Overseas* (1964), provide detailed treatment of the expansion of international mail conveyance.

General and historical literature includes HANS RACKOW (ed.), *Handwörterbuch des Postwesens*, 2nd ed. (1953), a small but comprehensive encyclopaedia; HMSO, *The Post Office: An Historical Summary* (1911); IVIE G.J. HAMILTON, *An Outline of Postal History and Practice with a History of the Post Office of India* (1910); HOWARD ROBINSON, *The British Post Office* (1948, reissued 1970); and D. NORONA (ed.), *Cyclopedia of United States Postmarks and Postal History* (1933-35, reprinted 1975). Studies concerning the United States include PRESIDENT'S COMMISSION ON POSTAL ORGANIZATION, *Towards Postal Excellence*, 5 vol. (1968), also known as the Kappel Commission Report; CARL H. SCHEELE, *A Short History of the Mail Service* (1970); G. CULLINAN, *The Post Office Department* (1968); ROBERT J. MYERS, *The Coming Collapse of the Post Office* (1975); ALAN L. SORKIN, *The Economics of the Postal System: Alternatives and Reform* (1980); RICHARD J. MARGOLIS, *At the Crossroads: An Inquiry into Rural Post Offices and the Communities They Serve* (1980); JOHN T. TIERNEY, *Postal Reorganization: Managing the Public's Business* (1981); and *Evaluation of The United States Postal Service* (1982), a report by a panel of the National Academy of Public Administration. Somewhat dated but still useful are WILLIAM SMITH, *The History of the Post Office in British North America, 1639-1870* (1920, reprinted 1973); and WAYNE E. FULLER, R.F.D., *The Changing Face of Rural America* (1964, reprinted 1966). The postal history of France is extensively described in EUGÈNE VAILLÉ, *Histoire générale des postes françaises*, 6 vol. (1947-53), and *Histoire des postes françaises*, 2 vol. (1946-47). Postal services in developing countries are treated in UNION POSTALE UNIVERSELLE, *Memorandum on the Role of the Post as a Factor in Economic and Social Development* (1969).

The origins, development, and procedures of the Universal Postal Union are treated in GEORGE A. CODDING, JR., *The Universal Postal Union* (1964); see also the bimonthly review *Union Postale*, which is devoted to a wide range of questions concerning the UPU and various general aspects of postal activities; and "Collection of Postal Studies," a series by the UPU's CONSULTATIVE COUNCIL FOR POSTAL STUDIES, comprising more than 150 reports on postal service modernization, mechanization, economics, transport, and working methods, available in French with much of the material also available in English.

Prague

One of the finest cities of Europe, Prague (Czech: Praha), the capital of Czechoslovakia and that nation's major economic and cultural centre, lies at the heart of the Continent. The city has a rich architectural heritage that reflects both the uncertain currents of history in Bohemia and an urban life extending back more than 1,000 years. The physical attractions and landmarks of the city are many. Among the finest is the Charles Bridge (Karlův most), which stands astride the Vltava River. The winding course of the Vltava, with its succession of bridges and changing vistas, contrasts with the ever-present backdrop of the great castle of Hradčany (Prague Castle), which dominates the left-bank region of the city from behind massive walls set high on a hill. The narrow streets and little taverns and restaurants of the older quarters contrast with the broad sweep of Wenceslas Square and modern parks and housing developments, while the great 18th-century Baroque palaces have their own elegance and splendour. Seen from the surrounding hills, the many church towers make up a unique perspective, giving

Prague its description as the "city of a hundred spires." This architectural harmony has been enhanced by post-1945 planning, which has preserved the ancient core of the city as a major monument and has carefully supervised all modern building.

Prague is famous for its cultural life. Wolfgang Amadeus Mozart lived there, and his *Prague Symphony* and *Don Giovanni* were first performed in the city. In addition, the lyric music of the great Czech composers Bedřich Smetana, Antonín Dvořák, and Leoš Janáček is commemorated each year in a spring music festival. The U kalicha ("At the Chalice") beer parlour, which is still popular with local residents and tourists alike, provided the setting for the humorously anti-authoritarian activities of Schweik, immortalized by the novelist Jaroslav Hašek in *The Good Soldier Schweik*. The writings of Franz Kafka, dwelling in a different way on the dilemmas and predicaments of modern life, also seem indissolubly linked with life in this city.

Physical and human geography

THE LANDSCAPE

From its original small riverside settlements Prague has spread over its hills, up river valleys, and along riverside terraces. The Prague metropolitan area covers 192 square miles (496 square kilometres).

The city's core, with its historic buildings, bridges, and museums, is a major centre of employment and traffic congestion. Around the core is a mixed zone of industrial and residential areas, containing about half the city's population and nearly half its jobs. Surrounding this area is the outer city development zone and beyond this yet another zone of development containing new industrial areas, parks and recreation areas, and sports facilities. Finally, there is a belt of agricultural land and open countryside, where state farms and market gardening projects satisfy Prague's demand for food.

The lowest point in the city is 623 feet (190 metres) above sea level and the highest is 1,247 feet, on White Mountain (Bílá hora). The climate of Prague is typically mid-continental, with a July average temperature of 67° F (19.3° C), while that of January averages 31° F (−0.6° C).

THE PEOPLE

Prague has a homogeneous population. There is a small Slovak community, but the overwhelming majority of residents are Czechs. The city has a number of demographic peculiarities stemming mainly from the effects of World War II; there are more women than men, and a sizable proportion of the female population is past the age of fertility. The natural rate of population increase is very small. A tendency toward small families is a reflection of both difficulties in housing and increased participation by both parents in the work force. Migration into the city has continued.

THE ECONOMY

Industry and employment. Though Prague is renowned for its cultural life and monuments, it has also played an important role in the economic life of Czechoslovakia since the early and intensive development in the 19th century of such industries as those producing textiles and machinery. Industry is the largest employer, followed by commerce, construction, education, culture, administration, and transport and communications. Nearly half the labour force is female; the proportion of women in manufacturing is almost one-half, but in education and culture, in trade, and in the health field, it is considerably higher.

In manufacturing, the production of machinery occupies the majority of workers, followed, in about equal numbers, by the production of food, electronics, and chemicals. A large portion of the city's manufactured products are consumer goods.

As part of a decentralization plan for the city's growth, since the 1950s industrial districts and warehouses have been located or relocated on the outskirts of Prague. The aim is to provide increased job opportunities in the vicinity of new residential areas, thereby reducing the pressure on the city's central core.

Transportation. Much of the inner-city transportation is handled by bus, tram, and subway (metro) systems, which are inexpensive and subsidized. Despite the efforts to meet the demands of the growing population with an adequate public transportation system, the number of passenger cars and commercial vehicles has increased, resulting in plans for a major urban motorway system to include 10 radial arteries connecting Prague with the national road network.

Prague is one of the nation's major railway junctions, with three main stations and three freight transport circuits. The international airport at nearby Ruzyně was expanded and modernized in the 1960s to serve as a hub at the centre of the Continent. A new port has been built

Women in the labour force

Statue of Jan Hus in the Old Town Square.

at the confluence of the Vltava and Berounka rivers. The passenger boats that ply the Vltava during the summer are a popular tourist attraction.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Prague is one of two cities (the other is Bratislava) that have equal rank with the 10 regions that constitute the Czechoslovak federation. The city is the administrative centre for the Central Bohemian Region, of which the conurbation occupies about one-third. The Prague Municipal National Committee and the Central Bohemian Regional National Committee coordinate town planning, environmental control, and other projects. Prague is divided into districts, each with its own district national committee, while the settlements included in Prague since the late 1940s have retained their own local national committees.

Public services. The standard municipal services—the supply of natural gas, electricity, and water and the treatment and disposal of sewage and refuse—were consolidated under state control after World War II and have been considerably modernized and expanded as part of overall urban planning. The high percentage of employed women has caused municipal authorities to turn attention toward the provision of nurseries for the children of working mothers. Other facilities include swimming pools, often run in conjunction with sports organizations. On the river the city provides mooring positions for pleasure boats.

Like cities in other eastern European countries, Prague has difficulties with the supply and maintenance of housing. Much of the housing in the inner city consists of small apartments in need of renovation and modernization, while the rate of construction of apartments in the newer zones lags behind the need. Privately owned houses constitute less than 15 percent of all Prague's housing units. In

response to the problem, new housing developments have been built in the peripheral areas. Referred to as "towns," they include North Town (Severní město), South Town (Jižní město), and Southwest Town (Jihozápadní město).

During the Communist era, all retail establishments—food and department stores and self-service establishments—were publicly owned and were part of the municipal system. There are numerous small restaurants and taverns, many of which—especially in the Malá Strana (Lesser Quarter)—have an intimate and historic atmosphere and offer fine views over the city and the river.

Education. There are several institutions of higher education in Prague, but by far the most famous is Charles University, founded in 1348 and the oldest in central Europe. The Academy of Arts and the Academy of Music (with a conservatory founded in 1811) are also important. The activity of the Czechoslovak Academy of Sciences, founded in 1952, is supplemented by many specialized institutions; the academy sponsors a number of international congresses. Higher education in the city benefits from a tradition that can count among its scholars and teachers the great 17th-century astronomers Tycho Brahe and Johannes Kepler and the noted modern physicist Albert Einstein, who taught in Prague in 1911–12.

Health. As the capital city, Prague contains some of the country's main health facilities. These include hospitals, specialized medical clinics, and outpatient clinics. The most noted facilities are those that specialize in plastic surgery, orthopedics, and urology.

CULTURAL LIFE

Prague has a renowned and active musical life, which reaches a high point each year in the internationally known spring music festival. The city's fine orchestras—the Prague Symphony and the Czech Philharmonic—have

Housing
shortage

Architecture

won reputations abroad. Theatrical traditions are also strong, with more than 20 well-attended theatres in the city. There are also many museums and galleries, and a Palace of Culture was completed in 1981.

Perhaps the greatest treasures of the city, however, are the 2,000 officially recognized architectural and artistic monuments, ranging in period from the Romanesque through the Gothic to the Baroque, Rococo, Classical, and Neoclassical. The interiors of the buildings, which often house major art collections, have been restored since 1945. The most notable Romanesque monument is probably the 10th-century Church of St. George, behind the north wall of Hradčany. To the west is its more massive successor, the basically Gothic St. Vitus' Cathedral, the twin spires of which dominate the city skyline. Other Gothic monuments include the Týn Church on Staroměstské Square; the elegant Powder Tower, marking the former city walls in what is now the busy Příkopy shopping area; the restored Bethlehem Chapel, where Jan Hus preached in the 15th century; and the St. Agnes Convent, built in 1234 and notable for its collection of 14th-century paintings. The Old-New Synagogue and the tumbling, crowded gravestones of the Old Jewish Cemetery—Europe's oldest—betoken the strong Jewish tradition in Prague life.

Baroque buildings are the city's greatest single artistic treasure, among them the splendid Valdštejn and Clam-Gallas palaces, St. Nicholas Church, and the Antonín Dvořák Museum. The geometric tiling of the Golz-Kinský Palace facade provides a distinctive glimpse of the Rococo style. Classical buildings include the Bedřich Smetana Museum on the riverside and the elegant Belvedere Palace (the former Royal Summer Palace). The National Museum and the National Theatre are the main Neoclassical buildings.

The beauty of the city is enhanced by its many parks and gardens, including a major cultural, entertainment, and sports centre in the park named for Julius Fučík (a resistance leader of World War II) and a large zoo in suburban Troja. Recreational facilities also include the vast Strahov sports complex—containing three stadiums, the largest of which, Spartakiáda Stadium, holds 250,000 spectators and is used for the mass gymnastic display known as the Spartakiáda—as well as numerous other sports and cultural centres, with emphasis on facilities for youth. The film studios at Barrandov, on the city outskirts, have produced

a number of high-quality motion pictures, and there is a museum of modern sculpture at Zbraslav.

History

THE EARLY PERIOD

The foundation of the city. For thousands of years that portion of the Vltava's course where Prague was to rise was crossed by trade routes linking northern and southern Europe. The region is replete with Paleolithic relics, and Neolithic farmers inhabited the region from around 5000 to 2700 BC. Celts had settlements in the region from about 500 to 200 BC, including the fortified Závist, to the south of Prague. From the 4th to the 6th century AD, Slavs appeared on the Vltava banks, followed by the Avars.

The first settlement at what is now Prague has been traced to the second half of the 9th century. The oldest building was Vyšehrad (*hrad*, "castle"), set on a commanding right-bank hill. It was followed by what was to become Hradčany, set on an equally commanding left-bank site a little downstream. Legend (stirring told in Smetana's opera *Libuše*) ascribes the foundation of Prague to a Princess Libuše and her husband, Přemysl, founder of the Přemyslid dynasty; legend notwithstanding, the Přemyslids, in power from about 800 to 1306, consolidated a political base centred on Prague that was to be the nucleus of the Bohemian state and that enabled the natural trade advantages of the city site to develop under defensive protection. The dynasty included St. Wenceslas (Václav), who was murdered by his brother Boleslav in about 939 and whose statue now looks down upon the square to which his name has been given; and Boleslav I, whose reign (c. 936–967) witnessed the consolidation of power against a German threat. The little community flourished, and in 965 the Jewish merchant and traveler Ibrāhīm ibn Ya'qūb was able to describe it as a "busy trading centre." In 973 the bishopric of Prague was founded.

Medieval growth. The economic expansion of the community was reflected in the topography of the city. A market centre on the right bank, opposite Hradčany, developed into the Old Town (Staré město), particularly after the construction of the first stone bridge, the Judith Bridge, over the river in 1170. By 1230 the Old Town had been given borough status and was defended by a system of walls and fortifications. On the opposite bank, under the

The role of Charles IV in planning the city

walls of Hradčany, the community known as Malá Strana (literally, "Small Side") was founded in 1257. Following the eclipse of the Přemyslids, the House of Luxembourg came to power when John of Luxembourg, son of the future emperor Henry VII, became king of Bohemia. His son, Charles IV, Bohemian king and Holy Roman emperor, had his capital at Prague from 1346 to 1378 and took considerable personal interest in the development of the city. In 1348 he founded Charles University, the first in central Europe, which was later to attract scholars and students from throughout the Continent. His reign also saw the growth of the planned New Town (Nové město) adjacent to the Old Town; construction of the Charles Bridge (1357, reconstructed in 1970) linking the Old Town and the Malá Strana; and the beginning (1344) of the great St. Vitus' Cathedral, which was not completed until 1929. Other buildings included the Carolinum (the central hall of the university), the town hall (destroyed in 1945), and several churches and monasteries in the New Town. The Jewish ghetto was also developed, and the bishopric was raised to an archbishopric in 1344.

By the 14th century Prague had become a major central European city, with the Czech money minted at nearby Kutná Hora serving as the hard currency of the entire region. Foreign merchants, notably Germans and Italians, became economically and politically powerful in uneasy alliance with the kings. The social order, however, became less stable because of the emergent guilds of craftsmen, themselves often torn by internal conflicts. The town paupers added a further volatile element.

The Reformation and the Thirty Years' War. Prague played a significant role in the Reformation. The sermons of Jan Hus, a scholar at the university, begun in 1402 at the now-restored Bethlehem Chapel and carrying forward the criticisms of the church developed by the English reformer John Wycliffe, endeared him to the common people but brought him into conflict with Rome; he was burned at the stake in the town of Constance (Konstanz, W.Ger.) in 1415. Popular uprisings in 1419, led by the Prague priest Jan Želivský, included the throwing of city councillors from the windows of the New Town Hall in the incident known as the first Defenestration of Prague. The next year Hussite peasant rebels, led by the great military leader Jan Žižka, joined forces with the Hussites of Prague to win a decisive victory over the Roman Catholic king (later emperor) Sigismund at nearby Vitkov Hill.

During the next 200 years, the wealthy merchants became ascendant once more, and the late Gothic architectural style flourished in many churches and buildings, reaching a peak in the fine Vladislav Hall of Hradčany. In 1526, however, the Roman Catholic Habsburgs became rulers of Bohemia and attempted to crush Czech Protestantism. The second Defenestration of Prague (1618), when the governors of Bohemia were thrown from the windows of the council room in Hradčany—one of the major events precipitating the Thirty Years' War—was followed by the decisive defeat of Protestant forces at the Battle of the White Mountain, near the city, in 1620. Twenty-seven Prague commoners and Czech noblemen were executed on the Staroměstské Square in 1621; the city ceased to be the capital of the empire, was occupied by Saxons (1631) and Swedes (1648), and went into a decline hastened by two outbreaks of plague.

EVOLUTION OF THE MODERN CITY

The return of more settled conditions in central Europe was marked by renewed economic growth, and Prague's population grew from 40,000 in 1705 to more than 80,000 by 1771. In 1784 the Old Town, the New Town, the Malá Strana, and the Hradčany complex were administratively united into one city. The merchants and the mostly German, Spanish, and Italian nobility who were active in and around Prague in this period had an enormous effect on both architecture and cultural life. Outstanding architects created magnificent palaces and gardens, and churches in the Prague version of the Baroque style sprang up throughout the city.

The onset of the Industrial Revolution had major effects in Prague. The first suburb (Karlín) was established in

1817, and in the next 20 years many factories sprang up, often in association with the coal mines and ironworks at Kladno and Králův Dvůr, not far away. The population exceeded 100,000 by 1837, and expansion continued after the city received its first railway eight years later. The rise of a working class and of strong nationalistic sentiments had a profound effect on the city; students, artisans, and workers took to the barricades against the ruling Austrians when revolution flared briefly in 1848. Within 20 years Czechs had won a majority on the City Council, and Czech cultural life was experiencing a renaissance centred on Prague. The Neoclassical building of the National Museum and the National Theatre are only two examples of the building that took place in this period. By the 1890s the first electric streetcars (trams) were running in the city, urban services were being reorganized, and a replica of the Eiffel Tower overlooked the city from Petřín Hill.

In 1918 Prague became the capital of the newly independent Czechoslovak republic, and a Greater Prague of 19 districts had been established within two years. By 1930 the population had reached 850,000. The city suffered a severe setback following the surrender of large parts of Bohemia and Moravia to Germany under the Munich Agreement of 1938. The citizens rose in revolt on May 5, 1945, and held the city until the Red Army arrived four days later. The post-World War II period was marked by economic reconstruction and by careful planning with a view to restoring and preserving the historic monuments of the city centre. From the 1970s there was an increasing emphasis on the development of new satellite communities and of a regional plan for the entire Prague conurbation. The city continued to grow, although most of its population growth was attributable to annexation. The so-called Prague Spring of 1968, a short-lived excursion into liberalized social and governmental controls attempted by the government of Alexander Dubček, was terminated by Soviet military action in August of that year.

In November 1989, Prague's Wenceslas Square became the cradle of the movement that swiftly ended four decades of Communist rule in Czechoslovakia. An officially sanctioned march in the city, commemorating the death of a student at the hands of Nazis in 1939, resulted in police violence and public disorder. Indignation at the current regime kindled further unrest, and in the second half of November students, young intellectuals, and later older people, totaling some half a million, demonstrated in the streets of the capital. Subsequent pressure led to the resignation of the entire Communist Party leadership and the formation of a coalition government headed by non-Communists.

BIBLIOGRAPHY. GEOFFREY MOORHOUSE, *Prague* (1980), offers information on all aspects of the city. Guidebooks, with information on history, include ALOIS SVOBODA, *Prague* (1965, reissued 1968), in English; EMANUEL POCHE, *The Golden Lane on Prague Castle* (1969; originally published in Czech, 1969), a description of the picturesque street of Hradčany; and FRANTIŠEK KAFKA, *Baedeker's Prague*, trans. from German (1987). Photographic views of the city are presented in JIŘÍ DOLEŽAL and EVŽEN VESELÝ, *Památky staré Prahy* (1966), a survey of historical Prague, with brief commentary; EUGEN VASILIAK, *Nad Prahou: Prague Seen from Above* (1966), a book of aerial photographs of old and new Prague with text in six languages; MIROSLAV KORECKÝ, *Prague in Colour* (1976; originally published in Czech, 1975), which portrays the city's many architectural styles and major landmarks; and BOHUMIL LANDISCH and VÍT PALOCH, *Praha: Praha: Prague* (1982), with annotations in Czech, English, German, and Russian. A study of the city from the perspective of urban sociology is provided by F.W. CARTER, "Prague and Sofia: An Analysis of Their Changing Internal City Structure," ch. 15 in R.A. FRENCH and F.E. IAN HAMILTON (eds.), *The Socialist City: Spatial Structure and Urban Policy* (1979), pp. 425-459. See also JIŘÍ HRŮZA and BLAHOŠ BOROVÍČKA, *Prague: A Socialist City* (1985). F.W. CARTER, "Kafka's Prague," ch. 2 in J.P. STERN (ed.), *The World of Franz Kafka* (1980), pp. 30-43, is an essay on Prague in Kafka's lifetime. Works describing the history of the city include COUNT (FRANZ) LÜTZOW, *The Story of Prague* (1902, reprinted 1971); JOSEF JANÁČEK (ed.), *Dějiny Prahy* (1964), covering the development and history of the city from the earliest times to 1960; JOSEPH WECHSBERG, *Prague: The Mystical City* (1971), essays on Prague's history; and JOSEF JANÁČEK, *Malé dějiny Prahy*, 3rd rev. ed. (1983), on history and architecture. (Ja.K./R.H.O./F.W.C.)

Effects of the Industrial Revolution

The democratic revolution
