The exterior and the interior of the Schwarzschild radius are not cut off from each other entirely, however. Suppose an observer were to attach himself to a particle that is falling freely straight toward the centre and that this observer is equipped with a clock that reads its own proper time. This observer would penetrate the Schwarzschild radius within a finite proper time (see Figure 3); moreover, he would find no abnormalities in his environment as he did so. The reason is that his clock would deviate from one permanently kept outside and at a constant distance from the centre, so grossly that the same event that seen from the outside takes forever occurs within a finite time to the free-falling observer.

From P. Bergmann, *The Riddle of Gravitation*; Charles Scribner's Sons

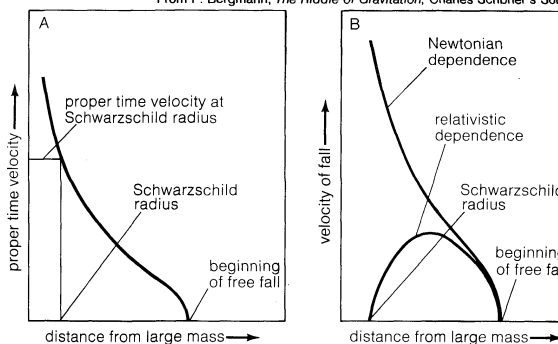

Figure 3: Free fall in a Schwarzschild field (A) seen by an outside observer and (B) in terms of proper time of the falling object.

These peculiarities of the Schwarzschild field may well have practical applications in astronomy. In 1931 the Indian-born U.S. astrophysicist Subrahmanyan Chandrasekhar, and in 1939 the U.S. physicist J. Robert Oppenheimer, established that a star whose mass exceeds the mass of the Sun by an appreciable factor is bound to contract and, eventually, to collapse under the influence of its own gravity, no matter how resistant its constituent matter. As many stars are believed to have such large masses, it is likely that there already exist some collapsed stars, so-called black holes. Though continuing to make its presence known by the gravitational attraction it exerts on other stars, a black hole would not emit light, and thus be invisible, hence its name.

APPLICATIONS OF RELATIVISTIC PRINCIPLES

Particle accelerators. Modern particle accelerators raise particles to speeds very near that of light. At these energies and speeds the differences in behaviour predicted by classical physics and by the special theory of relativity are huge; the machines must be designed in accordance with relativistic principles, or they will not operate.

Electron synchrotrons operate at energies of several thousand million electron volts, which means that the rela-

Operations
of the
synchro-
tron

tivistic mass of an electron orbiting at maximum energy is roughly 10,000 times its rest mass. Accordingly, the magnetic field required to maintain the electrons in orbit is 10,000 times as powerful as it would have to be if non-relativistic physics held, at the same speed. On the other hand, at that given energy the speed of the electrons is in fact very nearly equal to the speed of light, the difference amounting to no more than one part in 100,000,000 (10^8). At the same energy, but by nonrelativistic mechanics, the speed of the electrons would be about 100 times the speed of light. This difference has a very practical consequence: in those particle accelerators designed for highly relativistic energies, the synchrotrons, particles are injected into a circular orbit already near the speed of light, and their velocities change only slightly as their energies are brought up to the highest design value. If the orbit diameter is kept nearly constant, particles at all energies will circulate at the same frequency, and only the magnetic field that keeps them in orbit needs to be increased to keep pace with the increasing mass. The accelerating voltage is applied at the constant frequency required so that the particles will always be accelerated forward.

Relativistic particle physics. The physics of subatomic particles depends on the principles of the special theory of relativity. These principles have their most direct application when particles are created, annihilated, or converted into different particles. In most particle transformations, large amounts of energy are involved; the total (rest) masses of the particles involved in the transformations will change, and this change will be related to the amounts of energy expended or gained by the rule that the change in mass (Δm_0) is balanced by a corresponding change in energy (ΔE), divided by the square of the speed of light (c^2): $\Delta m_0 = -c^{-2}\Delta E$. This rule has been confirmed universally and, by now, is being taken for granted.

The units, or quanta, of electromagnetic energy, called photons, have long been regarded as a species of particle in which are combined the properties of zero rest mass with nonvanishing relativistic mass, because they travel at the speed of light. The relativistic mass equals its total energy E divided by c^2 . The energy of a photon also is equal to the product of its frequency ν and Planck's constant h . The relativistic mass of a photon can be checked experimentally if the photon is absorbed or deflected in its interactions with particles, when the change in its linear momentum (product of velocity and relativistic mass) results in a recoil by the other particles. If a high-frequency photon, a gamma photon, collides with a free electron, the result is called the Compton effect, which involves both an observable recoil on the part of the electron and an altered frequency of the deflected photon. Again, relativity is confirmed by experiment.

It has been conjectured that gravitational waves, also, are composed of zero-rest-mass quanta travelling at the speed of light (gravitons). As the quantum theory of the gravitational field has not been definitely established and as the detection of individual gravitons may remain beyond experimental capabilities for years to come, the existence of gravitons cannot be considered assured.

There is another species of zero-rest-mass particles, produced in radioactive decay involving the ejection of electrons or positrons from atomic nuclei (so-called beta decay). These particles, known as neutrinos, have no electric charge and travel at the speed of light. Several distinct species of neutrinos are now known, each produced in a different kind of beta decay. Neutrinos interact with other particles extremely weakly. As a result, they can traverse large amounts of matter with little chance of being deflected or absorbed. Though their existence has been confirmed beyond a doubt, their detection and detailed examination remain challenging problems.

Relativistic cosmology. Theories concerning the structure and history of the whole universe have assumed an increasingly empirical aspect in the 20th century. Beginning in the 1960s, particularly, a combination of new observation techniques, new discoveries, and applications of special and general relativity has resulted in considerable progress. The most important techniques added to those of observations by means of visible light were radio

astronomy; infrared, ultraviolet, X-ray, and gamma-ray astronomy from extraterrestrial platforms; cosmic-ray investigations; neutrino astronomy; and examination of the Moon and other astronomical bodies by unmanned and manned space exploration.

Edwin Powell Hubble, a U.S. astronomer, had discovered that the more distant astronomical objects exhibited a shift of spectral lines toward the red (long wavelength) end of the spectrum, the extent of the shift increasing the greater their distance from Earth. This cosmological red shift has been generally interpreted as evidence of rapid recession of these distant objects in an expanding universe. The present rate of expansion is expressed as the amount of recession per unit distance and is known as the Hubble constant. It amounts to about a mile per second recession velocity for a distance of 10^5 light-years. Equivalently, if the expansion has been occurring at a constant rate, it must have started about 2×10^{10} years ago.

Quasars, also called quasi-stellar objects (qso's), appear to be structures that combine extreme luminosity (100 times that of a bright galaxy) with great compactness, taking up less space than the distance between the Sun and its nearest neighbour star. Wherever a spectral analysis of a quasar's emitted light has been possible, the spectral lines have been found considerably red shifted. If these red shifts are cosmological (an interpretation now accepted by most astronomers), some quasars are more distant from the Galaxy than any other known objects. As such they may provide indications of the large-scale structure of the universe, which could not be obtained from investigations confined to "close" surroundings. The term close is to be understood in relation to distance in which Hubble's red shift becomes large ("cosmological distances"), distances amounting to thousands of millions of light-years.

Finally, the term primeval fireball refers to the discovery of an all-pervasive background of radiation whose frequencies lie in the border region between microwave radio frequencies and infrared, corresponding to wavelengths of the order of millimetres and centimetres. In the early 1970s this radiation was interpreted as a remnant of the original intensive radiation that must have been associated with the early history of the universe, when matter was both extremely dense and extremely hot; hence its name. Its spectral composition, which has been the object of intensive investigation, might provide some clues to the early history of the universe.

General relativity contributes to a theoretical discussion of cosmology the idea that the universe as a whole need not be flat even on the average and that it probably is not. Even if one were to assume that on a very large (cosmological) scale the universe is homogeneous and isotropic (*i.e.*, having the same properties in all directions), which appears a reasonable working hypothesis in the absence of any evidence to the contrary, there are a number of different possibilities. The universe might be spatially open (as a flat one surely is), or it might be closed, somewhat as the surface of a sphere is closed, without boundaries. Likewise, in the time direction the universe might be either open or closed; it is a little difficult to visualize a time-wise closed universe, which appears to be inconsistent with ordinary notions of cause and effect. But because these notions are distilled out of normal experience, they might be inapplicable on the scale of billions of years. In brief, many different cosmological models have been proposed and investigated theoretically, but observational information does not seem to favour one particular type. The information appears to favour types that expand from an early stage involving fireball conditions.

MODIFICATIONS OF GENERAL RELATIVITY

An outgrowth of a unified field theory of the early 1920s has been the development of a class of theories based on the hypothesis that underlying the four-dimensional space-time of our experience is a manifold having a higher dimensionality, whose geometric structure can accommodate all known force fields, including those associated with stable and unstable subatomic particles. Though these concepts remained highly speculative, they offered much promise and occupied many investigators.

The notion
of the
primeval
fireball

Neutrinos

Apart from the attempts to devise unified field theories, several modifications of general relativity have been proposed during the late 20th century. One of these was presented by the British scientist Fred Hoyle, whose results, together with the proposals of the astronomers Hermann Bondi and Thomas Gold, became the basis of the so-called steady-state cosmological theory. Bondi, Gold, and Hoyle opposed the "big-bang" theory of the origin of the universe, arguing instead that matter is being created continuously at a very low rate, just sufficient to maintain the constant average density of the universe in spite of the observed expansion. Though the steady-state hypothesis evoked much interest for some years, the existence of the cosmic background radiation (established in the 1960s) has been generally accepted as proof that the universe has in fact passed through a highly dense stage.

The Study and Classification of Religions

The history of mankind has shown the pervasive influences of religion, and thus the study of religion, involving the attempt to understand its significance, its origins, and its myriad forms, has become increasingly important in modern times. Broadly speaking, the study of religion comprehends two aspects: assembling information and interpreting systematically the material gathered in order to elicit its meaning. The first aspect involves the psychological and historical study of religious life and must be supplemented by such auxiliary disciplines as archaeology, ethnology, philology, literary history, and other similar disciplines. The facts of religious history and insight into the development of the historical religious communities are the foundation of all else in the study of religion. Beyond the historical basis lies the task of seeing the entirety of human religious experience from a unified or systematic point of view. The student of religions attempts not only to know the variety of beliefs and practices of *homo religiosus* ("religious man"), but also to understand the structure, nature, and dynamics of religious experience. The student of religion attempts to

discover principles that operate throughout religious life—on the analogy of a sociologist seeking the laws of human social behaviour—to find out whether there are also laws that operate in the religious sphere. Only with the attempt to discern the system and structure binding together the differentiated historical richness of religion does a true science of religion, or *Religionswissenschaft*, begin.

The 19th century saw the rise of the study of religion in the modern sense, in which the techniques of historical enquiry, the philological sciences, literary criticism, psychology, anthropology, sociology, and other disciplines were brought to bear on the task of estimating the history, origins, and functions of religion. Rarely, however, has there been unanimity among scholars about the nature of the subject, partly because assumptions about the revealed nature of the Christian (or other) religion or assumptions about the falsity of religion become entangled with questions concerning the historical and other facts of religion. Thus, the subject has, throughout its history, contained elements of controversy.

The descriptive study of essence and content

NATURE AND SIGNIFICANCE

The essence of religion and the context of religious beliefs, practices, and institutions. An acceptable definition of religion itself is difficult to attain. Attempts have been made to find an essential ingredient in all religions (*e.g.*, the numinous, or spiritual, experience; the contrast between the sacred and the profane; belief in gods or in God), so that an "essence" of religion can be described. But objections have been brought against such attempts, either because the rich variety of men's religions makes it possible to find counterexamples or because the element cited as essential is in some religions peripheral. The gods play a very subsidiary role, for example, in most phases of Theravāda ("Way of the Elders") Buddhism. A more promising method would seem to be that of exhibiting aspects of religion that are *typical* of religions, though they may not be universal. The occurrence of the rituals of worship is typical, but there are cases, however, in which such rituals are not central. Thus, one of the tasks of a student of religion is to gather together an inventory of types of religious phenomena.

The fact that there is dispute over the possibility of finding an essence of religion means that there is likewise a problem about speaking of the study of religion or of religions, for it is misleading to think of religion as something that "runs through" religions. This brings to light one of the major questions of method in the study of the subject. In practice, a religion is a particular system, or a set of systems, in which doctrines, myths, rituals, sentiments, institutions, and other similar elements are interconnected.

Thus, in order to understand a given belief that occurs in such a system, it is necessary to look at its particular context—that is, other beliefs held in the system, rituals, and other aspects. Belief in the lordship of Christ in the early Christian Church, for example, has to be seen in the context of a belief in the Creator and of the sacramental life of the community. This systematic character of a religion has been referred to by the 20th-century Dutch theologian Hendrik Kraemer as "totalitarian"; but a better term would be "organic." Thus, there arises the problem of whether or not one belief or practice embedded in an organic system can properly be compared to a similar item in another organic system. To put the matter in another way, every religion has its unique properties, and attempts to make interreligious comparisons may hide these unique aspects. Most students of religion agree, however, that valid comparisons are possible, though they are difficult to make. Indeed, one can see the very uniqueness of a religion through comparison, which includes a contrast. The importance of setting religions side by side is why the study of religions is sometimes referred to as the "comparative study of religion"—though a number of scholars prefer not to use this phrase, partly because some comparative work in the past has incorporated value judgments about other religions.

But even if an inventory of types of belief and practices can be gathered—so as to provide a typical profile of what counts as religion—the absence of a tight definition means that there will always be a number of cases about which it is difficult to decide. Thus, some ideologies, such as Soviet Marxism, Maoism, and Fascism, may have analogies to religion. Certain attempts at an essentialist definition of

Uniqueness and similarities in religions

Attempts to arrive at a definition of religion

religion, such as that of the German-American theologian Paul Tillich (1886–1965), who defined religion in terms of man's ultimate concern, would leave the way open to count these ideologies as proper objects of the study of religion. Tillich, incidentally, calls them "quasi-religions." Though there is no consensus on this point among scholars, it is not unreasonable to hold that the frontier between traditional religions and modern ideologies represents one part of the field to be studied.

Neutrality and subjectivity in the study of religion. Discussion about religion has been complicated further by the attempt of some Christian theologians, notably Karl Barth (1886–1968), to draw a distinction between the Gospel (the proclamation peculiar to Christianity) and religion. This distinction depends, to some extent, upon taking a projectionist view of religion as a human product. This tradition goes back in modern times to the seminal work of the German philosopher Ludwig Feuerbach (1804–72), who proposed that God was the extension of human aspirations, and is found in the work of Karl Marx, Sigmund Freud, and others. The distinction attempts to draw a line between the transcendent, as it reveals itself to men, and religion, as a human product involved in the response to revelation. The difficulty of the distinction consists chiefly in a denial that God (*e.g.*, Yahweh or Christ) as the object of man's response is a "religious" being (*i.e.*, God is transcendent, not "religious" in the sense of being a part of the human product), and thus the question about revelation as a religious fact needs to be answered. This account of religion, however, incorporates a theory about it, which is characteristic of a number of definitions of religion and creates a difficulty in that the field—namely, the study of religion—is being defined in terms of a theory within it.

Subjectivity in the study of religion. There are, however, doubts about how far there can be neutrality and objectivity in the study of religion. Is it possible indeed to understand a faith without holding it? If it is not possible, then cross-religious comparisons would mostly break down, for normally it is not possible to be inside more than one religion. But it is necessary to be clear about what objectivity and subjectivity in religion means. Religion can be said to be subjective in at least two senses. First, the practice of religion involves inner experiences and sentiments, such as feelings of God guiding the life of the devotee. Here religion involves subjectivity in the sense of individual experience. Religion may also be thought to be subjective because the criteria by which its truth is decided are obscure and hard to come by, so that there is no obvious "objective" test in the way in which there is for a large range of empirical claims in the physical world. As to the first sense, one of the challenges to the student of religion is the problem of evoking its inner, individual side, which is not observable in any straightforward way. In considering a religion, however, the scholar is not only concerned with individual responses but also with communal ones. In any case, very often he is confronted only with texts describing beliefs and stories, so that he needs to infer the inner sentiments that these both evoke and express. The adherent of a faith is no doubt authoritative as to his own experience, but he is not necessarily so in regard to the communal significance of the rites and institutions in which he participates. Thus, the matter of coming to understand the inner side of a religion involves a dialectic between participant observation and dialogical (interpersonal) relationship with the adherents of the other faith. Consequently, the study of religion has strong similarities to, and indeed overlaps with, anthropology. General agreement upon scholarly methods, however, does not exist, partly because different scholars have come to the study of religion from different disciplines and points of view—such as history, theology, philosophy of religion, and sociology.

The other sense of the subjectivity of religion is properly a matter for philosophy of religion and theology (Christian and otherwise). The study of religion can roughly be divided between descriptive and historical inquiries, on the one hand, and normative inquiries, on the other. The latter primarily concern the truth of religious claims, the acceptability of religious values, and other such normative

aspects; the former, only indirectly involved with the normative elements of religion, are primarily concerned with its history, structure, and similar descriptive elements. The distinction, however, is not an absolute one, for, as has been noted, descriptions of religion may sometimes incorporate theories about religion that imply something about the truth or other normative aspects of some or all religions. Conversely, theological claims may imply something about the history of a religion. The dominant sense in which one speaks nowadays of the study of religion is the descriptive sense.

Neutrality in the study of religion. The attempt to be descriptive about religious beliefs and practices, without judging them to be valuable or otherwise, is often considered to involve *epochē*—that is, the suspension of belief and the "bracketing" of the phenomena under investigation. The idea of *epochē* is borrowed from the philosophy of the German thinker Edmund Husserl (1859–1938), the father of Phenomenology, and the procedure is regarded as central to the phenomenology of religion.

In this context the term phenomenology refers first to the attempt to describe religious phenomena in a way that brings out the beliefs and attitudes of the adherents of the religion under investigation, but without either endorsing or rejecting these beliefs and attitudes. Thus, the bracketing means forgetting about one's own beliefs that might endorse or conflict with what is being investigated. Second, phenomenology of religion refers to the attempt to devise a typology of religious phenomena—to classify religious activities, beliefs, and institutions.

To some extent the emphasis on neutral description arises in modern times as a reaction against "committed" accounts of religion, which were for long the norm and still exist where religion is treated from a theological point of view. The Christian theologian, for example, may see a particular historical process as providential or as providing significance for Christian living. This is a legitimate perspective from the standpoint of faith. But the historical process itself has to be investigated in the first instance "scientifically"—that is, by considering the evidence, using the techniques of historical enquiry and other scientific methods. Conflict sometimes arises because the committed point of view is likely to begin from a more conservative stance—*i.e.*, to accept at face value the scriptural accounts of events—whereas the "secular" historian may be more sceptical, especially of records of miraculous events. The study of religion may thus come to have a reflexive effect on religion itself, such as the manner in which modern Christian theology has been profoundly affected by the whole question of the historicity of the New Testament.

The reflexive effect of the study of religion on religion itself may in practice make it more difficult for the student of religion to adopt the detachment implied by bracketing. Scholars generally agree, however, that the pursuit of objectivity is desirable, provided this does not involve sacrificing a sense of the inner aspect of religion. Thus, the stress on the distinction between the descriptive and normative approaches is becoming more frequent among scholars of religion.

The study of religion may thus be characterized as concerned with man's religious behaviour in relation to the transcendent, to God or the gods, and whatever else is regarded as sacred or holy, and as a study that attempts to be faithful both to the outer and inner facts. Its present-day concern is predominantly descriptive and explanatory and hence embraces such various disciplines as history, sociology, anthropology, psychology, and archaeology. Traditionally, however, the study has been more oriented toward truth claims in religion—these being properly the concern of theology and philosophy of religion. Needless to say, there are different sorts of theology, related to the different religious traditions, such as Christian, Muslim, and Buddhist. But insofar as the theologian expresses and articulates a tradition, he belongs to it and thus is part of the subject matter studied by the student of religion.

HISTORY OF THE STUDY OF RELIGION

No single history of the study of religion exists since the major cultural traditions (Europe, the Middle East, India,

Phenom-
enology

Study of
individual
and
communal
responses

Western
orientation
to the
study of
religion

China) have been mutually independent over long periods. The primary impulse that prompts many to study religion, however, happens to be the Western one, especially because other cultural traditions utilized categories other than that denoted in the Western concept of "religion." On the whole, in the ancient world and in the Middle Ages the various approaches to religion grew out of attempts to criticize or defend particular systems and to interpret religion in harmony with changes in knowledge. The same is true of part of the modern period, but increasingly the idea of the nonnormative (descriptive-explanatory) study of religions, and at the same time the attempt to understand the genesis and function of religion, has become established. Viewed thus, the 19th century is the formative period for the modern study of religion. The ensuing accounts here of the history of the subject take it up to the modern period and then consider the various disciplines connected with religion in detail—i.e., in relation to their development since the 19th century.

The Greco-Roman period. *Early attempts to study religion.* One of the earliest attempts to systematize the seemingly conflicting Greek myths and thereby bring order into this rather chaotic Greek tradition was the *Theogony* of the Greek poet Hesiod (flourished c. 800 bc), who rather laboriously put together the genealogies of the gods. His work remains an important source book of ancient myth. The rise of speculative philosophy among the Ionian philosophers (e.g., Thales, Heraclitus, and Anaximander) led to a more critical and, to some extent, rationalistic treatment of the gods. Thus, Thales (6th century bc) and Heraclitus (flourished c. 500 bc) considered water and fire, respectively, to be the first substance, out of which everything else is made, though Aristotle reported mysteriously in the 4th century bc that Thales believed that everything was filled with the gods. Anaximander (6th century bc) called the primary substance the infinite (*apeiron*). In these various schemes of religious belief, there is a unitary something that transcends the many clashing forces in the world, transcending even the gods. Heraclitus refers to the controlling principle as *logos*, or reason, though the philosopher, poet, and religious reformer Xenophanes (6th–5th centuries bc) directly assailed the traditional mythology as immoral, out of his concern to express a monotheistic religion. This theme of criticism of the myths was taken over and elaborated in the 4th century bc by the philosopher Plato. More conservatively, the poet Theagenes (6th century bc) allegorized the gods, treating them as standing for natural and psychological forces. To some extent, this line was pursued in the works of the Greek tragedians and by the philosophers Parmenides and Empedocles (5th century bc). Criticism of the ancient Greek tradition was reinforced by the reports of travellers as Greek culture penetrated widely into various other cultures. The Greek historian Herodotus (5th century bc) attempted to solve the problem of the plurality of cults by identifying foreign deities with Greek deities (e.g., those of the Egyptian Amon with Zeus). This kind of syncretism was widely employed in the merging of Greek and Roman culture in the Roman Empire (e.g., Zeus as the Roman god Jupiter).

Skepticism
in the
study of
religion

The plurality of cults and gods also induced skepticism, as with the Sophist Protagoras (c. 481–411 bc), who was driven from Athens because of his impiety in questioning the existence of the gods. Prodicus of Ceos (5th century bc) gave a rationalistic explanation of the origin of deities that foreshadowed Euhemerism (see below *Later attempts to study religion*), and another Sophist, Critias (5th century bc), considered that religion was invented to frighten men into adhering to morality and justice. Plato was not averse to providing new myths to perform this alleged function—as is seen in his conception of the "noble lie" (i.e., the invention of myths to promote morality and order) in *The Republic*. He was strongly critical, however, of the older poets' (e.g., Homer's) accounts of the gods and substituted a form of belief in a single creator, the Demiurge or supreme craftsman. This line of thought was developed in a stronger way by Aristotle, in his conception of a supreme intelligence that is the unmoved mover. Aristotle combined elements of earlier thinking in his account

of the genesis of the gods (coming from the observation of cosmic order and stellar beauty and from dreams).

Later attempts to study religion. Later Greek thinkers tended to vary between the positions adumbrated in the earlier period. The Stoics (philosophers of nature and morality) opted for a form of naturalistic monotheism, while the philosopher Epicurus (341–270 bc) was skeptical of religion as ordinarily understood and practiced, though he did not deny that there were gods who, however, had no transactions with men. Of considerable influence was Euhemerus (c. 330–c. 260 bc), who gave his name to the doctrine called Euhemerism, namely, that the gods are divinized men. Though Euhemerus' own argument was based largely upon fantasy, there are certainly some examples, both in Greek religion (e.g., the god Heracles) and elsewhere, of the tendency to make men into gods, but it is obviously not universal.

Most of the Greek concepts about religion proved to be influential in the Roman world also. The atheistic Atomism of the Roman natural historian Lucretius (c. 95–55 bc) owed much to Epicurus. The eclectic thinker and politician Cicero (106–43 bc), in his *De natura deorum* ("Concerning the Nature of the Gods"), criticized Stoic, Epicurean, and later Platonic ideas about religion, but the book remains, however, incomplete. Much of the skepticism about the gods in the ancient world was concerned with the older traditional religions, whether of Greece or Rome. But in the early empire, the mystery cults, ranging from the Eleusinian mysteries of Greece to those of the Anatolian Cybele and the Persian Mithra, together with philosophically based religions such as Neoplatonism and Stoicism, had the greatest vitality. The patterns of religious belief were complex and of different levels, with various types of religion existing side by side. Into this situation Christianity was injected, and in its encounter with classical civilization it absorbed a number of the critiques of the gods of the older thinkers. In particular, Euhemerism was fashionable among the Church Fathers (the religious teachers of the early church) as an account of paganism. On the "pagan" side, there were persistent attempts to justify the popular cults and myths by the extensive use of allegory—a technique well adapted to the attempt to synthesize philosophical and popular religion. Christianity's own contribution to theories of the genesis of polytheism was through the doctrine of the fall of man, in which pure monotheism was believed to have become overlaid by demonic cults of the gods. Such an account could help to explain some underlying similarities between the Judeo-Christian tradition and certain aspects of Greco-Roman paganism. In this view there is the germ of an evolutionary account of religion. On the whole, however, the theories of religion in the ancient world were naturalistic and rationalist in emphasis.

The Middle Ages to the Reformation. *Theories of the Middle Ages.* The spread of Christianity into northern Europe and elsewhere beyond the confines of the Roman Empire presented similar problems to those encountered in the pagan world. Similar solutions were offered—e.g., the identification of northern and Roman and Greek gods, sometimes using etymologies owing much to superficial resemblances of names. Thus, the Icelandic historian Snorri Sturluson (1179–1241) made use of this method in his handbook of Icelandic mythology—a work necessitated by the need to pass on the myth-laden Norse poetic lore that had survived the Christianization of the north—by adding to it Euhemeristic elements.

Meanwhile, Islāmic theology had had an impact on Western Christianity, notably upon medieval Scholastic philosophy, in which the values of both reason and revelation were maintained. Muslim knowledge of other religions was in advance of European knowledge, notably in the work of the theologian Ibn Hazm (994–1064). Nevertheless, the reports of some European travellers, such as the Italian Marco Polo (1254?–?1324) and also Odoric of Pordenone (14th century), gave Westerners some knowledge of Asian religions. This opened the way toward a more inductive treatment of the phenomena of other religions, based on factual knowledge. Though most Christian, as well as Islāmic and Jewish, theologians tended to consider

European
contacts
with other
religions

the question of whether or not natural religion gives insight in God's nature—treating religion as a relation to the first cause of the universe—the English philosopher Roger Bacon (c. 1220–c. 1292) preferred to categorize the various manifest types of religion as a preliminary effort to establishing a true theology. Theorists of the medieval period continued to accept the thesis that polytheism had its origin in the Fall of man, but two new theories modified attitudes of Christians to other faiths. First, the theory arose that God adapts customs and rites having a pagan style in order to combat paganism itself—as a concession to the human condition. This theory could be used to explain the divergencies of practice within Christendom and to show points of contact between Christianity and paganism. Second, the doctrine of man's innate capacity to know God by reason enabled thinkers to discern some measure of truth in other religions. The questions raised by such theories were intensified during the Renaissance.

Theories of the Renaissance and Reformation. The Renaissance consisted in the invigoration of European culture through the rediscovery of the Greek and Roman classics, art, and architecture and thus was bound to set up tensions among Christians about paganism. The Italian Humanist Giovanni Boccaccio (1313–75) attempted to resolve these tensions in a medieval way by extensively allegorizing the ancient myths. The Dutch Humanist Erasmus (c. 1466–1536) and others, however, went further in stating that the ancient thinkers had a direct knowledge of the highest truth and sometimes in comparing them favourably with Scholastic theologians. One of the interlocutors in his *Convivium Religiosum* suggests that it would be better to lose the Scholastic theologian Duns Scotus than the ancient Roman thinkers Cicero or Plutarch, while another speaker restrains himself with difficulty from praying to the Greek philosopher Socrates (c. 470–399 BC) as though he were a Catholic saint. But a new turn to the arguments about idolatry, which were essentially apologetic, was given by the Protestant Reformers' attack on idolatry within the Roman Catholic Church and by their comparison between what they took to be the Christianity of the New Testament and the religion of Rome.

Thus, the need for a comparative treatment of religion became clear, and this prepared the way for more modern developments. Also preparatory for the modern study of religion was the new trend toward more or less systematic compilations of mythological and other material, stimulated partly by the Renaissance itself and partly by the discovery of America and other lands—conveying to the inhabitants of Europe a new perspective on the richness and variety of man's customs and histories. The most important figures in the exploration of the religions of the non-European world were the Spanish monk Bernardino de Sahagún (c. 1499–1590), who conscientiously gathered information in New Spain, J. Lafitau (1685–1740), a French missionary in Canada, and the Italian Jesuits Roberto De Nobili (1577–1656) and Matteo Ricci (1552–1610). The last two, who brought to bear a deep understanding of Indian and Chinese cultures, were unparalleled in that area of study until modern times. Thus, some of De Nobili's discussions with Brahmins were probably the first profound dialogues between Hindus and Christians. The inquiries of the 16th to 18th centuries thus initiated an accumulation of data about other cultures that stimulated studies of other men's religions and went beyond apologetic concerns, which hitherto had been dominant.

The beginnings of the modern period. The late 17th and 18th centuries. Attempts at a developmental account of religion were begun in the late 17th and 18th centuries. Notable was the scheme worked out, though not in great detail, by the Italian philosopher Giambattista Vico (1668–1774), who suggested that Greek religion passed through various stages: the divinization of nature, then of those powers that man had come to control (such as fire and crops), then of institutions (such as marriage), and finally the process of humanizing the gods, as in the works of Homer. The English philosopher David Hume (1711–76) gave another account in his *Natural History of Religion*, which reflected the growing Rationalism of the epoch. For Hume, original polytheism was the result of a

naïve anthropomorphism (conceiving the divine in human form) in the assignment of causes to natural events. The intensification of propitiatory and other forms of worship, he believed, led to the exaltation of one infinite divine Being. His "Essay upon Miracles" was also important in posing vital questions about the historical treatment of sacred texts, a set of problems that was to preoccupy 19th- and 20th-century Christian theologians.

The Rationalism of the period often involved a rejection both of paganism and dogmatic Christianity in the name of "natural religion." This natural religion, also called Deism, was the intellectual counterpart of the more emotional antidogmatic faith of the Pietists, who advocated "heart religion" over "head religion." Among the French Philosophes and Encyclopaedists, Voltaire (1694–1778) espoused an anticlerical Deism, which viewed the genesis of polytheism in the work of priests—a point also developed by another Encyclopaedist, Denis Diderot (1713–84). Voltaire was, incidentally, somewhat influenced and impressed by reports of the ethics of the Chinese social and religious sage Confucius (6th century BC).

The culmination of 18th-century Rationalism was found in the works of the German philosopher Immanuel Kant (1724–1804), but it was a rationalism modified to leave room for religion, which he based essentially on ethics. He held that all men in their awareness of the categorical imperative (*i.e.*, the notion that one must act as though what one does can become the universal law for mankind) and reverence for it share in the one religion and that the preeminence of Christianity lay in the conspicuous way in which Jesus enshrined the moral ideal. A series of reactions against the highly influential Kantian account paved the way for the various approaches to religion in the 19th century. In the meantime, the first beginnings of the development of Oriental studies and of ethnology and anthropology were making available more data about religion, though discussion in the 18th century continued, as in earlier centuries, the concern for the problems of religions other than those of the Judeo-Christian tradition largely in terms of the paganism of the ancient world. In this connection, the French scholar and politician Charles de Brosses (1709–77) attempted to explain Greek polytheism partly through the fetishism (belief in the magical powers of certain objects) found in West Africa. This foreshadowed later attempts to use comparative material in the elucidation of Greek myths. The French abbé Bergier (1718–90) explained primitive religions by means of a belief in spirits arising from a variety of psychological causes, which thus was a precursor of animism (a belief in souls in persons or certain natural objects).

One of the critics of Kant's view of religion was the German philosopher Johann Gottfried von Herder (1744–1803), who adopted an evolutionary account of the human race and who saw in mythology something much deeper and more significant for the understanding of human language and thought than a record of follies. His concern with symbolic thinking makes him the first modern student of myth. The German philosopher Friedrich Schelling (1775–1854) continued this positive approach, in the tradition of Romanticism. Furthermore, the advances in the knowledge of non-European, especially Indian, religion gave a wider perspective to discussions of the nature of religion, as was clear in the work of the German philosopher G.W.F. Hegel (1770–1831). The latter's self-confidence, in supposing that his philosophy represented the culmination of the history of philosophy, may amuse present-day scholars in view of the fact that many changes have occurred in philosophical enquiry since his day. Hegel was, nevertheless, immensely influential over a wide range of scholarship, including the study of religion. His followers were in large measure the founders of modern scientific history. Admittedly his theory of the historical dialectic—in which one movement (the thesis) is countered by another (the antithesis), both in interplay giving rise to a third (the synthesis), which now becomes the thesis of a new dialectical interplay, and so on—has been viewed as too artificial. But in providing a theoretical skeleton, it inspired attempts to make sense of the multitude of historical data, so that scholars were driven

The need for a comparative study of religion

Beginnings in the modern study of myth and evolutionary theories

to the investigation and discovery of particular facts that might exhibit the universal patterns postulated. Hegel also had a modified relativism, which implied that each phase of religion has a limited truth. This, together with his dialectic scheme, led to a general theory of religions, which though dated, much too neat, and based on imperfect information, nevertheless represents an important attempt at a comparative treatment, and one that was evolutionary or developmental.

The early 19th century. Hegel, as an Idealist, stressed the formative power of the spiritual on human history. By contrast, the French social philosopher Auguste Comte (1798–1857), from a Positivistic and Materialist point of view, devised a different evolutionary scheme in which there are three stages of human history: the theological, in which the supernatural is important; the metaphysical, in which the explanatory concepts become more abstract; and the positivistic—i.e., the empirical. A rather different Positivism was expressed by the English philosopher Herbert Spencer (1820–1903), in which religion has a place beside science in attempting to refer to the unknown, and unknowable, Absolute. Evolutionary accounts were much boosted in the latter part of the 19th century by the new theory of biological evolution and had a marked effect both on history of religions and anthropology.

Meanwhile, the German philosopher Ludwig Feuerbach (1804–72) propounded, in his *Lectures on the Essence of Religion*, a view of religion as a projection of the aspirations of men, a thesis that was to be taken up in various ways by, among others, Marx, Freud, and Barth.

These various movements were supplemented by the growth of scientific history, archaeology, anthropology, and other sciences, which increased comparative knowledge of civilizations and cultures. The major figures and trends in the relevant disciplines are dealt with below.

Though the 19th-century theories that form the starting point of the modern study of religion were often based directly on metaphysical schemes in competition with Christian and other theologies, there was a notably different atmosphere in comparison with preceding periods, and the stage was set for a more complex and mutual attempt to understand the history and nature of religion.

BASIC AIMS AND METHODS

The growth of various disciplines in the 19th century, notably psychology and sociology, stimulated a more analytic approach to religions, while at the same time theology became more sophisticated and, in a sense, scientific as it began to be affected by and thus to make use of historical and other methods. The interrelations of the various disciplines in relation to religion as an area of study can be described as follows.

Religions, being complex, have different aspects or dimensions. Thus, the major world religions typically possess doctrines, myths, ethical and social teachings, rituals, social institutions, and inner experiences and sentiments. These dimensions lie behind the creation of buildings, art, music, and other such extensions of basic beliefs and attitudes. But not all religions are like Christianity and Buddhism, for example, in possessing institutions such as the church and the *saṅgha* (Buddhist monastic order), which exist across national and cultural boundaries. In opposition to such institutionalized religions, tribal religion, for example, is not usually separately institutionalized but in effect is the religious side of communal life and is not treated as distinct from other things that go on in the community.

The various dimensions of religion noted above represent a cross section of a tradition; but to see the latter in a well-balanced perspective it is necessary to view it as historical—as a religion having a past and the capacity for development in the future (“dead” religions, obviously enough, being the exception). Thus, there are various disciplines that may examine a religion cross-sectionally to find its basic patterns or structures. Psychology views religious experience and feelings and to some extent the myths and symbols that express experience; sociology and social anthropology view the institutions of religious tradition and their relationship to its beliefs and values; and

literary and other studies seek to elicit the meanings of myths and other items. These structural enquiries sometimes benefit from being comparative—as when recurrent motifs in the doctrines of different religions are noticed. On the other hand, the aforementioned disciplines need to be supplemented by history, archaeology, philology, and other such disciplines, which have their own various methods of elucidating the past. Philosophy generally has attempted wide-ranging accounts of the nature of religion and of religious concepts, but it is not always easy to disentangle these enquiries from issues raised by normative theology.

Historical, archaeological, and literary studies. *Historical and literary studies.* The expansion of European empires in the early 19th century and the growth of scientific methods in history and philology combined to place Oriental and other non-European studies on a new basis. Another stimulus to the new approach to history and philology was Napoleon’s expedition to Egypt, which was accompanied by scholars and scientists; it was a notable attempt to gather knowledge of a culture systematically. The discovery and editing of sacred and other texts from other cultures also had profound effects upon European thinking. A notable publishing venture was the series *Sacred Books of the East*, edited under the leadership of the German Orientalist and philologist Max Müller (1823–1900), which placed at the disposal of Westerners translations of the major literary sources of the non-Christian world. Earlier, Müller had published translations of the more important Vedic texts (Hindu sacred works), of which the R̥gveda was given a complete scholarly edition in 1861–77. Interest in these ancient Indian texts was intense among Europeans and Americans in that earlier reports had suggested that these represented a world outlook from the “dawn of humanity” and that the origin of polytheism lay in nature worship. The Vedas, however, turned out to be of a very different character. The length of human history and prehistory, as implied by evolutionary theory and the growing archaeological discoveries, precluded looking upon the Vedic hymns as anything but late; though the contents showed them to be highly artificial and complex compilations for use in a priest-dominated ritual context, they were not at that time seen as spontaneous outpourings of the human spirit. Müller himself reacted rather sharply by adopting a different theory, which expressed his philological slant—namely, that polytheism was the result of a disease of language, in which the terms for natural phenomena came to be treated as having independent and personal reality: *nomina* (“names”) became *numina* (“spirits”). The theory was in vogue for a time but was later replaced by more realistic insights drawn from anthropology. Furthermore, study of the greater part of the corpus of Indian sacred writings, including those in vernacular languages (especially Tamil), gradually modified the preoccupation with the earliest texts—the Vedic hymns and the *Upaniṣads* (philosophical treatises).

Throughout the development of the study of non-European languages there was a supposition that a non-Christian equivalent of the Bible could be found, a sacred writing that would thus provide the authoritative key to the beliefs, practices, and institutions of the religion under consideration. Gradually, however, it became apparent that sacred scriptures play very different roles in different religious cultures. Somewhat later in developing were studies of the Buddhist canon in Pāli (an ancient Indian language), which, through the work of such scholars as the English Orientalist T.W. Rhys Davids (1843–1922) and of the Pāli Text Society, which he founded, had a remarkable impact in revealing to the West the full range of Theravādin (southern Buddhist) religious literature; it tended to make Western scholars look upon the Theravāda as the earlier, “purer” form of Buddhism; but the editing of early Mahāyāna (“Greater Vehicle,” or northern Buddhist) texts and the recognition of the different strata in the Pāli canon have modified this view. Buddhist studies were enhanced by the growth of Tibetan, Chinese, and Japanese studies. Some of the more important modern scholars of Zen Buddhism (a Mahāyāna sect) have been Japanese, notably the philosopher D.T. Suzuki (1870–1966), sometimes called

Discovery and publication of non-Western sacred writings

The various dimensions of religion

the apostle of Zen Buddhism to America, whose editions and interpretations have been widely influential.

The productivity of the study of religious literature of the late 19th century was immense, for it was not confined to the foregoing literary and archaeological activities but to the investigation of the Chinese Classics and the roots of Chinese civilization as well. Thus, by the early 20th century, Western scholars were in a position to study the main range of non-Western literary cultures. The wave of interest in these texts and the freeing of their dissemination from some of their traditional constraints (e.g., the restriction of Vedic revelation to the upper classes of the Indian caste system) contributed to the revival of other religious cultures—notably Hinduism and Buddhism, under the stimulus of the Western challenge. Modern scholarship thus provided the basis for a new self-understanding among such religious traditions.

Meanwhile, the texts of Zoroastrianism, an Iranian religion originating in the 6th century BC, were being discovered and edited (from 1850 onward). The disentangling of different layers of varying antiquity indicated the complex ways in which the religion of Zoroaster had developed.

During the latter part of the 19th and early part of the 20th century, there was a remarkable flowering of ancient Middle Eastern studies. Archaeology contributed to the unravelling of non-Jewish and Jewish religious history. The discovery of the *Epic of Gilgamesh*, a major work of Mesopotamian religious literature, and other materials brought a whole new perspective to the development of ideas in Mesopotamia; and in Egypt archaeological and papyrological studies brought to light the famous and revealing Egyptian funerary text, the Book of the Dead. These various ancient Middle Eastern discoveries have thrown light on the evolution of Judaism, and Semitic studies have likewise illuminated the origins and background of Islam. Furthermore, classical and European studies assembled data about the pre-Christian religions of the West so that scholars might gain a more detailed and scientific understanding of them. Compilations such as the *Corpus Inscriptionum Graecorum* and the *Corpus Inscriptionum Latinarum*, assembled in the 19th century, and the publication of Germanic, Celtic, and Scandinavian texts provided the tools for a reappraisal of these older traditions. Throughout the period intense researches into the composition and milieu of the Old and New Testaments reflected a new and “scientific” spirit of enquiry—which was, however, not without its controversial elements, sometimes because of the intimate tie between religious positions and evaluations of the Bible and sometimes because of the application of speculative patterns in the history of (non-Christian) religions to the New Testament. Meanwhile, the assemblage of materials extended forward into Christian history through the application of classical philological methods to patristic texts (the writing of the early Church Fathers) and to the corpus of Reformation writings.

Archaeological studies. The great archaeological discoveries of Heinrich Schliemann, the German excavator of Troy; the English archaeologists Arthur Evans in Crete and Wm. M. Flinders Petrie in Egypt; the French archaeologist Jacques de Morgan in Elam; the German Orientalist Hugo Winckler in Boğazköy (Anatolia); the French archaeologists Claude Schaeffer and C. Virolleaud in Ras Shamra (Ugarit); and other archaeologists greatly enlightened modern knowledge of the Greco-Roman and ancient Middle Eastern worlds. Biblical archaeology, culminating perhaps in the discovery of Masada, the Judaean hill fortress where the Jews made their last stand against the Romans in the revolt of AD 66–73 and that was mainly excavated in 1963, has given a new perspective to Old Testament, intertestamental, and later studies of ancient Judaism. The spectacular discovery by the English archaeologist John Marshall and others of the Indus Valley civilization pushed back knowledge of Indian prehistory to about 3500 BC and called into question the earlier theory of the primacy of Vedic culture in the formation of the Indian tradition, many features of which appear to have their first manifestation in the Indus Valley cities.

Archaeology made another profound impact on the study

of religion when in 1841 the discovery of prehistoric human artifacts and later finds gave clues to early man’s magico-religious beliefs and practices. These discoveries, notably the cave paintings in the Dordogne, northern and eastern Spain, and elsewhere, gave scholars encouragement to work out the course of man’s religious evolution from earliest times. Spectacular as prehistoric archaeology was proving to be, however, it could only yield fragments of a whole that is difficult to reconstruct. Even the famous cave paintings of Les Trois Frères, in the Dordogne, for example, which portray among other things a dancing human with antlers on his head and a stallion’s tail decorating his rear, does not yield an unambiguous interpretation: is the dancing figure a sorcerer, a priest, or what? He very likely is a priest presenting himself as a divine figure connected with animal fertility and hunting rites—but this remains as only an educated guess. Hence, it became attractive to many scholars of religion to try to supplement ancient archaeological evidence with data drawn from contemporary primitive peoples—i.e., to interpret the prehistoric Stone Age through present-day stone age cultures. This procedure has several pitfalls—partly because contemporary “primitives” are themselves the product of a long historical process and because their culture may have changed over the millennia in many and various ways.

The work of the archaeologists has not merely stimulated new thinking about the early stages of religious history but it has also been a factor in drawing attention to the roles of buildings and art objects in religion. During the present century, spectacular religious monuments of the past, such as Angkor Wat (Cambodia), Borobudur (Indonesia), Ellora and Ajantā (India), and the Acropolis (Athens), have been officially preserved for scholarly and public viewing. Though iconography (the study of content and meaning in visual arts) has been better developed among art historians, students of religion are now paying increased attention to the religious decipherment of the visual arts. By contrast, very little has been done in the sphere of music, despite the considerable role it plays in so many religions. This is a further way in which the study of texts and ideas needs to be supplemented by knowledge of the milieu in which they have their meaning.

Anthropological approaches to the study of religion.

Theories concerning the origins of religion. To draw a clear line between anthropology and sociology is difficult, and the two disciplines are divided more by tradition than by the scholarly methods they employ. Anthropology, however, has tended to be chiefly concerned with nonliterate and technologically primitive cultures and thus has stressed a certain range of techniques, such as the use of participant observation. Much anthropological investigation, however, has been carried out recently in more complex societies, such as in various Hindu areas of India, where there are different layers of society, ranging from an educated elite to illiterate workers who carry out the traditional menial tasks of the lowest castes and the outcasts. Because of the anthropologists’ interest in tribal and “primitive” societies, it has not been unnatural for them to try to use the data gained in the study of such societies to speculate about the genesis and functions of religion.

An early attempt to combine archaeological evidence of prehistoric peoples, on the one hand, and anthropological evidence of primitive peoples, on the other, was that of the English anthropologist John Lubbock (1834–1913). His book, *The Origin of Civilization and the Primitive Condition of Man*, outlined an evolutionary scheme, beginning with atheism (the absence of religious ideas) and continuing with fetishism, nature worship, and totemism (a system of belief involving the relationship of specific animals to clans), shamanism (a system of belief centring on the shaman, a religious personage having curative and psychic powers), anthropomorphism, monotheism (belief in one god), and, finally, ethical monotheism. Lubbock recognized a point later made by the German theologian and philosopher Rudolf Otto (1869–1937) in distinguishing between the unique holiness (separateness) of God and his ethical characteristics. Unfortunately, much of his information was unreliable, and his schematism was open

ary
theories
about
religion

to question; he foreshadowed, nevertheless, other forms of evolutionism, which were to become popular both in sociology and anthropology. The English ethnologist E.B. Tylor (1832–1917), who is commonly considered the father of modern anthropology, expounded, in his book *Primitive Culture*, the thesis that animism is the earliest and most basic religious form. Out of this evolves fetishism, belief in demons, polytheism, and, finally, monotheism, which derives from the exaltation of a great god, such as the sky god, in a polytheistic context. A somewhat similar system was advanced by Herbert Spencer (1820–1903) in his *Principles of Sociology*, though he stresses ancestor worship rather than animism as the basic consideration.

The classifications of religion—polytheism, henotheism (i.e., the worship of one god as supreme without necessarily excluding the possibility of other groups' gods), and monotheism—begin from concern with gods and often imply the superiority of monotheism over other forms of belief. Naturally, the anthropologists of the 19th century were deeply influenced by the presuppositions of Western society.

The English anthropologist R.R. Marett (1866–1943), in contrast to Tylor, viewed what he termed animatism as of basic importance. He took his clue from such ideas as *mana*, *mulungu*, *orenda*, and so on (concepts found in the Pacific, Africa, and America, respectively), referring to a supernatural power (a kind of supernatural "electricity") that does not necessarily have the personal connotation of animistic entities and that becomes especially present in certain men, spirits, or natural objects. Marett criticized Tylor for an overly intellectual approach, as though primitive men used personal forces as explanatory hypotheses to account for dreams, natural events, and other phenomena. For Marett, primitive religion is "not so much thought out as danced out," and its primary emotional attitude is not so much fear as awe (in this he is close to Otto, whom he influenced).

Theories of
Sir James
Frazer

Another important figure in the development of theories of religion was the British folklorist Sir James Frazer (1854–1941), in whose major work, *The Golden Bough*, is set forth a mass of evidence to establish the thesis that men must have begun with magic and progressed to religion and from that to science. He owes much to Tylor but places magic in a phase anterior to belief in supernatural powers that have to be propitiated—this belief being the core of religion. Because of the realization that magical rituals do not in fact work, primitive man then turns, according to Frazer, to reliance on supernatural beings outside his control, beings who need to be treated well if they are to cooperate with human purposes. With further scientific discoveries and theories, such as the mechanistic view of the operation of the universe, religious explanations gave way to scientific ones. Frazer's scheme is reminiscent of that of the French "father of sociology," Auguste Comte.

These and other evolutionary schemes came in for criticism, however, in the light of certain facts about the religions of primitive peoples. Thus, the Scottish folklorist Andrew Lang (1844–1912) discovered from anthropological reports that various primitive tribes believed in a high god—a creator and often legislator of the moral order. Marett and other anthropologists contended that Lang's attempt to argue for an *Urmonotheismus* (primordial monotheism) was contrary both to evolutionary ideas and to the established view of the lack of sophistication and half-animal status of the so-called savage. Since Lang was more of a brilliant journalist than an anthropologist, his view was not taken with as much seriousness as it should have been.

The German Roman Catholic priest and ethnologist Wilhelm Schmidt (1868–1954), however, brought anthropological expertise to bear in a series of investigations of such primitive societies as those of the Tierra del Fuegians (South America), the Negrillos of Rwanda (Africa), and the Andaman Islanders (Indian Ocean). The results were assembled in his *Der Ursprung der Gottesidee* ("The Origin of the Idea of God"), which appeared in 12 volumes from 1912 to 1955. Not surprisingly, Schmidt and his collaborators saw in the high gods, for whose cultural existence

they produced ample evidence from a wide variety of unconnected societies, a sign of a primordial monotheistic revelation that later became overlaid with other elements (this was an echo of earlier Christian theories invoking the Fall to similar effect). The interpretation is controversial, but at least Lang and Schmidt produced grounds for rejecting the earlier rather naïve theory of evolutionism.

Modern scholars do not, on the whole, accept Schmidt's scheme. Some, such as the Italian anthropologist Raffaele Pettazzoni (1883–1959), have stressed merely that a sky god has a certain natural preeminence; others emphasize that the high god is often a *deus otiosus* ("idle god")—i.e., not active in the world and hence not the recipient of a functioning cult. In any event, it is a very long jump from the premise that primitive tribes have high gods to the conclusion that the earliest men were monotheists.

Others who have looked at religions from an anthropological point of view have emphasized the importance, in a number of cultures, of the mother goddess (as distinct from the male sky god). A pioneer work in this direction was that of the Swiss anthropologist and jurist J.J. Bachofen (1815–87), whose *Das Mutterrecht* ("The Mother Right") unravelled some puzzles in ancient law, mythology, and art in terms of a matriarchal society.

Functional and structural studies of religion. The search for a tidy account of the genesis of religion in prehistory by reference to primitive societies was hardly likely to yield decisive results. Thus, anthropologists became more concerned with functional and structural accounts of religion in society and relinquished the apparently futile search for origins.

Notable among these accounts was the theory of the French sociologist Émile Durkheim (1858–1917). According to Durkheim, totemism was fundamentally significant (he wrongly supposed it to be virtually universal), and in this he shared the view of some other 19th-century savants, notably Salomon Reinach (1858–1932) and Robertson Smith (1846–94), not to mention Sigmund Freud (1856–1939). Because Durkheim treated the totem as symbolic of the god, he inferred that the god is a personification of the clan. This conclusion, if generalized, suggested that all the objects of religious worship symbolize social relationships and, indeed, play an important role in the continuance of the social group.

Various forms of functionalism in anthropology—which understood social patterns and institutions in terms of their function in the larger cultural context—proved illuminating for religion, such as in the stimulus to discover interrelations between differing aspects of religion. The Polish-British anthropologist Bronisław Malinowski (1884–1942), for instance, emphasized in his work on the Trobriand Islanders (New Guinea) the close relationship between myth and ritual—a point also made emphatically by the "myth and ritual" school of the history of religions (see below *Other studies and emphases*). Furthermore, many anthropologists, notably Paul Radin (1883–1959), moved away from earlier categorizations of so-called primitive thought and pointed to the crucial role of creative individuals in the process of mythmaking.

A rather different approach to myths was made by the 20th-century French anthropologist Claude Lévi-Strauss, whose rather formalistic structuralism tended to reinforce analogies between "primitive" and sophisticated thinking and also provided a new method of analyzing myths and stories. His views had wide influence, though they are by no means universally accepted by anthropologists.

Specialized studies. The impact of Western culture, including missionary Christianity, and technology upon a wide variety of primitive and tribal societies has had profound effects and represents a specialized area of study closely related to religious anthropology. One pioneering work is *Religions of the Oppressed* by the Italian anthropologist and historian of religion Vittorio Lanternari. What is striking is the way in which similar types of reaction, creating new religious movements, occur at different points across the world. There are, thus, many possibilities of a comparative treatment.

Among a number of contemporary anthropologists, including the American Clifford Geertz, there is a concern,

Theories of
primordial
mono-
theism

Analyses
of social
patterns
and
institutions

after a period of functionalism, with exploring more deeply and concretely the symbolism of cultures. The English social anthropologist E.E. Evans-Pritchard (1902–73), noted among other things for his work on the religion of Nuer people (who live in The Sudan), produced in his *Theories of Primitive Religion* a penetrating critique of many of the earlier anthropological stances. Though it has always been difficult to confirm theories in view of the complexity of the data, a statistical approach has been attempted—e.g., by G. Swanson in his *Birth of the Gods*, which attempts to exhibit correlations between types of social arrangement and religious beliefs, such as the caste system and belief in reincarnation.

Because of the nature of the societies that typically have come under the scrutiny of anthropology, the discipline has necessarily had to come to terms with religion. In terms of the methods used, the anthropological approach is of considerable interest to historians of religion and is a corrective to overintellectual, text-based accounts of religions. Also, the present concerns for comparative studies and symbolic analysis coincide with existing concerns in the phenomenology of religion (see below *History and phenomenology of religion*).

Sociological studies of religion. *Theories of stages.* Auguste Comte (1798–1857) is usually considered the founder of modern sociology. His general theory hinged substantially on a particular view of religion, and this view has somewhat influenced the sociology of religion since that time. In his *Cours de philosophie positive* (*The Positive Philosophy of Auguste Comte*) Comte expounded a naturalistic Positivism and sketched out the following stages in the evolution of thought. First, there is what he called the theological stage, in which events are explained by reference to supernatural beings; next, there is the metaphysical stage, in which more abstract unseen forces are invoked; finally, in the positivistic stage, men seek causes in a scientific and practical manner. To seek for scientific laws governing human morality and society is as necessary, in this view, as to search for those in physics and biology—hence Comte's role in advocating a science of society, namely sociology. Among the leading figures in the development of sociological theories were Spencer and Durkheim (see above *Anthropological approaches to the study of religion*).

A rather separate tradition was created by the German economic theorist Karl Marx (1818–83). A number of Marxists, notably Lenin (1870–1924) and K. Kautsky (1854–1938), have developed social interpretations of religion based on the theory of the class struggle. Whereas sociological functionalists posited the existence in a society of some religion or a substitute for it (Comte, incidentally, propounded a positivistic religion, somewhat in the spirit of the French Revolution), the Marxists implied the disappearance of religion in a classless society. Thus, in their view religion in man's primordial communist condition, at the dawn of the historical dialectic, reflects ignorance of natural causes, which are explained animistically. The formation of classes leads, through alienation, to a projection of the need for liberation from this world into the transcendental or heavenly sphere. Religion, both consciously and unconsciously, thus becomes an instrument of exploitation. In the words of the young Marx, religion is "the generalized theory of the world . . . , its logic in popular form." The modern intellectualist accounts of religion, tending to ignore the rituals, experiences, and institutions but concentrating rather on the doctrines and myths, have proved something of a problem for later Marxist applications of their theory. Since the theory was a product of a rather early and unsophisticated stage of theorizing about religion, it was not adapted particularly well to deal with other cultures—hence a considerable debate in modern China on the status of Chinese religion in the light of Marxism, some holding that Marx's critique did not, for example, fit Buddhism.

Comparative studies. One of the most influential theoreticians of the sociology of religion was the German scholar Max Weber (1864–1920). He observed that there is an apparent connection between Protestantism and the rise of capitalism, and in *The Protestant Ethic and*

the Spirit of Capitalism he accounted for the connection in terms of Calvinism's inculcating a this-worldly asceticism—which created a rational discipline and work ethic, together with a drive to accumulate savings that could be used for further investment. Weber noted, however, that such a thesis ought to be tested; and a major contribution of his thinking was his systematic exploration of other cultural traditions from a sociological point of view. He wrote influentially about Islām, Judaism, and Indian and Chinese religions and, in so doing, elaborated a set of categories, such as types of prophecy, the idea of charisma (spiritual power), routinization, and other categories, which became tools to deal with the comparative material; he was thus the real founder of comparative sociology. Because of his special interest in religion, he can also be reckoned a major figure in the comparative study of religion (though he is not usually reckoned so in most accounts of the history of religions). Though he made significant contributions to the study of religion, his judgments on Indian and other religions are not all or mostly accepted now—since he necessarily based his views on secondary sources—and some of his categorial distinctions are open to debate, such as his rather broad use of the category of prophet.

Weber's comparative method in the scientific sociology of religion introduced an analogue to experimentation (i.e., looking at similar patterns in independent cultures with varying contextual conditions). Since the 1950s there has been considerable emphasis on statistical methods, side by side with the more theoretical discussions arising from classical sociology. Typical of the trend is the American sociologist Gerhard Lenski's *Religious Factor*, which delineates the relations between religious allegiance and other factors in a large city in the United States.

Other sociological studies. An extensive literature on religious sects and similar groups has also developed. To some extent this has been influenced by the German theologian Ernst Troeltsch in his distinction between church and sect (see below *Theological studies*). Notable among modern investigators of sectarianism is the British scholar Bryan Wilson. Church organizations also have attempted to use the insights of sociology in the work of evangelism and other church-related activities—a use of the discipline that is sometimes called "religious sociology" to distinguish it from the more theoretical and "objective" sociology of religion.

Coordination between sociology and the history of religions is not usually very close, since the two disciplines operate as separate departments in most universities and often in different faculties. From the sociological end, Weber represents one kind of synthesis; from the history-of-religions end, the writings of the German-American scholar Joachim Wach (see below *The "Chicago school"*) were quite influential. In his book *Sociology of Religion* he attempted to exhibit the ways in which the community institutions of religion express certain attitudes and experiences. This view was in accordance with his insistence on the practical and existential side of religion, over against the intellectualist tendency to treat the correlate of the group as being a system of beliefs.

Among the more recent theorists of the sociology of religion is the influential and eclectic American scholar Peter Berger. In *The Sacred Canopy* he draws on elements from Marx, Durkheim, Weber, and others, creating a lively theoretical synthesis. One problem is raised by his method, however; he espouses what he calls "methodological atheism" in his work, which appears to presuppose a view about religion. Despite Berger's sympathy in dealing with religious phenomena, the methodological stance adopted in this book seems to imply a reductionist position—namely, one in which religious beliefs are explained by reference to basically nonreligious sentiments, sociopsychological circumstances, and other factors. In itself, this is a theory having possibilities, for the study of religion cannot rule out a priori the thesis that religion is a projection—e.g., that it rests upon an illusion—or other such theses; but the question arises as to whether or not the methods espoused in the scientific study of religion have already secretly prejudged the issue.

Recent
socio-
logical
studies

On the whole, modern sociology is largely geared to dealing with Western religious institutions and practices, though some notable work has been done, especially since World War II, in Asian sociology of religion. Emphasis has been placed upon the process of secularization in a number of Western sociological studies (which have had some impact on the formation of modern Christian theology), notably in *The Secular City* of the American theologian Harvey Cox. There are indications that the process of secularization does not occur in the same degree or occurs in a different manner in non-Western cultures.

In general, the main question of the sociology of religion concerns the effectiveness with which it can relate to other studies of religion. This question is posed in *The Scientific Study of Religion*, by the American sociologist J. Milton Yinger. A similar tendency is noted in the synthesis between the history and the sociology of religion in a new-style evolutionism propounded by another American scholar, Robert Bellah.

The psychology of religion. The study of religious psychology involves both the gathering and classification of data and the building and testing of various (usually rather wide-ranging) explanations. The former activity overlaps with the phenomenology of religion, so it is to some extent an arbitrary decision under which head one should include descriptive studies of religious experience and related subjects.

Psychological studies. Notable among investigations by psychologists was *The Varieties of Religious Experience*, by the American philosopher and psychologist William James (1842–1910), in which he attempted to account for experiences such as conversion through the concept of invasions from the unconscious. Because of the clarity of his style and his philosophical distinction, the work has had a lasting influence, though it is dated in a number of ways and his examples come from a relatively narrow selection of individuals, largely within the ambit of Protestant Christianity. This points to a recurring problem—that of relating individual psychology to the institutions and symbols of different cultures and traditions.

More radical, but drawing from a rather larger range of examples, was the American psychologist J.H. Leuba (1868–1946). In *A Psychological Study of Religion* he attempted to account for mystical experience psychologically and physiologically, pointing to analogies with certain drug-induced experiences. Leuba argued forcibly for a naturalistic treatment of religion, which he considered to be necessary if religious psychology was to be looked at scientifically. Others, however, have argued that psychology is in principle neutral, neither confirming nor ruling out belief in the transcendent. Most scholars would, however, consider the problem to be a complex philosophical one, which goes beyond psychology as such.

Among those who have attempted a fairly detailed classification of mystical experience, but not necessarily from a scientific-psychological point of view, mention should be made of the English scholar Evelyn Underhill (1875–1941), drawing on examples from the Jewish, Christian, and Islamic traditions. Recently, systematic explorations (taking into account Eastern mysticism as well) have been undertaken. Rudolf Otto was important in elucidating the nature of numinous experience, and there has also been a certain amount of scholarly work performed in the description and classification of types of shamanism, spirit possession, and similar phenomena.

Psychoanalytical studies. More influential than James and Leuba and others in that tradition were the psychoanalysts. Freud gave explanations of the genesis of religion in various of his writings. In *Totem and Taboo* he applied the idea of the Oedipus complex (involving unresolved sexual feelings of, for example, a son toward his mother and hostility toward his father) and postulated its emergence in the primordial stage of human development. This stage he conceived to be one in which there were small groups, each dominated by a father. According to Freud's reconstruction of primordial society, the father is displaced by a son (probably violently), and further attempts to displace the new leader bring about a truce in which incest taboos (proscriptions against intrafamily

sexual relations) are formed. The slaying of a suitable animal, symbolic of the deposed and dead father, connected totemism with taboo. In *Moses and Monotheism* Freud reconstructed biblical history in accord with his general theory, but biblical scholars and historians would not accept his account since it was in opposition to the point of view of the accepted criteria of historical evidence. His ideas were also developed in *The Future of an Illusion*. Freud's view of the idea of God as being a version of the father image and his thesis that religious belief is at bottom infantile and neurotic do not depend upon the speculative accounts of prehistory and biblical history with which Freud dressed up his version of the origin and nature of religion. The theory can still stand as an account of the way in which religion operates in individual psychology, though of course it has also attracted criticism on grounds other than historical ones (e.g., Buddhism does not have a father figure to worship).

A considerable literature has developed around the relationship of psychoanalysis and religion. Some argue, despite the atheistic mood of Freud's writing and his critique of religious belief, that the main theory is compatible with faith—on the grounds, for instance, that the theory describes certain mechanisms operative in people's religious psychology that represent modes in which people respond to the challenge of religious truth. Even if this position can be sustained, it is clear, nevertheless, that acceptance of Freudian insights makes a considerable difference to the way in which religious experience and behaviour are viewed. Questions have arisen about the range of applicability of Freud's ideas—e.g., whether or not his theories apply outside the Western milieu, such as in Theravāda Buddhism, which does not possess a father figure or worship a god. Various attempts have been made to test Freud's theory of religion empirically, but the results have been ambiguous.

The Swiss psychoanalyst C.G. Jung (1875–1961) adopted a very different posture, one that was more sympathetic to religion and more concerned with a positive appreciation of religious symbolism. Jung considered the question of the existence of God to be unanswerable by the psychologist and adopted a kind of agnosticism. Yet he considered the spiritual realm to possess a psychological reality that cannot be explained away, and certainly not in the manner suggested by Freud. Jung postulated, in addition to the personal unconscious (roughly as in Freud), the collective unconscious, which is the repository of human experience and which contains "archetypes" (i.e., basic images that are universal in that they recur in independent cultures). The irruption of these images from the unconscious into the realm of consciousness he viewed as the basis of religious experience and often of artistic creativity. Religion can thus help men, who stand in need of the mysterious and symbolic, in the process of individuation—of becoming individual selves. Some of Jung's writings have been devoted to elucidating some of the archetypal symbols, and his work in comparative mythology, the history of alchemy, and other similar areas of concern has proved greatly influential in stimulating the investigations of other interested scholars. Thus, the Eranos circle, a group of scholars meeting around the leadership of Jung, contributed considerably to the history of religions. Associated with this circle of scholars have been Mircea Eliade, the eminent Romanian-French historian of religion, and the Hungarian-Swiss historian of religion Károly Kerényi (1897–1973). This movement has been one of the main factors in the modern revival of interest in the analysis of myth.

Among other psychoanalytic interpreters of religion, the American scholar Erich Fromm (1900–80) modified Freudian theory and produced a more complex account of the functions of religion. Part of the modification is viewing the Oedipus complex as based not so much on sexuality as on a "much more profound desire"—namely, the childish desire to remain attached to protecting figures. The right religion, in Fromm's estimation, can, in principle, foster an individual's highest potentialities, but religion in practice tends to relapse into being neurotic.

Investigations of religious experience

Theories of Freud and Jung

Authoritarian religion, according to Freud, is dysfunctional and alienates man from himself.

Other studies. Apart from Jung's work, there have been various attempts to relate psychoanalytic theory to comparative material. Thus, the English anthropologist Meyer Fortes, in his *Oedipus and Job in West African Religion*, combined elements from Freud and Durkheim, and G.M. Carstairs (a British psychologist), in *The Twice Born*, investigated in depth the inhabitants of an Indian town from a psychoanalytic point of view and with special reference to their religious beliefs and practices. Among the more systematic attempts to evaluate the evidences of the various theories is *Religious Behaviour*, by Michael Argyle, another British psychologist.

A certain amount of empirical work in relation to the effects of meditation and mystical experience—and also in relation to drug-induced “higher” states of consciousness—has also been carried on. Investigation of religious responses as correlated with various personality types is another area of enquiry; and developmental psychology of religion, largely under the influence of the French psychologist Jean Piaget (1896–1980), has played a prominent part in educational theory in the teaching of religion. Most scholars agree, however, that more needs to be done to make results in the psychology of religion more precise; and also, for reasons that are unclear, very few people recently have concerned themselves with the field, which thus is in a state of suspension after a flurry of activity in the late 19th and early 20th centuries.

Philosophy of religion. *The concerns of the philosophy of religion.* The scope of the philosophy of religion has changed somewhat in the last century and a half—that is, in the time since it came to be recognized as a separate branch of philosophy. Its nature is, as is typically the case in philosophy, open to debate. Three main trends, however, can be noted: (1) the attempt to analyze and describe the nature of religion in the framework of a general view of the world; (2) the effort to defend or attack various religious positions in terms of philosophy; and (3) the attempt to analyze religious language. Philosophical materials are also often incorporated into theologies—a modern example being the use of Existentialism in the theology of Rudolf Bultmann, the German New Testament scholar (see below *Neo-orthodoxy and demythologization*), and others; an older example is the medieval theologian Thomas Aquinas' use of Aristotle and of his (Aquinas' own) insights in the service of a systematic Christian theology. The different activities mentioned above overlap substantially. The second of them is usually taken to include the exploration of natural theology (*i.e.*, the truths about God that can be known, as it is claimed, by the aid of reasoning and insight, independently of the truths vouchsafed by revelation). Metaphysical systems (concerning the nature of reality) sometimes function as analogues to natural theology and thus provide a kind of support for a revealed religious belief system. Thus, much of philosophy of religion is concerned with questions not so much of the description of religion (historically and otherwise) as with the truth of religious claims. For this reason philosophy can easily become an adjunct of theology or of antireligious positions. To this extent, philosophy lies outside the main disciplines concerned with the descriptive study of religion; thus, it is often difficult to disentangle descriptive problems from those bearing on the truth of the content of what is being described. Feuerbach's “projection” theory of religion, for example, possessed a metaphysical framework, but it also included empirical claims about the nature of religion. The following brief account of philosophical trends is necessarily selective, leaning toward those philosophical theories that have a stronger content of, or relevance to, descriptive claims about religion.

Theories of Schleiermacher and Hegel. Immanuel Kant's powerful critique of traditional natural theology appeared to rob religion of its basis in reason and to make it an adjunct to morality. But Kant's system depended on drawing certain distinctions, such as that between pure and practical reason, which were open to challenge. One reaction that attempted to place religion in a more realis-

tic position (*i.e.*, as neither primarily to do with pure nor with practical reason) was that of the German theologian and philosopher Friedrich Schleiermacher (1768–1834) in his *On Religion: Speeches to Its Cultured Despisers*. He attempted there to carve out a separate territory for religious experience, as distinct from both science and morality. For him the central attitude in religion is “the feeling of absolute dependence.” In drawing attention to the affective and experiential side of religion, usually neglected in preceding philosophical discussions, Schleiermacher set in motion the modern concern to explore the subjective or inner aspect of religion. Schleiermacher's main goal, however, was not the exploration of religion as such but rather the construction of a new type of theology—the “theology of consciousness.” In so doing he relegated doctrines to a secondary role, their function being to express and articulate the deliverances of religious consciousness. Thus, incidentally, it became important for New Testament historians who were influenced by Schleiermacher to penetrate the religious consciousness of Jesus—this becoming, in effect, the reputed locus of his divinity.

G.W.F. Hegel had, as noted above, a profound effect upon the development of historical and other studies. His own system, the system of the Absolute, contained a view of the place of religion in human life. According to this notion, religion arises as the relation between man and the Absolute (the spiritual reality that undergirds and includes the whole universe), in which the truth is expressed symbolically, and so conveyed personally and emotionally to the individual. As the same truth is known at a higher—that is, more abstract—level in philosophy, religion is, for all its importance, ultimately inferior to philosophy. The relationship between abstract and concrete truth was, incidentally, taken up in the 19th-century Hindu renaissance as a parallel to the doctrine of the Absolute—the Advaita (nondualism), the dominant expression of Hindu metaphysics—held by the 8th-century Hindu philosopher Śaṅkara. The Hegelian account of religion was worked out in the context of the dialectical view of history, according to which opposites united in a synthesis, which in turn produced its opposite, and so on. Hegel was influential in the interpretation of Christian history: Jesus as thesis, Paul as antithesis, and early Catholicism as the synthesis, the latter becoming a new thesis that would elicit a new antithesis, Protestantism.

Hegel attracted some radical criticism, however. One such was that of the aforementioned German philosopher Ludwig Feuerbach (1804–72), whose ideas have been sketched above. Another was that of the Danish philosopher and theologian Søren Kierkegaard (1813–55), sometimes regarded as the father of modern Existentialism, who reacted against the metaphysical and “rational” approach to Christianity in Hegel's thought. Kierkegaard's penetrating psychological insights were put to the service of philosophy and theology and threw new light on the nature of religious experience and its relation to features of man's inner life, such as dread and despair. Kierkegaard's main concern, however, was prophetic rather than descriptive. From a very different standpoint (*i.e.*, that of liberal Protestantism), the German theologian Albrecht Ritschl (1822–89) made an apologetic defense of Christianity in his attempt to analyze theological utterances as essentially affirming value judgments.

Schleiermacher's delineation of religious experience was complemented by attempts among the Romantics and by the German philosopher Ernst Cassirer (1874–1945) to exhibit the nature of symbolic thinking and in particular the special character of religious symbolism. This was some distance from the rationalism of Kant, though Cassirer was nevertheless influenced by the Neo-Kantian tradition.

Empiricism and Pragmatism. The Hegelian school, very influential in the 19th century, entered a period of rapid decline in the early part of the 20th. The common sense and scientifically oriented philosophy of the English scholars G.E. Moore (1873–1958) and Bertrand Russell (1872–1970) introduced a period of Empiricism in Britain, while William James's Pragmatism had a similar effect in America. Theologically, there was an antimetaphysical revolution during and after World War I. On the conti-

Analysis

ment of Europe, the increasing influence of Existentialism was hostile to the old type of metaphysics. British Empiricism was expressed very strongly in Logical Positivism (maintaining the exclusive value of scientific knowledge and the denial of traditional metaphysical doctrines) and its linguistic aftermath. This stimulated the analysis of religious language, and the movement was complicated by the transformation in the thought of the Austrian-English philosopher Ludwig Wittgenstein (1889–1951), who in his later thought was very far removed from his early, rather formalistic treatment of language.

Theoretically, the Analytic attempt to exhibit the nature of religious language could have been a chiefly descriptive task, but, in fact, most analyses have occurred in the context of questions of truth—thus some scholars have been concerned with exhibiting how it is possible to hold religious beliefs in an Empiricist framework, and others with showing the meaninglessness or incoherence of belief. A landmark was the publication, in 1955, of *New Essays in Philosophical Theology*, edited by the English philosophers A.G.N. Flew and A. MacIntyre. Though Wittgenstein stressed the idea of “forms of life,” according to which the meaning of religious beliefs would have to be given a practical and living contextualization, little has been done to pursue the idea empirically. The discovery by the English philosopher J.L. Austin (1911–60) and others of performative uses of language has stimulated some enquiry in this direction. On the whole, however, the Analytic philosophy of religion has been pursued rather independently of the descriptive study and history of religion.

Modern Existentialist and Phenomenological studies. Since linguistic philosophy tends to be considered by its proponents to be a method or a group of methods, internal diversity within the area of concern is not surprising. Similarly, Existentialism, which is less of an “-ism” than an attitude, expresses itself in a variety of ways. The most influential modern Existentialists have been the German philosopher Martin Heidegger (1889–1976) and the French philosopher, dramatist, and novelist Jean-Paul Sartre (1905–80); the former was especially important in the development of modern continental theology, particularly for the use made of some of his ideas by Rudolf Bultmann.

According to Heidegger, man’s existence is characterized as “care.” This care is shown first in possibility: man makes things instrumental to his concerns and so projects forward. Secondly, there is his facticity, for he exists as a finite entity with particular limitations (his “thrownness”). Thirdly, man seeks to avoid the anxiety of his limitations and thus seeks inauthentic existence. Authenticity, on the other hand, involves a kind of stoicism (positive attitude toward life and suffering) in which death is taken up as a possibility and man faces the “nothing.” The structure of man’s world as analyzed by Heidegger is revealed, in a sense, affectively—i.e., through care, anxiety, and other existential attitudes and feelings.

Sartre’s thought has had less direct impact on the study of religion, partly because his account of human existence represents an explicit alternative to traditional religious belief. Sartre’s analysis begins, however, from the human desire to be God: but God is, on Sartre’s analysis, a self-contradictory notion, for nothing can contain the ground of its own being. In searching for an essence man fails to see the nature of his freedom, which is to go beyond definitions, whether laid down by God or by other human beings.

The French philosopher Gabriel Marcel (1889–1973) is not individualistic like Sartre (or at least the early Sartre, whose thinking was modified by Marxism); instead, he stresses the communal character of human existence—the highest virtue being fidelity. Marcel also emphasizes the mysterious (as distinguished from the empirically problematic) character of love, evil, hope, freedom, and, above all, being. His work provides a rich analysis and interpretation of the religious dimensions of human experience and thus is a philosophical basis for the study of religious experience.

The Existentialist approach attempts to describe and evoke the way human beings are and thus can lay claim

to be phenomenological. It is clear, however, from the divergencies among Existentialists, that they contain speculative and idiosyncratic elements, and one question raised about the general applicability of their characterizations is how far they are bounded by the product of a particular mood in Western culture.

The German philosopher Edmund Husserl (1859–1938) has had, as the main exponent of Phenomenology, a wide effect on the study of religion. His program of describing experience and “bracketing” the objects of experience, in the pursuit of essences of types of experience, was in part taken up in the phenomenology of religion. Husserl distinguished Phenomenology from psychology, however, because, in his view, the latter concerns facts in a spatio-temporal setting, whereas Phenomenology uncovers timeless essences. This aspect of Husserl’s thinking has not always or wholly been accepted by phenomenologists of religion, who have been much more oriented toward facts, though Husserl’s emphasis on essences often has tended to make religious phenomenology lean toward a static typology.

Relationship between Western and non-Western philosophy in regard to religion. Western philosophy has thus had a significant influence on the study of religion. It has also come into contact with non-Western traditions and has thus stimulated concern with the problem of the nature of religious truth in a world perspective. The most influential product of this interplay has most likely been the neo-Advaitin philosophy (a new version of Advaita, or nonduality) espoused by a number of modern Indians, such as Swami Vivekananda (1863–1902), who made a sensational appearance at the Parliament of Religions in Chicago in 1893, and the Indian philosopher Sarvepalli Radhakrishnan (1888–1975). Both of these thinkers attempted to reveal the underlying unity in the great religions—a unity described from a point of view drawing on the thought of Śaṅkara.

The U.S. philosopher William Ernest Hocking (1873–1966) pursued similar interests in the construction of a world faith that he considered might come about through the mutual modification of, and interchange between, the great religious traditions. These concerns have raised important questions about the criteria of truth between religions, the tests of whether one religion is truer than others, and the extent to which valid identifications of belief can be made between one faith and another. The various elements of the philosophical traditions of the last two centuries have thus had a bearing on religious questions, and most scholars consider that though the philosophy of religion tends to be normative rather than descriptive, it is a necessary adjunct to descriptive studies. Philosophical insights and expertise are of significant relevance to the numerous questions of method that arise in the study of religion. (See also PHILOSOPHIES OF THE BRANCHES OF KNOWLEDGE: *Philosophy of religion*.)

Theological studies. Historical-critical studies. The major feature in the development of Christian theology during the 19th and 20th centuries has been the impact of historical enquiry on the biblical sources of belief (there has also been a similar effect on Jewish and other theologies, but Christian theology has been the most influential in the development of Western culture). A pioneer in the attempt to understand the mythological elements in the New Testament was the German theologian David F. Strauss (1808–74), whose controversial *Life of Jesus* (published in German, 1835–36) was an attempt to sift out the historical Jesus from the overlay of myth created by the poetic imagination of the early church. Similarly, the German church historian Adolf von Harnack (1851–1930), influenced by Albrecht Ritschl, intended to penetrate the accretions of dogma attached to the historical Jesus. Such attempts were later to come under radical criticism from, among others, the Alsatian philosopher-theologian and Nobel laureate Albert Schweitzer (1875–1965) for describing the alleged Jesus of history in terms tailored to fit the presuppositions of liberal Protestantism. Thus was raised an important methodological question on how to deal with such material as the Gospels.

Principles of historical criticism

with the material was Ernst Troeltsch, who argued that history has to be written in accordance with the following principles: first, the principle of criticism—*i.e.*, the sifting of the evidences and testing of conclusions (thus historical certainty about much in the ancient witnesses to Jesus is impossible); second, the principle of analogy—*i.e.*, in the absence of firsthand experience, scholars must treat reports of miraculous events with skepticism since people do not encounter such events in their own experiences (here Troeltsch adopts the position of David Hume); and third, the principle of correlation—*i.e.*, events in history are continuous with one another in a causal nexus, which rules out irruptions into the causal order by God: if he works in history he is immanently in all of it. Troeltsch, it may be noted, had some effect on the sociology of religion—*e.g.*, in his distinction between church-type and sect-type organizations in the history of Christianity, a distinction that has formed the starting point of considerable researches in recent times, as noted above. The implications of Troeltsch's historical treatment of religion seemed to be relativistic. Christianity, at any rate, is viewed as a part of religious history as a whole, a point that had not always been clearly recognized by theologians. Troeltsch thereby raised some important questions about the relationship between Christianity and other religions and showed how Christian theology was beginning to take a more realistic view of mankind's religious experience and history, in distinction to the earlier rather simplistic dichotomies between special (*i.e.*, Judeo-Christian) and general (*i.e.*, natural) revelation.

Discoveries about ancient Middle Eastern religions were also bound to affect biblical studies, and a well-defined school developed in Germany—the *Religionsgeschichtliche Schule* (History of Religions school)—which was critical of the rather unhistorical treatment of Jesus by Ritschl and others. This school emphasized the degree to which biblical ideas were the product of the ancient cultural milieu. Important in this line of development was Albert Schweitzer, in whose *Quest of the Historical Jesus* the eschatological teachings (statements about the "last times," or end of the world as it is now understood) of Jesus are emphasized, together with the dissimilarity of his thought world from our own. Criticism of Harnack also came from a different direction. The French theologian Alfred Loisy (1857–1940), from a Roman Catholic point of view but taking into account the work of Protestant biblical critics, found the essence of Christianity in the faith of the developed church, which could not be found simply by trying to discover the nature of the historical Jesus. The founder, in effect, of Modernism within the Roman Catholic Church, Loisy was excommunicated; and this was a main factor in discouraging some of the livelier Roman Catholic studies of the New Testament until after the epochal ecumenical second Vatican Council (1962–65).

Neo-orthodoxy and demythologization. Liberal Protestantism of the Harnack type was severely criticized by Karl Barth, the founder of Neo-orthodoxy; liberalism's optimism, in any event, came under a cloud through the outbreak of World War I. Barth's *Epistle to the Romans* and his later *Church Dogmatics* became highly influential. His theology depended in part on a distinction between the Word (*i.e.*, God's self-revelation as concretely manifested in Christ and in preaching) and religion. The latter, according to Barth, is the product of human culture and aspirations and is not to be identified with saving revelation (for salvation cannot come from mankind, only from God). This rather uncompromising view made use of the projectionist theory of religion expressed by Feuerbach and others. Barth's conclusion was challenged somewhat by another Swiss theologian, Emil Brunner (1889–1966), who allowed a modicum of insight for fallen man into God's nature. The concession was, however, a slight one. The Dutch theologian Hendrik Kraemer (1888–1965) applied the doctrine of the theology of the Word to non-Christian religions in *The Christian Message in a Non-Christian World*, which had a wide impact on the overseas mission field. Since man's religions are cultural products and since each system of belief is organic and particular, there are, according to Kraemer, no points of contact between them

and the Gospel (even Christianity as an empirical religion must be distinguished from it: its only advantage is to have been continuously under the judgment and influence of the Gospel). Kraemer's position has come under some criticism from students of comparative religion; one of the theological problems it poses is that it seems to shut off the possibilities of dialogue between religions.

After Barth, the most influential theologian in the 20th century has been Rudolf Bultmann (1884–1976). Though he was mainly concerned with the presentation of the faith, his project of "demythologization" has had a wide significance for the historian of religions, for it involves a theory of myth. Bultmann came to the New Testament material partly as a historian and partly as a theologian influenced by the Existentialism of Heidegger. He centred his interest on the difference between the style of thinking in the early church, as expressed in the New Testament writings, and modern thought. Modern man, he held, cannot think in the mythological terms employed in the New Testament presentation of the Gospel. Therefore, it is necessary to demythologize the New Testament message. For Bultmann, the mythological elements are belief in the pre-existence of Christ, the three-layer universe (heaven, earth, and hell), miracles, ascension into heaven, demonology, and various other elements of the Judeo-Christian-Hellenistic world view. The inner meaning of the myths, he claimed, must be explicated in existential terms and purged of the objectifications that they contain. Thus, his theory contains an empirical claim, namely about the original function of myths (expressing existential attitudes through objectified representations). Bultmann's theory, however, has not yet been brought together with anthropological and other theories of myth.

A follower of Bultmann, Fritz Buri, considers Bultmann's stance to be insufficiently radical, for Bultmann differentiated between the kerygma (the essential proclamation of the early church) and the myths, desiring to retain the former, but not the latter. Buri has attempted to overcome this distinction. Authentic existence is not, according to Buri, distinctively Christian, and he has been led to a position not altogether different in principle from that of Troeltsch. Buri's views have also led him into considering in some depth the significance of other religions.

The relationship of Western Christianity to other religions. Since World War II, Western Christianity has found it difficult, from a cultural point of view, to ignore the challenge of other religions; and the mood has changed somewhat from the more rigorous climate in which the theology of the Word (*i.e.*, Barth's position) was dominant. The "theology of religions" (analogous to the "history of religions") has moved in the direction of dialogue, which sometimes simply refers to mutual acquaintance in charity so that people of differing faiths can come to understand more deeply the meaning of each other's religions. More significantly, it means a kind of mutual theologizing. Among the more prominent writers who have been involved one way or another in the process of dialogue have been the Jewish philosopher Martin Buber (1878–1965), the English Islāmic scholar Kenneth Cragg, and the Canadian Islāmic scholar Wilfred Cantwell Smith. In effect, modern dialogue continues an earlier tradition that emphasized some continuities between religions, notably the work of the British theologian John Oman (1860–1939), who was influenced both by Schleiermacher and Otto, though critical of the latter. Oman contrasted prophetic and mystical religion and considered that the former had the highest conception of the supernatural. There are analogies between his position and that of the important Swedish theologian, historian of religion, and archbishop Nathan Söderblom (1866–1931).

A rather different theory of myth and symbolism from that of Bultmann was expressed by Paul Tillich, who viewed religion as having to do with what concerns man ultimately. He taught that symbolic and mythological language, used by all religions, points beyond itself to the being in which the symbols participate. Tillich used the term being in an existential sense (one related directly to human experience and commitment) rather than a strictly metaphysical sense. Also, he claimed that it is not possible

Influence of Barth and Bultmann

Inter-religious dialogue

to dispense with the symbolic, which is essential to the task of speaking about ultimate reality, but the myths are to be "broken"—that is, they are to be seen as not being literally true.

Christian theology, in the 19th and 20th centuries, has been more concerned with intellectual and social challenges, however, than with the analysis of religion, which has been secondary to that concern.

History and phenomenology of religion. The history of religions and the phenomenology of religion are generally understood by scholars to be nonnormative—that is, they attempt to delineate facts, whether historical or structural, without judging them from a Christian or other standpoint. At any rate, their tasks are considered to be different from that of articulating and systematizing a faith. The same, in principle, is true for the comparative study of religion, though this sometimes is thought to cover the theology of other religions, such as the Christian appraisal of Hindu history. Needless to say, the fact that a discipline aims to be nonnormative does not mean that it will succeed in being so. Also, the history and phenomenology of religion tend to raise essentially philosophical questions of explanation, where the issues are often debatable.

Modern origin and development of the history and phenomenology of religion. The history of religions on a cross-cultural basis, though it has quite an ancient pedigree, came into its own in a modern sense from about the time of Max Müller. During the latter part of the 19th century an attempt was made to place comparative methodology on a systematic basis (often called the Science of Religion), and in this connection the work of the Dutch theologians P.D. Chantepie de la Saussaye (1848–1920) and C.P. Tiele (1830–1902) was important. During this period, various lectureships and chairs in the subject were instituted. In The Netherlands, following the reform of the theological faculties in 1876, four chairs in the history of religions were founded. In 1879 a chair was founded at the Collège de France (followed by others elsewhere in France), while a number were created in Switzerland. The subject also spread to Great Britain (where chairs at Manchester and London were instituted), the United States (at Harvard and Chicago), and elsewhere in the Western world. In Germany, on the other hand, there was strong resistance, notably from Adolf von Harnack, who thought that theology should avoid what he regarded as dilettantism and that the subject was sufficiently covered in the study of biblical religion.

The first congress of *Religionswissenschaft* (Science of Religion) took place in Stockholm in 1897, and a similar one in the history of religions at Paris in 1900. Later, the International Association for the History of Religions, dedicated to a mainly nonnormative and nontheological approach, was formed. Also important was the compilation of encyclopaedias, notably Hastings' *Encyclopaedia of Religion and Ethics*, with many distinguished contributions. Thus, there were development and progress in the new subject in the latter part of the 19th and early part of the 20th century. In the 1960s came the next major burst of expansion.

A great amount of the work of scholars in the field has been devoted to exploring particular histories—piecing together, for instance, the history of Gnosticism (a Hellenistic-Christian heretical sect that emphasized dualism) or of early Buddhism. In principle, Christianity is considered from the same point of view, but much significant work has also been comparative and structural. This can range from the attempt to establish rather particular comparisons, such as Otto's comparison (in his *Mysticism East and West*) of the medieval German mystic Meister Eckehart and the medieval Hindu philosopher Śaṅkara, to a systematic typology, as in *Religion in Essence and Manifestation* by the Dutch historian of religion Gerardus van der Leeuw.

There have been many significant scholars in the history and phenomenology of religion since Max Müller. Rudolf Otto (1869–1937) made a profound impression on the scholarly world with the publication of *The Idea of the Holy* (in its German edition of 1917), which showed the influence of Schleiermacher, Marett, Edmund Husserl,

and the Neo-Kantianism of Jakob Fries (1773–1843). More important than the philosophical side of his enterprise, however, was the excellent delineation of a central experience and sentiment and the elucidation of the concept of the Holy. The central experience Otto refers to is the numinous (Latin *numen*, "spirit") in which the Other (i.e., the transcendent) appears as a *mysterium tremendum et fascinans*—that is, a mystery before which man both trembles and is fascinated, is both repelled and attracted. Thus, God can appear both as wrathful or awe inspiring, on the one hand, and as gracious and lovable, on the other. The sense of the numinous, according to Otto, is *sui generis*, though it may have psychological analogies, and it gives an access to reality, which is categorized as holy. Otto stresses what he calls the nonrational character of the numinous, but he does not deny that rational attributes may be applied to God (or the gods or other numinous powers), such as goodness and personality. The impact of Otto's work, however, does not depend on the now rather curious Neo-Kantian scheme into which he presses his data. Not all scholars would agree that the numinous is universal as a central element in religion, as Otto seems to have supposed: early Jainism and Theravāda Buddhism, for example, have other central values. Otto's treatment of mysticism, which is central to Buddhism, wavers somewhat, and the notions of the "wholly Other" and of the *tremendum* do not easily apply to the experience of Nirvāṇa (the state of bliss) or to other deliverances of the contemplative mystical consciousness.

Friedrich Heiler (1892–1967), like Otto a professor at Marburg (Germany), was a strong proponent of the phenomenological and comparative method, as in his major work on prayer. Heiler, however, went beyond the scientific study of religion in attempting to promote interreligious fellowship, partly through the Religiöser Menschheitsbund (Union of Religious Persons), which he helped to found. Heiler believed in the essential unity of religions—a recurring theme in various guises in the period, though open to question because of the widely apparent divergences between prophetic and other religions, such as Theravāda Buddhism and Jainism, which do not believe in a supreme personal being.

The phenomenologist of religion who probably has had the greatest influence after Otto, partly because he is fairly explicit about method, is Gerardus van der Leeuw (1890–1950), who was somewhat influenced by the French anthropologist Lucien Lévy-Bruhl (1857–1939) and his notion of prelogical mentality, which he applied to primitive cultures to distinguish them from civilized cultures. Van der Leeuw emphasized power as being the basic religious conception. His major work, *Religion in Essence and Manifestation*, is an ambitious and wide-ranging typology of religious phenomena, including the kinds of sacrifice, types of holy men, categories of religious experience, and other types of religious phenomena. The work has been criticized, however, as being unhistorical. Partly because of his philosophical presuppositions, borrowed chiefly from Husserl, van der Leeuw held the disputable doctrine that Phenomenology knows nothing of the historical development of religion: it picks out timeless essences of religious phenomena. Apparently it is not necessary, however, to hold this doctrine, since one could as well classify types of religious change (i.e., temporal sequences), as indeed Max Weber attempted to do. Classificatory and historical techniques and conclusions are not incompatible, however. Thus, the work of Nathan Söderblom, who, as well as being a historian of religions, was prominent in the ecumenical movement, combined the two aspects in his *Living God*.

The "Chicago school." The phenomenological method was brought to the United States primarily by the German-American historian of religions Joachim Wach (1898–1955), who established *Religionswissenschaft* (Science of Religion) in Chicago and was thus the founder of the modern "Chicago school" (though his successor, Mircea Eliade, has a rather different slant). Wach was concerned with emphasizing three aspects of religion—the theoretical (or mental; i.e., religious ideas and images), the practical (or behavioral), and the institutional (or social); and be-

The concept of the Holy

Emphases of Joachim Wach and Mircea Eliade

cause of his concern for the study of religious experience, he interested himself in the sociology of religion, attempting to indicate how religious values tended to shape the institutions that expressed them. Wach, however, was not committed to a religious neutralism in his use of the idea of a "science of religion." For him, *Religionswissenschaft* deepens the sense of the numinous and strengthens, rather than paralyzes, religious impulses.

Mircea Eliade (1907–), a Romanian scholar who emigrated to the United States after World War II, has had a wide influence, partly because of his substantive studies on *yoga* (a Hindu meditation technique) and on shamanism (both these major works are now regarded as classical studies of their subjects) and partly because of his later writings, which attempt to synthesize data from a wide variety of cultures. The synthesis incorporates a theory of myth and history. Eliade was also a founder of the journal *History of Religions*, which expresses the "Chicago school" viewpoint. Eliade has been somewhat influenced by Jung, both in his psychological interpretations of certain religious experiences (such as those attained in the practice of *yoga*) and more importantly in his attempt to give an interpretation in depth to the mythic material over which he ranges so widely. He also affirms strongly the importance of the history of religions in the intellectual world and is thus concerned to emphasize its unique and positive role in providing a "creative hermeneutics" (critical interpretive method) of man's religious and existential condition. Two important elements in the theory of Eliade are, first, that the distinction between the sacred and the profane is fundamental to religious thinking and is to be interpreted existentially (the symbols of religion are, typically, profane in literal interpretation but are of cosmic significance when viewed as signs of the sacred); and, second, that archaic religion is to be contrasted with the linear, historical view of the world. The latter essentially comes from biblical religion; the former viewpoint tends to treat time cyclically and mythically—referring to foundational events, such as the creation, the beginning of the human race, and the Fall of man, on to *illud tempus* (the sacred primordial time), which is re-enacted in the repetitions of the ritual and in the retelling of the myth. Though Christianity has contained archaic elements, in essence it is linear and historical. Thus, faith in Christianity involves a kind of fall from archaic timelessness, and secularization—in which the overt symbolism of religion is driven underground into the unconscious—is a second fall. Eliade is not very explicit about his meaning beyond this point. Not only is he concerned with descriptive phenomenology, in which context his analysis of the religious functions of time and space is most illuminating, but also with a kind of metaphysical speculation (as exemplified in his idea of the "fall").

Other studies and emphases. Though not always giving a detailed account of the correlation between myth and ritual, Eliade is indebted to the so-called myth and ritual school, which has influenced thinking in the history of religions and which was important in the 1930s, especially in the interpretation of Middle Eastern mythology. Thus, the *Enuma elish*, the Babylonian creation epic, was discovered to be no mere set of stories but rather a mythic drama re-enacted every year at the spring festival, at which time the foundation of the world is ritually renewed. More generally, it was seen that for a wide range of sacred stories it was important to discover the ritual context. The most influential statement of the school's position is to be found in *Myth and Ritual* (1933), edited by the English biblical scholar and Orientalist Samuel Hooke.

Meanwhile, the categorization of types of religion (e.g., as polytheism, henotheism, or other) continued to stimulate attempts at a deeper understanding of the emergence of monotheism. To some extent scholars remained under the influence of the older evolutionism. An important work in this connection was *Dio: Formazione e sviluppo del monoteismo nella storia delle religioni* ("God: Formation and Development of Monotheism in the History of Religions"), by the Italian historian of religion Raffaele Pettazzoni (1883–1959), who emphasized the importance of the divinized sky in the development of monothe-

ism. He was critical of the *Urmonotheismus* of Wilhelm Schmidt, considering that the latter's theory of an original monotheism went very far beyond the evidence. At best, the facts could only support the conclusion that primitive peoples believed in a supreme celestial being. Pettazzoni, in his concern for problems of method, was critical of the sharp division between phenomenology and history. He considered that the former cannot exist without the historical sciences—e.g., history, philology, and archaeology—but that it supplies scholars in the latter fields a sense of the religious significance of what they discover. This point of view has also been more vigorously espoused by the Swedish scholar Geo Widengren (1907–), who has specialized mainly in Iranian religions. The need to integrate historical and structural studies has caused some debate in recent years; and there has also been some contrast made between historical approaches and contemporary sociological and (essentially theological) dialogical approaches to religion. To some extent, such debates represent different ideals of scholarship; but it is difficult to note where the essential incompatibilities lie. For many scholars, the multidisciplinary way of studying religion is difficult to comprehend.

Meanwhile, the longstanding interest in the Indo-European group of religions was given a new impetus in the work of the French comparative philologist and mythologist Georges Dumézil (1898–), who broke away from an etymological (analysis of word derivations) approach and sought instead the thematic traits of the gods in the mythical material. This approach, pioneered by others before Dumézil, also was skeptical of the easy identification of gods with natural forces and emphasized the sociological functions of the divinities—without, however, holding to a reductionist theory. Dumézil's theory was partly stimulated by discoveries in the Middle East, notably that of Boğazköy (Turkey), which revealed a similarity between some of the chief gods of the Indo-European Mitannians and those of the Aryans of the Indian Vedic tradition. His theory correlated the functions of the gods with the tripartite division of Indo-European societies—namely the priestly regal, the nobility, and the producers (agriculturalists, craftsmen). Though his work has been controversial (there are, for instance, some difficulties about its application to ancient Greece, despite the fact that the analysis seems to apply to the threefold division of society into philosophers, warriors, and producers in Plato's *Republic*), there is no doubt that the search for correlated functions of the kind Dumézil postulated has been significant in the area of Indo-European mythology.

Dumézil's work is one example of a thematic, comparative study. The interest in such studies has grown since World War II. Examples can be found in the writings of such thinkers as the English scholar S.G.F. Brandon (1907–71) in his treatment of ideas such as creation and time in different religions, but with special reference to the ancient Middle East, and the English Indo-Iranian scholar R.C. Zaehner (1913–74), notably in his work on mysticism, as in his *Mysticism Sacred and Profane*. Zaehner's was a definitely Christian approach rather than a scientific-descriptive one; and his concern was to distinguish between theistic and other forms of mysticism, such as monistic mysticism as found, according to him, in Yoga, Advaita, and even Theravāda Buddhism.

Apart from the comparative, phenomenological studies, there has also been a strong growth of historical work in regard to particular religions. This has been most obvious in Indian religions—in Hinduism and Buddhism especially. In part, this is the result of a general growth in non-Christian religions in the post-World War II era and of the need to come to terms with Asian and African cultures after the demise of European hegemony.

PROBLEMS AND DIRECTIONS

The foregoing, a necessarily rather selective account of some of the principal developments and scholars in the various disciplines related to the descriptive, analytical study of religion, emphasizes the artificiality of some of the divisions between traditional disciplines. Thus, Dumézil's work could as easily fall under sociology or anthropology

Studies on the sociological functions of deities

The myth and ritual school

as under the history of religions; and there are obvious connections between philosophy and sociology in, for example, Marxist interpretations of religion. Again, the description and typology of religious experience belong as much to psychology as to the phenomenology of religion, and the analysis of the nature of symbolism requires a variety of disciplinary approaches. To some extent, the study of religion has suffered from the barriers between disciplines, and this fact is increasingly recognized in the formulations, notably in the United States, of the idea of religion as a subject that should be institutionalized in a university department or program in which historians, phenomenologists, and members of other disciplines work together. There are some, however, who consider that there are dangers in such an arrangement; thus Eliade prefers to work rather tightly within the framework of the history of religions, concerned lest the social sciences overwhelm and distract the interpreter of religious meanings. Similarly, the theological tradition in the West remains powerfully operative (quite legitimately) in regard to the articulation of the Christian faith and sometimes resists any attempt to treat Christianity itself in the manner dictated by the history and phenomenology of religion. Thus, the history of religions and the comparative study of religion still tend to mean in practice "the study of religions other than Judaism and Christianity." Educational and social pressures have arisen, however, within a secularistic, increasingly pluralistic society and (in effect) a shrunken world, increasing the tendency toward a pluralism in the study of religion that expands the viewpoints of traditional faculties and departments of theology, both in universities and theological seminaries.

A further problem about the multidisciplinary study of religion is that little has been done to explore the problem of the people to whom religions are interpreted—the clientele for the subject. Hitherto, the main assumption has been that the study is for Westerners, though a number of distinguished Asian and African scholars are working in the field. Until recently, owing to the unequal cultural and political relationship between Western and non-Western religions, however, some of the most vital contributions have been primarily attempts to articulate (for the new apologetic situation) the old traditions. This has been a main concern of scholars of Asian religions such as Sarvepalli Radhakrishnan, T.R.V. Murti, and K.N. Jayatilleke. The prospect is, however, that an intellectual community will be the clientele of the subject. To this extent the study of religions will most likely involve, as it does already to some extent, a complex dialogue between religions.

Another problem is the need to elucidate the basis of a dynamic typology of religion in which phenomenology and history are properly brought together. The tendency toward a rift between the historians and phenomenologists is unnecessary and causes harm to the pursuit of the subject.

Meanwhile, some emergent tendencies within the various disciplines can be perceived. There is an increased concern in anthropological theory for the content of religious symbolism, such as in the work of the English anthropologist Mary Douglas; and the sociology of religion is, in a sense, returning to the method of Max Weber in stressing the comparison of cultures. The important development of Oriental and African studies since World War II has made this task easier—American sociologists have, for example, examined in some detail Japanese culture and religion. The interest in symbolism and mythology coincides with developments in the philosophy of religion, which, under the influence of Wittgenstein (in his later, more open phase), is concerned with explicating different functions of language. One area of the study of religion that is seriously underdeveloped at the present time—other than in respect to the psychoanalytic approaches—is the psychology of religion, although current interest in mysticism and other forms of religious experience has stimulated the collection and interpretation of data. One of the difficult problems to be solved is the extent to which cultural conditioning exerts an influence on the actual content of such experience.

In many ways the present position promises well for an expanding multidisciplinary approach to problems in the study of religion. Historians of religion are recognizing some of the contributions to be made by modern sociology, and sociologists—partly because of the development of the sociology of knowledge—have become more aware of the need for accounting for the particular systems of meaning in religion. An area that may very well exhibit the new synthesis is the study of new religious movements.

After a period of relative unconcern, Christian theology is increasingly aware of the challenge of other religious beliefs, so that there are greater impulses toward blending Christian and other studies—often kept rather artificially apart, though biblical studies, especially Old Testament studies, have usually been quite closely related to the history of the relevant religions of the ancient Middle East.

Meanwhile, in a number of Western countries (chiefly in Europe, but also to some extent in the United States), the study of religion on a pluralistic and multidisciplinary basis is being increasingly viewed as an important element in the education of secondary school students. This, together with the popularity of the subject in universities, may ensure that the study of religion will increase in significance.

(N.Sm./Ed.)

The classification of forms and phenomena

The classification of religions, the attempt to systematize and bring order to a vast range of knowledge about man's religious beliefs, practices, and institutions, has been the goal of students of religion for many centuries but especially so with the increased knowledge of the world's religions and the advent of modern methods of scientific inquiry in the last two centuries.

The classification of religions involves: (1) the effort to establish groupings among historical religious communities having certain elements in common or, (2) the endeavour to group similar religious phenomena in categories that serve to reveal the structure of human religious experience as a whole.

FUNCTION AND SIGNIFICANCE

The many schemes suggested for classifying religious communities and religious phenomena all have one purpose in common; *i.e.*, to bring order, system, and intelligibility to the vast range of knowledge about human religious experience. Classification is basic to all science as a preliminary step in reducing data to manageable proportions and in moving toward a systematic understanding of a subject matter. Like the zoologist who must distinguish and describe the various orders of animal life as an indispensable stage in the broad attempt to understand the character of such life as a whole, the student of religion also must use the tool of classification in his outreach toward a scientific account of man's religious experience. The growth of scientific interest in religion in Western universities over the past 130 years has compelled most leading students of religion to discuss the problem of classification or to develop classifications of their own.

The difficulty of classifying religions is accounted for by the immensity of religious diversity that history exhibits. As far as scholars have discovered, there has never existed any people, anywhere, at any time, who were not in some sense religious. The individual who embarks upon the arduous task of trying to understand religion as a whole confronts an almost inconceivably huge and bewilderingly variegated host of phenomena from every locale and every era. Empirically, what is called religion includes the mythologies of the preliterate peoples on the one hand and the abstruse speculations of the most advanced religious philosophy on the other. Historically, religion, both ancient and modern, embraces both primitive religious practices and the aesthetically and symbolically refined worship of the more technologically progressive and literate human communities. The student of religion does not lack material for his studies; his problem is rather to discover principles that will help him to avoid the confusion of too much information. Classification is precisely the appeal to such principles; it is a device for making the

Classification as a tool in understanding religion

otherwise unmanageable wealth of religious phenomena intelligible and orderly.

The endeavour to group religions with common characteristics or to discover types of religions and religious phenomena belongs to the systematizing stage of religious study. According to Max Müller,

All real science rests on classification and only in case we cannot succeed in classifying the various dialects of faith, shall we have to confess that a science of religion is really an impossibility.

PRINCIPLES OF CLASSIFICATION

The criteria employed for the classification of religions are far too numerous to catalogue completely. Virtually every scholar who has considered the matter has evidenced a certain amount of originality in his view of the interrelationships among religious forms. Thus, only some of the more important principles of classification will be discussed.

Normative. Perhaps the most common division of religions—and in many ways the most unsatisfactory—distinguishes true religion from false religion. Such classifications may be discovered in the thought of most major religious groups and are the natural, perhaps inevitable, result of the need to defend particular perspectives against challengers or rivals. Normative classifications, however, have no scientific value, because they are arbitrary and subjective, inasmuch as there is no agreed method for selecting the criteria by which such judgments should be made. But because living religions always feel the need of apologetics (systematic intellectual defenses), normative classifications continue to exist.

Many examples of normative classification might be given. The early Church Fathers (*e.g.*, Clement of Alexandria, 2nd century AD) explained that Christianity's Hellenistic (Greco-Roman culture) rivals were the creations of fallen angels, imperfect plagiarisms of the true religion, or the outcome of divine condescension that took into account the weaknesses of men. The greatest medieval philosopher and theologian, Thomas Aquinas, distinguished natural religion, or that kind of religious truth discoverable by unaided reason, from revealed religion, or religion resting upon divine truth, which he identified exclusively with Christianity. In the 16th century Martin Luther, the great Protestant Reformer, forthrightly labelled the religious views of Muslims, Jews, and Roman Catholic Christians to be false and held the view that the gospel of Christianity understood from the viewpoint of justification by grace through faith was the true standard. In Islām, religions are classified into three groups: the wholly true, the partially true, and the wholly false, corresponding with Islām, the Peoples of the Book (Jews, Christians, and Zoroastrians), and polytheism. The classification is of particular interest because, being based in the Qur'ān, (the Islāmic sacred scripture), it is an integral part of Islāmic teaching, and also because it has legal implications for Muslim treatment of followers of other religions.

Although scientific approaches to religion in the 19th century discouraged use of normative categories, elements of normative judgment were, nonetheless, hidden in certain of the new scientific classifications that had emerged. Many evolutionary schemes developed by anthropologists and other scholars, for example, ranked religions according to their places on a scale of development from the simplest to the most sophisticated, thus expressing an implicit judgment on the religious forms discussed. Such schemes more or less clearly assume the superiority of the religions that were ranked higher (*i.e.*, later and more complex); or, conversely, they serve as a subtle attack on all religion by demonstrating that its origins lie in some of humanity's basest superstitions, believed to come from an early, crude stage. A normative element is also indicated in classification schemes that preserve theological distinctions, such as that between natural and revealed religion. In short, the normative factor still has an important place in the classification of religions and will doubtless always have, since it is extraordinarily difficult to draw precise lines between disciplines primarily devoted to the normative exposition of religion, such as theology and philosophy

of religion, and disciplines devoted to its description or scientific study.

Geographical. A common and relatively simple type of classification is based upon the geographical distribution of religious communities. Those religions found in a single region of the earth are grouped together. Such classifications are found in many textbooks on comparative religion, and they offer a convenient framework for presenting man's religious history. The categories most often used are: (1) Middle Eastern religions, including Judaism, Christianity, Islām, Zoroastrianism, and a variety of ancient cults; (2) Far Eastern religions, comprising the religious communities of China, Japan, and Korea, and consisting of Confucianism, Taoism, Mahāyāna ("Greater Vehicle") Buddhism, and Shintō; (3) Indian religions, including early Buddhism, Hinduism, Jainism, and Sikhism, and sometimes also Theravāda Buddhism and the Hindu and Buddhist-inspired religions of South and Southeast Asia; (4) African religions, or the cults of the tribal peoples of black Africa, but excluding ancient Egyptian religion, which is considered to belong to the ancient Middle East; (5) American religions, consisting of the beliefs and practices of the Indian peoples indigenous to the two American continents; (6) Oceanic religions—*i.e.*, the religious systems of the peoples of the Pacific islands, Australia, and New Zealand; (7) classical religions of ancient Greece and Rome and their Hellenistic descendants. The extent and complexity of a geographical classification is limited only by the classifier's knowledge of geography and his desire to seek detail and comprehensiveness in his classification scheme. Relatively crude geographical schemes that distinguish Western religions (usually equivalent to Christianity and Judaism) from Eastern religions are quite common.

Although religions centred in a particular area often have much in common because of historical or genetic connections, geographical classifications present obvious inadequacies. Many religions, including some of the greatest historical importance, are not confined to a single region (*e.g.*, Islām), or do not have their greatest strength in the region of their origins (*e.g.*, Christianity, Buddhism). Further, a single region or continent may be the dwelling place of many different religious communities and viewpoints that range from the most archaic to the most sophisticated. At a more profound level, geographical classifications are unacceptable because they have nothing to do with the essential constitutive elements or inner spirit of religion. The physical location of a religious community reveals little of the specific religious life of the group. Though useful for some purposes, geographical classifications contribute minimally to the task of providing a systematic understanding of man's religions and religiousness.

Ethnographic-linguistic. Max Müller, often called the "Father of the history of religions," stated that "Particularly in the early history of the human intellect, there exists the most intimate relationship between language, religion, and nationality." This insight supplies the basis for a genetic classification of religions (associating them by descent from a common origin), which Müller believed the most scientific principle possible. According to this theory, in Asia and Europe dwell three great races, the Turanians (including the Ural-Altaic peoples), the Semites, and the Aryans, to which correspond three great families of languages. Originally, in some remote prehistory, each of these races formed a unity, but with the passage of time they split up into a myriad of peoples with a great number of distinct languages. Through careful investigation, however, the original unity may be discerned, including the unity of religion in each case. Müller's principal resource in developing the resulting classification of religions was the comparative study of languages, from which he sought to demonstrate similarities in the names of deities, the existence of common mythologies, the common occurrence of important terms in religious life, and the likeness of religious ideas and intuitions among the branches of a racial group. His efforts were most successful in the case of the Semites, whose affinities are easy to demonstrate, and probably least successful in the case of the Turanian peoples, whose early origins are hypothetical. Müller's greatest contribution to scholarship, however, lay in his study of

Geo-
graphical
categories

True
and
false
religion

Use of the
compara-
tive
study of
languages

Aryan languages, literatures, and comparative mythology.

Because Müller was a scholar of the first rank and a pioneer in several fields, his ethnographic-linguistic (and genetic) classification of religions has had much influence and has been widely discussed. The classification has value in exhibiting connections that had not been previously observed. Müller (and his followers) discovered affinities existing among the religious perspectives of both the Aryan and Semitic peoples and set numerous scholars on the path of investigating comparative mythology, thus contributing in a most direct way to the store of knowledge about religions.

There are, nevertheless, difficulties with the ethnographic-linguistic classification. To begin with, Müller's evidence was incomplete, a fact that may be overlooked given the state of knowledge in his day. More important is the consideration that peoples of widely differing cultural development and outlook are found within the same racial or linguistic group. Further, the principle of connection among race, language, and religion does not take sufficiently into account the historical element or the possibility of developments that may break this connection, such as the conversion of the Aryan peoples of Europe to a Semitic religion, Christianity.

Other scholars have developed the ethnographic classification of religion to a much higher degree than did Müller. The German scholar Duren J.H. Ward, for example, in *The Classification of Religions* (1909) accepted the premise of the connection between race and religion but appealed to a much more detailed scheme of ethnological relationship. He says that "religion gets its character from the people or race who develop or adopt it" and further that

the same influences, forces, and isolated circumstances which developed a special race developed at the same time a special religion, which is a necessary constituent element or part of a race.

In order to study religion in its fullness and to bring out with clarity the historical and genetic connections between religious groups, the ethnographic element must thus have adequate treatment. Ward devised a comprehensive "Ethnographic-historical Classification of the Human Races to facilitate the Study of Religions—in five divisions." These major divisions were (1) the Oceanic races, (2) the African races, (3) the American races, (4) the Mongolian races, and (5) the Mediterranean races, each of which has its own peculiar religion. The largest branch, the Mediterranean races, he subdivided into primeval Semites and primeval Aryans, in order to demonstrate in turn how the various Semitic, Indo-Aryan, and European races descended from these original stocks.

Philosophical. The past 150 years have also produced several classifications of religion based on speculative and abstract concepts that serve the purposes of philosophy. The principal example of these is the scheme of G.W.F. Hegel, a seminal German philosopher, in his famous *Lectures on the Philosophy of Religion* (1832). In general, Hegel's understanding of religion coincided with his philosophical thought; he viewed the whole of human history as a vast dialectical movement toward the realization of freedom. The reality of history, he held, is Spirit, and the story of religion is the process by which Spirit—true to its own internal logical character and following the dialectical pattern of thesis, antithesis, and synthesis (the reconciliation of the tension of opposite positions in a new unity that forms the basis of a further tension)—comes to full consciousness of itself. Individual religions thus represent stages in a process of evolution (*i.e.*, progressive steps in the unfolding of Spirit) directed toward the great goal at which all history aims.

Hegel classified religions according to the role that they have played in the self-realization of Spirit. The historical religions fall into three great divisions, corresponding with the stages of the dialectical progression. At the lowest level of development, according to Hegel, are the religions of nature, or religions based principally upon the immediate consciousness deriving from sense experience. They include: immediate religion or magic at the lowest level; religions, such as those of China and India plus Buddhism,

that represent a division of consciousness within itself; and others, such as the religions of ancient Persia, Syria, and Egypt, that form a transition to the next type. At an intermediate level are the religions of spiritual individuality, among which Hegel placed Judaism (the religion of sublimity), ancient Greek religion (the religion of beauty), and ancient Roman religion (the religion of utility). At the highest level is absolute religion, or the religion of complete spirituality, which Hegel identified with Christianity. The progression thus proceeds from man immersed in nature and functioning only at the level of sensual consciousness, to man becoming conscious of himself in his individuality as distinct from nature, and beyond that to a grand awareness in which the opposition of individuality and nature is overcome in the realization of Absolute Spirit.

Many criticisms have been offered of Hegel's classification. An immediately noticeable shortcoming is the failure to make a place for Islām, one of the major historical religious communities. The classification is also questionable for its assumption of continuous development in history. The notion of perpetual progress is not only doubtful in itself but is also compromised as a principle of classification because of its value implications.

Nevertheless, Hegel's scheme was influential and was adapted and modified by a generation of philosophers of religion in the Idealist tradition. Departure from Hegel's scheme, however, may be seen in the works of Otto Pfleiderer, a German theologian of the 19th century. Pfleiderer believed it impossible to achieve a significant grouping of religions unless, as a necessary preliminary condition, the essence of religion were first isolated and clearly understood. Essence is a philosophical concept, however, not a historical one. Pfleiderer considered it indispensable to have conceptual clarity about the underlying and underived basis of religion from which all else in religious life follows. In *Die Religion, ihr Wesen und ihre Geschichte* ("Religion, Its Essence and History"), Pfleiderer held that the essence of religious consciousness exhibits two elements, or moments, perpetually in tension with one another: one of freedom and one of dependence, with a number of different kinds of relationships between these two. One or the other may predominate, or they may be mixed in varying degrees.

Pfleiderer derived his classification of religions from the relationships between these basic elements. He distinguished one great group of religions that exhibits extreme partiality for one over against the other. The religions in which the sense of dependence is virtually exclusive are those of the ancient Semites, the Egyptians, and the Chinese. Opposite these are the early Indian, Germanic, and Greek and Roman religions, in which the sense of freedom prevails. The religion of this group may also be seen in a different way, as nature religions in the less-developed cultures or as culture or humanitarian religions in the more advanced. A second group of religions exhibits a recognition of both elements of religion, but gives them unequal value. These religions are called supernatural religions. Among them Zoroastrianism gives more weight to freedom as a factor in its piety, and Brahmanism and Buddhism are judged to have a stronger sense of dependence. The last group of religions is the monotheistic religions: Islām, Judaism, and Christianity, which are divided again into two sub-groups, *i.e.*, those that achieve an exact balance of the elements of religion and those that achieve a blending and merging of the elements. Both Judaism and Islām grant the importance of the two poles of piety, though there is a slight tendency in Islām toward the element of dependence and in Judaism toward freedom. It is Christianity alone, he claimed, that accomplishes the blending of the two, realizing both together in their fullness, the one through the other.

The intellectual heritage that lies behind this classification will be immediately apparent. The classification reflects its time (19th century) and place (western Europe) of conception in the sense that the study of religion was not yet liberated from its ties to the philosophy of religion and theology.

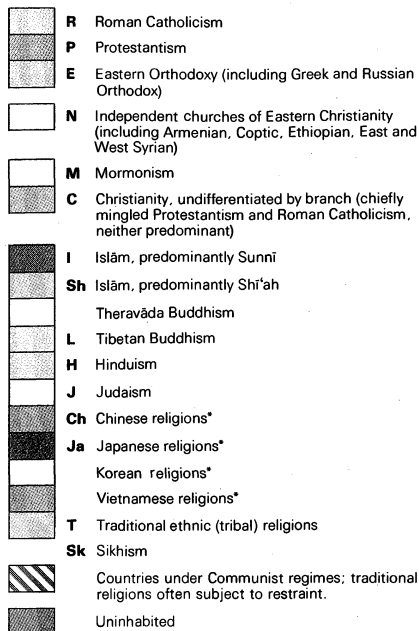

Morphological. Considerable progress toward more scientific classifications of religions was marked by the

RELIGIONS

The majority of the inhabitants in each of the areas colored on the map share the religious tradition indicated. Letter symbols show religious traditions shared by at least 25 percent of the inhabitants within areal units no smaller than one thousand square miles. Therefore minority religions of city-dwellers have generally not been represented.

*In certain eastern Asian areas, most of the people have plural religious affiliations. Chinese, Korean, and Vietnamese religions include Mahāyāna Buddhism, Taoism, Confucianism, and folk cults. The Japanese religions include Shintō and Mahāyāna Buddhism.

Geographical distribution of the religions of the world in the early 1980s.

Old World religions adapted from D. Sopher, *Geography of Religions* (© 1967)

emergence of morphological schemes, which assume that religion in its history has passed through a series of discernible stages of development, each having readily identifiable characteristics and each constituting an advance beyond the former stage. So essential is the notion of progressive development to morphological schemes that they might also be called evolutionary classifications. Trends in the comparative study of religions have retained the interest in morphology but have decisively rejected the almost universal 19th-century assumption of unitary evolution in the history of religion. The crude expression of evolutionary categories such as the division of religions into lower and higher or primitive and higher religions has been subjected to especially severe criticism.

The pioneer of morphological classifications was E.B. Tylor, a British anthropologist, whose *Primitive Culture* (1871) is among the most influential books ever written in its field. Tylor developed the thesis of animism, a view that the essential element in all religion is belief in spiritual beings. According to Tylor, the belief arises naturally from elements universal in human experience (e.g., death, sleep, dreams, trances, and hallucinations) and leads through processes of primitive logic to the belief in a spiritual reality distinct from the body and capable of existing independently. In the development of the idea, this reality is identified with the breath and the life principle; thus arises the belief in the soul, in phantoms, and in ghosts. At a higher stage, the spiritual principle is attributed to aspects of reality other than man, and all things are believed to possess spirits that are their effective and animating elements; for example, primitive men generally believe that spirits cause sickness and control their destinies.

Of immediate interest is the classification of religions drawn from Tylor's animistic thesis. Ancestor worship, prevalent in preliterate societies, is obeisance to the spirits of the dead. Fetishism, the veneration of objects believed to have magical or supernatural potency, springs from the association of spirits with particular places or things and

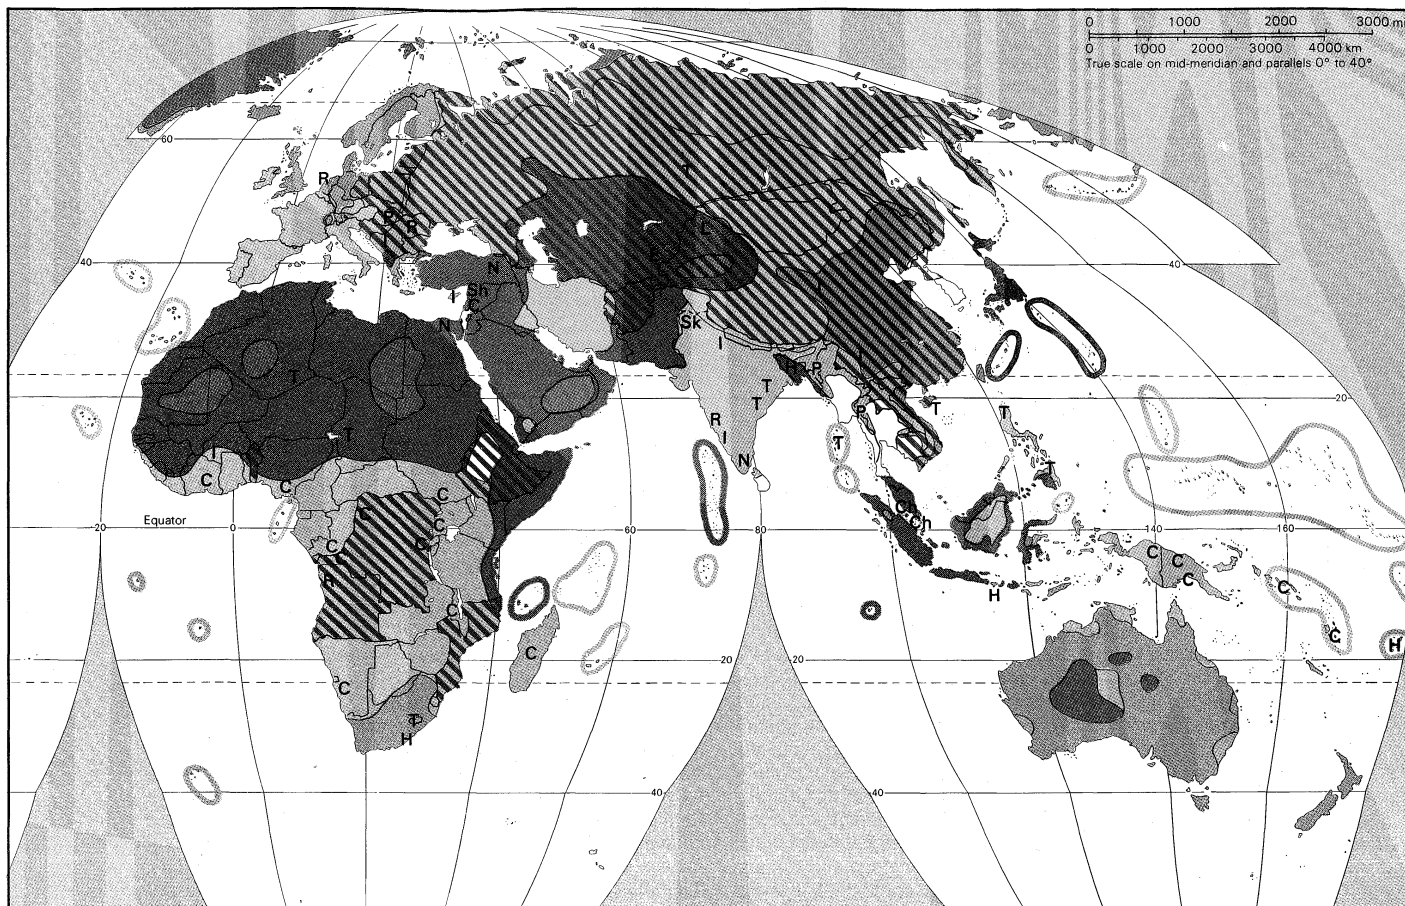

leads to idolatry, in which the image is viewed as the symbol of a spiritual being or deity. Totemism, the belief in an association between particular groups of people and certain spirits that serve as guardians of those people, arises when the entire world is conceived as peopled by spiritual beings. At a still higher stage, polytheism, the interest in particular deities or spirits disappears and is replaced by concern for a "species" deity who represents an entire class of similar spiritual realities. By a variety of means, polytheism may evolve into monotheism, a belief in a supreme and unique deity. Tylor's theory of the nature of religions and the resultant classification were so logical, convincing, and comprehensive that for a number of years they remained virtually unchallenged.

The morphological classification of religions received more sophisticated expression from C.P. Tiele, a 19th-century Dutch scholar and an important pioneer in the scientific study of religion. His point of departure was a pair of distinctions made by the philosophers of religion Abraham Kuenen and W.D. Whitney. In the Hibbert Lectures for 1882, *National Religions and Universal Religions*, Kuenen had emphasized the difference between religions limited to a particular people and those that have taken root among many peoples and qualitatively aim at becoming universal. Whitney saw the most marked distinction among religions as being between race religions ("the collective product of the wisdom of a community") and individually founded religions. The first are the result of nature's unconscious working through long periods of time, and the latter are characterized by a high degree of ethical awareness. Tiele agreed strongly with Whitney in distinguishing between nature and ethical religions. Ethical religion, in Tiele's views, develops out of nature religion,

But the substitution of ethical religions for nature-religions is, as a rule, the result of a revolution; or at least of an intentional reform.

Each of these categories (i.e., nature or spiritualistic-ethical) may be further subdivided. At the earliest and

and spirit-
ualistic-
ethical
religions

lowest stage of spiritual development was polyzoic religion, about which there is no information but which is based on Tiele's theory that man must have regarded natural phenomena as endowed with life and superhuman magical power. The first known stage of the nature religions is called polydaemonic (many spirits) magical religion, which is dominated by animism and characterized by a confused mythology, a firm faith in magic, and the preeminence of fear above other religious emotions. At a higher stage of nature religions is therianthrope polytheism, in which the deities are normally of mixed animal and human composition. The highest stage of nature religion is anthropomorphic polytheism, in which the deities appear in human form but have superhuman powers. These religions have some ethical elements, but their mythology portrays the deities as indulging in all sorts of shocking acts. None of the polytheistic religions, thus, was able to raise itself to a truly ethical point of view.

Ethical religions fall into two subcategories. First are the national nomistic (legal) religions that are particularistic, limited to the horizon of one people only and based upon a sacred law drawn from sacred books. Above them are the universalistic religions, qualitatively different in kind, aspiring to be accepted by all men, and based upon abstract principles and maxims. In both subtypes, doctrines and teachings are associated with the careers of distinct personalities who play important roles in their origin and formation. Tiele found only three examples of this highest type of religion: Islām, Christianity, and Buddhism.

Tiele's classification enjoyed a great vogue and influenced many who came after him. Nathan Söderblom, a Swedish archbishop who devoted much energy to problems of classification, accepted the division of higher religions into two great groups but used a varied terminology that pointed to some of the characteristics of the two types of religion. In addition to natural religion and revealed religion, or religions of nature and religions of revelation, Söderblom spoke of culture religions and prophetic religions, of culture religions and founded religions, and of nature religions and historical religions. The highest

expression of the first category is the "mysticism of infinity" that is characteristic of the higher aspects of Hindu and Buddhist religious experience. The apex of genuine prophetic religion is reached in the "mysticism of personality." All these distinctions mean the same thing, and all are indebted to Tiele's thought. Söderblom, however, sharply disagreed with Tiele's thesis of continuous development in the history of religion. In Söderblom's view, the line between nature religion and prophetic religion is a deep and unbridgeable chasm, a qualitative difference so enormous that one type could never evolve by natural historical processes into the other. Prophetic religion can be explained only as a radical and utterly new incursion into history. As Söderblom was a churchman and theologian as well as a distinguished historian of religion, there is without doubt an element of theological judgment influencing his stand on this matter. Söderblom was eager to defend the uniqueness of biblical religion, and he believed that his historical and scientific studies provided an objective basis for asserting not only the uniqueness but also the superiority of Christianity.

Tiele's enduring influence may also be seen in the classification of religions advanced by Mircea Eliade, a Romanian-American scholar who was one of the most prolific contemporary students of religion. Eliade, who in other respects might be considered among the phenomenologists of religion, was interested in uncovering the "structures" or "patterns" of religious life. The basic division that Eliade recognized is between traditional religions—including primitive religions and the archaic cults of the ancient civilizations of Asia, Europe, and America—and historical religions. The distinction is better revealed, however, in the terms cosmic religion and historical religion. In Eliade's estimation, all of traditional religion shares a common outlook upon the world—chiefly, the deprecation of history and the rejection of profane, mundane time. Religiously, traditional man is not interested in the unique and specific but rather exclusively in those things and actions that repeat and restore transcendental models. Only those things that participate in and reflect the eternal archetypes

Influence
of Nathan
Söderblom

or the great pattern of original creation by which cosmos came out of chaos are real in the traditional outlook. The religious activities of traditional man are the recurring attempts to return to the beginning, to the Great Time, to trace again and renew the process by which the structure and order of the cosmos were established. Traditional religions may, therefore, find the sacred in any aspect of the world that links man to the archetypes of the time in the beginning; thus, their typical mode of expression is repetitive. Further, their understanding of history, as far as they are concerned with it at all, is cyclical. The world and what happens in it are devalued, except as they show forth the eternal pattern of the original creation.

Modern, postarchaic, or historical religions (e.g., Judaism, Christianity, Islām) show markedly other features. They tend to see a discontinuity between God and the world and to locate the sacred not in the cosmos but somewhere beyond it. Moreover, they hold to linear views of history, believing it to have a beginning and an end, with a definite goal as its climax, and to be by nature unrepeatable. Thus, the historical religions are world affirming in the double sense of believing in the reality of the world and of believing that meaning for man is worked out in the historical process. By reason of these views, the historical religions alone have been monotheistic and exclusivist in their theologies. Although Eliade outstripped his predecessors in delineating the qualities of traditional religion in particular, much of his thought was anticipated in Söderblom's descriptions of nature religion and prophetic religion.

Phenomenological. All the principles thus far discussed have had reference to the classification of religions in the sense of establishing groupings among historical religious communities having certain elements in common. While attempts have been made to classify entire religions or religious communities, in recent times the interest in classifying entire religions has markedly declined, partly because of an emerging interest in the phenomenology of religion.

This new trend in studies, which has come to dominate the field, claims its origin in the phenomenological philosophy of Edmund Husserl, a German Jewish-Lutheran scholar, and has found its greatest exponents in The Netherlands. Phenomenology of religion has at least two aspects. It is first of all an effort at devising a taxonomic (classificatory) scheme that will permit the comprehensive cataloging and classifying of religious phenomena across the lines of religious communities, but it is also a method that aims at revealing the self-interpretation by religious men of their own religious responses. Phenomenology of religion thus rejects any overview of religion that would interpret religion's development as a whole, confining itself rather to the phenomena and the unfolding of their meaning for religious men. Phenomenologists are especially vigorous in repudiating the evolutionary schemes of past scholars, whom they accuse of imposing arbitrary semiphilosophical concepts in their interpretation of the history of religion. Phenomenologists also have little interest in history for its own sake, except as a preliminary stage of material gathering for the hermeneutical (critical-interpretive) task that is to follow.

One of the earliest Dutch phenomenologists, W. Brede Kristensen (1867-1953), spoke of his work as follows:

Phenomenology of Religion attempts to understand religious phenomena by classifying them into groups . . . we must group the phenomena according to characteristics which correspond as far as possible to the essential and typical elements of religion.

The material with which phenomenology is concerned is all the different types of religious thinking and action, ideas about divinity, and cultic acts. Kristensen's systematic organization of religious phenomena may be seen in the table of contents of his *Meaning of Religion* in which he divides his presentation of material into discussions of (1) cosmology, which includes worship of nature in the form of sky and earth deities, animal worship, totemism, and animism, (2) anthropology, made up of a variety of considerations on the nature of man, his life, and his associations in society, (3) cultus, which involves consideration of sacred places, sacred times, and sacred images, and (4) cultic acts, such as prayer, oaths and curses, and

ordeals. Kristensen was not concerned with the historical development or the description of a particular religion or even a series of religions but rather with grouping the typical elements of the entire religious life, irrespective of the community in which they might occur.

Probably the best known phenomenologist is G. van der Leeuw, another Dutch scholar. In his *Religion in Essence and Manifestation*, van der Leeuw categorized the material of religious life under the following headings: (1) the object of religion, or that which evokes the religious response, (2) the subject of religion, in which there are three divisions: the sacred man, the sacred community, and the sacred within man, or the soul, (3) object and subject in their reciprocal operation as outward reaction and inward action, (4) the world, ways to the world, and the goals of the world, and (5) forms, which must take into account religions and the founders of religions. Van der Leeuw was not interested in grouping religious communities as such but rather in laying out the types of religious expression. He discussed distinct religions only because religion in the abstract has no existence. He classified religions according to 12 forms: (1) religion of remoteness and flight (ancient China and 18th-century deism), (2) religion of struggle (Zoroastrianism), (3) religion of repose, which has no specific historical form but is found in every religion in the form of mysticism, (4) religion of unrest or theism, which again has no specific form but is found in many religions, (5) dynamic of religions in relation to other religions (syncretism and missions), (6) dynamic of religions in terms of internal developments (revivals and reformations), (7) religion of strain and form, the first that van der Leeuw characterizes as one of the "great" forms of religion (Greece), (8) religion of infinity and of asceticism (Indian religions but excluding Buddhism), (9) religion of nothingness and compassion (Buddhism), (10) religion of will and of obedience (Israel), (11) the religion of majesty and humility (Islām), and (12) the religion of love (Christianity). The above is not a classification of religions as organized systems. Categories 3, 4, 5, and 6 relate to elements found in many if not all historical religious communities, and the categories from 7 onward are not classifications but attempts to characterize particular communities by short phrases that express what van der Leeuw considered to be their essential spirit. The "primitive" religions of less-developed peoples are not classified.

Other principles. William James, the American philosopher and psychologist, in his book *The Varieties of Religious Experience*, differentiated two types of religion according to the attitude toward life—the religion of healthy-mindedness, which minimizes or ignores the evil of existence, and that of morbid-mindedness, which considers evil as the very essence of life. Max Weber, a German sociologist, distinguished between religions that express themselves primarily in mythopoeic ways and those that express themselves in rational forms. The distinction comes very close to that between traditional and historical religions, though its emphasis is somewhat different.

Nathan Söderblom, in his prolific scholarly career, devised several classifications other than the principal one discussed above. In his great work on primitive religions, *Das Werden des Gottesglaubens* ("Development of the Belief in God"), Söderblom divided religions into dynamistic, animistic, and theistic types according to the way primitive peoples apprehend the divine. In other works (*Einführung in die Religionsgeschichte*, or "Introduction to the History of Religion," and *Thieles Kompendium der Religionsgeschichte neu bearbeitet*, or "Tiele's Compendium of the History of Religion Revised") he contended that Christianity is the central point of the entire history of religions and, therefore, classified religions according to the historical order in which they came into contact with Christianity. Similarly, Albert Schweitzer, the French theologian, medical missionary, and Nobel laureate, in *Christianity and the Religions of the World*, grouped religions as rivals or nonrivals of Christianity. Still another scheme may be seen in Söderblom's Gifford Lectures, *The Living God*, in which religions were divided according to their doctrines of the relation between human and divine activity in the achievement of salvation. Thus, among higher religions

Significance of G. van der Leeuw

Purposes of the phenomenology of religion

Psychological and sociological types

there are those in which man alone is responsible for salvation (Buddhism), God alone is responsible (the Bhakti cults of India), or God and man cooperate (Christianity).

The American sociologist Robert Bellah, having in mind the advances of the social sciences in their understanding of religions, offers a refurbished and more highly sophisticated version of an evolutionary scheme that he thinks to be the most satisfactory possible in the present state of scholarly knowledge. He views religion as having passed through five stages, beginning with the primitive and proceeding through the archaic, the historical, and the early modern to the modern stage. The religious complexes that emerge in each stage of this evolution have identifiable characteristics that Bellah studies and differentiates according to the following categories: symbol systems, religious actions, religious organizations, and social implications. Two basic concepts run through Bellah's classification, providing the instruments for the division of religions along the evolutionary scale. The first is that of the increasing complexity of symbolization as one moves from the bottom to the top of the scale, and the second is that of increasing freedom of personality and society from their environing circumstances or, in other words, the growing secularization of the religious field. Bellah's classification is important because of the wide discussion it has awakened among social scientists.

One may find additional classifications based upon the content of religious ideas, the forms of religious teaching, the nature of cultus, the character of piety, the nature of the emotional involvement in religion, the character of the good toward which religions strive, and the relations of religions to the state, to art, to science, and to morality.

CONCLUSION

The classification of religions that will withstand all criticism and serve all the purposes of a general science of religions has not been devised. Each classification presented above has been attacked for its inadequacies or distortions, yet each is useful in bringing to light certain aspects of religion. Even the crudest and most subjective classifications throw into relief various aspects of religious life and thus contribute to the cause of understanding. The most fruitful approach for a student of religion appears to be that of employing a number of diverse classifications, each one for the insight it may yield. Though each may have its shortcomings, each also offers a positive contribution to the store of knowledge and its systematization. The insistence upon the exclusive validity of any single taxonomic effort must be avoided. To confine oneself to a single determined framework of thought about so rich and variegated a subject as religion is to risk the danger of missing much that is important. Classification should be viewed as a method and a tool only.

Although a perfect classification lies at present beyond scholars' grasp, certain criteria, both positive and negative in nature, may be suggested for building and judging classifications. First, classifications should not be arbitrary, subjective, or provincial. A first principle of the scientific method is that objectivity should be pursued to the extent possible and that findings should be capable of confirmation by other observers. Second, an acceptable classification should deal with the essential and typical in the religious life, not with the accidental and the unimportant. The contribution to understanding that a classification may make is in direct proportion to the penetration of the bases of religious life exhibited in its principles of division. A good classification must concern itself with the fundamentals of religion and with the most typical elements of the units it is seeking to order. Third, a proper classification should be capable of presenting both that which is common to religious forms of a given type and that which is peculiar or unique to each member of the type. Thus, no classification should ignore the concrete historical individuality of religious manifestations in favour of that which is common to them all, nor should it neglect to demonstrate the common factors that are the bases for the very distinction of types of religious experience, manifestations, and forms. Classification of religions

involves both the systematic and the historical tasks of the general science of religion. Fourth, it is desirable in a classification that it demonstrate the dynamics of religious life both in the recognition that religions as living systems are constantly changing and in the effort to show, through the categories chosen, how it is possible for one religious form or manifestation to develop into another. Few errors have been more damaging to the understanding of religion than that of viewing religious systems as static and fixed, as, in effect, ahistorical. Adequate classifications should possess the flexibility to come to terms with the flexibility of religion itself. Fifth, a classification must define what exactly is to be classified. If the purpose is to develop types of religions as a whole, the questions of what constitutes a religion and what constitutes various individual religions must be asked. Since no historical manifestation of religion is known that has not exhibited an unvarying process of change, evolution, and development, these questions are far from easily solved. With such criteria in mind it should be possible continuously to construct classification schemes that illuminate man's religious history. (C.J.A.)

BIBLIOGRAPHY. JAN DE VRIES, *The Study of Religion* (1967), a fairly useful and brief historical survey of the development of the subject; H. PINARD DE LA BOULLAYE, *L'Étude comparée des religions*, 2 vol. (1922-25), a thorough and excellent account; J. MILTON YINGER, *The Scientific Study of Religion* (1970), an attempt to indicate the multidisciplinary approach to the study of religion; J. HASTINGS (ed.), *Encyclopaedia of Religion and Ethics*, 13 vol. (1908-26), dated in many respects but still enormously important; PAUL EDWARDS (ed.), *Encyclopedia of Philosophy*, 8 vol. (1967), many entries on world religions, doctrines, and religious thinkers; JOHN MACQUARRIE, *Twentieth Century Religious Thought* (1963), a survey, despite its title, of both 19th- and 20th-century thinkers, including many important in the history and phenomenology of religion (also a good general guide to issues in modern Western theology); G. VAN DER LEEUW, *Phänomenologie der Religion* (1933; Eng. trans., *Religion in Essence and Manifestation*, 1938), the most wide-ranging and ambitious attempt at a systematic and classificatory phenomenology of religion; RUDOLF OTTO, *Das Heilige* (1917; Eng. trans., *The Idea of the Holy*, 2nd ed., 1950), a highly influential classic; J. WACH, *The Comparative Study of Religion* (1958) and *Sociology of Religion* (1962), still useful compendiums; J. HINNELL (ed.), *The Comparative Study of Religion in Education* (1970); MICHAEL BANTON (ed.), *Anthropological Approaches to Religion* (1966); E. EVANS-PRITCHARD, *Theories of Primitive Religion* (1965), which, with Banton, indicates the main issues about the genesis and function of religion debated by anthropologists; THOMAS O'DEA, *The Sociology of Religion* (1966), a useful survey; and MAX WEBER, *Religions-soziologie* (1922; Eng. trans., *The Sociology of Religion*, ed. by TALCOTT PARSONS, 1963), a good introduction to the thought of Weber. PETER BERGER, *The Sacred Canopy* (also published as *The Social Reality of Religion*, 1969), more speculative but a stimulating example of modern sociological theorizing about religion; V. LANTERNARI, *The Religions of the Oppressed* (1963), an example of comparative sociology of religion; and J. HICK, *The Philosophy of Religion* (1963), a useful survey of issues in the philosophy of religion. MIRCEA ELIADE wrote widely from a standpoint that combines elements drawn from depth psychology, phenomenology, and the history of religions: his *Sacred and the Profane* (1961) and *The Quest* (1969) give an insight into his general approach. (N.Sm.)

Two monographs dealing specifically with the classification of religions, each of which offers a survey of previous classifications in addition to the author's own scheme, are DUREN J.H. WARD, *The Classification of Religions: Different Methods, Their Advantages and Disadvantages* (1909); and FRED LOUIS PARRISH, *The Classification of Religions: Its Relation to the History of Religions* (1941), containing a full survey of classification schemes with brief characterizations of each and the best bibliographical guide for pursuing the subject in depth. Other books for further study are as follows: P.D. CHANTEPIE DE LA SAUSSAYE, *Lehrbuch der Religionsgeschichte*, 2 vol. (1887-89; Eng. trans. of vol. 1, *Manual of the Science of Religion*, 1891), which includes classification problems at the beginning of vol. 1; C.P. TIELE, *Elements of the Science of Religion*, 2 vol. (1897-99), a classic work by an important scholar on this subject; and F. MAX MUELLER, *Introduction to the Science of Religion* (1873), another classic work. Of more recent origin is GUSTAV MENSCHING, *Die Religion: Erscheinungsformen, Strukturtypen und Lebensgesetze* (1959), a popular manual of the history of religions that includes a long section on classification problems. cations

Systems of Religious and Spiritual Belief

Man, it has been said, is incurably religious. This is an epigrammatic and somewhat facetious statement of the most impressive feature of religions—their wide distribution. All through human history and all through present-day societies, there appears some systematic relation to what is regarded as sacred. To cover all these phenomena, however, the definition of religion must be so comprehensive as to become ambiguous, if not meaningless. Each successive broadening of the geographic horizon, moreover, has necessitated a redefinition of religion to include unfamiliar phenomena and to exclude features that had been part of the older definition because of a generalization based on too few forms.

This article examines the structural categories into which religious and spiritual belief systems, and various repudiations of such systems, are conventionally grouped for comparison and contrast. The more particularized elements of belief within such systems and of practice or

worship are treated cross-culturally in the *Macropædia* articles DOCTRINES AND DOGMAS, RELIGIOUS; and RITES AND CEREMONIES, SACRED, respectively. The particular religions themselves are discussed in the *Macropædia* in either of two ways: articles on the non-surviving religions of ancient peoples are grouped under the regional headings MIDDLE EASTERN RELIGIONS, ANCIENT; and EUROPEAN RELIGIONS, ANCIENT; and individual articles on the particular extant religions are to be found under their respective names (e.g., CHRISTIANITY; ISLĀM, MUḤAMMAD AND THE RELIGION OF; ZOROASTRIANISM AND PARIISM). The history and methods of the study of religions are discussed in the *Macropædia* article RELIGIONS, THE STUDY AND CLASSIFICATION OF.

For coverage of related topics in the *Macropædia* and the *Micropædia*, see the *Propædia*, sections 811, 812, and 10/53, and the *Index*.

Nature worship

In the history of religions and cultures, nature worship as a definite and complex system of belief or as a predominant form of religion has not been well documented. Among primitive peoples the concept of nature as a totality is unknown; only individual natural phenomena—e.g., stars, rain, and animals—are comprehended as natural objects or forces that influence them and are thus in some way worthy of being venerated or placated. Nature as an entity in itself, in contrast with man, human society and culture, or even God, is a philosophical or poetic conception that has been developed among advanced civilizations. This concept of nature worship, therefore, is limited primarily to scholars involved in or influenced by the modern (especially Western) study of religion.

NATURE AS A SACRED TOTALITY

To students of religion, the closest example of what may be termed nature worship is perhaps most apparent in ancient or nonliterate cultures in which there is a high god as the lord in heaven who has withdrawn from the immediate details of the governing of the world. This kind of high god—the *Deus otiosus*, hidden, or idle, god—is one who has delegated all work on earth to what are called “nature spirits,” which are the forces or personifications of the forces of nature. High gods exist, for example, in such indigenous religions on Africa's west coast as that of the Dyola of Guinea. In such religions the spiritual environment of man is functionally structured by means of personified natural powers, or nature spirits.

Pantheism (a belief system in which God is equated with the forces of the universe) or deism (a belief system based on a non-intervening creator of the universe), as was advocated in the rationalistic philosophy of religion of western Europe of the 16th to 18th centuries, is not appropriate in studies of nature worship in preliterate cultures. Worship of nature as an omnipotent entity, in the pantheistic sense, has not as yet been documented anywhere.

The concepts of mana, orenda, wakan, and manitou

The power or force within nature that has most often been venerated, worshipped, or held in holy awe is mana. Mana, often designated as “impersonal power” or “supernatural power,” is a term used by Polynesians and Melanesians that 19th-century Western anthropologists appropriated to apply to that which affected the common processes of nature. Mana was conceptually linked to North American Indian terms that conveyed the same or similar notions—e.g., orenda of the Iroquois, wakan of the Dakotas, and manitou of the Algonkin. Neither the designation “impersonal power” nor “supernatural power” implies what mana really means, however, because mana usually issues from persons or is used by them, and the concept of a supernatural sphere as distinct or separate from a natural sphere is seldom recognized by preliterate peoples.

Thus, a better designation for mana is “super force” or “extraordinary efficiency.” A person has mana when he is successful, fortunate, and demonstrates extraordinary skill—e.g., as an artisan, warrior, or chief. Mana can also be obtained from the *atuas* (gods), providing that they themselves possess it. Derived from a root term that has aristocratic connotations, mana corresponds to Polynesian social classifications. The *ariki*, or *alii*, the nobility of Polynesia, have more power (mana), and the area that belongs to them and even the insignia associated with them have mana. Besides areas and symbolic elements that are associated with the *ariki*, many objects and animals having special relationships with chiefs, warriors, or priests have mana.

The concept of *hasina* of the Indonesian Hova (or Me-

rina) on Madagascar is very similar to mana. It demonstrates the same aristocratic root character as the word mana, which is derived from the Indonesian *manang* (“to be influential, superior”).

The Iroquoian term orenda, similar to mana, designates a power that is inherent in numerous objects of nature but that does not have essential personification or animistic (soul) elements. Orenda, however, is not a collective omnipotence. Powerful hunters, priests, and shamans have orenda to some degree. The *wakanda*, or wakan, of the Sioux Indians is described similarly, but as Wakan-Tanka it may refer to a collective unity of gods with great power (wakan). The manitou of the Algonkin is not merely an impersonal power, comparable to the wakan, that is inherent in all things of nature but is also the personification of numerous manitous (powers), with a Great Manitou (Kitchi-Manitou) at the head. These manitous may even be designated as protective spirits that are akin to those of other North American Indians, such as the *digi* of the Apaches, *boha* of the Shoshones, and *maxpe* of the Crow, as well as the *sila* of the Eskimos.

The super forces (such as Mulungu, Imana, Jok, and others in Africa) that Western scholars have noted outside of the Austronesian-American circles of peoples are often wrongly interpreted as concepts of God. Only the *barakah* (derived from the pre-Islamic thought world of the Berbers and Arabs), the contagious superpower (or holiness) of the saints, and the power Nyama in western Sudan that works as a force within large wild animals, certain bush spirits, and physically handicapped people—appearing especially as a contagious power of revenge—may be added with a certain justification to that force of nature that is designated by mana. A striking similarity with mana may also be noted in the concepts of *heil* (good omen), *saell* (fortunate), and *hamingja* (luck) of the Germanic and Scandinavian peoples.

HEAVEN AND EARTH AS SACRED SPACES, FORCES, OR PROCESSES

Heaven and earth, as personified powers of nature and thus worthy of worship, are evidently not of equal age. Though from earliest times heaven was believed to be the residence of a high being or a prominent god, the earth as a personified entity is much rarer; it probably first occurred among archaic agrarian civilizations, and it continues to occur in some primitive societies in which agriculture is practiced. Gods of heaven, however, are characteristic spiritual beings of early and contemporary hunter and collector cultures and are found in almost all cultures.

Primitive world views generally assume the earth to be simply given (i.e., as continuously existing). Sometimes the earth is believed to have emerged out of chaos or a primal sea or to have come into existence by the act of a heavenly god, transformer, or demiurge (creator). Even in such world views, however, the earth usually remains without a divine owner, unless through agriculture and the cult of the dead the earth is conceived as the underworld or as the source of the renewing powers of nature. The fact that heaven is animated by rain-giving clouds (with lightning and thunder) and by a regular chorus of warming and illuminating celestial bodies (sun, moon, and stars) led to concepts of the personification of heaven from earliest times.

Heaven. Heavenly deities, as the personification of the physical aspects of the sky, appear in variations that are adapted to the types of cultures concerned. The listing offered below does not represent a unilinear development that is applicable everywhere.

The father of the family. The god of heaven is often

Heaven and earth as personified powers of nature

Relation-
ship of the
"high god"
to men

viewed as an ever-active father of the family, often called upon but rarely the recipient of sacrifices. He is able to intervene in human and natural affairs without the aid of an intermediary (e.g., priest, medicine man, or ancestors). As a numinous (spiritual) being, he is closer to man than other spiritual powers. He sends lightning and rain and rules the stars that are at most essential aspects of himself or are members of his family subject to him. He is the creator and the receiver of the dead. Modern scholars have designated such a being as the "high god," "supreme god," the "highest being" of the "original monotheism" (according to the theories of a German scholar, P.W. Schmidt), the idealized god of heaven (according to the views of an Italian historian of religion, Raffaele Pettazzoni), or the familiar father deity (according to the views of a British anthropologist, Andrew Lang). Very human, often comical, or even unethical and repulsive traits of such deities are often represented in myths that also sometimes include legends of animal or human ancestors.

This type of deity is generally found in its most developed form among the old hunter and collector peoples of the temperate and arid areas (e.g., forest Indians of North America, Indians of California and of Tierra del Fuego in South America, Australian Aborigines, and African Bushmen) and of the tropic primeval forests, where he is usually conceived as a storm and thunder being (e.g., Tore of the Ituri Pygmies or Karei of the Semang of the Andaman Islands). He is also worshipped among the pastoral peoples as the "blue" or "white" sky of the wide pastures in the steppes of northeastern Africa (e.g., Waka of the Galla) and of Central and North Asia (e.g., Torem, Num, and Tengri of the Ugrians, Samoyeds, and Mongols).

Among such peoples, heaven is often merged with an old hunting deity, the Lord of the Animals, or it allows the latter to exist as a hypostasis by his side.

The withdrawn god. The god of heaven may be a *Deus otiosus*, who has, after completing the creation, withdrawn into heaven and abandoned the government of the world to the ancestors of men or to nature spirits that are dependent on him and act as mediators between him and men. This type of the god, who is able to intervene directly only when there are widespread existential necessities or needs (e.g., drought, pestilence, or war), can be found primarily where worship of the dead or worship of individual local "earth spirits"—not yet integrated into an all-inclusive earth deity—obscures everything else. This type of god occurs especially in areas of so-called primitive agriculture (e.g., large parts of Africa, Melanesia, and South America).

Relation-
ships of the
"high god"
to other
deities

The first among equals. The god of heaven also may be the head of a pantheon of gods, the first among equals, or the absolute ruler in a hierarchy of gods. This occurs in polytheism (belief in many gods) in its purest form. The deities associated with him are often related to him by family ties (genealogies of gods). Occasionally, the heavenly phenomena are distributed among members of the clan of gods, the god of heaven himself thus becoming rather vague. The divine pair heaven—earth represents only one among many possible combinations—e.g., Dyaus-pitri (= heaven, male) and Prithivi (= earth, female) in Vedic India or, with an unusual distribution of the sexes, Nut (= heaven, woman) and Geb (= earth, man) in ancient Egypt.

Occasionally, generations of gods succeed each other (e.g., Greece, western Asia). In such instances, the more universal god of heaven is often replaced by the younger god of thunderstorms (e.g., Zeus of the Greeks, Teshub of the Hittites, or Hadad of the Semites) or is even relegated to the background by a goddess, such as Inanna-Ishtar (the love or fertility goddess in Babylonia) or Amaterasu, the sun goddess of Japan.

In ancient China, Heaven (T'ien, or Shang Ti, the highest lord) ruled over the many more popular gods and was even closely related to the representatives of the Imperial household. Deification of the celestial emperor is a cultic practice that extends from Korea to Annam (part of Vietnam). The roots of the worship of heaven in Asia are probably the beliefs of central and northern Asiatic nomadic peoples in a solitary god of heaven. Gods of heaven, above or behind a pantheon (grouping of gods),

probably originated in areas where a theocratic stratified bureaucracy existed or where sacral kingdoms exist or have existed—e.g., in The Sudan or northeastern Africa (Akan-Baule, Dahomey, Yoruba-Benin, Jukun, Buganda, and neighbouring states), western Indonesia, Polynesia and Micronesia, and in the advanced civilizations of pre-Columbian Meso-America and South America (see also *Polytheism* below).

Heaven and earth deities as partners. The god of heaven in many areas is a partner of an earth deity. In such cases, other numina (spirits) are missing or are subject to one of the two as spirits of nature or ancestors. Myths depicting the heaven—earth partnership usually describe the foundations or origins of the partnership in terms of a separation of a primeval chaos into heaven and earth or in terms of a later separation of heaven and earth that originally lay close together, and they describe the impregnation of the earth by the seed of the god (e.g., *Hieros gamos*, or the sacred marriage). This partnership of the god of heaven and the goddess of earth may be found in areas of Africa that have been influenced by advanced civilizations (especially The Sudan and northeastern Africa), in eastern Indonesia, and in some areas of America under the influence of advanced civilizations.

Not infrequently the god of heaven and the goddess of earth are fused into a hermaphroditic higher deity. This accords with certain traits of ancient civilizations which try to show in customs and myths that the dichotomies, for example, of heaven and earth, day and night, or man and woman, need to be surmounted in a kind of bisexual spiritual force. Certain myths express the loss of an original bisexuality of the world and people. In a creation myth found in the Vedas, for example, it was Puruṣa, an androgynous primal man, who separated into man and woman and from whom the world was created with all its contrasts. Another such creation myth is the cosmic egg, which was separated into the male sky and the female earth.

The god of heaven viewed dualistically. In several religions the god of heaven has an antagonistic evil adversary who delights in destroying completely or partially the good creative deeds of the god of heaven. This helps to explain the insecurity of existence and concepts of ethical dualism. In most such cases, the contrasts experienced in the relationship between heaven and earth deities have been re-evaluated along ethical lines by means of exalting the heavenly elements at the expense of the earthly ones (especially in Jewish, Christian, and Islāmic sects in Europe, west central and northern Asia, and certain areas in the northern half of Africa). The figure of an antagonistic trickster or demiurge that has a somewhat ethical component may be the result of diffusion and is rather rare in primitive cultures—e.g., African Bushmen, Australian Aborigines, and North American Indians (see also *Religious dualism* below).

The god of heaven viewed monotheistically. The god of heaven, viewed in his ethical aspect, is always an active, single god—e.g., Christian, Jewish, and Islāmic monotheism (see also *Monotheism* below).

Earth. Although in polytheistic religions the earth is usually represented as a goddess and associated with the god of heaven as her spouse, only rarely is there an elaborate or intensive cult of earth worship. There are in many religions mother goddesses who have elaborate cults and who have assumed the function of fertility for land and man, but they hardly have a chthonic (earth) basis. Some mother goddesses, such as Inanna-Ishtar, instead have a heavenly, astral origin. There are, however, subordinate figures of various pantheons, such as Nerthus (Jörd) in Germanic religion or Demeter and Persephone (earth mother and corn girl) in Greek religion, who have played greater roles than the world mother (Gaea). Among Indo-Europeans, western Asiatics (despite their various fertility deities), Chinese, and Japanese, the gods of heaven, sun, and thunderstorms have held a paramount interest.

When the common people have displayed intensive attention to "mother earth" (such as the practice of laying down newborn babies on the earth and many other rites), this partially reflects older cults that have remained

Exaltation
of heavenly
elements
over
earthly
elements

"Mother
earth"

relatively free from warrior and nation-building peoples with their emphasis on war (as in western Sudan, pre-Aryan India, and the Indian agrarian area of northern Mexico). The Andean earth-mother figure, Pacha-Mama, worshipped by the Peruvians, stands in sharp contrast to the sun religion of the Inca (the conquering lord of the Andes region). Earth deities are most actively venerated in areas in which people are closely bound to ancestors and to the cultivation of grain.

Mountains. Especially prominent mountains are favourite places for cults of high places, particularly when they are isolated as island mountains, mountains with snowcaps, or uninhabited high mountain ranges. The psychological roots of the cults of high places lie in the belief that mountains are close to the sky (as heavenly ladders), that clouds surrounding the top of mountains are givers of rain, and that mountains with volcanoes form approaches to the fiery insides of the earth.

Mountains, therefore, serve as the abodes of the gods, as the centres of the dead who live underground, as burial places for rainmakers (medicine men), and as places of oracles for soothsayers. In cosmogenic (origin of the world) myths, mountains are the first land to emerge from the primeval water. They frequently become the cosmic mountain (*i.e.*, the world conceived as a mountain) that is symbolically represented by a small hill on which a king stands at the inauguration. Pilgrimages to mountain altars or shrines are favourite practices of cults of high places.

The larger mountain ranges and canyons between volcanic mountains—especially in Eurasia from the Pyrenees to the Alps, the Carpathian Mountains, the Caucasus Mountains, the Himalayas, the mountainous areas of northern China and Japan, and the mountainous areas of North and South America (the Rocky Mountains, the Andes)—are most often centres of cults of high places. Elevations of the East African Rift Valley (Kenya, Tanzania, Uganda), volcanic islands of the Pacific Ocean (*e.g.*, Hawaii), and the mountains of the Indian Deccan have also served as centres of the cult of high places.

The high places as the abodes of the gods

In the early civilizations, the cult of high places was closely combined with that of the earth (*e.g.*, Olympus of the Greeks, the mountains of Enlil or of the Mountain Mother Cybele in western Asia, and the Meru mountain of India) were believed to bring heaven and earth into a close relationship and were often viewed as the middle pillar of the world pillars upholding the sky. Bush and wild spirits (Lord of the Animals) of the cultures of the hunters and collectors were often believed to reside in inaccessible mountainous areas (*e.g.*, Caucasus).

In addition to other mountain deities of a more recent date (*e.g.*, God of the Twelve Mountains and the One-Legged Mountain God), the mountain deity Yama-no-kami has been demonstrated to be a deity of the hunt (*i.e.*, god of the forest, Lord of the Animals) of ancient Japan. Through the worship of farmers, Yama-no-kami assumed the elements of a goddess of vegetation and agriculture. The mountain goddesses (earth mothers) of non-Aryan India still incorporate numerous features of hunt deities, and, because of indigenous influences, the Vedic (early Aryan scriptural) gods and their wives (*e.g.*, Pārvatī, Umā, and Durgā) have their abodes on mountains. The isolated mountains of East Africa, surrounded by clouds, are believed to be the dwelling places of the heaven and rain gods, and in the area of Zimbabwe (Rhodesia) there are pilgrimages to mountain sanctuaries that are viewed as the seats of the gods.

Pre-Islāmic peoples of North Africa and the extinct inhabitants of the Canary Islands (Guanches) associated mountain worship with a cult of goats (and sheep), which, when practiced in rituals, was believed to secure rain and thunderstorms in the often arid landscape. Similar cults are also found on the Balkans and in the valleys of the southern Alps.

Beliefs about the causes of earthquakes

Earthquakes. According to the beliefs of many peoples, earthquakes originate in mountains. In areas of Africa, where the concept of mana is particularly strong, many believe that the dead in the underworld are the causes of earthquakes, though in the Upper Nile, The Sudan, and East Africa, an earth deity is sometimes blamed. In some

areas, a bearer who holds the world up—a concept that probably came from Arabia, Persia, India—is believed to cause an earthquake when he changes his position or when he moves his burden from one shoulder to the other. In the Arab world, on the east coast of Africa and in North Africa, an ox generally is viewed as the bearer, sometimes standing on a fish in the water. World bearers often are giants or heroes, such as Atlas, but they also may be animals: an elephant (India), a boar (Indonesia), a buffalo (Indonesia), a fish (Arabia, Georgian S.S.R., and Japan), a turtle (America), or the serpent god Ndengei (Fiji). Generators of earthquakes also may be the gods of the underworld, such as Tuil, the earthquake god of the inhabitants of Kamchatka (a peninsula in eastern Siberia), who rides on a sleigh under the earth. The earthquake is driven away by noise, loud shouting, or poking with the pestle of a mortar. Among peoples with eschatological (last times) views, earthquakes announce the end of the world (Europe, western Asia).

Tides. The view that the tides are caused by the moon can be found over almost all the earth. This regular natural phenomenon seldom gives rise to cults, but the ebb and flow of the coastal waters has stimulated mythological concepts. Not infrequently the moon acquires the status of a water deity because of this phenomenon. The Tlingit (of northwestern America) view the moon as an old woman, the mistress of the tides. The animal hero and trickster Yetl, the raven, is successful in conquering (with the aid of the mink) the seashore from the moon at low tide, and thus an extended area is gained for nourishment with small sea animals.

CELESTIAL PHENOMENA AS OBJECTS OF WORSHIP OR VENERATION

The sun. Generally, the sun is worshipped more in colder regions and the moon in warm regions. Also, the sun is usually considered as male and the moon as female. Exceptions to these generalizations, however, are notable: the prevalent worship of the sun in hot, arid ancient Egypt and in parts of western Asia; the conception of the moon as a man (who frequently is believed to be the cause of menstruation) among primitive hunter peoples (African Bushmen, Australian Aborigines, and hunters of South America) and among certain pastoral and royal cultures of Africa (*e.g.*, the Masai and the Hottentots); and the conception of the female sun ruling northern Eurasia from the Northern Sea to Japan and parts of North America.

In many state cults of ancient civilizations, the sun plays a special role, particularly where it has replaced an old god of heaven (*e.g.*, Egypt, Ethiopia, South India, and the Andes) and especially where it is viewed as a marker of time.

The sun as the centre of a state religion. In Africa, ancient Egypt was the main centre from which solar deity concepts emanated. The solar religion, promoted by the state, was concerned with the sun god Re (Atum-Re, Amon-Re, Chnum-Re), the sun falcon Horus, the scarab (Chepre), and a divine kingdom that was determined by the sun (*e.g.*, pharaoh Akhenaton's solar monotheism c. 1350 BC). The sun religion reached, by way of Meroe (a sun sanctuary until the 6th century AD) and the Upper Nile, as far as western Ethiopia (*e.g.*, the Hego cult in Kefa and the sun kings in Limmu) and Nigeria (*e.g.*, Jukun). In the Orient, the sun cult culminated in the religion of Mithra of Persia. Mithra was transported by Roman legionnaires to western Europe and became the Unconquerable Sun of the Roman military emperors. In Japan, the Imperial deity in state Shintō is Amaterasu, the sun goddess from whom Jimmu Tennō, the first human emperor, descended. In Indonesia, where the descent of the princes from the sun also is a feature, the sun often replaces the deity of heaven as a partner of the earth. In Peru, the ruling Inca was believed to be the sun incarnate (Inti) and his wife the moon. A sun temple in Cuzco contains a representation of Inti as the oldest son of the creator god. The Natchez Indians of southeastern United States, who are culturally connected with Central America, called their king "Great Sun," and the noblemen were called "the Suns."

The sun as a subordinate deity. The sun, within a polytheistic pantheon, often is revered as a special deity

Solar religions in Africa and the Orient

who is subordinate to the highest deity, usually the god of heaven. This may be observed in the great civilizations of ancient Europe and Asia: Helios (Greece); Sol (Rome); Mithra (Persia); Sūrya, Savitr, and Mitra (India); Utu (Sumer); and Shamash (Babylonian and other Semitic areas).

The sun not infrequently is considered female (Shams of some Arabs, Shaph of ancient Ugarit in Palestine, Sun of Arinna of the Hittites, as well as the female Sun of the Germans). Siberian people such as the Taimyr Samoyed (whose women pray in spring to the sun goddess in order to receive fertility or a rich calving of the reindeer) or the Tungus worship sun goddesses. They sacrifice to the sun goddess, and her symbols are embroidered on women's clothes.

The sun and moon as a divine pair. A sun god is often related to a moon goddess as one member of a divine pair (in the place of heaven and earth as "world parents"). A sun-moon god exists among the Munda-Dravida in India (Singbonga); a sun-moon (earth) pair, partially seen as bisexual, exists in eastern Indonesia; and Nyambe (the sun) among the Rotse in Zambia is represented as united with the moon goddess as the ruling pair.

The sun as an attribute of the highest being. The sun sometimes is viewed as a coordinated or subordinate attribute, or hypostasis, of the highest being. This may possibly occur because of a partially weakened influence of a stronger solarism in areas of older primitive peoples, such as in The Sudan, Upper Volta, Nigeria, northern East Africa, and Australia.

The sun as a mythical being. The sun, in some religions, is conceived as a purely mythical being, who is cultically recognized in sun dances (e.g., prairie Indians) and in celebrations of the solstice, with jumps over fires, sports festivals, and other events. These rites may be either survivals of an earlier local cult of a sun deity or influences of such a cult.

The moon. The moon is often personified in different ways and worshipped with ritual customs; nevertheless, in contrast to the sun, the moon is less frequently viewed as a powerful deity. It appears to be of great importance as the basis of a lunar calendar but not in the higher agrarian civilizations. The moon, infrequently associated with the highest god, is usually placed below heaven and the sun. When the moon with the sun together (instead of "heaven and earth") constitute an important pair of gods (world parents), it frequently assumes the features of an earth deity. In tropical South America, the sun and moon are usually purely mythical figures.

Between the Tropic of Capricorn and the Tropic of Cancer, the moon is predominantly female. Only some remainders of ancient peoples (hunter peoples) view the moon as a male being (e.g., African Bushmen, Australian Aborigines, Congo Pygmies, Semang, Andamans, Chaco Indians, Ona, and some Brazilian tribes). In the few significant moon gods of the Oriental civilizations (Khons in Egypt, Sin-Nanna in Babylonia, Candra in India)—in contrast with the female Selene and Luna in the Greek-Roman culture, a more ancient substratum may possibly be present. Where the moon is considered as male, he often determines the sexual life of the woman, especially among the Aborigines of Australia.

The phenomenon of the moon that attracts all people is the sequence of its phases. The waxing and waning of the moon crescent is often interpreted as gaining or losing weight (eating, dieting). Thus, the Taulipang in Guayaná believe that the moon is first nourished well and then inadequately by his two wives, Venus and Jupiter. Where the moon is viewed as female, the phases represent pregnancy and delivery. Elsewhere, people see childhood, maturity, and dying as the phases of the moon: the first crescent is thus the rebirth or the replacement of the old by a new moon.

The appearance of the crescent or the full moon is sometimes celebrated by a rest from work, and some attempt to participate in the waxing and waning of the moon by analogous magical rites. Girls with small breasts stand in the full moonlight (in the Salzburg, Austria, area); persons who desire a tumor to decrease point to the waning moon; and newborn children often are exposed to the waning

moonlight, or they and everything else that is desired to be healthy and permanent are dyed white; i.e., they are made "moonlike." Nearly everywhere, connections between the moon phases and the rhythm of nature (the tides) and humans (menstruation) are recognized.

The three dark days of the "death" of the moon are believed by many to be dangerous. During this period the moon is believed to be defeated in a battle with monsters who eat and later regurgitate the moon; or the moon is viewed as having been killed by other heavenly beings and later revived. The period is a time in which people, if possible, do not engage in a new enterprise.

The halo of the moon is also viewed as a bad omen among many peoples. Moon spots are regarded as testimonies of a battle with heavenly opponents. In addition to the popular Man in the Moon, there are also other figures represented: "the woman with the basket on her back," "the spinning woman," or "the weaving woman" (in Polynesia the woman who pounds tapa). The most popular animal figure recognized in the features of the moon, the rabbit (from Europe to America), presumably earned this role because of its fertility.

Eclipses of the sun and moon. Eclipses of the sun or the moon—usually interpreted as a battle, as the dying, or the devouring of one of the two heavenly bodies—in many religions are met with anxiety, shouting, drum beating, shooting, and other noises. Many North American Indian tribes, Hottentots in Africa, Ainu in Japan, and the Minangkabau in Sumatra interpret the eclipses as fainting, sickness, or the death of the darkened heavenly body. In Arctic America, Eskimos, Aleuts, and Tlingits believe that the sun and moon have moved from their places in order to see that things are going right on earth. The explanation that heavenly monsters and beasts pursue the stars and attempt to injure and to kill them, however, is a view found over a larger area. Noise and shooting are believed to deter the monsters from their pursuit or to force them to return the celestial bodies if they have already been captured. In China and Thailand the monster is the heavenly dragon; in China, among the Germanic tribes, and among northern American Indians, dogs and wolves (coyotes) are the culprits; in Africa and Indonesia, they are snakes; in South America, the beast is the jaguar; and in India they are the star monsters Rāhu and Ketu. The belief in the darkening of one star by the other in a battle—e.g., between the sun god Lisa and the moon goddess Gleti in Dahomey—is about as widespread. An eclipse may also be interpreted (as in Tahiti) as the lovemaking of sun and moon, who thus beget the stars and obscure each other in the process.

Stars and constellations. Worship of the stars and constellations in the modern world survives only in a very corrupt or hidden manner. True star worship existed only among some ancient civilizations associated with Mesopotamia, where star worship was practiced. Mesopotamia, where both astronomy and astrology reached a high degree of refinement—especially after a Hellenizing renaissance of astronomy—was the origin of astral religions and myths that affected religions all over the world. Though the view is controversial, Mesopotamian astral worship and influence may have reached as far as Central and Andean America (by way of China or Polynesia). Sumerian, Elamite, and Hurrian contemplation of the stars influenced not only Mesopotamia, Asia Minor, Egypt, Iran, and India but also other areas. Knowledge of the zodiac, the planets, and observation of precession extended from the West to south Asia—e.g., the Pythagoreans and Orphics (mystical philosophers) in the Mediterranean area and astrological mystical thinkers in India, Indonesia, China, and Polynesia. West Sudan, for example, was deeply influenced by the spirit of ancient Mediterranean and Oriental knowledge of the stars.

Apart from areas in The Sudan, northeast Africa, and Rhodesia (Mwene Matapa, or Monomotapa), not much of Africa has had any considerable knowledge of the stars. That knowledge of the stars is relatively limited among forest peoples, unless old hunting cultures survived, is explained by an Ekoi tribesman in southeast Nigeria, as follows: "Ekoi people do not trouble themselves about the stars, because the trees always hide them." Hunting pyg-

mies likewise have never achieved any significant knowledge of the stars, which the Bushmen on the steppe have.

Knowledge of the stars in the areas of the true primitive peoples rarely leads to a worship of the stars. True star gods are rare, for example, in large parts of Africa. In Polynesia, where significant knowledge of the stars by the seafaring people and fishermen was learned in regular schools of astronomy, there seldom occurred what can be called true religious worship of the stars. Knowledge of the stars, however, is still relatively significant among the hunting peoples in the Southern Hemisphere, especially among the African Bushmen and Australian Aborigines, who were formerly untouched by the high civilizations. Economic considerations connected with the rising and setting of the stars, however, surpasses their mythological significance by far. The stars are usually considered to be living beings, particularly animals that have been transferred to the sky. They evidently are taken seriously primarily because they indicate by their rising and setting the appearance of game to be hunted or fruits to be collected.

Widespread beliefs in the constellation Orion and the planet Venus

The widespread African interpretation of the constellation Orion as a hunter, as game, or as a dog (from East Africa to the lower Congo and in the area of the Niger) is most likely a vestige from an earlier hunting period that has survived in agricultural civilizations. In a different form, the constellation Orion is still known in Europe as a hunter, in north Asia as a hunter of reindeer and elk, and in North America as a hunter of bears. In South America—outside the Andean empires—a whole series of astral beliefs of the ancient hunting culture has been preserved: the concepts of stars and constellations as Lords of the Animals, as helpers of the hunter, or as animals themselves.

Venus, the best known planet, has probably experienced its most significant personification in the figure of the Mesopotamian goddess Inanna-Ishtar. She was viewed as a being, sometimes female and at other times bisexual. Through her identification with the Greek Aphrodite and the Roman Venus, Inanna-Ishtar, the queen of heaven, still survives in Roman Catholic iconography—e.g., as the Virgin Mary standing on the moon. African cultures also have been significantly impressed by this planet, not only in the rare figure of a Zulu heavenly goddess who determines the agricultural work of the women but even more as the evening and morning star, who are the wives of the moon. In the royal culture of Mwene Monomotapa (Rhodesia) and its influences in Buganda and southern Congo, the king is related to the moon, and his wedding with the Venus women is a type of *hieros gamos* ("sacred wedding"). In large areas of Africa the concept of "Venus wives of the moon" is preserved, although the moon is usually considered as the wife (or sister) of the sun. This concept was most likely prevalent at a time when the moon-king ideology was widespread in the eastern half of Africa from the Nile to South Africa, perhaps indicating south Arabian influences.

The Pleiades, Polaris, and the Milky Way

The Pleiades, a group in the constellation of Taurus (six to seven adjacent stars), is viewed in many parts of the world as maidens who are pursued by men (e.g., hunters). The Pleiades is also interpreted as a mother hen with her chickens, especially in Eurasia, where the star Aldebaran, which is located close to the Pleiades, is often included as a part of the constellation. In Africa the Pleiades designates the beginning of the agricultural year. Therefore, in many Bantu languages the verb *kulima* ("to hoe") furnishes the basis for their designation *kilimia*, the Pleiades. In addition to East and South Africa there is still a smaller area in the western Sudan that retains this belief.

Polaris (the north star) enjoys a central significance among the Finno-Ugric and Turkish Tatars as "nail of the world" or "pillar of heaven." Among Altai Tatars Polaris is viewed as the negotiator of the god of heaven Ülğan; in Japan, Polaris is a god of heaven above the ninth layer of clouds.

The Milky Way, depending on a group's economy and life style, is often simply named after hunting or domestic animals: way of the tapir, the donkey, or the camel. It also is called the seam of the heavenly tent or a water stream. As the footsteps of God or the way of God, as the way of the dead, or as a deserted way of the gods, the Milky Way

reveals older mythical conceptions, among which is that of the world (cosmic) tree.

Aurora borealis, the northern lights of the polar regions, is frequently interpreted by Arctic and sub-Arctic peoples (e.g., Eskimo, Athapascan, Tlingit) as the reflection of the dance fire of the ghosts or of the peoples further in the north, as the "cooking of meat," or the ball game of these peoples. Northern Germanic tribes saw in it the splendor of the shields of Valkyrie (warrior women).

ELEMENTS AND FORCES OF NATURE

The natural forces of fire and water, which evidently exclude each other, are brought together in a unity of opposites in the worldviews of early archaic civilizations. Both forces are purifying as well as protective, and are viewed by many as being connected with the cosmic powers of the sun and moon. Where they are truly combined, often genetically, fire (as the sun) is usually male, and water (as the moon), female. Where the fire is included more into the chthonic (earthly) sphere it may also receive a feminine character (e.g., fire in the earth, preserved in the womb); where rain is viewed as the semen of heaven, which is usually personified as male, it takes on a male character.

Water. Many of the qualities of water make it appear to be animated; on this basis it is psychologically understandable that water (e.g., rain, sea, lakes, and rivers) might become a natural phenomenon worthy of worship. Water is always in motion, changes color in the light of the stars, reflects the world and man, "speaks" with murmuring and roaring, brings new life to dried out vegetation, refreshes men and animals, the tired and the ill, and heals. Because it dissolves dirt it is also most suitable for purifying the soul (e.g., after the violation or the commission of a sin of any kind). Under certain circumstances, even pictures (icons) of gods have to be washed. Water also demonstrates destructive forces (seaquakes, floods, and storms). The most important mythical-religious facts symbolized by water are the following: the primal matter; the instrument of the purification and expiation; a vivifying force, a fructifying force; and a revealing and judging instrument.

Water as primal matter. The conception of a primal body of water from which everything is derived is especially prevalent among peoples living close to coasts or in river areas—e.g., the Egyptian Nu (the primordial ocean) and the Mesopotamian Apsu (the primeval watery abyss) and Tiamat (the primeval chaos dragon). The earth may be fished out or emerges from the primeval water; heavenly beings (e.g., Ataentsik, ancestress of the North American Iroquois) appear on the emerged earth; and birds lay an egg that is later divided into two halves (heaven and earth) on the chaotic sea. Thus, water is viewed as the foundation of all things. A survival of the original primeval sea, in such myths, is the water that flows around the earth's disk (e.g., Oceanus).

Water as an instrument for purification and expiation. Water is viewed as an instrument for purification and expiation, especially in arid areas. Cultic acts, in such areas, generally take place only after lustrations, sprinkling, or immersion in water. The same view holds true for entry into new communities or into life (e.g., baptism). Water lustration is especially necessary after touching the dead, and as a purificatory washing for priests and kings. Pictures of the gods also have had water poured over them.

Myths of a great flood (the Deluge) are widespread over Eurasia and America. This flood, which destroys with a few exceptions a disobedient original population, is an expiation by the water, after which a new type of world is created.

Water as a vivifying force. Water is viewed as vivifying, like the heavenly rainwater that moistens the earth. Water also is equated with the flowing life forces of the body (e.g., blood, sweat, and semen). In order to replace the lost liquids, water was added to the mummified dead in Egypt. The African Ashanti designate their patrilinear groups as *ntoro*, which means water, river, and semen, and the Wogeo of Papua call their patrilinear clans *dan*; i.e., both water and semen. The myth of the Kasuar ancestress of the But of Papua related how Kasuar's blood became sea (and salt).

The "living" qualities of water

Water equated with life forces in the body

Water as fructifying. Wherever early archaic culture spread the myth of the world parents heaven and earth, there also was a belief that heaven fructifies the earth with heaven's seed. The springs, pools, and rivers on the earth, therefore, may bring not only healing and expiation, but also fertility. The Scamander River in ancient Greece evidently was so personified; according to Aeschines, a 4th-century-*bc* Greek orator, girls bathed in it before marrying and said: "Scamander, accept my virginity." Magical rites in which water serves as a substitute for semen or the fertility of men are numerous.

At the corn festival Nsiä of the Bamessing (in Cameroon), which is celebrated in the dry season, the festival begins with the mourning of the dead vegetation. Reminiscent of the Egyptian Osiris and the Mesopotamian Tammuz festivals, the Nsiä festival emphasizes that the god who gave the nourishment has died and is being mourned like a chieftain. The chief, dying symbolically with the god, has to be strengthened with a miraculous "chieftain water," which has to be fetched by virgins of the chieftain's clan. For two weeks the chieftain drinks from the gourds of all the maidens after the women of the tribe have drunk from the holy water place.

Battles of gods and heroes with mythical beings, beasts, and monsters that hold back the fructifying water are widespread in mythology. The liberation of water during the mythical battle is equivalent to the end of the dry season or a drought, to the reviving of vegetation. In Indian mythology Indra slays Urtara; in Syrian and Palestinian mythology Baal battles with Leviathan; and in Huron (North American Indian) mythology Joskeha, the spring hero, kills the frog that attempted to restrain the water from flowing freely.

Water as a revealing or judging instrument. Water also serves as an instrument that reveals and judges. Reflections in the water led to a whole series of oracles originating from an alleged prophetic or divinatory power of water. A visionary look into the water surface was believed to reveal the future as well as past misdeeds. This ancient custom may have been preserved in the use of crystal balls by modern fortune tellers. The custom of water divination is found in ancient Europe, North Africa, the Near East (e.g., Babylonian fortune telling by means of cups), eastern and northern Asia (where the use of metal mirrors by the shamans often replaces the water as a divining means), and in Southeast Asia and Polynesia. Where such means of divination were severely repressed, as in sub-Saharan Africa, these methods of mirror and water gazing were changed into manipulated water ordeals.

Water is also used as a judging element: in ordeals believed to demonstrate the judgment of the gods, water ordeals (e.g., immersion in water), as well as the more frequent fire ordeals, appear. Here also the purifying character of the water plays a role.

Fire. Worship of fire is widespread, especially in areas where the earthly fire is believed to be the image of the heavenly fire.

Because of various psychological reasons, fire is considered to be a personified animated or living power: it moves vehemently, devours, and becomes hungrier; it spreads fast into a giant blaze and is red like human blood and warm like the human body. It makes the plants that it has devoured suitable for fertilizing the earth; it shines brightly in the night and, by transference, may have "eternal life" or by constant rekindling can be made into a "perpetual fire." In cremation it separates the body from the soul; it drives away predatory animals and insects that cause pestilence.

Its chief functions are similar to those of its main adversary, water: to purify and to ward off evil, especially from home and hearth. Fire magically drives away rain, but with its smoke it also attracts rain clouds during a period of drought. Fire is believed to have both heavenly and earthly origins: it is brought by lightning, and it lives in the volcano of the underworld.

Stories are told of ancestors, heroes, or animals of primeval times who purloined the fire from the higher numina (spiritual powers). Bringers of civilization, similar to the Greek god Prometheus, fetch it—often together

with fruits of the field, iron, or musical instruments—from heaven. Like Prometheus, Nommo, the primal being among the Dogon in Mali, brings fire and the first fruits of the field down to the earth. Prometheus steals the fire from the blacksmith Hephaestus, but Nommo himself is the first blacksmith. In both areas this cultural achievement is celebrated with annual torchlight parades (in Greece, called Promethea festivals). Elsewhere, birds, or animals, such as the dog (especially in Africa), who is closely allied to the hearth fire of man, are the bringers of fire. Animals often fetch the fire from the Lord of the Animals in the bush.

Where geysers and volcanos indicate that the oldest fire is beneath the surface of the earth, fire is brought forth by animals and heroes. The Maori hero Maui seizes it from his ancestress Mahuize in the depth of the earth and puts it into a tree. Since that time it has been possible to get fire from the wood of the trees (e.g., the fire borer). In areas practicing a definite ancestor worship, hunters obtained the fire from the subterranean world of the dead (as in East Africa). Previous to the Iron Age (15th century–2nd century *bc*), the generating of fire with the aid of fire borers, or fire saws, was viewed as a sexual act (male and female fire wood), especially in East and South Africa, India, Indonesia, and Mexico. In the creation myths of the Dayak of Borneo, fire is produced by rubbing a liana (male) on a tree (female) and is interpreted as coitus. The Tlingit (of northwest America) tell a story of the magical conception of a girl by the sawdust of the fire borer. The boring for the new state fire in the Loango empire (West Africa) coincides with the public coitus of a young couple.

This conceptual framework seems to be a late consequence of earlier ideas of fire in the body of humans, especially of women, as a centre of sexual life. Such views are probably most pronounced among the Aborigines of Papua and Australia. The Marind in New Guinea, who, in their myth of the origin of fire view it as being derived from the sexual act, undertake the new boring of fire in connection with a cultic act in which the raping of a girl is the central rite. Elsewhere in New Guinea, there is a concept that fire lies in the genitals of women, especially of the first woman.

When iron-smelting techniques by means of fire became common among Neolithic (New Stone Age) peoples of similar mentality, as in Indonesia and Africa, the making of iron in shaft furnaces (considered as female) and bellows (male) has been interpreted as coitus with a subsequent birth (especially among the Bantu).

In archaic civilizations with sacral kings, the sacred perpetual fire (i.e., the state fire) of the residences and temples of the royal ancestors was believed to have a phallic element. It was cared for by virgins, who were viewed as wives of the fire. Vestal virgins of this kind are documented in ancient Rome, Mwene Matapa (Africa), and pre-Columbian America. Among the Maya of Central America, an order of fire caretakers was founded by a deified "virgin of the fire." Extinguishing and rekindling of fire at the inauguration of a prince points to the idea of a spirit of the princes in the state fire and also to the cyclical renewal of the state in the purifying fire, which signifies the beginning of a new era.

Fire gods are found less frequently in primitive cultures than in archaic civilizations. That fire gods are not yet known in some ancient Oriental areas is probably because of the advanced development of a sun deity.

Iranian fire worship was derived from the cult of the god Ātar, but it was made a central act in Zoroastrianism (a religion founded by the 6th-century-*bc* Iranian prophet Zoroaster). Fire worship continues to be practiced among the Parsis (modern Zoroastrians) of India: in temples the sacred fire is maintained by a priest using sandalwood, while his mouth is bound with a purifying shawl; fire in new temples is kindled from the fire of the old temples; household fires are not permitted to go out and are greeted in the morning by the members of the household and offered sandalwood; and Aryan cremation practices are renounced because the fire would be contaminated, and the dead are thus deposited in the "temples of silence."

Weather. The worship of atmospheric powers can only

Fire as a living force or power

The
worship
of atmo-
spheric
powers

with difficulty be separated from the worship of heaven. In most cases the high god in heaven is also the god of thunderstorms and rain. Specific gods of wind and storm are found especially in countries with tornadoes and hurricanes (e.g., the Maya deity Huracan). People (e.g., the Tuareg and Arabs) in arid countries and deserts, dried out by the wind, speak of sand funnel spirits or of a desert god, such as the "boneless Kon" of the Peruvians.

From northern Europe to the tropical forests, thunderstorm deities rule heaven and earth. The most famous group of these numina (spiritual beings) are the Indo-European thunder gods (Thor-Donar of the Germans, Taranis of the Celts, Perkunis of the Slavs, Indra of the Indians, Zeus-Jupiter of the Greeks and Romans), who throw their thunderbolts or bundles of lightning. The Finnish god Ukko and the Basque god Orko probably stem from the same root; these gods still continue in the popular beliefs of Eastern Europe or Latin America today, such as St. Elijah or Santiago. These deities are related to the west Asiatic gods Teshub and Hadad (associated with the steer and with lightning) but also to the thunder god Shango of the Nigerian Yoruba, who is accompanied by a ram (as Thor uses a he-goat for pulling his wagon). Shango, as Yakuta, throws thunderbolts (i.e., stone axes) to the earth, as does the Mayan rain god, Chac.

The goat, the ram, or horses appear as companions of weather gods or as animals that pull the thundering sky vehicle. In other cultures thunderbirds are the companions of the thunder gods or are the lightning itself. The lightning bird Zu, or Imdugud, occurs in ancient Mesopotamia, and the Garuda (with Wajra) in Vedic India. Thunderbirds are represented (sometimes with arrows or spears in their bill or fangs) on archaeological artifacts of the Bronze Age in Dodona, Minussinsk in Siberia, Dong Son in Vietnam, and on pots in north Peru; they are described in myths of the Pueblo and prairie Indians and among East and South Africans.

Rain magic

Where prayers or sacrifices to gods and ancestors in the religious cult are not effective in producing rain, rain magic, which is practiced universally in similar rites, is often able to accomplish it. Trained magicians usually perform such rites, but ancestral priests or "persons holding power" also may do so. In rain magic, sprinkling, spitting, or immersion of people or things is often used to call down heavenly moisture. Smoke clouds to attract the rain accomplish the same purpose. There also must be suitable vestments (fresh greens, skins or pelts of water animals), body painting (representing clouds), or adornment with bird down. The colour black in the clothing or on a killed or exposed animal is believed to be especially effective. Animals held responsible for holding the rain or water back (frogs, snakes, or mythological dragons) must be challenged. The sound of rain or thunder is produced with "bull-roarers," whistling, noise pots, rattles, and chains. If excessive rain is to be stopped, the injunction to perform or refrain from certain acts (e.g., the prohibition of washing, boiling water, burning objects, making noise, and whistling) must be observed.

The rainbow often is considered a being, generally in the form of an animal, who swallows and holds back rain or water. The rainbow serpent (as a double bow also conceived as bisexual) is a figure that is found especially in the tropics of Africa, south Asia, north Australia ("ungud" snake), and Brazil. Elsewhere, the rainbow is viewed as a heavenly bridge that connects the worlds of gods and men: the Bifröst bridge in the Edda (a Norse saga); the bridge of the soul boats in Indonesia or of the creator god in Africa; and the path of the Greek goddess Iris. In Christian iconography, the rainbow is the throne of Christ; among Arabs and some Bantu of Central Africa it is the bow of god, and among the Nandi, Masai, and the Californian Yuki it is the robe of god.

WORSHIP OF ANIMALS

Among the numerous animals that are prominent in religion and magic, the wild animals of the forests, the sea, and the air that are most important for the hunter are the most significant. Hunters and collectors, rooted in the earliest cultures of man, believed that they not only had

to kill animals—which were important for their economy as nourishment and raw materials—but also that they had to avoid their revenge. The feeling of a close connection between men and animals that has been lost to the highly civilized people (broadly speaking) led to an anthropomorphizing of animals. They were not only considered as living beings but were humanized to such an extent that the borderline between man and animal became virtually nonexistent and animals were held responsible for crises.

The religious magical attitude by which primitive peoples confront animals may be called animism, regardless of whether the animal is thought to have life (animatism) or to have a soul (animism). See below, *Animism*.

The best known form of what may be called animal worship is totemism. An anthropologist, Sir James Frazer, defined totemism as "an intimate relation which is supposed to exist between a group of kindred people on one side and a species of natural or artificial objects on the other side, which objects are called the totems of the human group" (*Totemism and Exogamy*, 1910). Frazer added that the mentioned "species" generally is more "natural" than "artificial." In this "intimate relation" the animal has the prerogative and in true totemism this relationship represents a more or less reverent attitude of man toward his animal partner. In totemism the relationship with the animal has not only merged into the realm of religion but has at the same time become a phenomenon of social life. See below, *Totemism*. (Ed.)

Animism

Animism is the belief in innumerable spiritual beings concerned with human affairs and capable of helping or harming men's interests. Animistic beliefs were first competently surveyed by Sir Edward Burnett Tylor in a work, *Primitive Culture* (1871), to which is owed the continued currency of the term. While none of the "great" religions of the world is animistic (though they may contain some animistic elements), most of the "little" religions, those of the tribal (or "primitive") peoples, are. For this reason an ethnographic understanding of animism, based on field studies of the tribal peoples, is no less important than a theoretical one, concerned with the nature or origin of religion.

IMPORTANCE IN THE STUDY OF MAN AND RELIGION

The term animism denotes not a single creed or doctrine but a view of the world consistent with a certain range of religious beliefs and practices, many of which may survive in more complex and hierarchical religions. Modern scholarship's concern with animism is coeval with the problem of rational or scientific understanding of religion itself. After the age of exploration, Europe's best information on the newly discovered peoples of the Americas, Africa, Asia, and Oceania often came from Christian missionaries. While generally unsympathetic to what was regarded as "primitive superstition," some missionaries in the 19th century developed a scholarly interest in beliefs that seemed to represent an early type of religious creed, inferior but ancestral to their own. It is this interest that was crystallized by Tylor in *Primitive Culture*, the greater part of which is given over to the description of exotic religious behaviour. To the intellectuals of that time, profoundly affected by Darwin's new biology, animism seemed a key to the primitive mind—man's intellect at the earliest knowable stage of cultural evolution. Present-day thinkers consider this view to be rooted in a profoundly mistaken premise. All contemporary cultures and religions are regarded as comparable in the sense of reflecting a fully evolved human intelligence capable of learning the arts of the most advanced society. The religious ideas of the "stone-age" hunters interviewed in this century have been far from simple.

Since the "great" religions of the world have all evolved in historic times, it may be assumed that animistic emphases dominated the globe in the prehistoric era. In societies lacking any doctrinal establishment, a closed system of beliefs was less likely to flourish than an open one. There is, however, no ground for supposing that polytheistic

Definition
and limits
of the term
animism

and monotheistic ideas were excluded. But what is plain today—that no historically given creed has an inevitable appeal to the educated mind—had scarcely gained a place in scholarly argument 100 years ago.

THEORETICAL ISSUES

Tylor's theory of animism. For Tylor the concept of animism was an answer to the question, "What is the most rudimentary form of religion which may yet bear that name?" He had learned to doubt scattered reports of peoples "so low in culture as to have no religious conceptions whatever"—he thought religion was present in all cultures, properly observed, and might turn out to be present everywhere. Far from supposing religion of some kind to be a cornerstone of all culture, however, he entertained the idea of a pre-religious stage in the evolution of cultures and believed that a tribe in that stage might be found. To proceed in a systematic study of the problem, he required a "minimum definition of religion" and found it in "the Belief in Spiritual Beings." If it could be shown that no people was devoid of such minimal belief, then it would be known that all of mankind already had passed the threshold into "the religious state of culture."

But, if animism was ushered in as a "minimum definition," it became the springboard for a broad survey. Although anthropology in Tylor's day was mainly an "arm-chair" science, through wide and critical reading he had developed a good sense for what was credible in the ethnographic sources of his day. He assembled an array of cases and arranged them in series from what seemed to him the simplest or earliest to the most complex or recent. In this way he taught that religion had evolved from a "doctrine of souls" arising from spontaneous reflection upon death, dreams, and apparitions to a wider "doctrine of spirits," which eventually expanded to embrace powerful demons and gods. A fundamental premise was "that the idea of souls, demons, deities, and any other classes of spiritual beings, are conceptions of similar nature throughout, the conceptions of souls being the original ones of the series." Tylor asserted that men everywhere would be impressed by the vividness of dream images and would reason that dreams of dead kin or of distant friends were proof of the existence of souls. The simple belief in these spiritual beings independent of natural bodies would, he thought, expand to include more elaborate religious doctrines, accompanied by rites designed to influence powerful spirits and so control important natural events.

While Tylor offered no special theory for this expansion and so avoided most of the traps of early social evolutionism, he taught that cultures moved, though not along any single path, from simpler to more complex forms. The direction of movement was shown by the survival of animism in muted but recognizable forms (including most "superstitions" and many expressions such as "a spirit of disobedience" or common words like "genius") in the advanced civilization of his own day. This "development theory" he championed against the so-called degradation theory, which held that the religion of remote peoples could only have spread to them from centres of high culture, such as early Egypt, becoming "degraded" in the process of transfer. Tylor showed that animistic beliefs exhibit great variety and often are uniquely suited to the cultures and natural settings in which they are found.

In retrospect, Tylor seems more balanced in his judgments than later writers who constructed the problem of "minimal religion" in a narrower frame. Tylor's greatest limitation was self-imposed, since he narrowed his attention to what may be called the cognitive aspects of animism, leaving aside "the religion of vision and passion." Tylor took animism in its simplest manifestation to be a "crude childlike natural philosophy" that led men to a "doctrine of universal vitality" whereby "sun and stars, trees and rivers, winds and clouds, become personal animate creatures." But his cognitive emphasis led him to understate the urgent practicality of the believer's concern with the supernatural. Tylor's men are "armchair primitives" (the creatures of "armchair anthropologists"), not real men caught in the toils of discord, disease, and fear of perdition.

Counter theories. Tylor thought the idea of the human soul must have been the elementary religious idea and the model for all other supernatural beings. Later scholars, responding to evidence of simpler beliefs that yet entailed a properly religious awe toward the sacred, began to debate the probability of a "pre-animistic stage" of theological evolution. Corresponding to this turn in religious studies was a shift in anthropology toward a concern with "primitive thought" and, in particular, the explanation of religion as intellectual error. Émile Durkheim, a French sociologist, in his *Elementary Forms of the Religious Life* (1915), held that religion originated in totemism, conceiving that identification with a totem animal could result from an irrational projection of men's expectations of security in the bosom of society. He thought such collective projections were more solidly based in the human condition than the "hallucinations" (dreams) that Tylor had supposed must lead to the ideas of soul and supernatural being. Durkheim has been criticized for not seeing totemism as only one animistic cult among many, with special implications as an organizational schema but not "elementary." (See below, *Totemism*.)

English and German theorists conceived the invention of religion in more pragmatic terms: attempting to extend his control of nature beyond the limits his crude science imposed, man had invented supernatural power—magic. The most prolific scholar of this persuasion was Sir James G. Frazer, who argued in his massive work *The Golden Bough* (1890–1915) that "the magic art" had arisen as a pseudo-science, probably had achieved universality before the emergence of religion, and was more firmly rooted than religion in men's beliefs. He thought intelligent men had become disillusioned with earthly magicians and had invented infallible ones—gods. Frazer's work ranged over classical mythology and savage custom without distinction. Finding parallel traditions everywhere, he compiled a massive testament to the psychic unity of mankind. The myriad structures of both magic and religion that he surveyed all could be reduced to transparent intellectual error. The apparent mystery of religion was virtually explained away, for, if magic had become man-centred religion and religion god-centred magic, there was little to choose between them.

Since Frazer accepted the common notion that the sign of religion is man's humility before the gods and held that magic put man in the ascendancy, it followed that wherever the supernatural beings could be tricked, bribed, or otherwise mastered the system of beliefs was magical. This obscured Tylor's clear "minimum definition of religion" and threw an odd light on what he had called "lower animism," the belief in spirits that men with ritual knowledge can master. Any self-confident ritual act—for example, the Eskimo hunter's ritual control of game spirits or the shaman's cure of a grave affliction—had become magical and so transparently egoistic. The result for an ensuing generation of anthropologists was loss of focus upon the religions encountered in the field. Tylor had found animistic beliefs generally devoid of ethical content even when centred in men's urgent needs. Frazer, interjecting the image of the primitive magician with illusions of unlimited power, made it difficult to grant animistic religion even Tylor's minimum of dignity.

Frazer had identified Melanesia as an area in which, by his terms, magic dominated over religion. An admirer, Bronislaw Malinowski, was able to accomplish a thorough ethnographic study of the Trobriand Islanders in Melanesia during World War I, and it was Malinowski who dominated European ideas about the intimate life of "primitive man" in the following decades. Viewing his islanders within the frame of ideas Frazer had provided, Malinowski pictured them as secular in outlook. In numerous works on the Trobriand Islanders, published through the 1920s and 1930s, there was to be scarcely a mention of religion as such. The belief in spirits appeared only as mythical background to magical practices connected with gardening and seafaring and with a ceremonial cycle in which the competition for prestige was dominant. The effect was to reduce religion to its pragmatic and social aspects, thus de-emphasizing the very peculiarities of human belief and

The search for a pre-animistic stage

The predominance of human over supernatural spiritual powers

experience that first attracted men such as Tylor to the study of "primitives."

ANIMISTIC PHENOMENA IN THEIR SOCIAL CONTEXTS

While it is futile to seek cases of animism in "pure," "minimal," or "elementary" form, some social contexts are undeniably simpler than others, and it may be tempting to suppose that the religions found in those contexts would follow suit. On that principle, however, nomads such as the Australian Aborigines might be supposed (as they were supposed by Durkheim) to enjoy an uncomplicated religious life, but this is emphatically not the case. What complicates Australian religions is an elaborate ceremonialism not usually found in nomadic societies. Ceremonialism generally can be treated as an emphasis in the area of expressive behaviour, usually consistent with the animistic world view and unlikely to displace it. While it is an emphasis most common among agriculturists, its presence among nomads is by no means confined to Australia. Though there is no reason to suppose that ceremony is of any more recent origin than any other way of expressing man's relation to the spirit world, animistic religions (religious systems in which animism plays an essential role) can be sorted into those with and those without a ceremonial emphasis, and, in this formal sense, the latter are the simpler. The salient characteristic of all animistic religions is their particularism, a quality opposite to the universalism of the "great religions," which conceive man as subject to global powers and personal destiny.

Particularism is evident in the number and variety of spirits recognized and in the peculiar scope attributed to each. The pre-Christian Lapps of Scandinavia have sometimes been called fetishists because they propitiated nature spirits as well as personally named gods and demons. The nature spirits were generally benevolent and always localized. They could be addressed in particular objects, such as stones or posts, which men would set up in likely places. The few personally venerated spirits (gods) were identified with thunder, sun, moon, hunting, childbirth, and the winds. Evil spirits might be incarnate in animal or monstrous forms and could cause disease or other misfortune. In Minnesota-Ontario the Ojibwa world was animated by a great number of eternal spirits (manitous), all of about equal rank, represented in trees, food plants, birds, animals, celestial bodies, winds, and wonders of every description. Besides these esteemed spirits were other categories, which were dreaded: ghosts, monsters, and the windigo (a crazed man-eating ogre), who brought madness (a cannibalistic psychosis). The list of creatures, places, attributes, and events that could be treated as totems in Australia would be quite similar. The Buryat of Lake Baikal in Siberia, living on the fringes of empire (Mongolian and Chinese), developed an elaborate social order and viewed the spirit world as the twin of their own, organized in the same way into noble, commoner, and slave ranks. At death a man passed over to the other world, assuming his proper rank and acquiring fresh power over men, which he might exercise well or ill in accordance with his character in life. Evil men, as it were, became devils and great men gods.

In particularistic religions there is a range of spirits, from sojourning ghosts and mortal witches to perennial beings, whose natures and dispositions to man are attributed by categories (e.g., mermaids and leprechauns are both usually pictured as irresponsible), but in action individual spirits are independent of one another. If some spirits may be called gods, they do not constitute a ruling pantheon, for men do not conceive that any supernaturals enjoy comprehensive control of events. In animism, spirits represent particularistic powers and must be handled accordingly. Typically, men's primary emphasis is on avoidance of trouble, and this is the meaning of the many taboos and propitiatory observances, of an almost mechanical nature, that abound in some societies. When trouble is at last encountered, the responsible witch, demon, or disgruntled spirit must be identified, and this is the task of the diviner. The cure may rely upon ritual cleansing, propitiation, or even the overpowering of the malevolent force through supernatural counteragency—the specialty of the shaman.

Judging that an animal will not mind being killed if it is not offended ritually, Eskimos take various precautions before, during, and after the hunt. The rationale lies in the belief that animal spirits exist independent of bodies and are reborn: an offended animal will later lead his companions away so that the hunter may starve. If, in spite of their precautions, men are left without game, a shaman may be called to discover the transgression that has offended an animal spirit—or perhaps he may find that he must do battle with a malevolent being controlled by a rival shaman willing the community harm.

Ceremonialism, when its emphasis is upon feasting, exchange, and display, may be secular in its emphasis, as is the case in much of Melanesia and New Guinea; or if religious, it may be associated with totemic or ancestral cults, as in Australia or Africa, the expressive emphasis of which is on social ties rather than on the quality of relations between men and the supernaturals. Finally, ceremony may be used directly to dramatize the role of the spirits in men's lives, as it is by the Pueblo peoples of Arizona-New Mexico. At their height, the Pueblo ceremonial cycles were as rich as any in the world. Supernaturals were elaborately impersonated by the dancers, and the human condition was portrayed as one of dependency. But, for all this, particularism was not greatly compromised. The supernaturals were many and were represented in a realistic manner emphasizing their differences from ordinary men. The style was that of mummery and conjuring, consciously put on by grown-ups as a sort of morality play. There was no sense of incongruity in the fact that neighbouring pueblos cultivated other sets of spirits. In some pueblos, separate clan societies had complete charge of the ceremonial calendar and formally controlled communication with the supernatural, even to selecting the member who might be curer in case of an illness. But such a step toward ecclesiasticism in a very small community could not greatly affect its animistic premises, and witchcraft prevailed without the blessing of the ceremonial societies.

When the fullness and versatility of all these religions is considered, without any need to press them into simplified categories or evolutionary stages, it can be seen that openness, not narrowness, of doctrine is a general feature of animism. Wherever it is found, it is a grass-roots religion, not a doctrinaire one imposed from above. Ecclesiasticism may coexist with animism, as in China or Burma, where there are no pre-eminent gods whose universal claims presuppose mastery of the whole supernatural world. But the most likely context of animism is an uncensored social order in which secular power is not developed and each local settlement is at the focus of its own world.

THE ANIMISTIC WORLD VIEW

Part of the conceptual difficulty experienced both in anthropology and in the history of religions, when animism is to be placed among other systems of belief, springs not from the early association of animism with a speculative theory of religious evolution but directly from the huge variety of animistic cults. As a category, Tylor's concept is more general than either polytheism or monotheism, and its meaning is harder to delimit—the word applies broadly to most of the "little religions" but suggests nothing of their varieties. For this reason, much use is made of subordinate labels, such as shamanism, totemism, or ancestor propitiation. These cults do not, in any case, constitute the whole religion of a people. They are, however, institutions that are not bound to one culture area—an Australian totemic cult does bear a "family resemblance" to an African one, though their differences also are many. Shamanism, with its reliance on ecstasy, is found from Greenland to Mysore, and the propitiation of ancestors is not restricted to Africa and the Far East. It has long been recognized that the frequent recurrence of institutions fitting a certain pattern implies that there is a radically limited number of possible patterns, and, in this case, the premises of animism evidently have imposed the limitation. Animism attributes importance to categories of supernatural being whose individual members are attached to particular places and persons or resident in particular creatures and are autonomous in their dealings. In such a system, each human

A communication with supernatural beings about practical life needs

encounter with the supernatural must work itself out as a distinct episode. Even where ceremonialism emphasizes an enduring moral relationship to certain supernaturals, men are likely to conceive of alternative powers to which they might seek at need. In a crisis, loyalties may shift: in West Africa, gods have been sold to neighbouring villages, and, in Melanesia, a vision of European trade goods has inspired a series of new millenarian cults. The quality of openness lends itself to change and eclecticism, hardly ever to religious chauvinism.

Animistic creeds have in common an undertaking on the part of men to communicate with supernatural beings, not about metaphysics or the dilemmas of the moral life but about urgent practicalities: about securing food, curing illness, and averting danger. It is characteristic that genuine worship of a supernatural hardly is found. Creator gods often appear in myth but not in cult. In ancestor cults the most recently dead are the most vividly conceived—the original clan ancestor, for all his symbolic importance, is remote both from men and from godhead. If animistic spirits anywhere exercise authority, they do so in particularistic, even egoistic fashion, sanctioning men for ritual neglect or breaking taboos, not for acts of moral neglect or secular offense. Animistic religions do not readily coalesce with systems of political authority and probably do not favour their development. When it is asked whether the association of animism with smaller and simpler societies proves it the natural (original) religion, the answer can only be that it is not known (and perhaps not knowable) what a prehuman or panhuman religion would be like. The problem is as difficult as reconstructing protohuman speech. If religion is taken as a pattern of serious relations between men and supernaturals, then societies devoid of religion have not been found, and it may perhaps be concluded that religion is usually close to the vital centre of a culture, where the credibility of institutions is determined. The view of all nature as animated by invisible spirits—be it shades, demons, fairies, or fates—with which men could cope in meaningful ways may belong to the past, but philosophies that attribute powers of initiative and responsiveness to nature have not gone out of currency. The lesson of the study of animism is perhaps that religion did not arise, as some of Tylor's successors believed, out of *Urdummheit* ("primal ignorance") or delusions of magical power but out of men's ironic awareness of a good life that they are unable, by earthly means, to grasp and hold. Animistic beliefs have everywhere engaged men's susceptibility to private vision and enabled them to cope with it at the level of accepted meaning. (G.K.P.)

Totemism

Totemism is a system of belief in which man is believed to have kinship with a totem or a mystical relationship is said to exist between a group or an individual and a totem. A totem is an object, such as an animal or plant that serves as the emblem or symbol of a kinship group or a person. The term totemism has been used to characterize a cluster of traits in the religion and in the social organization of many primitive peoples.

Totemism is manifested in various forms and types in different contexts, especially among populations with a mixed economy (farming and hunting) and among hunting communities (especially in Australia); it is also found among tribes who breed cattle. Totemism can in no way be viewed as a general stage in man's cultural development; but totemism has certainly had an effect on the psychological behaviour of ethnic groups, on the manner of their socialization, and on the formation of the human personality.

The term totem is derived from *ototeman* from the language of the Algonkian tribe of the Ojibwa (in the area of the Great Lakes in eastern North America); it originally meant "his brother-sister kin." The grammatical root, *ote*, signifies a blood relationship between brothers and sisters who have the same mother and who may not marry each other. In English, the word totem was introduced in 1791 by a British merchant and translator who gave it a false meaning in the belief that it designated the guardian spirit

of an individual, who appeared in the form of an animal—an idea which the Ojibwa clans do indeed portray by their wearing of animal skins. It was reported at the end of the 18th century that the Ojibwa name their clans after those animals that live in the area in which they live and appear to be either friendly or fearful. The first accurate report about totemism in North America was written by a Methodist missionary, Peter Jones, himself an Ojibwa chief, who died in 1856 and whose report was published posthumously. According to Jones, the Great Spirit had given *toodaims* ("totems") to their clans; and because of this act, it should never be forgotten that members of the group are related to one another and on this account may not marry among themselves.

Generally speaking, totemistic forms are based on the psychomental habits of the so-called primitives, on a distinctive "thought style" which is characterized, above all, by an "anthropopsychic" apprehension of nature and natural beings, for instance, ascribing to them a soul like man's. Beasts and the things of nature are again and again thought of as "persons," but mostly as persons with superhuman qualities.

THE NATURE OF TOTEMISM

It is advisable to define totemism as broadly as possible but concretely enough so that some justice can be done to its many forms. Totemism is, then, a complex of varied ideas and ways of behaviour based on a world view drawn from nature. There are ideological, mystical, emotional, reverential, and genealogical relationships of social groups or specific persons with animals or natural objects, the so-called totems. It is necessary to differentiate between group and individual totemism. These forms exhibit common basic characteristics, which occur with different emphases and not always in a complete form. The general characteristics are essentially the following: (1) viewing the totem as a companion, relative, protector, progenitor, or helper—superhuman powers and abilities are ascribed to totems and totems are not only offered respect or occasional veneration but also can become objects of awe and fear; (2) use of special names and emblems to refer to the totem; (3) partial identification with the totem or symbolic assimilation to it; (4) prohibition against killing, eating, or touching the totem, even as a rule to shun it; and (5) totemistic rituals.

Though it is generally agreed that totemism is not a religion, in certain cases it can contain religious elements in varying degrees, just as totemism can appear conjoined with magic. Totemism is frequently mixed with different kinds of other beliefs—the cult of ancestors, ideas of the soul, beliefs in powers and the spirits. Such mixtures make the understanding of particular totemistic forms difficult. The cultic veneration of definite animals and natural things and powers by all those who belong to an ethnic unit do not belong to totemism itself.

Group totemism. Group (social or collective) totemism is the most widely disseminated form of totemism. Though the following characteristics can belong to it, they must not be taken to be part of a whole system: (1) mystic association of animal and plant species, natural phenomena, or created objects with unilineally related groups (lineages, clans, tribes, moieties, phratries) or with local groups and families; (2) hereditary transmission of the totems (patrilineal or matrilineal); (3) names of groups that can be based either directly or indirectly on the totem (the same holds true for personal names used within groups); (4) totemistic emblems, symbols, and taboo formulas are, as a rule, a concern of the entire group, but they can also belong to subdivisions of that group. Taboos and prohibitions can apply to the species itself or they can be limited to parts of animals and plants (partial taboos instead of partial totems). (5) Totems for groups are sometimes connected with a large number of animals and natural objects (multiplex totems) whereby a distinction can be made between principal totems and subsidiary ones (linked totems). Totems are associated or coordinated on the basis of analogies or on the basis of myth or ritual. (Just why particular animals or natural things—which sometimes possess absolutely no recognizable worth for

General characteristics

Characteristics of group totemism

Origin of the term totem

the communities concerned—were selected as totems is often hard to fathom and may be based on eventful and decisive moments in a people's past which are no longer known.) (6) Accounts of the nature of totems and the origin of the societies in question are informative, even if they are sometimes valuable only as supplementary rationalizations; they are especially informative with regard to their presuppositions. If, for example, one group supposes that it is derived directly or indirectly from the totem, this may be recounted (as a rationalization) that an animal progenitor was changed into a human being who then became the founder of the group or that the ancestral lord of the group was descended from a conjugal union between a man and a representative of the animal species. Groups of men and species of animals and plants can also have progenitors in common. In other cases, there are traditions that the human progenitor of a kin group had certain favourable or unfavourable experiences with an animal or natural object and then ordered that his descendants had to respect the whole species of that animal.

Group totemism is now found especially among peoples in Africa, India, Oceania (especially in Melanesia), North America, and parts of South America who farm rather than simply gather food from nature. Peoples with hunting and partly harvesting economies who exhibit this form of totemism include, among others, the Australian Aborigines (hunters who occupy a special position due to the many forms of totemism among them), the African Pygmies, and various tribes of North America—such as those on the northwest coast (predominantly fishermen), in parts of California, and in northeast North America. Moreover, group totemism is represented in a distinctive form among the Ugrians and west Siberians (hunters and fishermen who also breed reindeer) as well as among tribes of herdsmen in north and Central Asia.

Individual totemism. Individual totemism is expressed in an intimate relationship of friendship and protection between a person and a particular animal or a natural object (sometimes between a person and a species of animal); the natural object can grant special power to its owner. Frequently connected with individual totemism are definite ideas about the human soul (or souls) and conceptions derived from them, such as the idea of an alter ego and nualism—from the Spanish form of the Aztec word *naualli*, “something hidden or veiled”—which means that a kind of simultaneous existence is assumed between an animal or a natural object and a person; *i.e.*, a mutual, close bond of life and fate exist in such a way that in case of the injury, sickness, or death of one partner, the same fate would befall the other member of the relationship. Consequently, such totems became most strongly tabooed; above all, they were connected with family or group leaders, chiefs, medicine men, shamans, and other socially significant persons. In shamanism, an earlier trait of individual totemism is often ascertained: the animalistic protective spirits can sometimes be derived from individual totems. To some extent, there also exists a tendency to pass on an individual totem as hereditary or to make taboo the entire species of animal to which the individual totem belongs. In this can perhaps be seen the beginning of the development of totems that belong to a group. Many tales about the origins of the group totem could, perhaps, point in this direction.

Individual totemism is widely disseminated. It is found not only among the tribes of hunters and harvesters but also among farmers and herdsmen. Individual totemism is especially emphasized among the Australian Aborigines.

SOME EXAMPLES OF TOTEMISM

Wiradjuri. (New South Wales, Australia) Totem clans are divided among two subgroups and corresponding matrilineal moieties. The group totem, named “flesh,” is transmitted from the mother. In contrast to this, individual totems belong only to the medicine men and are passed on patrilineally. Such an individual totem is named *bala*, “spirit companion,” or *jarawaijewa*, “the meat (totem) that is within him.” There is a strict prohibition against eating the totem. Breach of the taboo carries with it sickness or death. It is said: “To eat your *jarawaijewa* is

the same as if you were to eat your very own flesh or that of your father.” The medicine man identifies himself with his personal totem. Every offense or injury against the totem has its automatic effect upon the man who commits it. It is a duty of the totem to guard the ritualist and the medicine man while he is asleep. In the case of danger or the arrival of strangers, the animal goes back into the body of the medicine man and informs him. After the death of the medicine man, the animal stands watch as a bright flickering light near the grave. The individual totem is also a helper of the medicine man. The medicine man emits the totem in his sleep or in a trance so that it can collect information for him. Finally, black magic (sorcery) is also practiced by the medicine man; by singing, for instance, the medicine man sends out his totem. To kill an enemy, the totem enters the chest of the enemy and devours his viscera. The transmission of the individual totem to novices is done through the father or the grandfather who, of course, himself is also a medicine man. While the candidate lies on his back, the totem is “sung into” him. The blood relative who is transmitting the totem takes a small animal and places it on the chest of the youngster. During the singing, the animal supposedly sinks slowly into his body and finally disappears into it. The candidate is then instructed on how he has to treat the animal that is his comrade, and he is further instructed in song and the ritual concentration that is necessary to dispatch the totem from his body.

Australian Aborigines dancing a corroboree. In dancing a corroboree the Australian natives imitate birds, animals, fish, and men, and also the movements of storms and floods.

Nor-Papua. (Murik Lakes, west of the mouth of the Sepik River, north New Guinea) Patrilineal, exogamous groups (consanguineous sibs) are spread over several villages and are associated with animals, especially fish. They believe that they are born from totems and they make them taboo. Children are given an opportunity to decide during their initiation whether they will respect the paternal or maternal totem. Each group of relatives has a holy place to which the totem animal brings the souls of the dead and from which the souls of children are also believed to come. Totem animals are represented in various manifestations, as spirit creatures in sacred flutes, in disguises, and in figures preserved in each man's house. At the end of initiation ceremonies, the totems are mimicked by the members of the group.

Iban. (Sungai Dayak, Sarawak, Malaysia) Among these peoples, individual totemism is clearly discernible. Particular persons dream of a spirit of an ancestor or a dead relative; this spirit appears in a human form, presents himself as a helper and protector, and names an animal (sometimes one of the natural objects) in which he is manifested. The Iban then observe the mannerisms of animals and recognize in the behaviour of the animals the embodiment of their protector spirit (*ngarong*). Sometimes, members of the tribe also carry with them a part of

Nagualism

Individual totems

such an animal. Not only the particular animal, but the whole species of the animal is given due respect. Meals and blood offerings are also presented to the spirit animal. Young men, who wish to obtain such a protector spirit for themselves, sleep on the graves of prominent persons or seek out solitude and fast so that they may dream of a helper spirit. Actually, only a few persons can name such animals as their very own. Individuals with protector spirits have also attempted to require from their descendants the respect and the taboo given the animal representing the spirit. As a rule, such descendants do not expect special help from the protector spirit, but they observe the totemistic regulations anyway. Thus it can be concluded that particular families or groups of relatives of the Iban represent totem communities.

Birhor. (Munda-speaking hunter and harvester tribe that resides in the jungle of Chotanāgpur Plateau, north-east Deccan, India) The Birhor are organized into patrilineal, exogamous totem groups. According to one imperfect list of 37 clans, 12 are based on animals, 10 on plants, eight on Hindu castes and localities, and the rest on objects. The totems are passed on within the group, but no account of their origin is available. From tales about the tribe's origins, it appears that the totem had a fortuitous connection with the birth of the ancestor of the clan. The Birhor think that there is a temperamental or physical similarity between the members of the clan and their totems. Prohibitions with regard to taboo are sometimes cultivated to an extreme degree. In regard to eating, killing, or destroying them, the clan totems are regarded as if they were human members of the group. Moreover, it is believed that an offense against the totems through a breach of taboo will produce a corresponding decrease in the size of the clan. If a person comes upon a dead totem animal, he must smear his forehead with oil or a red dye, but he must not actually mourn over it; he also does not bury it. The close and vital relationship between the totem and the clan is shown in a definite ceremony: the yearly offering to the chief spirit of the ancestral hill. Each Birhor has a tradition of an old settlement—thought to be located on a hill in the area. Once a year, the men of each clan come together at an open place. The elder of the clan functions as the priest who gives the offering. A diagram with four sections is drawn on the ground with rice flour. In one of these, the elder sits while gazing in the direction of the ancestral hill. The emblem of the particular totem is placed in one of the other places of the diagram; depending on the circumstances, this emblem could be a flower, a piece of horn or skin, a wing, or a twig. This emblem represents the clan as a whole. If an animal is needed for such a ceremony, it is provided by the members of another clan who do not hold it as a totem. The Birhor show great fear of the spirits of the ancestral hill and avoid these places as far as possible.

Kpelle. (Liberia, West Africa) In this society, there is not only group totemism but individual totemism as well. Both categories have the same designations, namely, "thing of possession," "thing of birth," "thing of the back of men." These phrases express the idea that the totem always accompanies man, belongs to him, and stands behind him as a guide and warner of dangers. The totem also punishes the breach of any taboo. The totems are animals, plants, and natural phenomena. The kin groups that live in several villages were matrilineal at an earlier time, but they are beginning to exhibit patrilineal tendencies. The group totems, especially the animal totems, are considered as the residence of the ancestors; they are respected and are given offerings. Moreover, a great role is played by individual totems that, in addition to being taboo, are also given offerings. Animal personal totems can be transmitted from father to son or from mother to daughter; on the other hand, individual plant totems are assigned at birth (plants of a tree of life for the child) or later. The totem also communicates magical powers. It is even believed possible to alter one's own totem animal; further, it is considered an alter ego. Persons with the same individual totem prefer to be united in communities. The well-known leopard confederation, a secret association, seems to have grown out of such desires. Entirely differ-

ent groups produce patrilineal taboo communities which are supposedly related by blood; they comprise persons of several tribes. The animals, plants, and actions made taboo by these groups are not considered as totems. In a certain respect, the individual totems in this community seem to be the basis of group totemism.

A SHORT HISTORY OF TOTEMISTIC THEORY

From McLennan to Lévi-Strauss. There are a number of theories or hypotheses concerning totemism. Many of them are marked by methodological deficiencies, preconceived ideas, and a prejudiced selection of source documents; nevertheless, some of these theories contain points of view that deserve consideration.

The first theory was proposed by the Scottish ethnologist John Ferguson McLennan. Following the vogue of 19th-century research, he wanted to comprehend totemism in a broad perspective, and in his study "The Worship of Animals and Plants" (1869, 1870) he did not seek to explain the specific origin of the totemistic phenomenon but sought to indicate that all of the human race had in ancient times gone through a totemistic stage.

In 1899 McLennan's theories were criticized by E.B. Tylor, an English anthropologist who rejected the confusion of totemism with mere worship of animals and plants. Tylor claimed to find in totemism the tendency of the human spirit to classify the world and its things. He thus viewed totemism as a relationship between one type of animal and a clan. But he was opposed to the idea of seeing totems as the basis of religion.

Another Scottish scholar, Andrew Lang, early in the 20th century advocated a nominalistic meaning for totemism, namely that local groups, clans, or phratries, in selecting totem names from the realm of nature, were reacting to a need to be differentiated. If the origin of the names was forgotten, there followed a mystical relationship between the objects—from which the names were once derived—and the groups that bore these names. Lang wanted to explain the relationship through nature myths according to which animals and natural objects were considered as the relatives, patrons, or ancestors of the respective social units. Thoughts by the tribes on these matters led eventually to taboos. Group exogamy first originated in the formation of totemistic associations.

The first comprehensive work on totemism was *Totemism and Exogamy*, published in 1910 in four volumes by the British anthropologist Sir James George Frazer. It presented a meritorious compilation of the then known worldwide data on the subject.

Basing his view on research done among primitives in Australia and Melanesia, Frazer saw the origin of totemism as one possibility in the primitive interpretation of the conception and birth of children ("conceptionalism"). According to this primitive idea, women become impregnated when a spirit of an animal or a spiritual fruit enters into their wombs. Since the children therefore participate in the nature of the animal or plant, these plants or animals take on significance. These ideas were hereditary and resulted in the beginning of totem clans derived from a particular natural creature.

A Russian-American ethnologist, Alexander Goldenweiser, subjected totemistic phenomena to sharp criticism. This critical work had lasting importance, especially in the United States, where it engendered a skeptical attitude concerning totemism. Goldenweiser saw in totemism three phenomena that could exist singly and actually coincided only in the rarest of cases. These phenomena were: (1) clan organization; (2) clans taking animal or plant names or having "emblems" obtained from nature; and (3) belief in a relationship between groups and their totems. Goldenweiser did not perceive these phenomena as a unity, since any of them could exist apart from the others.

In another treatise published in 1910, a German ethnologist, Richard Thurnwald, claimed to recognize in totemism the expression of a specific way of thinking among the primitives. Primitives judge the natural environment according to its external appearance without analyzing it any closer and assume that there are sympathetic connections and combinations of natural things; from these

Group
totems

Views of
E.B. Tylor,
Andrew
Lang, and
James G.
Frazer

ideas come lasting rules of behaviour (like taboos, respect, and social relationships). For the psychology of totemism, Thurnwald later (1917–18) put forth a detailed, systematic presentation; by means of concrete examples, he also raised questions about the connections of totemism with ancestor worship, notions of souls, belief in power, magic, offerings, and oracles.

Views
of Émile
Durkheim

The founder of a French school of sociology, Émile Durkheim, in a general work concerning the elementary forms of religion (1912), also examined totemism from a sociological and theological point of view. Durkheim hoped to discover a pure religion in very ancient forms and generally claimed to see the origin of religion in totemism. For Durkheim, the sphere of the sacred is a reflection of the emotions that underlie social activities, and the totem was, in this view, a reflection of the group (or clan) consciousness, based on the conception of an impersonal power. The totemistic principle was then the clan itself, and it was permeated with sanctity. Such a religion reflects the collective consciousness that is manifested through the identification of the individuals of the group with an animal or plant species; it is expressed outwardly in taboos, symbols, and rituals that are based on this identification.

In further contributions, Goldenweiser in 1915–16 and 1918 criticized Lang, Frazer, and Durkheim and insisted that totemism had nothing to do with religion; that man in no way viewed his totem as superior to himself or as a deified being but viewed it as his friend and equal. Goldenweiser also rejected Frazer's thesis of "conceptionalism" as an explanation of totemism. On the other hand, Goldenweiser was of the opinion that all totemistic manifestations do have at least something of a kind of religion, but he was not inclined to include the guardian spirit conception within totemism.

In 1916, an American ethnologist, Franz Boas, posited a theory of totemism as an "artificial" unity, existing only in the thinking of ethnologists. For Boas, totemism exhibited no single psychological or historical origin; since totemistic features can be connected with individuals and all possible social organizations, and they appear in different cultural contexts, it would be impossible to fit totemistic phenomena into a single category. Boas was against systematizing and thought it senseless to ask questions about the origins of totemism.

Views of
F.
Graebner
and B.
Anker-
mann

The first theoretician of the Vienna school of ethnology, Fritz Graebner, attempted to explain the forms of both individual totemism and group totemism and designated them as a moderately creedal or semireligious complex of ideas according to which individual members or subgroups of a society are thought to be in an especially close (but not cultic) relationship to natural objects. According to Graebner, with the help of the cultural-historical method, one can establish (1) the extent to which totemistic forms belong to one definite cultural complex, (2) which forms are "older" or "younger," and (3) the extent to which forms belong together genetically. Graebner tried to work out a "totemistic" complex (a "culture circle") for the South Seas. This complex entailed a patrilineal group totemism as well as the material, economic, and religious elements that, in his opinion, appear to be combined with the totemism in that area.

Another member of the same school, Bernhard Ankermann, in 1915–16 championed the view that all totemisms, regardless of where they are found, contained a common kernel around which new characteristics are built. As seen from the standpoint of what was found in Africa, this kernel appeared to him to be the belief in a specific relationship between social groups and natural things—in a feeling of unity between both—a relationship he believed to be spread throughout the world, even if only in a modified or diminished form. Magical and animalistic ideas and rites are merged with totemism in a strong inseparable unity. The genesis of this type of relationship presupposes a state of mind that makes no distinction between man and beast. Although magic can be closely connected with totemism, the feeling of unity between man and beast has nothing to do with magic, which was connected with it only later. According to Ankermann, the totems are not

something perilous, something to be shunned, but, on the contrary, totems are something friendly; and since this is directly due to kinship, a totem is thought to be like a brother and is to be treated as such. The totemistic taboo is believed to be due to the fact that the totem is a relative. Ankermann was inclined to see the formation of totemism in a "lower" form of hunting, in an emotional animal-man relationship, in animalistic behaviour. Men of early times, he thought, might have imitated those animals that attracted their attention most of all. According to Ankermann, pretension and reality, however, for the "primitives" are blurred into one thing. Primitive man identifies himself with the animal while he is imitating it; the habit of so doing could lead to a continuing identification. Early man imitated all animals that interested him, but he imitated those that shared his place of habitation above all.

In 1915–16 Wilhelm Schmidt, then the leader of the Vienna school of Ethnology, viewed totemism strictly according to the then-existing schemes of culture circles (today long abandoned); because totemism was disseminated throughout the world, he thought of it as a closed cultural complex in spite of local differences. He maintained that the differences in totemism shown by earlier theories are exaggerations and could, moreover, be due to the lack of particular elements of totemism, to the loss of certain forms of totemism, to incursions from the outside, or to different stages of the development of totemism, none of which would exclude a unified origin for all of totemism. Schmidt believed that the cultural-historical school of ethnology had produced proof that the older, genuine totemism occurred as an integral part of a culture located in a definite area and that it was "organically" connected with definite forms of technology, economy, art, and world view. From a "pure" totemism, Schmidt wanted to separate similar forms, such as sex and individual totemism. Moreover, though he did not designate totemism as a religion, he saw that it did have some sort of religious meaning. Schmidt (in opposition to Ankermann) wanted to regard the higher form of hunting as the economic basis for the totemistic "culture circle."

The leading representative of British social anthropology, A.R. Radcliffe-Brown, took a totally different view on the totemistic problem. Like Boas, he was skeptical of the reality of totemism. In this he opposed the other pioneer of social anthropology in England, Bronislaw Malinowski, who wanted to admit the reality of totemism in some way and looked at it more from a biological and psychological point of view than from an ethnological one. According to Malinowski, totemism was not a cultural phenomenon but was the result of trying to satisfy basic human needs within the natural world. As far as Radcliffe-Brown was concerned, totemism was composed of elements that were taken from different areas and institutions, and what they have in common is a general tendency to characterize segments of the community through a connection with a portion of nature. In opposition to Durkheim's theory of sacralization, Radcliffe-Brown took the point of view that nature is introduced into the social order rather than secondary to it. At first, he shared with Malinowski the opinion that an animal becomes totemistic when it is "good to eat." He later came to oppose the usefulness of this viewpoint since many totems—such as crocodiles and flies—are dangerous and unpleasant.

In 1952, when Radcliffe-Brown rethought the problem, he found that the similarities and differences between species of animals are to a certain degree translated into ideas of friendship and conflict, or close relationships and opposition among people. The natural world is represented in the form of social relationships to the extent that these social relationships become valid in primitive societies. The structural principle which Radcliffe-Brown believed he had discovered at the end of his comparative study is based on the fusion of the two contrary ideas of friendship and animosity. Thus totemism speaks in its own way of interrelationships and antitheses, ideas that are also found in moieties. So totemism is formulated as a general problem in which the contrasts in nature serve to create an integral whole. Thinking in terms of opposing

Strauss

things is, according to Radcliffe-Brown, an essential structural principle for evaluating totemism.

The most incisive critique of totemistic phenomena, one that denied the reality of totemism, was supplied by the French ethnologist Claude Lévi-Strauss in *Le Totémisme aujourd'hui* (English translation, *Totemism*, 1963). As a chief representative of modern structuralism, Lévi-Strauss was especially stimulated by Radcliffe-Brown, whose views he further attempted to expand. Lévi-Strauss believed that he was to approach the apparent, acknowledged difficulties in the study of totemism from the viewpoint of a study of structure. In order to study the structure of totemism, Lévi-Strauss devised a scheme to illustrate the abstract polarities that he saw in totemism as a phenomenon in human culture. This scheme was implemented in a table of oppositions or polarities, or mutual relationships. The basic opposition, or relationship, was between nature and culture. On the one hand, there were in nature certain natural realities such as species of animals or plants and specific animals or plants. On the other hand, there were in culture various groups and individuals who identified themselves with particular species or with specific animals or plants. Lévi-Strauss distinguished four kinds of opposition, or relationship, between nature and culture within totemism: (1) a species of animal or plant identified with a particular group, (2) a species of animal or plant identified with an individual, (3) a particular animal or plant identified with an individual, and (4) a particular animal or plant identified with a group.

According to Lévi-Strauss, each of these four combinations corresponds to the phenomena that are to be observed in one people or another. The first antithesis holds good, for example, for the Australians, for whom natural things are associated with cultural groups (moieties, sections, subsections, phratries, clans, or the association of persons from the same sex). As an example of the second combination, there is the individual totemism of North American Indians, in which a person is correlated with a species of nature. For the third type of combination, Mota in the Banks Islands of Melanesia is cited: the individual child is thought of as the incarnation of a particular animal, plant, or natural creature that was found and consumed by the mother at the time that she was conscious of her pregnancy. For the fourth type of correlation, Lévi-Strauss cited examples from Polynesia and Africa where definite individual animals formed the object of group patronage and veneration.

Lévi-Strauss also critiqued the findings of A.P. Elkin, a specialist on Australia, where totemism had already played a special role in the formation of theories and where it exhibits an abundance of forms for expressing totemism. Elkin had differentiated the following forms: (1) individual totemism; (2) social totemism—i.e., totemism that is in a family, moiety, section, subsection, patrilineal clan, or matrilineal clan; (3) cultic totemism with a religious content that is patrilineal and “conceptional” in form; (4) dream totemism—totemistic content in dreams—found in social or individual totemism. Elkin denied the unity of totemism, but (according to Lévi-Strauss) wanted to preserve its reality on the condition that he might trace it back to a multiplicity of types. For Elkin, there is no longer “one” totemism but many totemisms, each in itself a single irreducible whole.

In connection with the Australian material, Lévi-Strauss argued that matrilineal clan totemism—that passed on the “flesh” or “blood”—and the patrilineal clan totemism—based on dreaming—were in no way heterogeneous but were to be thought of as being mutually complementary. They were different means of connecting the material and spiritual world; they were two different, but correlative, types that express the relationship between nature and society.

Lévi-Strauss concluded that not the similarities but the dissimilarities correspond to the so-called totemism. Such a pattern was clearly expressed in the basic model of the contrasts of the natural with the cultural (that were outlined above). Depending on the ideas of Radcliffe-Brown, Lévi-Strauss claimed to perceive antithetical thinking as a crucial structural principle in totemism and believed that

the similarity among totemistic ideas in various cultures lay in similarities between both systems of differences—those documented in the natural sphere and those in the culturally defined social groups. Lévi-Strauss concluded that the distinction between the classes of man and animal serves as the conceptual basis for social differences. For Lévi-Strauss, totemism is therefore an “illusion” reduced to a form of thinking, and this so-called totemism is connected with understanding the demands that it answers as well as the way in which it seeks to satisfy those demands. Since it is a “logic that classifies,” totemism in this sense has nothing of the archaic itself. Its picture is projected onto the material (the natural phenomena), not taken from it. It does not take its substance from without.

Present situation and emerging trends. From the publications of Lévi-Strauss and the contributions of his predecessors, it is obvious that difficulties stand in the way of an adequate interpretation of the intricate profusion of totemistic phenomena. But it seems fair to many authorities to ask whether it is possible to dispose of totemism simply as an illusion, whether the very abstract structural interpretation of the facts is actually legitimate. To those who question the position, it seems clear that even though all totemistic forms of expression can hardly be seen under one common denominator, reality cannot be totally denied to totemism. A specific relationship between man and nature, one that serves as a basic scheme of classification, seems to be at the basis of all the various forms of totemism. Indeed, this can be regarded as the prevailing characteristic of totemism in the form in which it manifests itself. A special problem, however, must be taken into consideration: since totemism can be connected with different ideas and practices, of religious, magical, or ideological natures, it is difficult to decide what is “totemistic” and what is “nontotemistic.” (Jo.H.)

Totemism
as
“illusion”

Ancestor worship

The term ancestor worship describes, in a broad and loose sense, a variety of religious beliefs and practices concerned with the spirits of dead persons regarded as relatives, some of whom may be mythical. Although far from universal, ancestor worship exists or formerly existed in societies at every level of cultural development.

NATURE AND SIGNIFICANCE

The core of ancestor worship is the belief in the continuing existence of the dead and in a close relation between the living and the dead, who continue to influence the affairs of the living. Beliefs in a surviving element of the human person (e.g., the soul) and in an afterlife have been held in all kinds of societies. Attitudes toward the spirits of the dead vary from love, respect, and trust, mingled with special feelings of reverence, to outright fear; the attitudes are sometimes ambivalent. The spirits of the dead are often thought to help the living, but they often are thought to do harm if they are not propitiated. All societies give ritual attention to death or to the souls of the dead, but not all of these practices may appropriately be called ancestor worship. If death itself, rather than the ancestral relationship, is the focus of attention, the name death cults is more appropriate. The deification of dead heroes is similarly poorly distinguished from ancestor worship. Death cults, the worship of dead heroes who may or may not be regarded as ancestors, and clearly distinguishable rites of ancestor worship may all exist in the same society.

Ancestors venerated by elaborate rites are those persons who in their lifetimes held positions of importance, such as heads of families, lineages, clans, tribes, kingdoms, and other social groups. Depending on the manner in which kin are organized into social groups, ancestral spirits that are worshipped may be limited to one sex, or may include both sexes. Among primitive societies that trace descent only through male lines, for example, the titular positions of prestige are held by males, and only male ancestors are significant.

Ancestral spirits that are worshipped also vary in nearness or remoteness in time from the living. In some societies only the spirits of the recently deceased are given atten-

tion; in others, all ancestors, near and remote in time, are included. In still other societies, one ancestor, real, honorary, or mythical, may be the focus of attention, and he is often regarded as a hero.

BASIC PATTERNS AND FUNCTIONS

Importance of kinship

The presence or absence of ancestor worship relates in a general way to the importance of kinship in the societies concerned. In the primitive world society is ordered and life made possible through bonds of kinship, though intergenerational continuity of kinship extending to deceased forebears may not be regarded as important. Among societies of higher levels of cultural complexity, the importance of kinship and the size of actively functioning kin groups decreases. Where continuity of kinship and inheritance of property are very important, elders are characteristically regarded with respect, and the persistence of bonds of affinity with ancestors is favoured, as was the case in traditional China and Japan. Societies in which the only important kin group is the nuclear family composed of parents and immature children, and where economic support as well as emotional well-being among adults do not depend upon kinship, are ill-suited for the development or maintenance of ancestor worship. Illustrative examples are modern China and Japan, where sociocultural changes, brought about by adaptation to Western civilization and modern technology, have included a great decline in the importance of kinship and the size of kin groups, and where traditional practices of ancestor worship have correspondingly declined.

Ancestor worship includes all of the attitudes and acts usually associated with the worship of nonancestral gods and spirits. According to some scholars and theorists, ancestral spirits are anthropocentric conceptions similar to other supernatural beings; that is, the spirits have the qualities of personality and the capabilities of man, to which supernatural potency is added. The spirits see, hear, feel, understand, and communicate with the living; they make moral judgments; they are wishful, willful, joyful, angry, stern, permissive, kind, cruel, and sometimes capricious; and they have all the other emotions and traits of human beings. All of the behaviour and practices that are customary with regard to other kinds of supernatural beings are found in rites of ancestral worship—veneration and propitiation in the forms of prayers, offerings, sacrifices, the maintenance of moral standards, and festivals of honour that may include pageantry, music, dance, and other forms of art. Where ancestral spirits directly control the affairs of the living, their continued favour is sought by established periodic rites, and their special aid may be requested at times of crisis. Perhaps the only truly distinctive ritual acts of ancestor worship are commemorative ceremonies, held annually or at other fixed intervals, and tendance of graves, monuments, or other symbols commemorating them (see also RITES AND CEREMONIES: *Death rites and customs*).

Motives for acts of piety toward ancestors are diverse, and they differ from devotional acts toward other gods or spirits principally in reflecting the idea that the spirits continue in some measure to be kin and are active participants in the life of the community. Rituals directed toward ancestral spirits maintain communion with them in ways that reflect human regard for the deceased elders and desires to aid them in their spiritual existence. These rites and devotional acts also seek to gain spiritual and practical benefits for the living. The powers the ancestral spirits are believed to possess vary greatly from society to society, as do the powers of other supernatural beings. Their powers may be weak or strong, generalized or specific. In some societies, their supernaturalistic roles include that of being intermediaries between living relatives and the gods. Where neglected ancestral spirits are thought to be harmful to the living, the goals of ritual observances may include or emphasize the desire for protection from them. Whether ancestral spirits are themselves gods with powers or are intermediaries, communion with them is a form of transcendence of ordinary states of existence, which may be a conscious or unconscious goal of the acts of devotion.

ANCESTOR WORSHIP IN RELIGIONS OF THE WORLD

Until the 19th and 20th centuries ancestor worship in various forms and of varying importance in total religious complexes was widely but irregularly distributed throughout the world. In most societies, however, it was only one element of a complex of supernaturalism, and seldom a dominant feature. The spread of European culture weakened, displaced, or otherwise put an end to ancestor worship in most nonliterate societies, and technological, social, and ideological changes discouraged its continuation in culturally advanced societies.

In nonliterate societies. Among nonliterate societies, well-developed ancestor cults are limited principally to peoples of sub-Saharan Africa, Melanesia, and some tribal groups of India and adjacent parts of Asia. The greatest development was in Africa, where ancestral spirits are commonly an important part of the roster of supernatural beings. In the aboriginal kingdoms and near-kingdoms of sub-Saharan Africa, the spirits of kings and paramount chiefs were often regarded as generalized ancestors and were venerated by all members of society. Spirits of the heads of clans, often a mythical couple, were also worshipped, as were the spirits of founders of lineages and of deceased heads of individual families. Ancestral spirits of kings and high chiefs often were believed to have power over matters of concern to the entire society, such as rain and the growth of crops and cattle, whereas spirits of heads of families, lineages, and clans influenced matters of immediate concern to the particular social groups. Acts of piety were numerous and included sacrifice, prayers, and hospitable celebrations that honoured the spirits by storytelling and other forms of entertainment. The spirits were generally regarded as very helpful to their living descendants and were propitiated in established cyclic ceremonies as well as at times of crisis when help was needed.

In Melanesia the spirits of the dead generally were held to be important, and in some societies were the focus of much attention. An outstanding example is the ancestor cult of the Manus of the Bismarck Archipelago, where Sir Ghost, the spirit of the living male head of the household, was the tutelary god of the family and supervised the behaviour of its members. Only spirits of the newly dead were worshipped, and when the head of a household died, the old tutelary god was discarded. The skull of the deceased household head was placed above the entrance in the dwelling, where it watched the conduct of all within, giving rewards and punishments in accordance with their deeds, and protected the family from the malign influences of the guardian spirits of other families.

Among the Trobriand Islanders near New Guinea, the dead had two spirits, one of which was a harmless ghost that vanished a few days after death. The other spirit, *baloma*, had an eternal existence as an ancestral spirit abiding in another world. Death rites were clearly distinguishable from ceremonies directed to the *baloma*. Communion was maintained with these ancestral spirits, who returned to their villages when annual feasts were held by their living relatives, and also appeared in dreams and trances. Seers with special powers of communication with the supernatural world brought news of the spirits by visiting them in person in the land of the dead. The *baloma* were propitiated but were never feared. They were invoked and believed to provide supernatural aid in numerous acts of magic, especially in connection with the raising of the crops upon which the livelihood of the people depended.

Elsewhere in nonliterate societies, ancestral spirits sometimes were important, but nowhere were they the lone or primary supernatural beings. In aboriginal Polynesia, where people of high social status were regarded as descendants of the gods, the spirits of kings and high chiefs had power to help men, but they were not the objects of worship to any great extent. Indian tribes of North and South America seldom gave much ritual attention to ancestors. Among tribes of the present-day United States, for example, the greatest ritual elaboration was among the Pueblo tribes of the Southwest, whose complex ceremonial calendar included impressive rites honouring generalized ancestral spirits. These ancestors were impersonated in

Japan

ritual and appealed to for aid in providing rain, bountiful crops, and general well-being.

In Eastern societies. Among the civilizations of Asia, the classic examples of ancestor worship have been China and Japan. In both societies, however, reverence for, rather than worship of, ancestors is a more nearly accurate description of the beliefs and practices. In China the ancestor cult is extremely ancient and emphasized continuity of familial lines. Reverence for elders was an act of filial piety strongly supported by the teachings of the sage Confucius of the 6th–5th centuries BC. The family was viewed as a closely united group of living and dead relatives rather than a group of individuals. Unity of the larger kin group was also stressed through devotional acts at clan temples that honoured all ancestral spirits. Rites of reverence were held in the home, at temples, and in graveyards. Ancestral shrines containing tablets bearing the names of recent ancestors and especially notable forebears were maintained in the homes, and rites were observed before them. Temple rites were also observed; funerals and commemorative ceremonies were elaborate, and custom also called for pilgrimages to graves. Motives for performing rites involved concern for the welfare of the ancestors, who were thought to require solicitous care and, since the kin group was an indivisible unit with common goals and fortunes, a means of continuing to receive the aid and cooperation of the deceased relatives.

The early background of Japanese ancestral veneration is obscure, but most of the historically known practices are adaptations of Chinese customs. Some sort of ancestor cult may have existed in the native Shintō religion before the diffusion of Buddhism from China in the 6th century. When Buddhism came to Japan it was a comprehensive religious system. With the passage of time and in coexistence with the Shintō religion, Japanese Buddhism began to emphasize death rites and commemorative ceremonies, and Shintō became more concerned with matters of daily life. Confucianism was never an organized religion in Japan, but quasi-religious Confucian ideals of filial piety were very important and were sometimes incorporated in the teachings of Japanese Buddhist sects, thereby reinforcing ancestral veneration. Japanese rites, like those of China, consisted of elaborate funerals and many commemorative rites at the home, the temple, and the grave. A great annual ceremony honours all spirits of the dead, who return to their homes at that time. Until recent years Shintō rites of passage at death also were conducted in the home.

The state of ancestor worship in modern China is unclear, but it may be disappearing. In modern Japan ancestors have declined in importance, and Buddhist ritual tends to emphasize funerals, giving less attention than formerly to later commemorative ceremonies.

Ancestor
worship
in India

In India the vast, locally variable, and unorganized complex of theology and rites of the Hindu religion conspicuously includes ceremonies honouring ancestors, but the cult of ancestors is nevertheless a relatively small part of the full religious system. Characteristically, funeral rites are very elaborate and have many motifs of supernaturalism, among which is attention to ancestral spirits. The practices relating to ancestors reflect ideas concerning reincarnation and the system of castes, which are in turn closely intertwined. One of the manifest goals of the funeral rites is to guide the spirits of the deceased during the perilous time between death and rebirth. The idea that one's moral behaviour in life determines his fate in the next life is also connected with caste affiliation. Sinful behaviour will bring rebirth in a low caste. Among some castes and in some regions of India, annual rites are performed in honour of the spirits of the ancestors of the male heads of household, who are believed to give spiritual aid in promoting the growth of crops and in other important matters of everyday life.

In ancient Middle Eastern and European societies. Ancestor worship in various forms existed among the ancient civilization of the Mediterranean, where cults of the dead sometimes also existed, and among later European peoples. Ancient Egyptian religion featured a cult of the dead but gave little attention to ancestral spirits except

to those of royalty, which were venerated by the people and especially honoured in rites observed by their royal descendants. In ancient Babylonia a cult of the dead also existed, and among the members of the ruling class ancestral spirits were honoured by festive rites and sometimes deified. Beliefs and practices of late Zoroastrianism (a religion founded by the 6th–7th-century-BC Iranian prophet Zoroaster) included rites for the spirits of the dead, who were believed to have power in the affairs of the living. In ancient Greece ancestor worship overlapped with hero worship. Some ritual attention was given to spirits of household heads and political leaders, and the spirits of men whose deeds were heroic were sometimes elevated to immortality and made the objects of rites of reverence. In ancient Rome ancestor worship was a familial cult activity. Ancestral spirits were believed to have influence on mortal life and to return to visit their relatives, when rites were held in their honour.

Among various northern and eastern peoples of Europe, ancestral spirits also held some importance. Ancient Celts, Teutons, Vikings, and Slavic groups conducted rites of propitiation and sacrifice.

THEORIES AND INTERPRETATIONS

The 19th-century sociologist Herbert Spencer regarded fear and consequent propitiation of the souls of ancestors as the earliest form of religion, an interpretation that later scholars set aside as unverifiable. Reflecting the decline of ancestor worship among societies of the world, modern scholarship has seldom given much concern to this subject in isolation but has instead followed the trend of the social sciences in considering ancestor cults in relation to other elements of religious complexes, the social order, and the whole of culture. Early writings often expressed the idea that all people fear death, but this idea is questioned by Hindu thought, in which extinction rather than eternal life is the ultimate goal. It is generally held that all peoples have some beliefs of an afterlife. Such beliefs are presumed by anthropologists to be very ancient, as seems evident from Paleolithic burials dating from perhaps as much as 60,000 years ago containing stone tools, shells, and other objects, and the abundance of later prehistoric burials with grave goods.

No recent study of wide comparative scope attempts to interpret the significance of ancestor worship, and modern interpretations of these practices view them as having essentially the same social and psychological value as other beliefs and practices of supernaturalism. Through their symbolic representations of kinship and of the social hierarchy of kin groups, the beliefs and acts of ancestor worship may be seen as establishing and reinforcing ideas of social roles and identities, thereby contributing to psychological well-being and social harmony. Joint rites promote social solidarity, and characteristically display and thereby reinforce the social order. Where ancestral spirits have power in mortal affairs, they are psychologically and socially significant in ways similar to those of gods and other supernatural beings. In the many matters of life over which man lacks secular control, for example, the intervention of ancestral spirits alleviates anxiety. But, quite like various other beliefs of supernaturalism, ideas about ancestors may also be seen sometimes to instill as well as to allay anxiety. In this connection ancestor cults may have an important moral significance by serving as sanctions of social conformity. In many societies, improper behaviour is usually thought to reflect unfavourably upon both living and dead relatives, whether or not ancestor cults exist. Scholars often interpret the primary significance of ancestor cults in some societies as a sanctioning force. Ancestral spirits are viewed as approving or disapproving the behaviour of their descendants, in a generalized way, without exercising specific sanctions, or they may be regarded as vigilant protectors of morality. Among the Manus of Melanesia, the ancestral tutelary spirit was believed to punish all moral defections by removing the "soul stuff" from the wrongdoer, thereby causing illness. When the offense was serious, death followed unless penitential acts were performed. Where, as among the Manus, ancestral wrath might affect any member of the group for

Modern
interpreta-
tions of
ancestor
worship

an offense committed by another member, the sanctioning force is viewed as powerful, operating so that all living members monitor the behaviour of each other.

Special value is attributed to the rites of ancestral reverence in promoting familial solidarity, and, to the extent that such rites are emphasized, in promoting the unity of larger kin groups and entire societies. Information is most abundant on traditional practices of familial ancestor worship in China and Japan. In these societies in former times the individual was submerged in the family, and rites of ancestral reverence may thus be viewed as both reflections and reinforcements of the social order. As acts of supernaturalism, they place a special stamp of approval upon familial roles, unity, and continuity. (E.N.)

Polytheism

Polytheism, the belief in many gods, characterizes virtually all religions other than Judaism, Christianity, and Islam, which share a common tradition of monotheism, the belief in one God. Sometimes above the many gods a religion will have a supreme creator and focus of devotion, as in certain phases of Hinduism (there is also the tendency to identify the many gods as so many aspects of the Supreme Being); sometimes the gods are considered as less important than some higher goal, state, or saviour, as in Buddhism; sometimes one god will prove more dominant than the others without attaining overall supremacy, as Zeus in Greek religion. Typically, polytheistic cultures include belief in many demonic and ghostly forces in addition to the gods, and some supernatural beings will be malevolent; even in monotheistic religions there can be belief in many demons, as in New Testament Christianity. Polytheism can bear various relationships to other beliefs. It can be incompatible with some forms of theism, as in the Semitic religions; it can coexist with theism, as in Vaisnavism; it can exist at a lower level of understanding, ultimately to be transcended, as in Mahāyāna Buddhism; it can exist as a tolerated adjunct to belief in transcendental liberation, as in Theravāda Buddhism.

THE NATURE OF POLYTHEISM

In the course of analyzing and recording various beliefs connected with the gods, historians of religions have used certain categories to identify different attitudes toward the gods. Thus, in the latter part of the 19th century, the terms henotheism and kathenotheism were used to refer to the exalting of a particular god as exclusively the highest within the framework of a particular hymn or ritual; e.g., in the Vedic hymns (the ancient sacred texts of India). This process often consisted in loading other gods' attributes on the selected focus of worship. Within the framework of another part of the same ritual tradition, another god may be selected as supreme focus. Kathenotheism literally means belief in one god at a time. The term monolatry has a connected but different sense; it refers to the worship of one god as supreme and sole object of the worship of a group while not denying the existence of deities belonging to other groups. The term henotheism is also used to cover this case, or more generally to mean belief in the supremacy of a single god without denying others. This seems to have been the situation for a period in ancient Israel in regard to the cult of Yahweh.

The term animism has been applied to a belief in many *animae* ("spirits") and is often used rather crudely to characterize so-called primitive religions. In evolutionary hypotheses about the development of religion that were particularly fashionable among Western scholars in the latter half of the 19th century, animism was regarded as a stage in which the forces around man were less personalized than in the polytheistic stage. In actual instances of religious belief, however, no such scheme is possible: personal and impersonal aspects of divine forces are interwoven; e.g., Agni, the fire god of the Rgveda (the foremost collection of Vedic hymns), is not only personified as an object of worship but is also the mysterious force within the sacrificial fire.

Belief in many divine beings, who typically have to be worshipped or, if malevolent, warded off with appropriate

rituals, has been widespread in human cultures. Though a single evolutionary process cannot be postulated, there has been a drift in various traditions toward the unification of sacred forces under a single head, which, in a number of nonliterate "primal" societies, has become embedded in a supreme being. Sometimes this being is a *deus otiosus* (an "indifferent god"), regarded as having withdrawn from immediate concern with men and thought of sometimes as too exalted for men to petition. This observation led Wilhelm Schmidt, an Austrian anthropologist, to postulate in the early 20th century an *Urmonotheismus*, or "original monotheism," which later became overlaid by polytheism. Like all other theories of religious origins, this theory is speculative and unverifiable. More promising are attempts by sociologists and social anthropologists to penetrate to the uses and significance of the gods in particular societies.

Besides the drift toward some unification, there have been other tendencies in human culture that entail a rather sophisticated approach to mythological material—e.g., giving the gods psychological significance, as in the works of the Greek dramatists Aeschylus and Euripides and similarly, but from a diverse angle, in Buddhism. At the popular level there has been, for instance, the reinterpretation of the gods as Christian saints, as in Mexican Catholicism. A fully articulate theory, however, of the ways in which polytheism serves symbolic, social, and other functions in human culture requires clarification of the role of myth, a much debated topic in contemporary anthropology and comparative religion.

FORMS OF POLYTHEISTIC POWERS, GODS, AND DEMONS

Natural forces and objects. A widespread phenomenon in religions is the identification of natural forces and objects as divinities. It is convenient to classify them as celestial, atmospheric, and earthly. This classification itself is explicitly recognized in Indo-Aryan religion: Sūrya, the sun god, is celestial; Indra, associated with storms, rain, and battles, is atmospheric; and Agni, the fire god, operates primarily at the earthly level. Sky gods, however, tend to take on atmospheric roles; e.g., Zeus's use of lightning as his thunderbolt.

In the earliest cultural levels, in which hunting and then pastoralism and agriculture are clearly vital, religion exhibits these identifications in rites connected with fertility. The sun's vitality is seen in the cyclical effects of causing things to grow and wither. Moreover, because of its dominance of the world, the sun is often seen as all-knowing, and thus sky gods of various cultures tend to be highly powerful and knowledgeable, if also sometimes rather remote. The sky is also often associated with creation. By contrast the moon is rarely of the same importance (though in Ur, a city of ancient southern Babylonia, the moon god Sin was supreme). The role of the sky god in ensuring food and in providing light and warmth, over against the chaotic effects of darkness, was a theme of various myths of the cosmic drama and was one main reason for the connection in mythic thought between creation and light.

Heavenly divinities have also been influential in the development of astrology, which assigns a special significance to stars and planets. In the Middle East astrology was important but was weakened by monotheism; and in Indian culture it came to be deeply woven into the fabric of both Hinduism and Buddhism. Astrology was influential in the Greco-Roman world and in the astral religion attached to Gnosticism (dualistic sects that emphasized salvation through esoteric knowledge) and other cults of the early Christian Era. Astrology was also elaborated in Central America, for instance in Aztec religion.

Gods of the sky become especially powerful when they take on an atmospheric guise. The association of gods such as Zeus and Indra with storm, as well as with fertility-bearing rain, makes their connection with warfare fairly natural; thus, Indra is the most perfect example of an Indo-Aryan warrior. Many societies, however, have had separate gods of war. The ambivalence of atmospheric deities is paralleled in female counterparts who are both creative and destructive. The combination of sky and earth and the joining of differing cosmic forces are sometimes

toward
the gods

represented in the *hieros gamos* ("sacred marriage"); e.g., between Apsu and Tiamat in Mesopotamia, Śiva and Śakti in India, and Gaea and Uranus in Greece. The forces of water and fire are particularly significant in bridging the gap between the earthly and heavenly realms. Fire is manifested not only in the hearth but also in lightning and the sun; water is sometimes connected with the moon. Thus, earthly fire and water can also be seen at work higher in the cosmos.

Important in the development of fertility religion were the "dying and rising" gods, such as Adonis, Attis, Osiris, and Tammuz. Their cults had a new life in the mystery cults of the Greco-Roman world, where the original agricultural significance of the rites was transformed into more personal and psychological terms.

On earth, besides the divine mother out of whose womb plant life has its birth, there are a host of divinities connected with agricultural and pastoral life. In addition, sacred significance is often attached to features of the particular environment in which a given group finds itself. Thus, sacred mountains, such as Olympus in Greece, have their resident deities; a river, such as the Ganges (Ganga), may be divinized. Underground rivers have special significance in connecting with the underworld, or nether regions, which can be important as the place of repose of the dead but also as the matrix for the re-creation of life. Geographical locations can also have cosmic significance; e.g., Delphi, Greece, was known as the navel of the earth. Further, many cultures have gods and goddesses associated with the sea.

Plants and
animals
as divine
forces

Vegetation. In a number of cultures trees are seen as a primordial form of vegetation and have a symbolic connection both with heaven and earth; sometimes they are held to contain spirits, as the *yakṣas* of Indian tradition. Particular sorts of trees, such as the *aśvattha*, or pipal (sacred fig), are held in special veneration. Among plant deities, however, probably the most important are those connected with cultivated plants, such as maize in Central America and the vine in the Mediterranean world. Notable is the cult of Dionysus, the ecstatic wine god who became one of the most influential objects of devotion in the classical period. The vine linked agriculture and ecstasy. The connection between vegetation and dying and rising gods has already been noted; to some extent such motifs were carried over into Christianity in the notion that the cross was the tree both of death and of new life. One of the most obvious modern survivals in the West of vegetation cults is the use at the winter solstice of mistletoe, symbolizing fertility and continued life.

Animal and human forms. Just as plants can be seen as divine forces, so can types or species of animals. For instance, the cult of the snake is widespread and is especially important in the Indian tradition. The serpent is vital in the Old Testament story of Adam and Eve and appears in the Babylonian *Epic of Gilgamesh* as one who knows the secret of rejuvenation. The snake has a fertility aspect because of its possible phallic significance and because it lives in holes in the life-giving earth. The cult of the monkey is important in India, having its essence in the figure of Hanumān, half monkey and half human. It is possible that such theriomorphic cults (in which gods are represented by various animal forms) have been assisted by rituals in which priests wear masks representing the relevant divinities, a practice that may in turn explain the hybrid half-human form. Examples of the wide variety of animal and living forms in which gods appear include Huitzilpochtli (hummingbird; Aztec); Cipactli (alligator; Aztec); Viṣṇu's avatars, or incarnations (fish, tortoise, boar, man-lion; Hindu); the Rainbow Snake (Australian Aboriginal); Cernunnos (stag god with antlers; Celtic religion); Nandi (bull; Hindu). A figure partly in animal guise found in Les Trois-Frères cave at Ariège, France, may represent a complex lord of the beasts analogous to the supposed Śiva (the destroyer and re-creator in Hindu mythology) figure found at sites in the Indus Valley; while a bird-man figure at Lascaux, France, may depict a priestly representation of a divine being. Thus, theriomorphism seems to have a very ancient pattern. In brief, various cultures have taken existing species in their environment

and woven them into the pantheon—partly because of their essential dependence on the animals and partly for other reasons, such as similarities between animal forms and other sacred forces (e.g., the analogy of the lion to the force behind kingship).

Because man can enter into living relationship with the supernatural beings that surround and dominate his life, it has always been natural to model the gods as human beings. Such anthropomorphism is most evident in the Greek tradition, in which the Homeric gods are brilliantly and unashamedly human in their passions and thoughts. The human model has been assisted by the representation of the gods in art; for a statue is not just a symbolic representation of a god but often his place of presence and influence. Thus, in a number of cultures, the images are treated as replete with divinity.

Gods as
human
and men
as divine

Just as gods can be human in character, so men can be conceived as divine, either by becoming identified with deities (e.g., through descent) or by displaying appropriate power. Thus, divine kingship was a not uncommon feature of the ancient Middle East; it was also found in the Roman world, when the emperors were divinized, and in Japan and China, where the emperor was son of heaven. Culture heroes and other significant humans could be elevated to semidivine status or more; e.g., Kuan Ti and other heroes in the Chinese tradition, Rāma and Kṛṣṇa (Krishna) in India. Strictly, the succession of sages known as buddhas and tīrthaṅkaras in the Buddhist and Jain traditions, respectively, were not conceived as divine but came to be objects of a cult. In the Mahāyāna (Greater Vehicle), celestial buddhas and *bodhisattvas* (those vowed to become buddhas) came to be profoundly important for devotional religion; from a functional point of view, the Mahāyāna has operated as a polytheistic system, united, however, under an overarching doctrine of emptiness, or the void (*śūnya*), according to which all things are said to be empty of the characteristics assigned to them. The Theravāda (Way of the Elders) accepted the principle that virtuous followers of the Buddha could be translated in the next life to a heavenly existence in which they would have godlike status (an impermanent status, however, for gods share the universal transitoriness of all living beings), but such gods were scarcely the objects of a cult.

Functional deities. In addition to the various forces operating in nature, various social and other functions are divinized. Thus, the god Brahmā in the Vedic tradition, besides being creator, contains and expresses in personal form the power implicit in the Brahmin class. Again, there are gods of healing, such as Asclepius in Greece, and of seafaring, agriculture, and so on. The most elaborate reflection of human concerns is, perhaps, to be found in the later Taoist pantheon, which provided a heavenly counterpart to the Chinese Imperial court. In a number of societies gods of war, such as Mars (ancient Rome) and Skanda (India); gods of learning, such as Sarasvatī (India); and gods of love, such as Aphrodite (Greece) and Kāma (India), have been important. Even such abstractions as the directions (north, south, east, and west) have been divinized. The fact that these varied entities and relationships have been taken as gods is, perhaps, partly the result of the mythic style of thinking, in which distinctions between natural forces and social conventions are not clearly perceived.

Of special importance regarding human affairs are the gods concerned with death and judgment after death, such as Osiris in ancient Egypt, Yama in India, Hades in Greece, and Hel in pre-Christian Scandinavian religion. There are also gods associated with cemeteries and more generally with patterns of the disposal of the dead.

The various gods must be seen against the background of a whole host of spirits, demons, and other supernatural forces prevalent in the environment of pastoral and agricultural communities. Among entities hostile to man are the antigods, very often older gods, such as the Titans in Greece, who have been displaced by later deities or gods worshipped by a people conquered by a new dominant folk. The warfare between the old and new can be woven into dramatic myths of the fight between good and evil. This is well brought out in the major myth of the

Super-
natural
forces

Orphic writings: Zeus's son Dionysus-Zagreus was killed and eaten by the Titans, who in turn were destroyed, burned up by Zeus's lightning flash. Man is made of the ashes, and therefore he is a compound of divinity and titanic evil. Purification from this evil brings redemption and release from the round of reincarnation. Sometimes, however, the ambivalence of good and evil is built into the same deity, so that creation and destruction and good and evil are seen as complementing one another.

TYPES OF POLYTHEISM

Greco-Roman religion. By the time of the establishment of the Roman Empire, the Greek tradition was already exerting considerable influence on the Roman, to the extent that once relatively independent traditions became somewhat fused. Equations between gods were freely made: Zeus became Jupiter, Aphrodite became Venus, and so on. Originally Roman *pietas* (sense of duty to the gods) was a good deal less personalized than the relationship to the anthropomorphic gods of the Homeric pantheon and was directed at spirits called *numina*. In addition, the various philosophical systems, such as Epicureanism and Stoicism, provided a more systematic cosmology and sense of man's destiny than traditional polytheism. Influential in the Hellenistic period were mystery cults—such as those of Isis, Cybele, Mithra, and Demeter—which catered more to personal concerns with salvation than did the official and civic cults. Under the mid-4th-century emperor Julian, a last vigorous attempt was made to revive paganism and to restore the cult of the gods over against the widespread grip of Christianity.

Germanic, Scandinavian, Celtic, and Slavic mythologies. The sources for a reconstruction of northern European religion are far better than those for the south Germanic peoples, but there were evidently similarities between the religions. The three main Scandinavian gods were Odin, Thor, and Freyr: Odin (or Wodan) had great magical power and wisdom and was called All-father; Thor (or Donar) was the warrior god; and Freyr was the god of fertility. It is possible that these gods are a reflection of the tripartite division of Indo-European society—priest, warrior, and cultivator. Among other deities, Balder, the dying god who was killed by a mistletoe branch, had a poignant charm. Nordic mythology also carries with it a sense of final doom of the gods, looking to the point when the world will be burned up, before its eventual re-creation.

The pattern of Celtic cults is not easy to decipher because of lack of written records; but the stag-headed god Cernunnos was highly significant in iconography. There was also a variety of ancestral gods and goddesses, including a "great mother" of the type found in fertility cults of the ancient Middle East. Celtic religion had a special reverence for water in such forms as pools and rivers.

The Slavic religions of eastern Europe and Russia are likewise imperfectly known, but they involved worship of a high god who is both a creator and an atmospheric force. Another important figure in Slavic mythology was the war god Svantovit. Finno-Ugrian pre-Christian religion bears some resemblance to the Scandinavian, possibly indicating some mutual influences, while Baltic cults are of Indo-European type.

Egypt and the Middle East. The Egyptian pantheon evolved into a complex form; many deities were theriomorphic but were presided over by such great gods as Re, the sun god, and Nut, the sky goddess. Re's transformation as Horus, with a hawk's head, was connected with the Osiris legend. The pharaoh was identified with him as the "living Horus." Despite the attempt of Akhenaton, pharaoh in the 14th century BC, to exalt Aton as the single god, the Egyptian cult remained essentially polytheistic but highly articulated. With the domination of Egypt by the Ptolemies about 10 centuries later, the worship of Sarapis, a hybrid Greco-Egyptian deity, was instituted as a means of binding together the two groups.

Though in Egypt the cause of the rise and fall of gods was partially the political struggles between the major city-states, the Sumerian religion was much less affected by such "earthly" considerations. An, the god of heaven, remained supreme, and such deities as the water god

Enki and the air god Enlil were prominent. In Babylon, partly the successor state of Sumer, the most vital god was Marduk, creator of the world and of mankind, and victor over the primeval Tiamat, or chaos, who all but absorbed the older surrounding gods. His story is recounted in the epic *Enuma elish* ("When on High"). In Assyrian religion Marduk was in effect replaced by Ashur; and Ishtar, the mother goddess, was also important. In general, it can be said that Middle Eastern religion stemmed from early Sumerian and Egyptian sources and that the latter eventually had some effect on Hellenistic religion.

Early Indo-Iranian religions. For almost a millennium close relations existed between the Vedic and Iranian religions—from before the time of the Iranian prophet Zoroaster, who reformed the ancient religion in the late 7th and early 6th centuries BC, back to the time of the Vedic religion of the Aryans, who invaded India about 1500 BC. Zoroaster, in his reforms, succeeded in excising the many gods, some of whom were subsumed as qualities of the supreme Ahura Mazda. The rich pantheon of the Vedic hymns developed into the world of classical Hindu mythology, which was fed by streams other than the Aryan.

Classical and modern Hinduism. Certain gods of no great importance in the Vedic tradition came to dominate classical Hinduism, above all Śiva and Vishnu. The latter was associated with belief in *avatar*, or incarnation. Most male gods in the Hindu pantheon also came to be represented with a female consort, symbolizing the *śakti*, or creative power of the deity. The increasing elaboration of Hindu cults as different groups were absorbed into a systematized social fabric has led to the estimate of as many as 33,000,000 Hindu gods. It has been common practice for devotees to select the form under which the divine is worshipped, and such a deity is called the *iṣṭadevatā*. Most Hindus are inclined to interpret the many gods as being symbols of the one divine reality.

Buddhism. Buddhism's tolerance of popular cults, provided that the main essentials of the faith are maintained, means that in most Buddhist cultures several gods are worshipped. In Mahāyāna Buddhism, increased devotion to the Buddha became elaborated as a belief in many celestial beings, notably Amitābha and Avalokiteśvara (Kwannon), who were, however, in essence all unified in the absolute (*sūnya*, the void). In Tibet, a synthesis between the indigenous religion and Buddhism was established. The most notable feature of this form of Buddhism, known as Vajrayāna (Vehicle of the Thunderbolt), was the use of divine forms to symbolize the various factors of existence, such as the different elements making up human personality.

Far Eastern religions. In ancient China the cult of Heaven and ancestor worship were elements woven into the system of Confucianism. Numerous lesser deities were worshipped in popular Chinese practice, and the dividing lines between Confucianism, religious Taoism, and Buddhism were hard to draw. In Taoism, an elaborate pantheon was evolved, modelled in part on the Imperial bureaucracy, and was presided over by the Jade Emperor (Yü-Huang). Other deities included atmospheric gods, gods of locality, and functional gods (of wealth, literature, agriculture, and so on). The Taoist gods were in part a response to the richness of Mahāyāna myth, with its cults of celestial buddhas and *bodhisattvas*.

The religions practiced in China influenced Japanese culture, which took over some main elements of Confucianism and Buddhism, that interacted with the indigenous polytheistic religion, Shintō (Way of the Gods). The divinities of Shintō tend to be connected with natural forces and localities; the most important deity is Amaterasu, who is the sun goddess and divine ancestress of the emperor.

Religions of ancient Meso-America. The Aztec culture, successor of earlier civilizations, together with the associated Maya culture, laid great emphasis on astronomical observation and on a complex religious calendar. Important were the high god Ometecuhtli, the morning star Quetzalcóatl, and the various legends woven round Tezcatlipoca, patron of warriors, who in the form of Huitzilopochtli was patron of the Aztec nation. Inca religion

Political considerations in Egypt

The Taoist pantheon

also possessed a high god, Viracocha; a number of the most important deities were associated with celestial bodies, notably the sun, patron of the Incas. Both in Central and South America, the fertility aspects of deities were also emphasized.

Modern ethnic religions in Africa and elsewhere. In some areas, such as much of Africa and Oceania, the indigenous religions are ethnic or tribal; each group has its own particular tradition. These traditions have been affected considerably by the impact of Christian missions and Western technology. Clearly there is no single pattern of belief, though certain patterns do recur in some of the cultures, such as belief in a high god, totemism (characterized by recognition of a relationship between certain human groups and particular classes of animal, plant, or inanimate object in nature), spirit possession, and so on. In various respects there are matches between myth and social organization that are likewise quite varied. Anthropologists, however, are far from a consensus on the role and origin of the gods.

(N.Sm.)

Pantheism and panentheism

Both "pantheism" and "panentheism" are terms of recent origin, coined to describe certain views of the relationship between God and the world that are different from that of traditional Theism (see *Theism* below). As reflected in the prefix "pan-" (Greek *pas*, "all"), both of the terms stress the all-embracing inclusiveness of God, as compared with his separateness as emphasized in many versions of Theism. On the other hand, pantheism and panentheism, since they stress the theme of immanence—i.e., of the indwelling presence of God—are themselves versions of Theism conceived in its broadest meaning. Pantheism stresses the identity between God and the world; panentheism (Greek *en*, "in") holds that the world is included in God but that God is more than the world.

The adjective "pantheist" was introduced by the Irish Deist, John Toland, in a book, *Socinianism Truly Stated* (1705). The noun "pantheism" was first used in 1709 by one of Toland's opponents. The term "panentheism" appeared much later, in 1828, when it was used to characterize the view that the world is a finite creation within the infinite being of God.

Although the terms are recent, they have been applied retrospectively to alternative views of the divine being as found in the entire philosophical traditions of both East and West.

NATURE AND SIGNIFICANCE

Pantheism and panentheism can be explored by means of a three-way comparison with traditional or Classical Theism viewed from eight different standpoints—i.e., from those of immanence or transcendence; of monism, dualism, or pluralism; of time or eternity; of the world as sentient or insentient; of God as absolute or relative; of the world as real or illusory; of freedom or determinism; and of sacramentalism or secularism.

Immanence or transcendence. The poetic sense of the divine within and around mankind, which is widely expressed in religious life, is frequently treated in literature. It is present in the Platonic Romanticism of Wordsworth and Coleridge, as well as in Tennyson, Emerson, and Goethe. Expressions of the divine as intimate rather than as alien, as indwelling and near dwelling rather than remote, characterize pantheism and panentheism as contrasted with Classical Theism. Such immanence encourages man's sense of individual participation in the divine life without the necessity of mediation by any institution. On the other hand, it may also encourage a formless "enthusiasm," without the moderating influence of institutional forms. In addition, some theorists have seen an unseemliness about a point of view that allows the divine to be easily confronted and appropriated. Classical Theism has, in consequence, held to the transcendence of God, his existence over and beyond the universe. Recognizing, however, that if the separation between God and the world becomes too extreme, man risks the loss of communi-

cation with the divine, panentheism—unlike pantheism, which holds to the divine immanence—maintains that the divine can be both transcendent and immanent at the same time.

Monism, dualism, or pluralism. Philosophies are monistic if they show a strong sense of the unity of the world, dualistic if they stress its twoness, and pluralistic if they stress its manyness. Pantheism is typically monistic, finding in the world's unity a sense of the divine, sometimes related to the mystical intuition of personal union with God; Classical Theism is dualistic in conceiving God as separated from the world and mind from body; and panentheism is typically monistic in holding to the unity of God and the world, dualistic in urging the separateness of God's essence from the world, and pluralistic in taking seriously the multiplicity of the kinds of beings and events making up the world. One form of pantheism, present in the early stages of Greek philosophy, held that the divine is one of the elements in the world whose function is to animate the other elements that constitute the world. This point of view, called Hylozoistic (Greek *hylē*, "matter," and *zōē*, "life") pantheism, is not monistic, as are most other forms of pantheism, but pluralistic.

Time or eternity. Most, but not all, forms of pantheism understand the eternal God to be in intimate juxtaposition with the world, thus minimizing time or making it illusory. Classical Theism holds that eternity is in God and time is in the world but believes that, since God's eternity includes all of time, the temporal process now going on in the world has already been completed in God. Panentheism, on the other hand, espouses a temporal-eternal God who stands in juxtaposition with a temporal world; thus, in panentheism, the temporality of the world is not cancelled out, and time retains its reality.

The world as sentient or insentient. Every philosophy must take a stand somewhere on a spectrum running from a concept of things as unfeeling matter to one of things as psychic or sentient. Materialism holds to the former extreme, and Panpsychism to the latter. Panpsychism offers a vision of reality in which to exist is to be in some measure sentient and to sustain social relations with other entities. Dualism, holding that reality consists of two fundamentally different kinds of entity, stands again between two extremes. A few of the simpler forms of pantheism support Materialism. Panentheism and most forms of pantheism, on the other hand, tend toward Panpsychism. But there are differences of degree, and though Classical Theism tends toward dualism, even there the insentient often has a tinge of Panpsychism.

God as absolute or relative. God is absolute insofar as he is eternal, cause, activity, creator; he is relative insofar as he is temporal, effect, passive (having potentiality in his nature), and affected by the world. For pantheism and Classical Theism, God is absolute; and for many forms of pantheism, the world, since it is identical with God, is likewise absolute. For Classical Theism, since it envisages a separation between God and the world, God is absolute and the world relative. For panentheism, however, God is absolute and relative, cause and effect, actual and potential, active and passive. The panentheist holds that, inasmuch as they refer to different levels of the divine nature, both sets of claims can be attributed to God without inconsistency, that just as a man can have an absolute, unchanging purpose, which gains now one embodiment and now another, so God's absoluteness can be an abstract unchanging feature of a changing totality.

The world as real or illusory. Panentheism, Classical Theism, and many forms of pantheism hold the world to be part of the ultimate reality. But for Classical Theism the world has a lesser degree of reality than God; and for some forms of pantheism, for which Hegel coined the term Acosmism, the world is unreal, an illusion, and God alone is real.

Freedom or determinism. In those forms of pantheism that envisage the eternal God literally encompassing the world, man is an utterly fated part of a world that is necessarily just as it is, and freedom is thus illusion. To be sure, Classical Theism holds to the freedom of man but insists that this freedom is compatible with a divine omniscience

Distinctions viewed from the metaphysical standpoint

Distinctions viewed from the human standpoint

that includes his knowledge of the total future. Thus the question arises whether or not such freedom is illusory. Panentheism, by insisting that future reality is indeterminate or open and that man and God, together, are in the process of determining what the future shall be, probably supports the doctrine of man's freedom more completely than does any alternative point of view.

Sacramentalism or secularism. Insofar as God is the indwelling principle of the world and of man, as in pantheism, so far do these take on a sacramental character; and insofar as God is separated from the world as in 18th-century Deism (see also *Deism* below), so far does it become secular, neutral, or even fallen. In contrast, Classical Theism, though basically sacramental, places this quality in an enclave, the church.

DIVERSE VIEWS OF THE RELATION OF GOD TO THE WORLD

On the basis of the preceding characteristics, seven forms of pantheism can be distinguished in addition to Classical Theism and panentheism:

Hylozoistic pantheism. The divine is immanent in, and is typically regarded as the basic element of, the world, providing the motivating force for movement and change. The world remains a plurality of separate elements.

Immanentistic pantheism. God is a part of the world and immanent in it. Though only a part, however, his power extends throughout its totality.

Absolutistic monistic pantheism. God is absolute and identical with the world. The world, although real, is therefore changeless.

Relativistic monistic pantheism. The world is real and changing and is within God (e.g., as the body of God). But God remains nonetheless absolute and is not affected by the world.

Acosmic pantheism. The absolute God makes up the total reality. The world is an appearance and ultimately unreal.

Identity of opposites pantheism. The opposites of ordinary discourse are identified in the supreme instance. God and his relation to the world are described in terms that are formally contradictory; thus reality is not subject to rational description. Whether being is stressed or the void, whether immanence is or transcendence, the result is the same: one must go beyond rational description to an intuitive grasp of the ultimate.

Classical Theism. God is absolute, eternal, first cause, pure actuality, an omniscient, omnipotent, and perfect being. Though related to the world as its cause, he is not affected by the world. He is essentially transcendent over the world; and the world exists relative to him as a temporal effect of his action—containing potentiality as well as actuality and characterized by change and finitude. Since all of time is part of God's eternal "Now," and since God's knowledge now includes the total future as though laid out before him like a landscape, it is not clear that, in this system, man can have freedom in any significant sense; for although foreknowledge does not of itself determine anything, it vouches for the existence of such determination. Nonetheless, human freedom is in fact asserted by Classical Theists.

Neoplatonic or emanationistic pantheism. God is absolute in all respects, remote from the world and transcendent over it. This view is like Classical Theism except that, rather than saying that God is the cause of the world, it holds that the world is an emanation of God, occurring by means of intermediaries. God's absoluteness is thus preserved while a bridge to the world is provided as well. In Plotinus (3rd century AD), the foremost Neoplatonist, the *Nous* (Greek, "mind"), a realm of ideas or Platonic forms, serves as the intermediary between God and the world, and the theme of immanence is sustained by positing the existence of a World-Soul that both contains and animates the world.

Panentheism. In this alternative, both sets of categories, those of absoluteness and of relativity, of transcendence and of immanence, are held to apply equally to God, who is thus dipolar. He is the cause of the world and its effect; his essence is eternal, but he is involved in time. God's knowledge includes all that there is to know; since

the future is genuinely open, however, and is not in any sense real as yet, he knows it only as a set of possibilities or probabilities. In this alternative man is held to have significant freedom, participating as a co-creator with God in the continuing creation of the world.

With only slight attention being accorded to Classical Theism (which is covered in another article), the incidence of the preceding eight forms of pantheism and panentheism in cultural history remains to be explored.

PANTHEISM AND PANENTHEISM IN NON-WESTERN CULTURES

Hindu doctrines. The gods of the Vedas, the ancient scriptures of India (c. 1200 BC), represented for the most part natural forces. Exceptions were the gods Prajāpati (Lord of Creatures) and Puruṣa (Supreme Being or Soul of the Universe), whose competition for influence provided, in its outcome, a possible explanation of how the Indian tradition came to be one of pantheism rather than of Classical Theism. By the 10th book of the *Rigveda*, Prajāpati had become a lordly, monotheistic figure, a creator deity transcending the world; and in the later period of the sacred writings of the *Brāhmaṇas* (c. 7th century BC), prose commentaries on the Vedas, he was moving into a central position. The rising influence of this Theism was later eclipsed by Puruṣa, who was also represented in *Rigveda* X. In a creation myth Puruṣa was sacrificed by the gods in order to supply (from his body) the pieces from which all the things of the world arise. From this standpoint the ground of all things lies in a Cosmic Self, and all of life participates in that of Puruṣa. The Vedic hymn to Puruṣa may be regarded as the starting point of Indian pantheism.

In the *Upaniṣads* (c. 1000–500 BC), the most important of the ancient scriptures of India, the later writings contain philosophic speculations concerning the relation between the individual and the divine. In the earlier *Upaniṣads*, the absolute, impersonal, eternal properties of the divine had been stressed; in the later *Upaniṣads*, on the other hand, and in the *Bhagavadgītā*, the personal, loving, immanentistic properties became dominant. In both cases the divine was held to be identical with the inner self of each man. At times these opposites were implicitly held to be in fact identical—the view earlier called identity of opposites pantheism. At other times the two sets of qualities were related, one to the unmanifest absolute Brahman, or supreme reality (sustaining the universe), and the other to the manifest Brahman bearing qualities (and containing the universe). Thus Brahman can be regarded as exclusive of the world and inclusive, unchanging and yet the origin of all change. Sometimes the manifest Brahman was regarded as an emanation from the unmanifest Brahman; and then emanationistic pantheism—the Neoplatonic pantheism of the foregoing typology—was the result.

Śaṅkara, an outstanding nondualistic Vedāntist and advocate of a spiritual view of life, began with the Neoplatonic alternative but added a qualification that turned his view into what was later called acosmic pantheism. Distinguishing first between Brahman as being the eternal Absolute and Brahman as a lower principle and declaring the lower Brahman to be a manifestation of the higher, he then made the judgment that all save the higher unqualified Brahman is the product of ignorance or nescience and exists (apparently only in men's minds) as the phantoms of a dream. Since for Śaṅkara, the world and individuality thus disappear upon enlightenment into the unmanifest Brahman, and in reality only the Absolute without distinctions exists, Śaṅkara has provided an instance of acosmism.

On the other hand, Rāmānuja, a prominent southern Brahmin who held to a qualified monism, argued strenuously against Śaṅkara's dismissal of the world and of individual selves as being mere products of nescience. In place of this acosmism he substituted the notion of world cycles. In the unmanifest state Brahman has as his body only the very subtle matter of darkness, and he decrees "May I again possess a world-body"; in the manifest state all of the things of the world, including individual selves, are part of his body. The doctrine of Rāmānuja approaches panentheism; he has certainly advanced beyond

The Vedas
and
Upaniṣads

The views
of Śaṅkara,
Rāmānuja,
and
Radha-
krishnan

God as
related to
time and
change

emanationistic pantheism. There are two aspects to the single Brahman, one absolutistic and the other relativistic. As in panentheism, the beings of the world have freedom. The only qualification is that, although it is Brahman's will to support the choices of finite beings, he has the power to prohibit any choice that displeases him. This power to prohibit indicates a preference for the absolute in Rāmānuja's thought, which is reflected in many ways: although God is the cause of the world, for example, and includes the world within his being, he is never affected by that world, and his motive in world creation is simply play. In sum, since the absolutistic categories were given the greater emphasis in his thought, Rāmānuja is representative of a relativistic monistic pantheism.

The presence in the Hindu tradition of both absolutistic and relativistic descriptions of the divine suggests that genuine pantheism might well emerge from the tradition; and, in fact, in the former president of India, S. Radhakrishnan, also a religious philosopher, that development did occur. Although Radhakrishnan had been influenced by Western philosophy, including that of A.N. Whitehead, later discussed as a modern pantheist, the sources of his thought lie in Hindu philosophy. He distinguishes between God as the being who contains the world and the Absolute, who is God in only one aspect. He finds that the beings of the world are integral with God, who draws an increase of his being from the constituents of his nature.

Buddhist doctrines. Some 600 years after Buddha, a new and more speculative school of Buddhism arose to challenge the 18 or 20 schools of Buddhism then in existence. One of the early representatives of this new school, which came to be known as Mahāyāna (Sanskrit "Greater Vehicle") Buddhism, was Āśvaghoṣa. Like Śaṅkara (whom he antedated by 700 years), Āśvaghoṣa not only distinguished between the pure Absolute (the Soul as "Suchness"; *i.e.*, in its essence) and the all-producing, all-conserving Mind, which is the manifestation of the Absolute (the Soul as "Birth and Death"; *i.e.*, as happenings), but he also held that the judgment concerning the manifest world of beings is a judgment of nonenlightenment; it is, he said, like the waves stirred by the wind—when the quiet of enlightenment comes the waves cease, and an illusion confronts a man as he begins to understand the world.

Whereas Āśvaghoṣa treated the world as illusory and essentially void, Nāgārjuna, the great propagator of Mahāyāna Buddhism who studied under one of Āśvaghoṣa's disciples, transferred *Śūnya* ("the Void") into the place of the Absolute. If Suchness, or ultimate reality, and the Void are identical, then the ultimate must lie beyond any possible description. Nāgārjuna approached the matter through dialectical negation: according to the school that he founded, the Ultimate Void is the Middle Path of an eightfold negation; all individual characteristics are negated and sublated, and the individual approaches the Void through a combination of dialectical negation and direct intuition. Beginning with the Middle Doctrine School, the doctrine of the Void spread to all schools of Mahāyāna Buddhism as well as to the Satyasiddhi (Sanskrit: "perfect attainment of truth") group in Hinayāna Buddhism. Since the Void is also called the highest synthesis of all oppositions, the doctrine of the Void may be viewed as an instance of identity of opposites pantheism.

In the T'ien-t'ai school of Chinese Buddhism founded by Chih-i, as in earlier forms of Mahāyāna Buddhism, the elements of ordinary existence are regarded as having their basis in illusion and imagination. What really exists is the one Pure Mind, called True Thusness, which exists changelessly and without differentiation. Enlightenment consists of realizing one's unity with the Pure Mind. Thus, an additional Buddhist school, T'ien-t'ai, can be identified with acosmic pantheism.

Indeed, although a mingling of types is discernible in the Hindu and Buddhist strands of Oriental culture, acosmic pantheism would seem to be the alternative most deeply rooted and widespread in these traditions.

Ancient Middle Eastern doctrines. Just as the early gods of the Vedas represented natural forces, so the Canaanite deities known as Baal and the Hebrew God Yahweh both began as storm gods. Baal developed into a Lord of na-

ture, presiding with his consort, Astarte, over the major fertility religion of the Middle East. The immanentism of this nature religion might have sustained the development of pantheistic systems; but, whereas the pantheistic Puruṣa triumphed in India, the Theistic Yahweh triumphed in the Middle East. And Yahweh evolved not into a Lord of nature but into a Lord of history presiding first over his chosen people and then over world history. The requirement that he be a judge of history implied that his natural "place" was outside and above the world; and he thus became a transcendent deity. Through much of the history of Israel, however, the people accepted elements from both of these traditions, producing their own highly syncretistic religion. It was this syncretism that provided the occasion that challenged certain men of prophetic consciousness to embark upon their purifying missions, beginning with Elijah and continuing throughout the Old Testament period. In this development, the absoluteness and remoteness of Yahweh came to be supplemented by qualities of love and concern, as in the prophets Hosea and Amos. In short, the categories of immanence came to supplement the categories of transcendence and, in the New Testament period, became overwhelmingly important. The transcendent Yahweh, on the other hand, had fitted more naturally into the categories of absoluteness. And, in the Christian West, it was the transcendent God who appeared in the doctrines of Classical Theism, while pantheism stood as a heterodox departure from the Christian scheme.

PANTHEISM AND PANENTHEISM IN ANCIENT AND MEDIEVAL PHILOSOPHY

Early Greek religion contained among its many deities some whose natures might have supported pantheism; and certainly the mystery religions of later times stressed types of mystical union that are typical of pantheistic systems. But in fact the pantheism of ancient Greece was related almost exclusively to philosophical speculation. For this reason it is more rationalistic, possessing a style quite different from the Pantheisms thus far examined.

Greco-Roman doctrines. The first philosophers of Greece, all of whom were 6th-century-BC Ionians, were hylozoistic, finding matter and life inseparable. The basic substances that they identified as the elements of reality—the water proposed by Thales, the boundless infinite suggested by Anaximander, and the air of Anaximenes—were presumed to have the motive force of living things and thus to be a kind of life, a position here called hylozoistic pantheism.

Impressed by the absolute unity of all things, the adherents of another philosophic position, that of Eleaticism (see PHILOSOPHICAL SCHOOLS AND DOCTRINES: *Eleaticism*), so-named from its centre in Elea, a Greek colony in southern Italy, found it impossible to believe in multiplicity and change. The first step in this direction was taken by Xenophanes, a religious thinker and rhapsodist, who, on rational grounds, moved from the gods and goddesses of Homer and Hesiod to a unitary principle of the divine. He believed that God is the supreme power of the universe, ruling all things by the power of his mind. Unmoved, unmoving, and unitary, God perceives, governs, and apparently contains, or at least he "embraces," all things. So interpreted, Xenophanes provides an instance of monistic pantheism, inasmuch as, in this view, the Absolute God is united with a changing world, while the reality of neither is attenuated. This paradox may have encouraged Parmenides, possibly one of Xenophanes' disciples (according to Aristotle), to accept the changeless Absolute, eliminating change and motion from the world. Reality thus became for him a unitary, indivisible, everlasting, motionless whole. This position is basically that of absolutistic monistic pantheism in that it views the world as real but changeless. Insofar as the change and variety of the world are only apparent, Parmenides also approaches acosmic pantheism.

A third fundamental position is that of the Ephesian critic Heraclitus, among whose cryptic sayings were many that stressed the role of change as the basic reality. Heraclitus continued the hylozoistic tendencies of the Ionian philoso-

Pre-Socratic views

Identity of
Suchness
and the
Void

Baal,
Yahweh

phers. Fire, his basic element, is also the universal *logos*, or reason, controlling all things; and since fire not only has a life of its own but exercises control to the boundaries of the universe as well, the system is more complex than hylozoistic pantheism. In view of the circumstance that everything is either on the way from, or to, fire, this basic element is actually or incipiently everywhere. Since the divine works here from within the universe, indeed from within a single, but basic, aspect of it, the system is an instance of immanentistic pantheism.

The philosopher Anaxagoras, one of the great dignitaries at Athens in the golden age of Pericles, approached the problem somewhat in the manner of Heraclitus. *Nous* (or Mind) he held to be the principle of order for all things as well as the principle of their movement. It is the finest and purest of things and is diffused throughout the universe. This, like the preceding system, is an instance of immanentistic pantheism.

Plato's
dualism

From the standpoint of the typology here employed, Plato may be regarded as the first Western philosopher to treat the problem of the absoluteness and the relativity in God with any degree of adequacy. In the *Timaeus* an absolute and eternal God was recognized, existing in changeless perfection in relation to the world of forms, along with a World-Soul, which contained and animated the world and was as divine as a changing thing could be. Although the material can be variously interpreted, pantheists hold that Plato has adopted a dual principle of the divine, uniting both being and becoming, absoluteness and relativity, permanence and change in a single context. To be sure, he envisioned the categories of absoluteness as situated in one deity, and those of relativity in another; but the separation seems not to have pleased him, and in the tenth book of the *Laws*, by invoking the analogy of a circular motion, which combines change with the retention of a fixed centre, he explained how deity could exemplify both absoluteness and change. Plato thus may be viewed as a quasi-pantheist.

Aristotle, on the other hand, with his exclusivistic, transcendent God, exemplifying only the categories of absoluteness, anticipated the absolute God of Classical Theism, existing above and beyond the world.

Stoic
pantheism,
Neo-
platonism

Stoicism, one of the foremost of the post-Aristotelian schools of thought, represents an immanentistic pantheism of the Heraclitean variety. First of all, the Stoics accepted the decision of Heraclitus that an indwelling fire is the principal element entering into all transformations and is also the principle of reason, the *logos*, ordering as well as animating all things, but that, second, there is a World-Soul, which is diffused throughout the world and penetrates it in every part. Rather than approximating Plato's spiritual World-Soul, the Stoic World-Soul is more like the *Nous* of Anaxagoras. The Stoics were Materialists, and their diffuse World-Soul is, thus, an extended form of subtle matter. That everything is determined by the universal reason is an unvarying theme in Stoicism; and this fact suggests that Stoic pantheism, despite its immanentism, stresses the categories of absoluteness rather than those of relativity in the relations holding between God and the world.

The life of reason brings man into harmony with God and with nature and helps him to understand his fate, which is his place in the universal system. Although the view is an amalgam of several types of pantheism, this particular mixture has retained its identity. It is therefore useful to call this position, or any similar combination of themes, by the name Stoic pantheism.

Plotinus, the creator of one of the most thoroughgoing philosophical systems of ancient times, may be taken to represent Neoplatonism, an influential modification of Plato's attempt to deal with absoluteness and relativity in the divine. Plotinus' system consists of the One—the absolute God who is the supreme power of the system—the intermediate *Nous*, and the World-Soul (with the world as its internal content). His World-Soul follows the Platonic model. The system really blends pantheism with Classical Theism, since the categories of absoluteness apply to the One, and the relativistic categories apply to the World-Soul. The doctrine of emanation, whereby the power of

the One comes into the world, is a clear attempt to bridge the gap between absoluteness and relativity. For Plotinus, as for Classical Theism, there is immanent in man an image of the divine, which serves as well to relate man to God as does the divine spark in Stoic pantheism. Even Classical Theism may thus contain a touch of immanentistic pantheism. This view, or any similar combination of themes, is an instance of emanationistic or Neoplatonic pantheism.

Medieval doctrines. Though Scholasticism, with its doctrine of a separate and absolute God, was the crowning achievement of medieval thought, the period was, nonetheless, not without its pantheistic witness. Largely through Jewish and Christian mysticism, an essentially Neoplatonic Pantheism ran throughout the age.

The only important Latin philosopher for six centuries after St. Augustine was John Scotus Erigena. Inasmuch as, in his system, Christ's redemptive sacrifice helps to effect a Neoplatonic return of all beings to God, Erigena can be said to have turned Neoplatonism into a Christian drama of fall into sin and redemption from its power. When Erigena said that, even in the stage of separation from God, God in his superessentiality is identical with all things, he advanced beyond a strictly Neoplatonic pantheism to some stronger form of immanentistic or monistic pantheism.

In the two principal writings of the esoteric Jewish movement called the Kabbala, known for its theosophical interpretations of the Scriptures, a mystically oriented system of 10 emanations is presented. A Spaniard, Avicébrón, a Jewish poet and philosopher, similarly presented a Neoplatonic scheme of emanations. And in Spain, Averroës, the most prominent Arabic philosopher of the period, represented an Aristotelian tradition that is heavily overlaid with Neoplatonism. For Averroës, the active intellect in man is really an impersonal divine reason, which alone lives on when man dies.

The German Meister Eckhart, probably the most significant of philosophical mystics, developed a markedly original theology. From his Stoic pantheism there arose his most controversial thesis—that there resides in every man a divine, uncreated spark of the Godhead, making possible both a union with God and a genuine knowledge of his nature. But Eckhart also distinguished between the unmanifest and barren Godhead and the three Persons who constitute a manifest and personal God. Thus, the system has similarities to both Stoic and Neoplatonic pantheism.

Cardinal Nicholas of Cusa, whose broad scholarship and scientific approach anticipated the coming Renaissance, continued the tradition into the 15th century. The "learned ignorance," in which a man separates himself from every affirmation, can have positive results, in Nicholas' view, because man is a microcosm within the macrocosm (or universe), and the God of the macrocosm is thus mirrored in all of his creatures. He also held that, in reference to God, contradictions are compatible—his "coincidence of opposites" doctrine, in which God is at once all extremes. Clearly, Nicholas wished to ascribe to God both the categories of transcendence and those of immanence without distinction. But in fact he displayed some preference for the categories of the absolute, insisting, for example, that the creatures of the world can add nothing to God since they are merely his partial appearances. Despite this bias toward absolutism, and even to acosmism, Nicholas can be appropriately viewed as espousing an identity of opposites pantheism.

PANTHEISM AND PANENTHEISM IN MODERN PHILOSOPHY

Renaissance and post-Renaissance doctrines. The humanism of the Renaissance included an enlarged interest in Platonism and in its historical carrier, Neoplatonism, as well as influences from Aristotle and from Kabbalistic sources. The view of man as a microcosm of the universe was widespread. Marsilio Ficino, one of the first leaders of the Florentine Academy, found the image and reflection of God in all men and anticipated the divinization of man and the entire cosmos. The humanist and syncretistic philosopher Pico della Mirandola, also a leading figure in the Academy, substituted for creation a Neoplatonic emanation from the divine.

The views
of Ficino,
Bruno, and
Böhme

The most famous scholar of the Italian Renaissance was Giordano Bruno. Combining Copernican astronomy with Neoplatonism, Bruno thought of the universe as an infinite organism with monads as its ultimate constituents and world-systems as its parts. The universe, he held, is in a continual process of development and is infused with the divine life. Accepting Nicholas of Cusa's doctrine of the identity of opposites, he taught that contradictory ascriptions apply equally to God in particular and that claims concerning his immanence and transcendence are equally valid. More open to the categories of relativity than Nicholas, Bruno, however, exemplified a neatly balanced instance of identity of opposites pantheism.

The next great innovator of mystical religious thought was Jakob Böhme, who, in developing the concept of the divine life, took a decisive step beyond mere absoluteness. God goes through stages of self-development, he taught, and the world is merely the reflection of this process. Böhme anticipated Hegel in claiming that the divine self-development occurs by means of a continuing dialectic, or tension of opposites, and that it is the negative qualities of the dialectic that men experience as the evil of the world. Even though Böhme, for the most part, stressed absoluteness and relativity equally, his view that the world is a mere reflection of the divine—apparently denying self-development on the part of creatures—tends toward acosmic pantheism.

Spinoza's
rational
pantheism

In the 17th century the foremost pantheist was a Jewish rationalist, Benedict Spinoza, whose training in the history of philosophy included both medieval Jewish philosophy and the Kabbala. He championed a rational rather than a mystical pantheism, so much so that all that remained of mysticism, in fact, was his concept of the intellectual love of God. The rationality of the system is suggested by Spinoza's argument that, since God is the infinite being, he must be identical with the world; for otherwise, God-and-world would be a greater totality than God alone. Also, since God is a necessary being and is identical with the world, the world must also be necessary in all its parts. It follows from this that human freedom is an impossible idea; and the sense that man has of such freedom is based on his ignorance of the causes that have determined him. Spinoza distinguished between God and the world in three ways: first, by stressing God's activity in the active sense of *natura naturans* ("the nature that [creates] nature"; i.e., God) compared to the passive sense of *natura naturata* ("the nature that [is created as] nature"; i.e., the world); second, he related God to eternity and the world to time; and third, he distinguished God as self-existing substance, the whole, from the world, which he conceived as the attributes and modes of that substance. In terms of the present classification, Spinoza represents a monistic pantheism tending toward absolutism.

Goethe, the incomparable German litterateur, claimed that he was a follower of Spinoza. In fact, however, his beliefs were rather different inasmuch as Goethe championed man's individuality; opposed mechanical necessity; and held a hylozoistic, or vitalistic, position in which nature was organic, a living unity. His personalistic pantheism mixes hylozoistic and Stoic types with a touch of relativism added to the mixture.

Nineteenth-century doctrines. During the 19th century, pantheism and panentheism were sustained by various kinds of Idealism that developed during the period. In these systems the categories of relativity gained in prominence; God was conceived as entering history and as being more intimately related to processes of change and development.

German Idealism. Although the philosophy of the German patriot J.G. Fichte, an immediate follower of Kant, began in the inner subjective experience of the individual, with the "I" positing the "not-I"—i.e., feeling compelled to construct a perceived world over against itself—it turns out eventually that, at a more fundamental level, God, as the universal "I," posits the world at large. The world, or nature, is described in organic terms; God is considered not alone as the Universal Ego but also as the Moral World Order, or Ground of ethical principles; and since every man has a destiny as a part of this order, man is in

this sense somehow one with God. In the moral world order, then, man has a partial identity with God; and in the physical order he has membership in the organic whole of nature. It is not clear, however, whether in Fichte's view God as Universal Ego includes all human egos, and the organic whole of nature. Should he do so, then Fichte would be a representative of dipolar Panentheism, since in his final doctrine the Universal Ego imitates an Absolute deity who is simply the divine end of all activity, serving equally as model and as goal. In this interpretation God is conceived both as absolute mobility and absolute fixity. It is not entirely clear whether the doctrine is to be understood as referring to two aspects of a single God, the pantheistic alternative, or to two separate gods, the alternative imbedded in Plato's quasipanentheism. In either case, Fichte has enunciated most of the themes of panentheism and deserves consideration either as a representative or precursor of that school.

A second early follower of Kant was F.W.J. von Schelling, who, in contrast to Fichte, stressed the self-existence of the objective world. Schelling's thought developed through several stages. Of particular interest to the problem of God are the final three stages in which his philosophy passed through monistic and Neoplatonic pantheism followed by a final stage that was panentheistic.

In the first of these stages, he posits the Absolute as an absolute identity, which nonetheless includes, as in Spinoza, both nature and mind, reality and ideality. The natural series culminates in the living organism; and the spiritual series culminates in the work of art. The universe is, thus, both the most perfect organism and the most perfect work of art.

In his second, Neoplatonic, stage he conceived the Absolute as separated from the world, with a realm of Platonic ideas interposed between them. In this arrangement, the world was clearly an emanation or effect of the divine.

In the final stage of his thought, Schelling presented a theophany, or manifestation of deity, involving the separation of the world from God, and its return. In appearance this was quite like the views of Erigena or like the unmanifest and manifest Brahman of Indian thought. But, since the power of God continues to infuse the world and there can be no real separation, the entire theophany is clearly the development of the divine life. The Absolute is retained as the pure Godhead, a unity presiding over the world; and the world—having in measure its own spontaneity—is both his antithesis and part of his being, the contradiction accounting for progress. The positing within God of eternity and temporality, of being-in-itself and of self-giving, of yes and no, of participation in joy and in suffering, is the very duality of Panentheism.

It was a disciple of Schelling, Karl Christian Krause, who coined the term panentheism to refer to the particular kind of relation between God and the world that is organic in character.

The third, and most illustrious, early post-Kantian Idealist was G.W.F. Hegel, who held that the Absolute Spirit fulfills itself, or realizes itself, in the history of the world. And in Hegel's deduction of the categories it is clear that man realizes himself through the attainment of unity with the Absolute in philosophy, art, and religion. It would appear, then, that God is in the world, or the world is in God, and that, since man is a part of history and thus a part of the divine realization in the world, he shares in the divine life; it would seem, too, that God is to be characterized by contingency as well as necessity, by potentiality as well as actuality, by change as well as permanence. In short, it would seem at first that the panentheistic dipolarity of terms would apply to the Hegelian Absolute. But this is not quite so; for Hegel's emphasis was on the deduction of the categories of logic, nature, and spirit, a deduction that provided the lineaments of Spirit-in-Itself (the categories of the intrinsic logic that the world, as Spirit, follows in its development), Spirit-for-Itself (nature as existing oblivious of its own context), and Spirit-in-and-for-Itself (conscious spiritual life, natural, and yet aware of its role in the developing world). This deduction, moving from the most abstract categories to the most concrete, is partly logical and partly temporal; it cannot be read either as a sheerly

Hegel's
notion of
Absolute
Spirit

logical sequence or as a sheerly temporal sequence. As a logical sequence, it has the appearance of a Neoplatonic scheme turned on its head, since the Absolute Spirit that emerges from the deduction includes all of the steps of the preceding rich and multifarious deduction. As a temporal sequence, the system would seem to be a species of Stoic (*i.e.*, Heraclitean) pantheism, qualified by a clear Parmenidean motif (see above), which appears in its stress on an absoluteness that, from the eternal standpoint, cancels out time. This Parmenidean quality is to be found not only in Hegel but in most of the Idealists who were influenced by him. Time is real, on this view, and yet not quite real, having already eternally happened. And when Hegel spoke of the Absolute Spirit, this phrase held the internal tension of a near contradiction, for spirit, however absolute, must surely be relative to what is around it, sensitive to and dependent on other spirits. The fact that Hegel wished to give something like equal emphasis, however, both to absoluteness and to relativity in the divine being or process suggests that his goal is identical with that of the panentheists, even though he is perhaps more fairly regarded as a Pantheist of an ambiguous type.

Monism and panpsychism. It is impossible for one to leave the 19th century without mention of the pioneering experimental psychologist Gustav Fechner (1801–87), founder of psychophysics, who developed an interest in philosophy. Fechner pursued the themes of panentheism beyond the positions of his predecessors. A panpsychist with an organic view of the world, he held that every entity is to some extent sentient and acts as a component in the life of some more inclusive entity in a hierarchy that reaches to the divine Being, whose constituents include all of reality. God is the soul of the world, which is, in turn, his body. Fechner contends that every man's volitions provide impulses within the divine experience, and that God gains and suffers from the experiences of men. Precisely because God is the supreme being, he is in process of development. He can never be surpassed by any other, but he surpasses himself continually through time. He, thus, argues that God can be viewed in two ways: either as the Absolute ruling over the world, or as the totality of the world; but both are aspects of the same Being. Fechner's affirmations comprise a complete statement of panentheism, including the dipolar deity with respect to whom the categories of absoluteness and relativity can be affirmed without contradiction.

Twentieth-century doctrines. The 20th century marks a decisive break with absolutism. In the first half of the century, panentheism gained in authority. The position of the Russian ex-Marxist Nikolay Berdyayev, a religious metaphysician, with his emphasis on divine and human freedom, is a manifesto of panentheism. Even more impressive was the work of the eminent British-American philosopher, Alfred North Whitehead. As in the case of Fechner, Whitehead came to philosophy from science and held an organismic view of the structure of the world. In Whitehead's view God has two natures: his primordial nature is abstract; his consequent nature is concrete and includes within itself the total history of the world. Whitehead was also a panpsychist and believed that feeling is present in some degree at every level of the world process. Whether or not he was, then, also a panentheist is in dispute. He held that the possible future and the total past are in God—in his primordial and consequent natures; but for Whitehead the present moment is relative, and contemporaries exclude each other. In the present moment of any entity, since it is the present of *that* entity, it is appropriate to say that God is in that entity, part of the data on which it acts; thus the Stoic spark of divinity has here a modern application. From the standpoint of God, on the other hand, all entities are part of God; they come from him and return to him in the passage of time, but they are not in God in the sense that their independence in the present moment is prejudiced.

It was left to Charles Hartshorne, one of Whitehead's followers, to provide the definitive analysis of panentheism. It is Hartshorne's suggestion that the organismic analogy, present in Whitehead as well as in many earlier thinkers, be taken seriously. For Hartshorne, God includes

the world even as an organism includes its cells, thus including the present moment of each event. The total organism gains from its constituents, even though the cells function with an appropriate degree of autonomy within the larger organism.

CRITICISM AND EVALUATION OF PANTHEISM AND PANENTHEISM

Panentheism is then a middle way between the denial of individual freedom and creativity characterizing many of the varieties of pantheism and the remoteness of the divine characterizing Classical Theism. Its support for the ideal of human freedom provides grounds for a positive appreciation of temporal process, while removing some of the ethical paradoxes confronting deterministic views. It supports the sacramental value of reverence for life. At the same time the theme of participation with the divine leads naturally to self-fulfillment as the goal of life.

Many pantheistic and Theistic alternatives claim the same advantages, but their natural tendency toward absoluteness may make justification of these claims in some cases difficult and, in others, some argue, quite impossible. It is for this reason that a significant number of contemporary philosophers of religion have turned to panentheism as a corrective to the partiality of the other competing views. (W.L.Re.)

Religious dualism

Dualism is the doctrine that the world (or reality) consists of two basic, opposed, and irreducible principles that account for all that exists. It has played an important role in the history of thought and of religion.

NATURE AND SIGNIFICANCE

In religion, dualism means the belief in two supreme opposed powers or gods, or sets of divine or demonic beings, that caused the world to exist. It may conveniently be contrasted with monism, which sees the world as consisting of one principle such as mind (spirit) or matter; with monotheism; or with various pluralisms and polytheisms, which see a multiplicity of principles or powers at work. As is indicated below, however, the situation is not always clear and simple, a matter of one or two or many, for there are monotheistic, monistic, or polytheistic religions with dualistic aspects.

Various distinctions may be discerned in the types of dualism in general. In the first place, dualism may be either absolute or relative. In a radical or absolute dualism, the two principles are held to exist from eternity; for example, in the Iranian dualisms, Zoroastrianism and Manichaeism, both the bright and beneficent and the sinister and destructive principles are from eternity.

In a mitigated or relative dualism, one of the two principles may be derived from, or presuppose, the other as a basis; for example, the Bogomils, a medieval heretical Christian group, held that the devil is a fallen angel who came from God and was the creator of the human body, into which he managed by trickery to have God infuse a soul. Here the devil is a subordinate being and not coeternal with God, the absolute eternal being. This, then, is clearly a qualified, not a radical, dualism. Both radical and mitigated types of dualism are found among different groups of the late medieval Cathars, a Christian heretical movement closely related to the Bogomils.

Another and perhaps more important distinction is that between dialectical and eschatological dualism. Dialectical dualism involves an eternal dialectic, or tension, of two opposed principles, such as, in Western culture, the One and the many, or Idea and matter (or space, called by Plato "the receptacle"), and, in Indian culture, *māyā* (the illusory world of sense experience and multiplicity) and *ātman-brahman* (the essential identity of mind and ultimate reality). Dialectical dualism ordinarily implies a cyclical, or eternally repetitive, view of history. Eschatological dualism—*i.e.*, a dualism concerned with the ultimate destiny of man and the world, how things will be in the "last" times—on the other hand, conceives of a final resolution of the present dualistic state of things, in

Fechner's
panen-
theism

The views
of White-
head and
Hartshorne

Types of
dualism

which evil will be eliminated at the end of a "linear" history constituted of a series of unrepeatable events, instead of a "cyclical," repetitive one. The ancient Iranian religions, Zoroastrianism and Manichaeism, and Gnosticism—a religiophilosophical movement influential in the Hellenistic world—provide examples of eschatological dualism. A type of thought, such as Platonism, that insists on a profound harmony in the cosmos, is thus more radically dualistic, because of its irreducibly dialectical character (see below) than Zoroastrianism and Manichaeism, with their emphasis on the cosmic struggle between two antithetical principles (good and evil). Midway between these extremes is Gnostic dualism, which has an ontology (or theory of being) of an Orphic-Platonic type (for Orphism, see below *Among ancient civilizations and peoples*) but which also affirms the final disappearance and annihilation of evil with the eventual destruction of the material world—and thus comprises both dialectical and eschatological dualism.

In philosophy, dualism is often identified with the doctrine of transcendence—that there is a separate realm or being "above" and "beyond" the world, as opposed to monism, which holds that the ultimate principle is inside the world (immanent). In the disciplines concerned with the study of religions, however, religious dualism refers not to the distinction or separation of God and the world but to the doctrine of two basic principles; a doctrine that, moreover, may easily be compatible with a form of monism (e.g., Orphism or Vedānta) that makes the opposition between the One and the many absolute and sees in multiplicity merely a fragmentation (or illusory obliteration) of the One.

HISTORICAL VARIETIES OF RELIGIOUS DUALISM

Among ancient civilizations and peoples. Dualism is a phenomenon of major importance in the religions of the ancient world. Those of the Middle East will be considered here.

Egypt and Mesopotamia. While there was generally no explicit dualism in ancient Egyptian religion, there was an implicit dualism in the contrast between the god Seth and the god Osiris. Seth, a violent, aggressive, "foreign," sterile god, connected with disorder, the desert, and loneliness, was opposed to Osiris, the god of fertility and life, active in the waters of the Nile. Seth also possessed some typically dualistic marks of a mythological character; his action, as well as his personality itself, was ambivalent; and, as a typical trickster, he was also capable, at times, of constructive action in the cosmos. The myths of Osiris and Seth may be compared in various ways with those recently discovered among the Dogon people of the western Sudan, which contrast Nommo, a fertile and happily mated primordial being pictured in fish form, with Yurugu ("Pale Fox"), an unhappy, sterile character who lives in the wilderness without a mate. Yurugu is considered to be the element that makes the universe complete (the same role assigned to Seth in the Egyptian myth).

Dualism, broadly speaking, was also present in ancient Mesopotamian religion. In myths pertaining to the origin of the gods and of the cosmos, the opposition between the primordial deities (Apsu, the Abyss; and Tiamat, the Sea) and the new ones (particularly Marduk, the demiurge, or creator) displayed some dualistic aspects. Though the earlier deities had established the basic reality of the universe—its ontological core—because of their chaotic and selfish nature they resisted their own offspring, who were later to create the now existing, definite order of the cosmos. A dualism of the ontological—basic reality or being—versus the cosmological—the form or order of the material universe—is thus implicitly affirmed.

Greece and the Hellenistic world. Analogous dualistic concepts may be found in the early Greek *Theogony* of Hesiod (fl. c. 700 bc) in his myths of the gods Uranus, Cronus, and Zeus, and the conflict between primordial and later gods. It was in the later, classical Greek world, however, that dualism was most evident. Many of the pre-Socratic philosophers (6th and 5th centuries bc) were dualistic in various ways. In the teachings of Parmenides, for example, noted for reducing the world to a static One—a

classical instance of monism—there is still a radical opposition between the realms of Being and Opinion—between ultimate reality and the world of human sense experience. On the other hand, in the doctrines of Heraclitus, noted for reducing the world to fiery Change, the conflict of opposites (hot–cold, day–night, beginning–end, the-way-up–the-way-down), called by Heraclitus *polemos* ("war"), was exalted to become a metaphysical principle. Though these opposites are piecemeal dyads ("pairs"), their effect, taken together, is, as a whole, dualistic. The dualism of Empedocles, simultaneously a religious teacher and a natural philosopher, is especially striking, for he viewed the primordial sphere of the universe as undergoing cycles alternately under the dominance of the antithetical principles of Love and Discord, which periodically break and then reconstruct it. In this context there exist *daimones* ("souls"), divine beings that have fallen from a superior world into this world and exist clothed in the "foreign robe of the flesh." These souls are therefore subject to transmigration through a series of vegetable, animal, and human bodies, owing to a primitive accident (for which credit was given "to the furious Discord").

The same antithetical principles are to be found in Orphism, a Greek mystical school, which constituted an independent development within Greek religion and philosophy; beginning in the 6th century bc, it was part of a "mysteriosophic" trend that sought to attain the wisdom of secret mystic and cultic doctrines. Orphism is characterized by its *sōma-sēma*, or body-tomb concept, which saw the body as a prison or tomb in which the soul—a divine element, akin to the gods—is incarcerated. In addition to this psychophysical dualism of soul and body, the Orphic idea that "everything comes from the One and returns to the One" demonstrates a typical dialectical dualism, in which an implicit monism is involved. Developing on an analogous level, Pythagorean numerical and mystical speculation, arising from the 6th-century-bc Greek philosopher and religious teacher Pythagoras, also stressed the dualistic opposition of Monad-Dyad (One-Two) and of other dialectical pairs of opposites.

Many of these dualistic ideas, especially the Orphic and Pythagorean ones, are also found in writings of the Greek philosopher Plato (428–348/347 bc), such as the *Timaeus*, *Phaedo*, *Gorgias*, and *Cratylus*. In these writings a divine part of the human soul that is directly infused by the divinity and a mortal part (passionate and vegetative) are defined and considered. The mortal part is assigned to man by inferior divinities, charged to do so by the supreme divinity; and the appetitive passions involved, if followed, are held to be responsible for the punishments that the soul will suffer during various periods of habitation in the other world and reincarnations in this one. Thus God remains free of blame for the destiny of man. The mortal or spoiled part of man is further attributed, in Plato's *Laws*, to the "titanic nature" within his makeup—an element of violence and impiety inherited from the primordial rebellious Titans, sons of the Earth.

Plato's notions of man were rooted in both ontology and cosmology; i.e., in views on being and on the orderly structure of the universe. In the *Timaeus* he considers the cosmos as a single harmony, which for the sake of completeness requires the existence of inferior levels that are bound not only to matter but also to Necessity (the realm of things that could not have been otherwise, and that are hence not amenable to divine activity). A different view is found in his *Laws*, which describes two "Souls" of the World, one of which causes good and one evil. The *Politicus* is concerned with two eternally recurring, alternating cycles in the cosmos, with successive epochs guided either by the gods or by men.

Plato's central inspiration, which unifies his metaphysics, his cosmology, his theory of man, and his doctrine of the soul, was basically dualistic (in the sense of dialectical dualism) with two irreducible principles: the Idea and the *chora* (or material "receptacle") in which the Idea impresses itself. All of this world is conditioned by materiality and necessity; and because of this, the descent of souls into bodies is said to be rendered necessary as well.

Neoplatonism, a 3rd-century-ad development from Pla-

Osiris and
Seth

Platonic
dualism

Gnosticism

to's thought, conceived the cosmos as a harmony with a succession of levels emanating from an ultimate unit. There was in the system, nevertheless, a rupture of the harmony of the cosmos called *tolma* ("the audacity"), which served as an explanation for the descent of Soul into the material world—and thus constituted a dualistic element.

In Gnosticism, a Hellenistic religious movement that entered original Christianity from earlier pagan sources, and which viewed matter as evil and spirit as good, dualism manifested itself in a more dramatic way. Gnostic dualism cannot be understood without reference to both Judaism and Christianity, and perhaps even to Zoroastrianism, since Gnostic eschatological characteristics were derived from them. Gnosticism was also connected with certain principles of Orphism and Platonism; reflecting the Orphic body-tomb doctrine, for example, Gnosticism adopted a firmly antisomatic stance (against the body), and similarly adopted the concept of the divine soul—the pneumatic, or spiritual, soul, as the Gnostic would say, of the same substance as the divinity—that is destined to free itself from the tyranny of a material, cosmic demiurge (or subordinate deity). Certain Gnostics, moreover, developed a radical anticosmism, in which they registered their animosity against the material universe by cursing the stars—which brought them bitter reproach from Plotinus (c. AD 205–269/270), the founder of Neoplatonism. As viewed by the Gnostic Ophite sect, which venerated the *ophis* (or "snake") as a symbol of knowledge, the cosmos comprises three parts: the superior world, the inferior world (material and chaotic), and the intermediate world, or *logos* ("word" or "reason")—the *logos* being depicted as a snake that impresses spiritual forms into the chaotic matter. These forms—life, soul, vital masculine substance—are later freed again, a liberation that completely empties the material world. Such Gnostic views are of two types: Iranian and Syrian-Egyptian. Iranian Gnosticism is characterized by an absolute, radical dualism: light and darkness, *pneuma* ("spirit") and chaotic formless matter, oppose each other from eternity. Syrian-Egyptian Gnosticism is characterized by a dualism that is mitigated (as earlier defined) but also drastic: the inferior world, the chaotic darkness, begins to exist only at a special moment owing to an accident in the divine world; and this accident is usually also identified with an "audacity," a defect in one of the "aeons," or divine entities.

Iran. In the Indo-Iranian period (2nd millennium BC) there were already tendencies toward dualistic thought, especially in myths relating to monstrous and demonic beings who still the movement of the waters and thus make cosmic life impossible; in later-archaic Indian speculation there was also a tendency to oppose *devas* ("gods") to *asuras* ("demons"). Iranian dualism, however, expressed itself most characteristically in Zoroastrianism. In the Zoroastrian religious texts, the *Gāthās*, there is an opposition between two spirits, the Beneficent Spirit (Spenta Mainyu) and the Destructive Spirit (Angra Mainyu, or Ahriman). These two spirits are different, irreducible principles; at the beginning they have chosen life and nonlife, respectively. Though the Beneficent Spirit is almost an hypostasis (the substance) of the divinity (Ahura Mazdā), nothing is said in the *Gāthās* about the origin of the Destructive Spirit. In any case, the very fact that the Destructive Spirit is said to be "twin brother" of the Beneficent One does not imply that he is a son of Ahura Mazdā but only that the two spirits are "symmetrical"; i.e., equal and contrary as to their respective efficacy and orientation.

Medieval Zoroastrian treatises present radical and eschatological dualisms in their extreme forms. According to the *Bundahishn* ("Primordial Creation") text, Ormazd (Ahura Mazdā) and Ahriman have always existed. Ormazd is represented as lofty, in the light, full of omniscience and goodness, while Ahriman is represented as debased, in darkness, full of aggressiveness and ignorance. Ormazd's omniscience allows him to conceive and to actualize the Creation and Time, because only these can offer him an arena in which to accost Ahriman and eliminate him.

The medieval Zoroastrian treatises also describe another "dual" formulation, the two realms of creation and of reality: the *mēnōk* ("potential, embryonic, initial, heavenly,

and invisible") and the *gētik* ("realized, final, worldly, concrete, and visible"). But this opposition does not imply a devaluation of the *gētik*, of this world.

Zurvanism, a Zoroastrian heretical movement (c. 3rd/4th century BC–7th century AD), was also dualistic. The very names of Zurvān (Time-Destiny) and the partially synonymous *zamān* ("time") already appear in the later Avesta and in medieval treatises, in which Time is the milieu in which Ormazd and Ahriman fight. Also, a myth attributed to Zoroastrian priests by later, non-Iranian sources speaks of Zurvān as the father of Ormazd and Ahriman. At times "Zurvanite" mythology tends toward formulations of a Gnostic and Manichaean type (women paid allegiance, for example, to Ahriman, who has partial authority in the world). Zurvanism also developed theosophic characteristics (involving mystical insights), such as that which discerned the ambivalence of Zurvān—viz., that although an evil element (an evil thought or spiritual corruption) has always existed within him, he nonetheless, so it seems, eliminates the evil by expressing it and is thus worthy to be identified with the supreme divinity (Yazdān).

Among religions of the East. Dualisms have also appeared in various forms in the religions of India and China.

India. Indian dualism has involved the opposition of the One and the many: of reality and appearance. In an ancient Hindu hymn (Rigveda, 10.90), Puruṣa, "the Immortal that is in heaven," is opposed to this world; the three quarters of the Puruṣa that comprise the transcendent world are opposed to the other quarter of him (his limbs) that is this world; i.e., the divine foundation, the divine substance of this world, is made out of his limbs. Early speculation on the identity of the *ātman* ("Self") and Brahman (the very core of reality), as opposed to the material and visible world that is subject to *māyā* (or "mundane illusion"), has been mentioned above.

The Sāṃkhya school of Indian philosophy presents another, probably later, formulation of dualism based on two eternal and opposed cosmic principles: *prakṛti* ("original matter") and *puruṣa* ("spirit"), the name of the ancient primordial Man, substance of the universe. Matter is differentiated into three different *guṇas* (or "qualities") that articulate the three levels of the being and essential nature of man in hierarchical connection with each other. Spirit, in itself free, eternal, and infinite, becomes involved in matter by the development of the latter. Salvation coincides with the knowledge of the state of things: "I (spirit) am one thing and It (matter) is another."

China. The first words of the Taoist text, the *Tao-te Ching*, express a doctrine that is typical of a pervasive Chinese dualism; i.e., that of the two opposed and complementary principles, the Yin and the Yang (respectively, feminine and masculine, lunar and solar, terrestrial and celestial, passive and active, dark and bright; in short, the entire series of opposites). The dialectics of Yin and Yang are the double manifestation of the one and only eternal, undividable, and transcendent principle: Tao ("the Way").

Among religions of the West. Dualisms have appeared in Western religions chiefly under the impact of Gnostic influences.

Judaism. No real dualism is found in Judaism, except in the Gnostic and theosophic forms of Jewish mysticism known as Kabbala. The presence of a vigorous and universal monotheism implies not only faith in a single creative god but also faith in a god who is the uncontested master of history; and neither Satan nor Belial detract from this absolute monotheism. Within these limitations, however, a tendency towards dualistic thought could be seen in such late noncanonical texts as the *First Book of Enoch* (c. 1st century BC), in which certain angels are said to have fallen as a consequence of their wedding with the daughters of men. These angels, it is held, taught mankind the malevolent arts of magic, seduction, and violence, together with such elements of culture as the use of metals and writing. Though there is no dualism in the proper sense in the *Manual of Discipline*, one of the Qumrān texts of the Dead Sea Scrolls, a certain polarity is nonetheless displayed in a passage that asserts of God that

he created man to have dominion over the world and made for him two spirits, so that he may walk by them until the

Ahura
Mazdā
versus
Ahriman

Yin and
Yang

time of his visitation: they are the spirits of truth and error. In the dwelling of light are the origins of the truth, and from a spring of darkness are the origins of error. In the hand of the Prince of Lights is dominion over all the children of righteousness, in the ways of light they walk. And in the hand of the angel of darkness is all dominion over the children of error; and in the ways of darkness they walk.

The context of this passage, however, is completely monotheistic. It expresses a doctrine also found in the *Didachē*, a Jewish-Christian work of the early 2nd century AD (better known as the *Teachings of the Twelve Apostles*), that of the two roads on which a man may walk, the good road and the bad, the road of life and that of death, with God leaving the choice of the road to man's free will; and also the later rabbinic doctrine of the struggle between the good and evil inclinations (*yetzer*) within man. There is also no hint of dualism in the two "sources" mentioned in the Qumrān texts, the bright source and the dark. These are hardly dualistic principles (in the ontological sense of the term) but are simply radical (*i.e.*, original) polarities in spiritual orientation. (Not even the "Angel of Darkness," mentioned in the same context is a principle, though he is a person and a power.)

There is thus no true parallelism with the two principles that appear in Iranian Zurvanism. Elements of dualistic thought (in a Platonic sense) are also found in the works of the Jewish Hellenistic philosopher Philo of Alexandria (1st century AD), whose philosophy was dualistic in its doctrines about the universe and man, but without shaking his basic adherence to biblical monotheism.

Christianity. In Christianity dualistic concepts appeared principally in its Gnostic developments. But even in the 2nd-century Judaizing sect of the Encratites, which was not really Gnostic, there were dualistic aspects that had modified some tendencies in later Judaism. These teachings were also particularly prominent in the writings of the supporters of Docetism (the doctrine that Christ, being divine, did not suffer and die; 2nd century), who held that matter is essentially evil and that the soul is a pre-existent substance. According to the Encratites, the pre-existent soul, once it "gets effeminized by concupiscence," drops into the carnal world. Since generation perpetuates the soul's state of decay in this bodily world, they condemned all sexual relations. The dualism of Marcion (a 2nd-century semi-Gnostic Christian heretic) was really a ditheism (a system positing two gods), though the common Gnostic presuppositions—such as antisomatism and anticosmism, the condemnation of the body and the material universe—were also present in his thought. For Marcion, the God of the Old Testament is an inferior and harsh creator demiurge, author of the world and man, who is nonetheless completely distinct from the supreme divinity, who manifested himself in Jesus and is a stranger to this world. For Saturninus (or Saturnil) of Antioch, the founder of a 2nd-century Syrian Gnostic group that was commonly connected with the tradition of Simon Magus (reputed leader of an earlier Gnostic sect), the God of the Old Testament is only one of the angels, the martial angel of the Judaic nation, although (as with Marcion) he is distinct from the devil, who is in fact his opponent. According to Saturninus a primordial accident caused a wave of *pneuma* ("spirit") to land in the inferior darkness, where it is said to have remained prisoner and now continues its existence in those who, characterized by the presence in them of this superior element, will later be conducted back to their heavenly origin by Jesus, a messenger coming from above. Conceptions of a similar type are also found in the "Psalm (or Hymn) of the Naassenes" (Naassene is the Hebrew term for Ophite, mentioned above) and in the "Song of the Pearl" in the Gnostic *Acts of Thomas*; here also occurs the concept of a "saviour to be saved," who has been sent from above and was made a prisoner by darkness. This basic concept was developed fully only in Manichaeism. The Gnostic-dualist view survived in late antiquity and into the Middle Ages, both in the East, among the Mandaeans, Yazidis, and some extreme sects within the Shi'ah branch of Islam and in the West among the Bogomils and Cathars. It is still present today in modern theosophy.

Among religions of modern nonliterate peoples. Religious dualism also manifests itself among nonliterate peoples, especially in the concept of a "second" figure, an ambivalent demiurge-trickster who can be both a collaborator and rival of the supreme being and independent of the latter in origin. Such tricksters include the Coyote (in North American Indian mythology), the Raven (among Paleosiberians), or the Crow (among the Southeast Australian tribes). To these animal figures are attributed the origin of such negative aspects of life as death and illness. But they are also credited as benefactors; *e.g.*, in creating utilities in the cosmos and in the invention of fire. The demiurge-trickster is typically ambivalent, tremendously frightful and efficacious, but also frequently limited in power. For example, such tricksters are often incapable of animating the beings that they have molded and must therefore request the help of the supreme being in bringing them to life. They are said to be selfish, lonely, and unhappy, and because of these qualities, they are moved, despite their arrogance, to attempt to relate themselves to or unite with the supreme being.

A typically dual composition (involving the coexistence and cooperation of two elements), or even a dualistic opposition (as two opposed elements that function as principles in respect to the actual creation), is found in the Dogon (western Sudanese) notions about Nommo and Yurugu, already mentioned. A series of "words" refers to both principles; *i.e.*, a series of realities and categories can be named that constitute the world in its functional variety, which transcend the simple good-evil opposition, and according to which both Nommo and Yurugu are dualistic "principles" essential to the actual dynamics of the world.

Other dualistic concepts among primitive peoples posit opposite the supreme being a violent and death-bearing "second" figure of a demiurgical type. The character of Erlik in the mythologies of the Central Asiatic Turks (*e.g.*, among the Altaics) is typical.

Erlik is a king of the dead and master of death who assumes the role of a fraudulent and unfortunate collaborator with the supreme being. In stories about the origin of the universe, he appears as an aquatic bird in charge (under the supreme being) of fishing a little earth from the bottom of the primordial sea—a theme also well-known in East European folklore. In other myths, a similar being spits on human beings at the time they are created by God or breathes his bad spirit into man or woman. Elsewhere there is depicted an opposition of two twin brothers, of whom one is the demiurge-creator of good things and the other of death; both, however, are the sons of a mother goddess of heavenly origin. This pattern is exemplified in the Iroquoian myth of Yoskeha and Tawiskaron—a myth curiously reminiscent of certain aspects of the Iranian Zurvanite mythology.

Other ethnological polarities, or pairs of opposites (eastern-western, celestial-terrestrial, solar-lunar divinities, right-left, full moon-dark moon, etc.) are dualistic in the sense of contrasting principles or creating agencies.

THEMES OF RELIGIOUS DUALISM

The sacred and the profane. Among the various themes of religious dualism the opposition between sacred and profane is also important. This distinction, appearing in some sense in nearly every religion, must be particularly acute, however, to qualify a religion as dualistic. Such an intensification of the sacred-profane opposition to the point at which it becomes a dualism is evident in the mid-20th century historian of religions Mircea Eliade's conception of religion. This contrasts time (the *illud tempus*, "those times," of the intact, sacred, primordial creation that are periodically restored by ritual) and the historical time (marked by decay, profaneness, and loss of plenitude and significance).

Good and evil. More pertinent (even if not always dualistic) is the opposition between good and evil, in the various meanings of these words. Whenever the problem of the origin of evil is solved by conceiving the real existence of another principle separate from the prime principle of the world, or by affirming an inner ambivalence, limited sovereignty, or inadequacy of the prime principle,

Role of the
trickster

and Jewish
Chris-
tianity

Encratism

The
problem
of evil

or of divine beings, a dualism then emerges; and through this good-evil opposition, the problems of theodicy (*i.e.*, of the doctrine of the justification of divine action in a world in which evil is present) are posed. If evil either is, or comes from, a self-existent principle antithetical to the principle of good, then this provides the divinity with a "justification." Such views are completely different from the justification of God in nondualistic religions, especially the monotheistic ones. In monotheistic religions evil does not originate within the divinity nor in general within a divine world (*plērōma*) as it does in Gnosticism; it arises instead from the improper use of freedom by created beings. In monistic religions—all of which are based on the opposition between the One and the many, seen either as an illusion or as the decay or fragmentation of the One—along with a strong ascetic emphasis, there is a notion of evil as being for man a painful and fatal essence that issues from a metaphysical cause or an ontologically negative principle. For the same reason, it is necessary to distinguish between the nondualistic concept of "original sin" in Christian theology and the concept of "previous sin"—in monistic religions with a dualist aspect; whereas "original sin" arises and spreads within the human sphere, "previous sin" is consummated in some sort of a "prologue in heaven" and generates the very existence of the world and of humanity itself.

Creation and destruction: life and death. Another important dualistic theme is that which opposes life to death based on two opposing metaphysical principles. A typical example of this dualistic opposition is found in Zoroastrianism. Zoroastrian doctrine is strongly vitalistic: Ahriman's chief acolytes are Aēshma (the fury), the Druj Nasu (the deadly agent of putrefaction), Jēh (the infertile whore), and Apaoša (the demon of sterility)—death-bearing forces. There is also a strong vitalistic formulation of these principles in Gnostic doctrines, especially in the Ophite and Barbelo-Gnostic (worshipping Barbelo as the Great Mother of life) varieties, which identify the *pneuma* and the light with the vital substance. At other times the opposition of life and death is formulated in a dialectical manner as a recurring alternation of the two principles. The complex Egyptian opposition between Osiris, the "dead god," who is nonetheless the principle of fecundity and life, and his counterpart Seth has already been mentioned (see above *Egypt and Mesopotamia*). The same dialectic is typical of the "fecundity cults," in which a god-genius of vegetation, a "dying god," is featured, who undergoes a seasonal disappearance and return (not to be interpreted as a "resurrection"). To such vegetation gods, death- or decay-producing figures are sometimes opposed—as Mot (the Death) opposed to Baal, and an infernal and lethal wild boar opposed to Adonis, and (in German religion and mythology) Loki opposed to Baldr. These figures, the agents for disastrous occurrences, were already implicit in the figure of the dying god himself and in his relation to the seasonal cycle of vegetation. To be sure, the growing season is limited; and the new arrival of vegetation each spring (and the wedding of the fertility god) is terminated in the fall by the god's departure to the netherworld (with appropriate lamentation). But the rise of vegetation, though ephemeral, is nonetheless basically benevolent. This complexity is also manifest in those agricultural religions that present themselves as mystery cults (*e.g.*, the Eleusinian mysteries), bestowing upon the initiate a hope for life after death.

But the dualistic theme is far more evident in "mysteriosophy"; *i.e.*, in the "sophic," or "wise," reinterpretation of mysteries (*e.g.*, Orphism). In this context, the divine soul replaces the dying god in the soul's descent from a superior world into the corporeal world—a concept that was later bequeathed to Gnosticism and is especially apparent in its transposed basic vitalism.

A dialectical formulation of the opposition of life and death is also found in the basic theology of Hinduism: with Viṣṇu (Vishnu) cast as the principle of creation (called Nārāyaṇa) and the sustenance of life and Śiva (Shiva) as the principle of destruction and death. The ambivalence of life-death is also found in a series of Hindu divinities (*e.g.*, Śiva, Kālī) and cults whose death-inflicting charac-

teristics are justified in a paradoxical celebration of the recurring triumph of life.

Polytheistic themes. Among the instances of dualistic structure in polytheistic religions are those that oppose celestial and terrestrial, male and female, actual and mythical primordial-chaotic, "diurnal" and "nocturnal," especially when they do so within the context of mythologies and cosmogonies belonging to the ancient world's polytheistic "high cultures" (see above *Egypt and Mesopotamia; Greece and the Hellenistic World*). Such pairs of opposites often provide a framework for polytheistic pantheons that would otherwise appear anarchic or less than comprehensive (see also *Polytheism* above).

FUNCTIONS OF RELIGIOUS DUALISM

Cosmological and cosmogonic functions. The essential function of any religious dualism is obviously ontological—to account for a duality of opposed principles in being—even when the two principles are not regarded as coeternal; and this underlies the cosmological-cosmogonic, anthropological, and sociological functions and expressions of dualism. Both dialectical dualism (*e.g.*, in the fertility cults, Orphic mysteriosophy, and Platonism) and eschatological dualism (*e.g.*, in the Zoroastrian and Manichaean notion of the "mixture" between the two creations good and bad) have a basically cosmological function—the explanation of the structure of the universe. Whenever the concept of a distinct creator, transcendent with respect to his work, is missing (as, for example, in monistic formulations of the Indian type or in polytheistic milieus), dualism has a cosmogonic function—the explanation of the origin of the universe.

On a cosmogonic level, dualistic opposition may also be manifest in the celestial world; *e.g.*, in the late Zoroastrian opposition between the beneficent fixed stars and the planets (which are negative, because they are alleged to proceed in the reverse sense); or else between the world of the Heptad (again the seven planets, under the dominion of the tyrannic archons, or rulers, that cause human passions) and the superior heaven of the Ogdoad (the group of eight divine beings or aeons), as in Gnosticism so also in Mithraism, where the monstrous figure of Leontocephalos (a human figure with a lion's head, belted by a snake with astral signs) represents the power of astral Destiny-Time to be transcended by the soul—a power that is a basic presupposition of astrology and magic. On the other hand, the heaven-earth opposition cannot be regarded as dualistic if the two elements are represented merely as cosmic progenitors.

Anthropological functions. The anthropological functions of dualism (dealing with the nature and destiny of man) are present in all those doctrines that consider man as a duality, or, rather, as an irreconcilable duality of opposed elements. Of particular importance is the opposition between masculine and feminine, in which their opposition involves a remarkable difference in level of being. In mythologies (whether dualistic or not) with a "second" figure, a demiurge, there is frequently a connection between the demiurge and the origin of women (*e.g.*, the myths of Prometheus-Epimetheus in ancient Greece, and of Paliyan in southeast Australia) or between the demiurge and the origin of sexuality (*e.g.*, the myths of the trickster Coyote and of the Gnostic demiurge). In the Platonic theory of man the first incarnation of the soul occurs in a masculine body, and only a subsequent incarnation, marking a later descent of the soul into the world of bodies, is feminine. In Gnosticism (Ophite sects) the vital substance that animates the universe is masculine (active), while the quality of the material world is feminine (passive); and in the last *logion* ("saying") of the Gnostic *Gospel of Thomas*, it is said that Mary will be saved by being made a male; *i.e.*, she will become a "living spirit" (*pneuma*). Gnostic and Manichaean antifeminism, as well as Encratite (and perhaps Orphic) antifeminism, are motivated by their hatred for procreation, which they believe implies the fall of the soul into the material world and its permanent abode there. At other times procreation is explained in terms of a division of a complete, originally androgynous (both male and female) being (as in Plato's *Symposium* and in

The dying
god and
vegetation
cults

Masculine
and
feminine

the Gnostic *Gospel of Philip*). There are other nondualistic doctrines in which woman is considered to be connected in some way with the origins of evil but not as the embodiment of the evil principle (e.g., in Genesis and the apocryphal late-Judaic *Book of Adam*).

Sociological functions. The sociological functions of religious dualism are less relevant. Among some Australian peoples the "totems" of the two classes of a tribe that intermarry are the Falcon-Eagle (Bundjil), the supreme being, and the Crow (Waang), a demiurge-trickster. According to the Menominee Indians, the highest region of the universe is inhabited by benevolent gods (among whom the supreme being is Mate Hāwātūk) and the inferior region by bad ones; and these two groups are constantly fighting. The Menominee believe that they come from an alliance of families that once belonged to these two groups, whose respective descendants have particular places in the assembly and clearly differentiated functions.

Sociological and economic class oppositions, however, cannot provide a general explication for dualism. All dualities (e.g., in the social structure) are necessarily relevant to religious dualism. On the ethnic level, sociological functions of dualism are found in the Zoroastrian opposition (even if not absolute) between Iran, with its so-called "good religion," and the Turanians, northern plunderers representing the aggressive world of evil. But this can by no means substantiate general hypotheses that explain dualistic oppositions between divinities or groups of divinities as a "projection" of a previously existing opposition between ethnic layers of conquerors and of conquered populations. (U.B.)

Monotheism

Monotheism and polytheism

Monotheism and polytheism, the beliefs in one god or many gods, are often thought of in rather simple terms; e.g., as a merely numerical contrast between the one and the many. The history of religions, however, indicates many phenomena and concepts that should warn against oversimplification in this matter. There is no valid reason to assume, for example, that monotheism is a later development in the history of religions than polytheism. There exists no historical material to prove that one system of belief is older than the other, although many scholars hold that monotheism is a higher form of religion and, therefore, must be a later development, assuming that what is higher came later. Moreover, it is not the oneness of god that counts in monotheism but his uniqueness; one god is not affirmed as the logical opposite to many gods but as an expression of divine might and power.

The choice of either monotheism, or polytheism, however, leads to problems, because neither can give a satisfactory answer to all questions that may reasonably be put. The weakness of polytheism is especially revealed in the realm of questions about the ultimate origin of things, whereas monotheism runs into difficulties in trying to answer the question concerning the origin of evil in a universe under the government of one god. There remains always an antithesis between the multiplicity of forms of the divine manifestations and the unity that can be thought or posited behind them. The one and the many form no static contradistinction: there is rather a polarity and a dialectic tension between them. The history of religions shows various efforts to combine unity and multiplicity in the conception of the divine. Because Christianity is a monotheistic religion, the monotheistic conception of the divine has assumed for Western culture the value of a self-evident axiom. This unquestioned assumption becomes clear when it is realized that for Western culture there is no longer an acceptable choice between monotheism and polytheism but only between monotheism and atheism.

THE SPECTRUM OF VIEWS: MONOTHEISMS AND QUASI-MONOTHEISMS

The basic monotheistic view. Monotheism is the belief in the existence of one god or, stated in other terms, that God is one. As such it is distinguished from polytheism, the belief in the existence of a number of gods, and atheism, the denial of the belief in any god or gods at all. The

God of monotheism is the one real god that is believed to exist or, in any case, that is acknowledged as such. His essence and character are believed to be unique and fundamentally different from all other beings that can be considered more or less comparable; e.g., the gods of other religions. The religious term monotheism is not identical with the philosophical term monism, referring to the view that the universe has its origin in one basic principle (e.g., mind, matter) and that its structure is one unitary whole in accordance with this principle; that is, that there is only a single kind of reality, whereas, for monotheism, there are two basically different realities: God and the universe.

God in monotheism is conceived of as the creator of the world and man; he has not abandoned his creation but continues to lead it through his power and wisdom; hence, viewed in this aspect, history is a manifestation of the divine will. God has not only created the natural world and the order existing therein but also the ethical order to which man ought to conform and, implicit in the ethical order, the social order. Everything is in the hands of God. God is holy—supreme and unique in being and worth, essentially other than man—and can be experienced as a *mysterium tremendum* ("a fearful mystery") but at the same time as a *mysterium fascinans*, ("a fascinating mystery"), as a mystery approached by man with attitudes of both repulsion and attraction, of both fear and love. The God of monotheism, as exemplified by the great monotheistic religions—Judaism, Christianity, and Islām—is a personal god. In this respect the one god of monotheism is contrasted with the conception of the divine in pantheism, which may also affirm one god or a divine unity. The god of pantheism, however, is impersonal, rather a divine fluid that permeates the whole world including man himself, so that Hinduism can say: *tat tvam asi*, literally "that is you," where "that" refers to the single, supreme reality or principle.

In monotheistic religions the belief system, the value system, and the action system are all three determined in a significant way by the conception of God as one unique and personal being. Negatively considered, the monotheistic conviction results in the rejection of all other belief systems as false religions, and this rejection partly explains the exceptionally aggressive or intolerant stance of the monotheistic religions in the history of the world. The conception of all other religions as "idolatry" (i.e., as rendering absolute devotion or trust to what is less than divine) has often served to justify the destructive and fanatical action of the religion that is considered to be the only true one.

The symbolic language of the monotheistic belief system has no proper terms of its own in speaking of God that cannot be found elsewhere also. God as Creator, Lord, King, Father, and other descriptive names are expressions found in many religions to characterize the various divine beings; the names do not exclusively belong to the religious language of monotheism. This common language is understandable because the monotheistic conception of God differs essentially only in one respect from that of other religions: in the belief that God is one and absolutely unique. Then, consequently, God is regarded as the one and only Creator, Lord, King, or Father. The conception of a divine Word is also to be found in a large number of religions, in accordance with the widespread belief that creation takes place through the word, or speech, of a god.

The extreme positions. The above is the basic monotheistic view. There is, however, a wide range of positions between exclusive monotheism at one extreme and unlimited polytheism at the other. A survey of the various positions may serve to provide a more adequate picture of the complex reality involved in the monotheisms and quasi-monotheisms.

Exclusive monotheism. For exclusive monotheism only one god exists; other gods either simply do not exist at all, or, at most, they are false gods or demons; i.e., beings that are acknowledged to exist but that cannot be compared in power or any other way with the one and only true God. This position is in the main that of Judaism, Christianity, and Islām. While in the Old Testament the other gods in most cases were still characterized as false gods, in later

The God of monotheism

The concept of idolatry

Ethical and
intellectual
mono-
theism

Judaism and in Christianity as it developed theologically and philosophically the conception emerged of God as the one and only, and other gods were considered not to exist at all.

There are two types of exclusive monotheism: ethical monotheism and intellectual monotheism. In ethical monotheism man chooses one god, because that is the god whom he needs and whom he can adore, and that god becomes for him the one and only god. In intellectual monotheism the one god is nothing but the logical result of questions concerning the origin of the world. In many African religions the one god postulated behind the many gods that are active in the world and in the life of man is little more than the prime mover of the universe. He is the intellectual apex necessitated by the system. In Christian theology, heavily influenced as it is by Greek philosophy, both conceptions can be found, usually together.

Unlimited polytheism. On the other hand, there is the extreme position of unlimited polytheism as, for instance, in the classical religions of Greece and Rome: each god has his own name and his own shape, and these are unalienably his and cannot be exchanged with those of any other god (not counting, of course, those cases in which gods are practically each other's duplicate and only bear a different name). The number of divinities is large and in principle unlimited. There are differences of status and power among the gods, of function and sphere of influence, but they are all equally divine. There is, in fact, an ordered pantheon. In unlimited polytheism, the number of gods that are actually worshipped seldom exceeds a few hundred within one religion, but in theory, as in India, millions and millions of gods may be thought to exist (see above *Polytheism*).

The middle positions. Between the extremes of exclusive monotheism and unlimited polytheism are the middle positions of inclusive monotheism and henotheism.

Inclusive monotheism. Inclusive monotheism accepts the existence of a great number of gods but holds that all gods are essentially one and the same, so that it makes little or no difference under which name or according to which rite a god or goddess is invoked. Such conceptions characterized the ancient Hellenistic religions. A well-known example is that of the goddess Isis in the Greco-Roman mystery religion that is called after her. In *The Golden Ass* of Apuleius, the goddess herself speaks: "My name, my divinity is adored throughout all the world, in divers manners, in variable customs, and by many names." Then there follows a number of divine names, and this enumeration ends: "And the Egyptians, which are excellent in all kind of ancient doctrine, and by their proper ceremonies accustomed to worship me, do call me by my true name, Queen Isis."

Henotheism, or kathenotheism. Henotheism (from Greek *heis theos*, "one god")—a belief in worship of one god, though the existence of other gods is granted—also called kathenotheism (Greek *kath hena theon*, "one god at a time")—which literally implies worship of various gods one at a time—has gone out of fashion as a term. It was introduced by the eminent 19th-century philologist and scholar in comparative mythology and religion Max Müller (1823–1900). Many later authors prefer the term monolatry—which is the worship of one god, whether or not the existence of other deities is posited—to the term henotheism. Both terms mean that one god has a central and dominating position in such a way that it is possible to address this god as if he were the one and only god, without, however, abandoning the principle of polytheism by denying or in any other way belittling the real existence of the other gods, as the above-mentioned forms of monotheism do. Henotheism as a religious concept is at home in cultures with a highly centralized monarchical government. It was especially prevalent in some periods in the history of Babylonia and Egypt.

Alternate positions. *Pluriform monotheism.* The complicated relations that exist between monotheism and polytheism become clear when pluriform monotheism is considered, in which the various gods of the pantheon, without losing their independence, are at the same time considered to be manifestations of one and the same di-

vine substance. Pluriform monotheism is one of the efforts to solve the problem of the coexistence of divine unity and divine pluriformity (multiplicity of forms), which was not recognized by an older generation of scholars, although part of the material was already available. It seems, indeed, that in many parts of the world and in many times religious thinkers have struggled with the perplexing problem of the unity and the pluriformity of the divine.

The Nuer, a Nilotic pastoral people of the eastern Sudan, venerate a being called Kwoth, the Nuer term for "spirit" (also translated as "God"). He is considered to be the spirit in or of the sky. Like all spirits Kwoth is invisible and omnipresent, but he manifests himself in a number of forms. Each of these manifestations bears a name of its own, but though they are addressed and treated as separate entities, they are essentially nothing but manifestations of the one spiritual being Kwoth and are themselves considered spirits and called *kwoth*. A sacrifice offered to one of these manifestations—e.g., a spirit of air, totem, or place—is not at the same time an offering to another; but all sacrifices, to whatever spirit they are offered, are sacrifices to the supreme Kwoth, or God. Nuer religion is certainly no clear monotheism as it is understood in the Bible and in the Qur'an (the sacred book of Islam), but neither is it polytheism in the popular sense of the word.

The case of the Nuer is not unique. The related Shilluk people have similar conceptions, and here again the idea of a kind of divine substance that manifests itself in various shapes and under different names is encountered. To give one instance, Macardit is God, but this pronouncement cannot be turned the other way round—it is not permissible to say that God is Macardit. The divine being Macardit represents the dire and fatal aspect of the divinity who orders everything; that is to say, who also sends misfortune and death. In Macardit the contradiction between the creative and constructive and the destructive forces of the divinity is resolved. The positive function of this representation of God lies in the fact that, without diminishing either the power or the justice of the total divinity, it enables man to find an answer for the vexing question of theodicy—the problem of affirming divine justice and goodness in the face of physical and moral evil. That this question is a difficult one, indeed, becomes clear when the reactions of the tribes of Patagonia in a case of death are compared. These tribes believe in a high god, a supreme being, who rules everything and is also responsible for misfortune and death. When someone dies they accuse their god of murder.

Many other instances of pluriform monotheism could be mentioned, and many more presumably still await detection. An interesting pluriform system is that of the Oglala Sioux of the United States, who venerate 16 gods divided into four groups of four. Each group of four forms one god. Thus there are four gods, but these four gods again are one god, Wakan Tanka—the Great Spirit or the Great Mystery.

Religious dualism. Some religions are in the main dualistic; they view the universe as comprising two basic and usually opposed principles, such as good and evil or spirit and matter. Insofar as the conception of a god and antigod rather than that of two gods is encountered, this kind of religion can be considered as another variation of monotheism. In some Gnostic systems (ancient heresies based on esoteric knowledge and the dualism of matter and spirit), Christianity came near to this idea: the demiurge who created the world and man is considered as an evil being and contrasted to the good god. The most important instance of a dualistic religion is the Persian religion Zoroastrianism as founded by Zoroaster (7th–6th century BC) in which Ormazd (the good god) and Ahriman (the evil god) are each other's opposite and implacable enemies. Dualism, the existence of two contrary and, as a rule, mutually inimical principles, must not be confused with the notion of polarity, in which both principles are mutually dependent so that the one cannot exist without the other. Within the religion of Zoroaster, this notion is also found. In the Zoroastrian variation known as Zurvanism, as it is called after the god Zurvān Akarana (Limitless Time), good and evil proceed from one and the

Nuer and
Shilluk
religion

Monolatry

Zoroastrian
dualism

same source and in the end they come together again (see above *Religious dualism*).

Pantheism and panentheism. Pantheism and panentheism are not necessarily connected with the notion of either monotheism or polytheism. In both cases the conception of the god or gods is impersonal, which tends, of course, to the conception of one god, of one divine substance, like Spinoza's *deus sive natura*, "god or nature." In pantheism god is immanent, in monotheism god is mostly transcendent, but in polytheism the gods may be either. Pantheism, however, is in most cases more a philosophical than a religious category. Sometimes the term panentheism is used to distinguish between the view that all is in God and that god is in all (see also *Pantheism and panentheism* above).

Primitive monotheism. In connection with monotheism it is necessary to mention the so-called high gods—the remote gods, usually sky gods, found in many primitive and archaic cultures—because this type of divine being has given rise to the theory of primitive monotheism (*Urmmonotheismus*). After the Scottish scholar Andrew Lang (1844–1912) had drawn attention to these gods, the Austrian scholar Wilhelm Schmidt (1868–1954) based on their existence in primitive culture and beliefs the theory that the oldest religion of mankind had been monotheistic and that polytheism as well as magic were later degenerations in the course of the history of a pure primeval religion. This theory, defended with great skill and an enormous mass of ethnological material by Schmidt and his collaborators, has long since been proved unsound and was abandoned even by his own students. The connection postulated between the high gods and monotheism has in most respects obscured rather than illuminated the situation. It is true that in many cultures the particular high god is considered as the creator, the founder of the order of the world, and also in some cultures as the reigning god according to whose will everything now happens, but such a god is rarely considered to be the one and only god that counts. Exclusive monotheism is not to be found in either primitive or archaic religions, according to present knowledge. The high god, however, can become a god of exclusive monotheism when circumstances are favourable, at least if he belongs to the active type of high god and not to the intellectual type, which serves mainly as an idea to answer the questions concerning the ultimate origin of things. (See the distinction above between ethical and intellectual monotheism.) This transformation probably occurred in the case of the Islāmic god Allāh. It seems to be more common, however, even for the active type of high god gradually to disappear behind a host of other, often minor, deities who are more concerned with the daily affairs of mankind.

The Deism of the 17th and 18th centuries is often compared to the conception of high gods as *dei otiosi*, "inactive gods," who have created the world and put it into order but after their work was done retreated from the world and left it to run in accordance with the order installed at the creation (see below *Deism*). Not all high gods, however, are inactive.

MONOTHEISM IN THE WORLD RELIGIONS

Classical monotheism. *Religion of Israel and Judaism.* There may be some reason to speak of the Old Testament conception of God as monolatry rather than as monotheism, because the existence of other gods is seldom explicitly denied and many times even acknowledged. The passionate importance given to the proclamation of Yahweh as the one god who counts for Israel and the equally passionate rejection of other gods, however, make it truer to speak of the monotheism of Israel; as in what became the Judaic affirmation of faith, "Hear, O Israel, the Lord is our God, one Lord" (from New English Bible) (Deut. 6:4). The eminent Dutch Old Testament scholar Theodorus C. Vriezen writes: "It is striking how the whole life of the people is seen as dominated by Yahweh and by Yahweh alone. Even if one cannot speak of a strictly maintained monotheistic way of thinking, it is yet clear that faith in Yahweh is the foundation of life for the Israelite." Monotheism is not a matter of mathematics—of opting for the number one as against other numbers—but the conscious choice of a person or group committing himself

or themselves to one god rather than to any other ones and putting their faith in that one god; Joshua proclaims: "But as for me and my house, we will serve the Lord" (Josh. 24:15). In Israel the ethical aspect was as important as the exclusiveness of their one god; the prophets stressed the ethical elements of an essentially exclusive God. The God of Israel was a jealous god who forbade his believers to worship other gods. In this respect he differed from other gods in the ancient Near Eastern religions who, as a rule, did not put such exclusive obligation on their adherents.

In later times—beginning in the 6th century bc and continuing into the early centuries of the Christian Era—Judaic monotheism developed in the same direction as did Christianity and also later Islām under the influence of Greek philosophy and became monotheistic in the strict sense of the word, affirming the one God for all men everywhere.

Christianity. Among the three great monotheistic religions, Christianity has a place apart, because of the trinitarian creed of this religion in its classic forms, in contradistinction to the unitarian creed of Judaism and Islām. The Christian Bible, including the New Testament, has no trinitarian statements or speculations concerning a trinitary deity, only triadic liturgical formulas invoking God the Father, Son, and Holy Spirit. It is true that Christianity also has had its Unitarians, such as the 16th-century Italian theologian Faustus Socinus, but this religion in its three classic forms of Roman Catholicism, Eastern Orthodoxy, and Protestantism acknowledges one God in three Persons: God the Father, God the Son, and God the Holy Spirit. According to Christian theology, this acknowledgment is not a recognition of three gods but that these three persons are essentially one, or as the dogmatic formulation, coined by the early Church Father Tertullian (c. 160–after 220), has it: three Persons and one substance. This conception was not accepted without contradiction as is proved by theological disputes of the 3rd and 4th century. It is evident that trinitarian speculation greatly resembles the way of thinking of pluriform monotheism. It is, of course, unlikely that there are any historical connections between these phenomena; both, however, try to solve what is more or less the same problem in more or less the same manner. The main distinction is that Christianity as a monotheistic religion restricts itself to three Persons, though primitive religions have no reason to restrict the number of possible forms of the one divine substance. Like other religions that cover a large territory and have a long history, Christianity appears in a multitude of variations: there is Christian pantheism, Deism, and even, paradoxically, Christian atheism, as exemplified in the mid-20th-century Death of God theologies.

Islām. No religion has interpreted monotheism in a more consequential and literal way than Islām. According to Islāmic doctrine the Christian dogma of a trinitarian god is a form of tritheism—of a three-god belief. There is no issue upon which this religion is so intransigent as the one of monotheism. The profession of faith, the first of the so-called Five Pillars of Islām (the basic requirements for the faithful Muslim), states clearly and unambiguously that "there is no God but Allāh," and in accordance with this principle the religion knows no greater sin than *shirk* ("partnership"), the attribution of partners to Allāh; that is to say, polytheism, or anything that may look like it—e.g., the notion of a divine trinity. The Qur'ān declares: "Say: He, Allāh, is one. Allāh, the eternal. Neither has he begotten, nor is he begotten. And no one is his equal" (112). This profession of faith in Allāh as the one god is encountered in a more popular form, for example, in the stories of *The Thousand and One Nights*: "There is no god except Allāh alone, he has no companions, to him belongs the power and he is to be praised, he gives life and death and he is mighty over all things." In only one respect has the uncompromising monotheism of Islām shown itself to be vulnerable; i.e., in the doctrine of the Qur'ān as uncreated and coeval with Allāh himself.

Monotheistic elements in ancient Middle Eastern and Mediterranean religions. *Egyptian religion.* Egyptian religion is of special interest with regard to the various topics treated in this article, for in it are found polytheism,

Trinitarianism

Yahweh,
the God
of Israel

henotheism, pluriform monotheism, trinitary speculations, and even a kind of monotheism. Especially in the time of the New Kingdom (16th–11th century BC) and later, there arose theological speculations about many gods and the one god, involving concepts that belong to the realm of pluriform monotheism. These ideas are especially interesting when related to trinitarian conceptions, as they sometimes are. In a New Kingdom hymn to Amon are the words: “Three are all gods: Amon, Re and Ptah . . . he who hides himself for them [mankind] as Amon, he is Re to be seen, his body is Ptah.” As Amon he is the “hidden god” (*deus absconditus*); in Re, the god of the sun, he becomes visible; as Ptah, one of the gods of the earth, he is immanent in this world.

Monotheistic reform of Akhenaton

Much attention has been given to the reform of Egyptian religion as effected by the pharaoh Akhenaton (Amenophis IV) in the 14th century BC. This reform has been judged in many ways, favourably and unfavourably; it is, however, clear that Akhenaton’s theology, if not fully monotheistic, in any case strongly tends toward monotheism. It is even possible to follow the gradual development of his ideas in this direction. At first he only singled out Aton, one of the forms of the sun god, for particular worship, but gradually this kind of henotheism developed in the direction of exclusive monotheism and even took on the intolerance peculiar to this religious concept. The names of the other gods were to be deleted. This un-Egyptian intolerance was probably the main reason for the speedy decline of this creed.

Babylonian religion. As far as is known, monotheism was largely absent from Babylonian religion. There henotheism seems to have been very important, since a person could choose one god for particular worship as if he were the only god.

Greco-Roman religions. The classic religions of Greece and Rome were in the main purely polytheistic, but in later times tendencies arose, partly stimulated by philosophy and later also by Judaism and Christianity, toward inclusive monotheism. The hymn to Zeus by the Stoic philosopher Cleanthes (c. 330–c. 230 BC) is the best known document of this process. It praises Zeus as the essence of divinity in all gods, creator and ruler of the cosmos, omnipotent, the giver of every gift, and the father of mankind. In the mystery religions of the Greco-Roman world and in the religious philosophies of later antiquity, such as Neoplatonism, Neopythagoreanism, and others, inclusive monotheism was more or less the rule.

Monotheistic elements in Indian and Chinese religions. The religions of India and China show an astonishing multiplicity of form, but exclusive monotheism, unless imported or stimulated by foreign influences, seems to be absent. All other phenomena treated in this survey of monotheism, however, are to be found in their religions. Inclusive monotheism and pantheism fit very well with the Indian notions of religion, particularly in Hinduism, as is witnessed by the reflections on Brahman, the self of the world, and *Ātman*, the self of individual man. As the *Upaniṣads* say: “Truly, in the beginning existed this Brahman, that only knew itself, saying: I am Brahman.” Although in many cases one god, such as Śiva (Shiva) or Vishnu, receives nearly all the attention of the faithful, this emphasis never leads to a negation of other gods as such. Jainism does not differ in this respect. Only the religion of the Sikhs, heavily influenced by Islām, can be said to teach a kind of exclusive monotheism.

Buddhism teaches in essence that there are no gods in the full sense of the world. Gods are higher beings, but they belong to the cosmos and are as much in need of salvation as man is.

The ancient Chinese religion of the heaven (Shang Ti T’ien) is comparable to the religions that proclaim a high god as creator and ruler of the world, but monotheism has not resulted from this conception. Neither has Taoism led to monotheism. (T.P.v.B.)

Theism

Theism is the view that all limited or finite things are dependent in some way on one supreme or ultimate reality of which one may also speak in personal terms.

Theism’s view of God can be clarified by contrasting it with that of deism, of pantheism, and of mysticism. Deism closely resembles theism; but for the deist, God is not involved in the world in the same personal way. He has made it, so to speak, or set the laws of it—and to that extent he sustains it in being. But subject to this final and somewhat remote control, God, as the deist sees him, allows the world to continue in its own way. This view simplifies some problems, especially those that arise from the scientific account of the world: one does not have to allow for any factor that cannot be handled and understood in the ordinary way. God is in the shadows or beyond; and, though men may still in some way centre their lives upon him, this calls for no radical adjustment at the human or finite level. The deist proceeds, for most purposes at least, as if there were no God—or only an absent one; and this approach is especially true of man’s understanding of the world. This is why deism appealed so much to thinkers in the time of the first triumphs of modern science. They could indeed allow for God, but they had “no need of that hypothesis” in science or in their normal account of things. Religion, being wholly superadded, was significant only in a manner that involved little else in the world or in the way man lives. The theist, on the other hand, questions this view and seeks in various ways (as noted below) to bring man’s relation to God into closer involvement with the way he understands himself and the world around him.

Theism also sharply contrasts with pantheism, which identifies God with all that there is; and with various forms of monism, which regards all finite things as parts, modes, limitations, or appearances of some one ultimate Being, which is all that there is. Some types of absolute Idealism, a philosophy of all-pervading Mind, while regarding every finite thing as comprising some limitation of the one whole of Being, seek also to retain the theistic element in their view of the world; and they do this normally—as in the works of A.E. Taylor, Andrew Pringle-Pattison, or G.F. Stout—by stressing the role of unifying finite centres, such as self-conscious human beings, in the way the universe as a whole functions. But there is no recognition here of the finality of what is technically known as “the distinctness of persons.” The theist, by contrast, considers the world to be quite distinct from its Author or Creator, human life being thus in no sense strictly the life of God, while also making room for a peculiarly intimate involvement of God in the world and in human life.

Mysticism in practice comes close to theism; but mystical thought, and much of its practice, has often involved a repudiation of the proper reality of finite things and sometimes (as in a work by W.T. Stace, *Mysticism and Philosophy*) tends to dismiss all of the finite manifold or multiplicity of things as some wholly unreal phantasm that has no place in the one undiversified Being, which alone is real. Theism is very far removed from ideas of this kind.

THEISM IN WESTERN THOUGHT

God encountered as person. The idea that the world, as man understands it in a finite way, is dependent on some reality altogether beyond his comprehension, perfect and self-sustained but also peculiarly involved in the world and its events, is presented with exceptional sharpness and discernment in the Old Testament, whence it became a formative influence in Hebrew history and subsequently in Christianity and Islām. Behind the creation stories; behind the patriarchal narratives, like that of Jacob at Bethel (Gen. 28) or wrestling with his strange visitor at Penueil (Gen. 32); and behind the high moments of prophecy, like Isaiah’s famous vision in the Temple (Isa. 6), and of moving religious experience in the Psalms, in the Book of Job, and (with remarkable explicitness) in some well-known passages, like the story of Moses at the burning bush (Ex. 3)—behind all of these there lies a sense of some mysterious, all-encompassing reality by which man is also in some way addressed and which he may also venture to address in turn. Moses wished to see God, to have some explicit sign that could convince the people and establish his own authority; but he was shown, instead, that this is just what he could not have: all that he could be assured

Theism, pantheism, and mysticism

Old Testament theophanies

of was that God is real and is bound to be—"I am who I am," he was told. On the other hand, in the throes of this humbling and staggering experience, Moses began to learn also what was expected of him and how his people should live and be led. The God who was so strange and elusive was somehow found to be a God who "talked" to him and with whom people could "walk." The same seemingly bewildering claim of remoteness, almost to the point of unreality, linked with a compelling explicitness and closeness, is also found in other cultures, as illustrated below. This claim presents the reflective thinker with the twofold problem of theism, viz., how, in the first place, a reality as remote and mysterious as the God of theism—the "wholly other," in the famous words of the German theologian Rudolf Otto—can be known at all; and, second, how, if it can be known, it can be spoken of in precise and intimate ways and encountered as a person.

The existence of God. There have been many attempts to establish the existence of one supreme and ultimate Being—whom in religion one speaks of as God—and some of these have been given very precise forms in the course of time.

The influence of Plato and Aristotle. The pattern for many of these was laid down in ancient Greece by Plato. He taught about God mostly in mythical terms, stressing the goodness of God (as in *The Republic* and *Timaeus*) and his care for man (as in the *Phaedo*); but in the *Phaedrus*, and much more explicitly in the *Laws*, he presented a more rigorous argument, based on the fact that things change and are in motion. Not all change comes from outside; some of it is spontaneous and must be due to "soul" and ultimately to a supreme or perfect soul. Whether God so conceived quite gives the traditional theist all that he wants, however, is not certain. For God, in Plato, fashions the world on the pattern of immutable Forms and, above all, on "the Good," which is "beyond being and knowledge"; i.e., it is transcendent and beyond the grasp of thought. But Plato's combination of the notion of the transcendent, which is also supremely good, and the argument from change, provided the model for much of the course that subsequent philosophical arguments were to take. Aristotle made the argument from motion more precise, but he coupled it with a doubtful astronomical view and a less theistic notion of God, who, as the unmoved mover, is the ultimate source of all other movement, not by expressly communicating it but by being a supreme object of aspiration, all appetite and activity being in fact directed to some good. Aristotle thus set the pattern for the more deistic view of God, whereas the theist, taken in the strict sense, turns more for his start and inspiration to Plato.

The causal argument. The argument for the existence of God inferred from motion was given a more familiar form in the first of the five ways of St. Thomas Aquinas, five major proofs of God that also owed much to the emphasis on the complete transcendence of God in the teaching of Plotinus, the leading Neoplatonist of the 3rd century AD, and his followers. (The word that Plotinus used for the ultimate but mysterious dependence of all things on God is emanation; but this characterization was not understood by him, as it has been by some later thinkers, as questioning the genuine independent existence of finite things.) In the first way, Aquinas put forward the view that all movement implies, in the last analysis, an unmoved mover; and though this argument, as he understood it, presupposes certain views about movement and physical change that may not be accepted today, it does make the main point that finite processes call for some ground or condition other than themselves.

This becomes more explicit in the second way, which proceeds from the principle that everything must have an "efficient cause"—i.e., a cause that actively produces and accounts for it—to the notion of a first cause required to avoid an infinite regress, or tracing of causes endlessly backward. As normally found, the idea of efficient causality, in respect to change and process, has many difficulties; and some would prefer to speak instead of regular or necessary sequence. But a more serious objection stresses the apparent inconsistency of thinkers who invoke a general

principle of causality and then exempt the alleged first cause. As the child is apt to put it, "Who then made God?" To this a defender of St. Thomas, or at least of the present approach to the idea of God, would reply that the first cause is not supposed to be itself a member of any ordinary causal sequence but altogether beyond it, an infinite reality not itself a part of the natural or temporal order at all. This point, in fact, is what the third way, starting from the contingency of the world, brings out more explicitly. Nothing explains itself, and all other explanations fall short of showing in any exhaustive way why anything is as it is, or why there is anything at all. But it is also hard to suppose that things just happen to be. Nothing could come out of just nothing, and so the course of events as men find and explain them points to some reality that is not itself to be understood or explained in the normal way at all: it is Explanation with a capital E, as it were, that is seen to be necessitated by all that there is—of whose nature, however, nothing may be directly discerned beyond the inevitability of its being as the ultimate or unconditioned ground of all else and in this way transcendent or utterly mysterious in itself.

This way of thinking of the being and necessity of God has been impressively presented in the mid-20th century by notable thinkers like Austin Farrer, E.L. Mascall, and H.P. Owen and also by the present writer (see below *Bibliography*). Generally known as the cosmological approach to the idea of God, it has much in common with the insistence on the transcendence of God in recent theology.

The ontological argument. Scholars have often converged upon the same theme in what appears to be a very different line of argument, namely the ontological one, with which are associated especially the names of St. Anselm, first of the Scholastic philosophers (in the 11th century), and René Descartes, first major modern philosopher (in the mid-17th century). Proponents of this argument try to show that the very idea of God implies his existence. God is the greatest or most perfect being. If the attribute of existence, however, is not included in man's concept of God, he can then think of something more perfect, viz., that which has existence as well. Critics, such as Gaunilo—a monk of Marmoutier—in Anselm's day and Immanuel Kant—one of the major architects of modern philosophy—many centuries later, have fastened on the weakness that existence is not a predicate or attribute in the same way, at least, as colour or shape; but there have been highly ingenious attempts by influential religious thinkers of today to restate the argument in an acceptable form. (See especially the writings of Charles Hartshorne and Norman Malcolm.) Others find in the argument an oblique and needlessly elaborate way of eliciting the feeling that there must be some reality that exists by the very necessity of its own nature and to which everything else directs man's thought.

The reference to value and design. Attempts to arrive at the idea of God in somewhat more comprehensible terms are reflected in the references to value and design in the fourth and fifth ways of St. Thomas; this approach, however, has been given a more explicit presentation and critical discussion in the works of David Hume, a mid-18th-century Scottish Skeptic, and in Kant. The main idea of the teleological argument, as it is called, is that of the worth and purpose, or apparent design, to be found in the world. This purposiveness is taken to imply a supreme Designer. It has been questioned, however (by Kant, for example), whether this argument can really get started without presupposing some feature of the causal argument. The presence of seemingly purposeless features of the world and of much that is positively bad, like wickedness and suffering, while always embarrassing for a theistic view, presents peculiar difficulties here. For the arguer is now throwing hostages to fortune in the shape of a special assessment of the way things actually happen, which goes far beyond the mere requirement of some ultimate ground, whatever the world appears to be like. The arguments from worth and design have, however, one considerable advantage, viz., that they provide a fairly straightforward way of learning about the nature of God and of ascribing a certain aim and character to him from

The arguments of Anselm and Descartes

The five ways of Aquinas

one's understanding of the phenomena that he is required to explain. The supreme Designer or Architect is known from his works, especially perhaps as reflected in the lives of men; and this approach opens up one way of speaking of God, not just as mysterious power behind the world but as some reality whom man may come to know in a personal way from the way the world goes and from his understanding of what it means.

Many thinkers in the late 19th and early 20th centuries sought to establish man's knowledge of God in the way suggested through his understanding of himself and the world; and of these the most notable and valuable still today are the British theists James Ward, a psychologist, and F.R. Tennant, a philosophical theologian. But the work of thinkers like Pierre Teilhard de Chardin, a Jesuit paleoanthropologist, and the spate of discussion that he has provoked are also relevant here; and such work, in turn, owes much—directly or otherwise—to the work of evolutionary thinkers like Samuel Alexander and Henri Bergson and of modern scientists like Julian Huxley.

The problem of particular knowledge of God. If the central theme of traditional theism, viz., that the finite world depends in some way on one transcendent and infinite Being, can be sustained, then a crucial problem presents itself at once: the question of how a being whose essence can never be known to man—who, as infinite, is bound to be beyond the grasp of reason and to remain wholly mysterious—how such a being can be said to be known at all, much less known and experienced in the close and intimate personal ways that the theist makes equally central to his claim. Part of the answer is that the theist does not claim to fathom the ultimate mystery of God or to know him as he is in himself. All that is claimed on this score is that man sees the inevitability of there being God in the contingent and limited character of everything else; and though this line of thought could not be adopted for any finite existence—since one could not normally affirm in any sensible way the existence of anything without specifying in some measure, however slight, what it is like—one can, nonetheless, regard the case of God as unique and not subject to the conditions of finite intelligibility. In these ways, an insight or intuition into the being of God may be claimed without a commitment to anything about his nature beyond the sort of completeness or perfection required to account for there being limited finite things. This insight is much in line with the “deliverances of religious consciousness” in which it is claimed that God is “hidden,” is “past finding out,” that his ways are not man's ways, that he is eternal, uncreated, and so on. But the theist still has a major problem on his hands, for he also makes a central issue of the claim that God can be known—“met” and “encountered” in some way—indeed, that some very bold affirmations about God and his dealings with men may be made.

Theism and natural theology. Theists have tried to deal with this problem in various ways. One of these ways is their use of the doctrine of analogy, which owes a great deal to the teaching of St. Thomas Aquinas. Various types of analogy are distinguished in the traditional doctrine; but the central claim is that certain predicates, such as “love,” “faithfulness,” or “justice,” may be affirmed of God in whatever way may reflect his involvement as the author of the limited realities, such as man, of which such predicates may be affirmed in the normal, straightforward way. The difficulty with this procedure is that, whatever it yields, the content of faith is still very thin and remote, far from the warm fellowship of personal relations. Most of the traditional sponsors of the doctrine admit this and contend, therefore, that the findings of their “natural theology,” as it is called, must be supplemented by that of revelation or of divine disclosure. Theism, in fact, is hardly conceivable without some doctrine of revelation. But even if the theologian says that God takes the initiative in communicating himself to man, the epistemological problem remains of how men's essentially finite minds can apprehend anything pertaining to infinite or eternal Being.

Theism and religious experience. At this point, recourse is sometimes had to authority, the authority of a sacred book, an institution, or a system of doctrines, or one of

divinely implanted images. But there must at least be some initial justification of an authority, to say nothing of an evaluation of rival claims. A more attractive solution, then, especially for those who stress the personal involvement of God in men's lives, is one posed in terms of religious experience. Such experience is usually given prominence in theistic contexts. It is sometimes understood in terms of paranormal phenomena, like hearing voices or seeing visions, which have no natural origin, or like being in some peculiar psychical state. Some of the faithful believe that God literally speaks to them (or spoke in times past to prophets) in this way. A more subtle view holds that men have reason to regard certain experiences as their clue to what they should say of God in his relation to them. The question then arises of how these experiences should be recognized; and various answers are given, such as that which stresses the formative influence (within such experiences) of the initial insight into the being of God and the patterning of the experiences, in themselves and in wider ramifications, as a result. Much use is made in this context of the analogy with men's knowledge of one another. Men do not know one another's minds, it is alleged, as they know their own but only as mediated through bodily states and behaviour. So a man may come to know God, who in his essence is impenetrable to him, from the impact that he makes within experiences and events that one would otherwise understand and handle just as one does other finite occurrences. In the molding and perpetuating of such experiences, prominence is given to imagination and to the place of figurative terms and symbolism. These forms have therefore a place of special importance in theistic types of religion, the personal encounter being extended and deepened through art and literature, song, dance, myth, and ritual. This fact, in turn, presents problems for thought and practice, since the art forms and ritual must not be allowed to take wing on their own and thereby be loosed from the discipline and direction of the proper dynamic of religious life.

Theism and religious language. Preoccupation with the forms in which religious life expresses itself has led some theistic writers to lean heavily on the contribution made to religious understanding today by studies of religious language. In some cases this concern has carried with it, as generally in much linguistic philosophy of today, a skeptical or agnostic view of the transcendent factor in religion. It is hard to see, however, how attenuations of this kind could be strictly regarded as forms of theism; though clearly, within their more restricted scope, they can retain many of the other characteristics of theism, such as the stress on personal involvement and response. This tendency is very marked in some recent studies of religion, in which the inspiration and form of theism are retained without the substance—though how long and how properly are moot points. There are others who, while retaining the transcendent reference of theism, look for the solution of the central problem less in the substance of religious awareness and in varieties of experience than in the modes of articulation and religious language. Controversy centres, to a great degree, on which of these approaches is the most fruitful.

In the work of some theists today, the preoccupation with language is also combined with the existentialist stress on personal involvement and commitment. A good example of this approach is found in the work of I.T. Ramsey, the bishop of Durham, who, in spite of his insistence on disclosure situations, in which something peculiarly significant becomes alive to man, seemed to concede more than a theist should to the skeptical strain in recent studies of religious language.

The nature of God in modern thought. Modern thought has thrown new light on issues, both old and new, regarding the nature of God.

Theism and incarnation. The core of human personality has often been thought to be man's moral existence, and, accordingly, theists have often taken this fact to be the main clue to the way they are to think of divine perfection and to the recognition of a peculiar divine involvement in the world. Prominence is thus accorded to the high ethical teaching and character of saints and prophets, who have

The
question of
transcendence
in
theism

a special role to play in transmitting the divine message. In some religions this tendency culminates in doctrines of incarnation, of God manifesting himself expressly in refined or perfected human form. This trend is peculiarly marked in the Christian religion, in which the claim is usually made that a unique and "once for all" incarnation of God has occurred in Christ. Incarnational claims seem certainly to take their place easily in some main forms of theism. The vindication of such claims, however—especially today—relies much on consideration of the personal factor in religion generally.

For these and related reasons, the theist today may find himself calling to his aid certain other disciplines that centre upon men as persons, such as psychology and anthropology. Not all of the forms and findings of these studies favour the theist, and he should take special note of their challenge when they seem hostile, for they may touch him at his tenderest spot. He may, on the other hand, find in such studies, and certain general literature that borders on kindred themes, substantial help in reconstructing his case in the full context of contemporary thought and culture.

Humanism and transcendence. It is indeed from certain modern studies of man and his environment that some of the most disturbing challenges to the theist have come. For it has been argued that the very idea of God, as well as the more specific forms that it takes, emanate from man's emotional needs for succour and comfort. It is in fact man himself, it is said, who has created God in his own image, and the attempt is made to substantiate this view from accounts of the proclivity of men, especially in early times, to personify natural objects—rivers, trees, mountains, and so forth—and, in due course, to confer peculiar properties upon them, leading in time to the notion of some superbeing in whom these powers and properties are concentrated. The classical statement of this position appeared before the development of anthropology and the modern systematic study of religions, viz., in David Hume's essay "The Natural History of Religion" (1757). This short but splendidly lucid and challenging work set the pattern for the more scientific and empirical studies of religion that began to take shape in the 19th century in pioneer work by E.B. Tylor, a British ethnologist and anthropologist, in his *Primitive Culture* (1871), and by Sir James Frazer, an ethnographer and historian of religion, in his *Golden Bough* (1890–1915). But a corrective to this approach was soon provided by other scholars equally renowned, who started from the historical and empirical evidence available to them at the time. Andrew Lang, a Scottish litterateur, drew attention to the phenomenon, among very early peoples, of the High God, a Supreme Being who created himself and the earth and dwelt at one time on earth. John H. King, in *The Supernatural: Its Origin, Nature and Evolution* (1892), stressed the importance of the element of mystery in all religions, and another pioneer of religious anthropology, R.R. Marett, showed how extensively the savage ascribes the mysteries of life and power to a supernatural source. Lucien Lévy-Bruhl, a French sociologist, noted the pervasiveness of prelogical factors in primitive mentality, and Rudolf Otto, the most famous name in this context, found evidence in early forms of religion of a response to "the wholly other," the *mysterium tremendum et fascinans*.

The idea of a finite God. Concern with the problem of evil—i.e., with reconciling the existence of evil with that of a good God—becomes acute for thinkers who rest their case mainly on what they find in the world around them; and this has led many to retreat to the notion of a finite God, according to which the world may be under the direction of a superior being who is nonetheless limited in power, though not in goodness. This is a serious alternative to the idea of a supreme and unlimited source of all reality as found in the usual forms of theism. Indeed, it is a moot point whether the idea of a finite God should be classified as a form of theism. It does come close to traditional theism, however, in its insistence on the unity and absolute benevolence of God. There are clearly advantages in the notion of God as a limited being, especially where evil is concerned; for though one could still insist that God intends nothing that is not wholly good,

he can now account for extensive suffering and other ills on the basis of the limits to God's power. He is doing his utmost, the finitist holds, but there are things—refractory materials or explicitly evil powers—that he has not yet subdued, though hopefully he will eventually do so. There is also induced in this way a sense of urgency in man's own obligation to cooperate with God—to be a "fellow worker." God will clearly need his help though he himself is in the vanguard of the battle against evil. Thus, those who incline to the idea of a finite God usually have been activist in thought and practice.

There are also grave difficulties to be met. For if a thinker has recourse to the idea of God simply to account for what is otherwise bewildering in the finite course of things, he may find no warrant for the inference involved and indeed may find himself desperately clinging to what is sometimes called "the God of the gaps" (i.e., of the gaps in man's explanations). If, on the other hand, he starts from the inherently incomplete character of finite explanation as such, or from the contingency of finite things, nothing short of an infinite or absolute God will meet the case. In addition, the usual attitude of religious people, or of what is sometimes known as "the religious consciousness," is that of a profound assurance and serenity that presupposes that God is "all in all" and beyond any possibility of being thwarted. It is also questionable whether the attitude of worship is appropriate for a limited being, however superior he may be to man.

Among the outstanding advocates of the idea of a finite God were, at the turn of the 20th century, the U.S. Pragmatist William James and some of his disciples, notably Ralph Barton Perry. Thus, it is not surprising that a closely similar notion arising in the mid-20th century finds its main inspiration and support in the United States, viz., in the work of process philosophers, such as Charles Hartshorne and Schubert Ogden, who have developed some of the leading ideas of A.N. Whitehead, an eminent metaphysician. In their view, God is himself in process of fulfillment in some kind of identification with the world, which at the same time leaves him distinct in some sense from the universe, which he permeates and unifies. There are grave and admitted paradoxes in this view; and, in spite of the remarkable ingenuity of its advocates and their logical nimbleness, it is not clear that the paradoxes can be sustained nor that the difficulties that are shared with the simpler notion of a finite God can be overcome. Much in recent religious thought centres on this issue.

Theism in Islām. The Muslim faith owes much to the Semitic outlook from which the Old Testament and Christianity arose. It centres on a transcendent personal deity; but, in its regard for the holiness and majesty of God, it rejects incarnational doctrines as a form of blasphemy. There is, however, a paradoxical side to one form of Islām: while insisting that God is all in all, it sometimes tends to represent all of man's own actions as the action of God within him and thus has some tendency to identify man with God. This tendency, most marked in the mysticism of the Šūfis, seems, as respects its monism, to veer away from theism but seems, as respects the sense of devotion and personal excitation that it inspires, to be in line with the more explicit forms of theism. In its main form, Islām, with its quite exceptional sense of the transcendence of God, is one of the most distinctively theistic religions, though at odds with the incarnational factor in Christian theism.

THEISM IN EASTERN THOUGHT

The trend toward the testing of theistic thought in the crucible of the special disciplines was continued not only in further anthropological studies (see *The Worship of the Sky-God*, by E.O. James) but also in extensive scholarly studies and translations of the sacred books of the great religions of the East.

Hindu theism. It was noted, for example, that the Vedic hymns that appear in the earliest Hindu scriptures contain significant intimations of a sense of "the wonder of existence," "the outpourings," as Savepalli Radhakrishnan, the former philosopher-president of India, has expressed it, "of poetic minds who were struck by the immensity of

Role of the sciences of religion

Theism
in the
Upaniṣads

the universe and the inexhaustible mystery of life." Note was taken also of early manifestations of henotheism, a view that exalts several deities to the first place. The theme of some one supreme reality, the first principle, or the supreme self becomes more explicit in the *Upaniṣads*, ancient Hindu scriptures, while retaining a sense of its ineffableness. One hears of "the way of silence" and of the ultimate absorption of all into the one supreme reality, the "one who breathes breathless." This one is variously conceived in its relation to finite things; and although the transcendent reference is rarely absent, there is not the same recognition of the distinctness of finite beings that there is in Western theism or of the eternal self being involved in the world in a personal way. The *Upaniṣads* have, in fact, a variety of themes and emphases, tending generally toward a monistic and mystical philosophy; but on occasion the theistic element is very marked, as in the *Kaṭha* and the *Śvetāśvatara* books of the *Upaniṣads*. The absolutist and the theistic views are not always felt to be exclusive. This climate of thought has set the course for much of subsequent Hinduism, in which, along with the persistence of the monistic strain, the theistic note is sounded much more distinctly, especially in the doctrine and practice of *bhakti*—devotion to a personal God who bestows grace. In the famous *Bhagavadgītā* (probably 3rd or 4th century BC), a classic of religious literature, and in the teaching of the Brahmin Rāmānuja (11th century), considered the founder of the Viśiṣṭādvaita (qualified non-dualism) school, the flowering of the more theistic side of Hinduism is found. In the Śaiva-siddhānta theology of South Indian Śaivism (a major cult of Hinduism), there is a firm insistence that the soul, in being united with God, is not annihilated or negated but only fused into the likeness of God, who, in turn, is always in loving pursuit of the soul. This doctrine makes the system "perhaps the highest form of theism that India was ever to develop" (R.C. Zaehner). In the closing words of the *Bhagavadgītā* is an insistence on a love of God for man and of man for God that represents a decisive turning point in the history of Hinduism:

Think on me, worship me, sacrifice to me, pay me homage, so shalt thou come to me, I promise thee truly, for I love thee well. Give up all things of *dharma*, turn to me only as thy refuge. I will deliver thee from all evil. Have no care.

This theology has been well reflected in the 20th century in the devotionalism of Gandhi and in the writings of Sri Aurobindo, a philosopher and Yoga devotee, which reflect an indwelling of the divine within the world and a summons to high moral endeavour on the part of man that comes close to theism without explicitly accepting it.

Buddhism and theism. The same diversity of strains is found in Buddhism. Though Buddhism was at one time regarded as an atheistic religion leading to total elimination of self in a state of Nirvāṇa, a close examination of the evidence—in the Pāli *Tiṇṇakā*, for example, the canon of the Theravāda school of Buddhism—leads to a revision in favour of the view that the seeming negativism of early Buddhist scriptures and the rejection of metaphysics reflect chiefly the caution arising from a profound recognition of the characterless elusiveness of the transcendent. And although the Buddhist doctrine of compassion and its rigorous intellectual and moral discipline may lack something of the warmth of a close personal commitment, the Buddhist adoration of the Buddha and of the *bodhisattvas* (those on their way to Enlightenment) afforded much scope to the religious responses that find their full expression in overt theism. This trend became more marked in the more popular forms of Buddhism and in the mythologies that centre upon the idea of the *bodhisattvas*.

Theism in other religions. In the same way, the seeming agnosticism of Confucian religion is qualified by its teaching about a power from beyond the world working for justice within it, a "Heaven-ordained relationship" that provides the basis of ethics and induces a deep consciousness of individuality. This trend became intensified in the conflations that resulted from the extension of Buddhism into China.

In the doctrines of Sikhism, a religion of the eastern Punjab that combines certain Muslim and Hindu elements, stress is laid upon personal awareness of God as a central and unifying factor in religion. In doctrine though not always in practice, however, the Sikhs reject every notion of an avatar, or incarnation. The religion of the Jains is nontheistic in theory, but the great figures of its tradition come to function as gods in popular religion. For a period in ancient Persia, there was established in the teaching of Zoroaster (Zarathushtra) a form of ethical monotheism in which the god Ahura Mazdā is the creator of the physical and moral world—though limited, for a time at least, by an opposing principle of evil (Ahriman).

The clue to the theistic element in the religions of primitive peoples may well be found in an observation by H.H. Farmer, a British philosophical theologian:

We may surmise that at moments of living prayer and worship there is in primitive man a turning to a god as if he were in fact the one and only God, though without any expressly formulated denial of the existence of others; for the time being, the god worshipped fills the whole sphere of the divine.

(H.D.L.)

Deism

Deism, as the word is customarily employed, describes an unorthodox religious attitude that found expression among a group of English writers beginning with Edward Herbert (later 1st Baron Herbert of Cherbury) in the first half of the 17th century and ending with Henry St. John, 1st Viscount Bolingbroke, in the middle of the 18th century. In general, however, it refers to what can be called natural religion, the acceptance of a certain body of religious knowledge that is inborn in every person or that can be acquired by the use of reason, as opposed to knowledge acquired through either revelation or the teaching of any church.

NATURE AND SCOPE

Though an initial use of the term occurred in 16th-century France, the later appearance of the doctrine on the Continent was stimulated by the translation and adaptation of the English models. The high point of Deist thought occurred in England from about 1689 through 1742, during a period when, despite widespread counterattacks from the established Church of England, there was relative freedom of religious expression following upon the Glorious Revolution that ended the rule of James II and brought William and Mary to the throne. Deism took deep root in 18th-century Germany after it had ceased to be a vital subject of controversy in England.

At times in the 19th and early 20th centuries, the word Deism was used theologically in contradistinction to theism, the belief in an immanent God who actively intervenes in the affairs of men. In this sense Deism was represented as the view of those who reduced the role of God to a mere act of creation in accordance with rational laws discoverable by man and held that, after the original act, God virtually withdrew and refrained from interfering in the processes of nature and the ways of man. So stark an interpretation of the relations of God and man, however, was accepted by very few Deists during the flowering of the doctrine, though their religious antagonists often attempted to force them into this difficult position. Historically, a distinction between theism and Deism has never had wide currency in European thought. As an example, when encyclopaedist Denis Diderot, in France, translated into French the works of Anthony Ashley Cooper, 3rd earl of Shaftesbury, one of the important English Deists, he often rendered "Deism" as *théisme*. The term is not in current usage as a metaphysical concept, and its significance is really limited to the 17th and 18th centuries.

THE HISTORICAL DEISTS

The English Deists. In 1754–56, when the Deist controversy had passed its peak, John Leland, an opponent, wrote a historical and critical compendium of Deist thought, *A View of the Principal Deistical Writers that Have Appeared in England in the Last and Present Century; with Observa-*

religion

tions upon Them, and Some Account of the Answers that Have Been Published Against Them. This work, which began with Lord Herbert of Cherbury and moved through the political philosopher Thomas Hobbes, Charles Blount, the Earl of Shaftesbury, Anthony Collins, Thomas Woolston, Matthew Tindal, Thomas Morgan, Thomas Chubb, and Viscount Bolingbroke, fixed the canon of who should be included among the Deist writers. In subsequent works Hobbes usually has been dropped from the list and John Toland included, though he was closer to pantheism than most of the other Deists were. Herbert was not known as a Deist in his day, but Blount and the rest who figured in Leland's book would have accepted the term Deist as an appropriate designation for their religious position. Simultaneously, it became an adjective of opprobrium in the vocabulary of their opponents. Bishop Edward Stillingfleet's *Letter to a Deist* (1677) is an early example of the orthodox use of the epithet.

Herbert's
five fun-
damental
beliefs

In Lord Herbert's treatises five religious ideas were recognized as God-given and innate in the mind of man from the beginning of time: the belief in a supreme being, in the need for his worship, in the pursuit of a pious and virtuous life as the most desirable form of worship, in the need of repentance for sins, and in rewards and punishments in the next world. These fundamental religious beliefs, Herbert held, had been the possession of the first man, and they were basic to all the worthy positive institutionalized religions of later times. Thus, differences among sects and cults all over the world were usually benign, mere modifications of universally accepted truths; they were corruptions only when they led to barbarous practices such as the immolation of human victims and the slaughter of religious rivals.

In England at the turn of the 17th century this general religious attitude assumed a more militant form, particularly in the works of Toland, Shaftesbury, Tindal, Woolston, and Collins. Though the Deists differed among themselves and there is no single work that can be designated as the quintessential expression of Deism, they joined in attacking both the existing orthodox church establishment and the wild manifestations of the dissenters. The tone of these writers was often earthy and pungent, but their Deist ideal was sober natural religion without the trappings of Catholicism and the High Church in England and free from the passionate excesses of Protestant fanatics. In Toland there is great emphasis on the rational element in natural religion; in Shaftesbury more worth is ascribed to the emotive quality of religious experience when it is directed into salutary channels. All are agreed in denouncing every kind of religious intolerance because the core of the various religions is identical. In general, there is a negative evaluation of religious institutions and the priestly corps who direct them. Simple primitive monotheism was practiced by early men without temples, churches, and synagogues, and modern men could readily dispense with religious pomp and ceremony. The more elaborate and exclusive the religious establishment, the more it came under attack. A substantial portion of Deist literature was devoted to the description of the noxious practices of all religions in all times, and the similarities of pagan and Roman Catholic rites were emphasized.

The Deists who presented purely rationalist proofs for the existence of God, usually variations on the argument from the design or order of the universe, were able to derive support from the vision of the lawful physical world that Sir Isaac Newton had delineated. Indeed, in the 18th century, there was a tendency to convert Newton into a matter-of-fact Deist—a transmutation that was contrary to the spirit of both his philosophical and his theological writings.

When Deists were faced with the problem of how man had lapsed from the pure principles of his first forebears into the multiplicity of religious superstitions and crimes committed in the name of God, they ventured a number of conjectures. They surmised that men had fallen into error because of the inherent weakness of human nature; or they subscribed to the idea that a conspiracy of priests had intentionally deceived men with a "rout of ceremonials" in order to maintain power over them.

The role of Christianity in the universal history of reli-

gion became problematic. For many religious Deists the teachings of Christ were not essentially novel but were, in reality, as old as creation, a republication of primitive monotheism. Religious leaders had arisen among many peoples—Socrates, Buddha, Muhammad—and their mission had been to effect a restoration of the simple religious faith of early men. Some writers, while admitting the similarity of Christ's message to that of other religious teachers, tended to preserve the unique position of Christianity as a divine revelation. It was possible to believe even in prophetic revelation and still remain a Deist, for revelation could be considered as a natural historical occurrence consonant with the definition of the goodness of God. The more extreme Deists, of course, could not countenance this degree of divine intervention in the affairs of men.

Natural religion was sufficient and certain; the tenets of all positive religions contained extraneous, even impure elements. Deists accepted the moral teachings of the Bible without any commitment to the historical reality of the reports of miracles. Most Deist argumentation attacking the literal interpretation of Scripture as divine revelation leaned upon the findings of 17th-century biblical criticism. Woolston, who resorted to an allegorical interpretation of the whole of the New Testament, was an extremist even among the more audacious Deists. Tindal was perhaps the most moderate of the group. Toland was violent; his denial of all mystery in religion was supported by analogies among Christian, Judaic, and pagan esoteric religious practices, equally condemned as the machinations of priests.

The Deists were particularly vehement against any manifestation of religious fanaticism and enthusiasm. In this respect Shaftesbury's *Letter Concerning Enthusiasm* (1708) was probably the crucial document in propagating their ideas. Revolted by the Puritan fanatics of the previous century and by the wild hysteria of a group of French exiles prophesying in London in 1707, Shaftesbury denounced all forms of religious extravagance as perversions of true religion. These false prophets were directing religious emotions, benign in themselves, into the wrong channels. Any description of God that depicted his impending vengeance, vindictiveness, jealousy, and destructive cruelty was blasphemous. Because sound religion could find expression only among healthy men, the argument was common in Deist literature that the preaching of extreme asceticism, the practice of self-torture, and the violence of religious persecutions were all evidence of psychological illness and had nothing to do with authentic religious sentiment and conduct. The Deist God, ever gentle, loving, and benevolent, intended men to behave toward one another in the same kindly and tolerant fashion.

Deists in other countries. Ideas of this general character were voiced on the Continent at about the same period by such men as Pierre Bayle, a French philosopher famous for his encyclopaedic dictionary, even though he would have rejected the Deist identification. During the heyday of the French Philosophes in the 18th century, the more daring thinkers—Voltaire among them—gloried in the name Deist and declared the kinship of their ideas with those of Rationalist English ecclesiastics, such as Samuel Clarke, who would have repudiated the relationship. The dividing line between Deism and atheism among the Philosophes was often rather blurred, as is evidenced by *Le Rêve de d'Alembert* (written 1769; "The Dream of d'Alembert"), which describes a discussion between the two "fathers" of the *Encyclopédie*: the Deist Jean Le Rond d'Alembert and the atheist Diderot. Diderot had drawn his inspiration from Shaftesbury, and thus in his early career he was committed to a more emotional Deism. Later in life, however, he shifted to the atheist materialist circle of the Baron d'Holbach. When Holbach paraphrased or translated the English Deists, his purpose was frankly atheist; he emphasized those portions of their works that attacked existing religious practices and institutions, neglecting their devotion to natural religion and their adoration of Christ. The Catholic Church in 18th-century France did not recognize fine distinctions among heretics, and Deist and atheist works were burned in the same bonfires.

English Deism was transmitted to Germany primarily through translations of Shaftesbury, whose influence upon

French
Deists

German
Deists

thought was paramount. In a commentary on Shaftesbury published in 1720, Gottfried Wilhelm Leibniz, a Rationalist philosopher and mathematician, accepted the Deist conception of God as an intelligent Creator but refused the contention that a god who metes out punishments is evil. A sampling of other Deist writers was available particularly through the German rendering of Leland's work in 1755 and 1756. H.S. Reimarus, author of many philosophical works, maintained in his *Apologie oder Schutzschrift für die vernünftigen Verehrer Gottes* ("Defense for the Rational Adorers of God") that the human mind by itself without revelation was capable of reaching a perfect religion. Reimarus did not dare to publish the book during his lifetime, but it was published in 1774–78 by Gotthold Ephraim Lessing, one of the great seminal minds in German literature. According to Lessing, common man, uninstructed and unreflecting, will not reach a perfect knowledge of natural religion; he will forget or ignore it. Thus, the several positive religions can help men achieve more complete awareness of the perfect religion than could ever be attained by any individual mind. Lessing's *Nathan der Weise* (1779; "Nathan the Sage") was noteworthy for the introduction of the Deist spirit of religion into the drama; in the famous parable of the three rings, the major monotheistic religions were presented as equally true in the eyes of God. Although Lessing's rational Deism was the object of violent attack on the part of Pietist writers and the more mystical thinkers, it influenced such men as Moses Mendelssohn, a German Jewish philosopher who applied Deism to the Jewish faith. Immanuel Kant, the most important figure in 18th-century German philosophy, stressed the moral element in natural religion; moral principles are not the result of any revelation but originate from the very structure of man's reason. English Deists, however, continued to influence German Deism. Witnesses attest that virtually the whole officer corps of Frederick the Great was infected with Deism and that Collins and Tindal were favourite reading in the army.

By the end of the 18th century, Deism had become a dominant religious attitude among intellectual and upper class Americans. Benjamin Franklin, the great sage of the Colonies and then of the new republic, summarized in a letter to Ezra Stiles, president of Yale College, a personal creed that almost literally reproduced Herbert's five fundamental beliefs. The first three presidents of the United States also held Deistic convictions, as is amply evidenced in their correspondence. "The ten commandments and the sermon on the mount contain my religion," John Adams wrote to Thomas Jefferson in 1816. (F.E.M.)

Agnosticism

The word agnosticism was first publicly coined in 1869 at a meeting of the Metaphysical Society in London by T.H. Huxley, a British biologist and champion of the Darwinian theory of evolution. He coined it as a suitable label for his own position. "It came into my head as suggestively antithetical to the 'Gnostic' of Church history who professed to know so much about the very things of which I was ignorant."

NATURE AND KINDS OF AGNOSTICISM

Huxley's statement brings out both the fact that agnosticism has something to do with not knowing, and that this not knowing refers particularly to the sphere of religious doctrine. Etymology, however, and now common usage, do permit less limited uses of the term. The Soviet leader Lenin, for instance, in his *Materialism and Empirio-Criticism* (1908), distinguished the extremes of true Materialism on the one hand and the bold Idealism of George Berkeley, an 18th-century Idealist, on the other. He recognized as attempted halfway houses between them the "agnosticisms" of the Scottish Skeptic David Hume and the great German critical philosopher Immanuel Kant—agnosticisms that here consisted in their contentions about the unknowability of the nature, or even the existence, of "things-in-themselves" (realities beyond appearances).

Huxley's nonreligious agnosticism. The essence of Huxley's agnosticism—and his statement, as the inventor

of the term, must be peculiarly authoritative—was not a profession of total ignorance, nor even of total ignorance within one special but very large sphere; rather, he insisted, it was "not a creed but a method, the essence of which lies in the rigorous application of a single principle," viz., to follow reason "as far as it can take you"; but then, when you have established as much as you can, frankly and honestly to recognize the limits of your knowledge. It is the same principle as that later proclaimed in an essay on "The Ethics of Belief" (1876) by the British mathematician and philosopher of science W.K. Clifford: "It is wrong always, everywhere and for everyone to believe anything upon insufficient evidence." Applied by Huxley to fundamental Christian claims, this principle yields characteristically skeptical conclusions: speaking, for example, of the Apocrypha (ancient scriptural writings excluded from the biblical canon), he wrote: "One may suspect that a little more critical discrimination would have enlarged the Apocrypha not inconsiderably." In the same spirit, Sir Leslie Stephen, 19th-century literary critic and historian of thought, in *An Agnostic's Apology, and Other Essays* (1893), reproached those who pretended to delineate "the nature of God Almighty with an accuracy from which modest naturalists would shrink in describing the genesis of a black beetle."

Agnosticism in its primary reference is commonly contrasted with atheism thus: "The Atheist asserts that there is no God, whereas the Agnostic maintains only that he does not know." This distinction, however, is in two respects misleading: first, Huxley himself certainly rejected as outright false—rather than as not known to be true or false—many widely popular views about God, his providence, and man's posthumous destiny; and second, if this were the crucial distinction, agnosticism would for almost all practical purposes be the same as atheism. It was indeed on this misunderstanding that Huxley and his associates were attacked both by enthusiastic Christian polemicists and by Friedrich Engels, the co-worker of Karl Marx, as "shame-faced atheists," a description that is perfectly applicable to many of those who nowadays adopt the more comfortable label.

Agnosticism, moreover, is not the same as Skepticism, which, in the comprehensive and classical form epitomized by the ancient Greek Skeptic Sextus Empiricus (2nd and 3rd centuries AD), confidently challenges not merely religious or metaphysical knowledge but all knowledge claims that venture beyond immediate experience. Agnosticism is, as Skepticism surely could not be, compatible with the approach of Positivism, which emphasizes the achievements and possibilities of natural and social science—though most agnostics, including Huxley, have nonetheless harboured reserves about the more authoritarian and eccentric features of the system of Auguste Comte, the 19th-century founder of Positivism.

Religious agnosticism. It is also possible to speak of a religious agnosticism. But if this expression is not to be contradictory, it has to be taken to refer to an acceptance of the agnostic principle, combined either with a conviction that at least some minimum of affirmative doctrine can be established on adequate grounds, or else with the sort of religion or religiousness that makes no very substantial or disputatious doctrinal demands. If these two varieties of agnosticism be admitted, then Huxley's original agnosticism may be marked off from the latter as (not religious but) secular and from the former as (not religious but) atheist—construing "atheist" here as a word as wholly negative and neutral as "atypical" or "asymmetrical." These, without pejorative insinuations, mean merely "not typical" or "not symmetrical" (the atheist is thus one who is simply without a belief in God).

Huxley himself allowed for the possibility of an agnosticism that was in these senses religious—even Christian—as opposed to atheist. Thus, in another 1889 essay "Agnosticism and Christianity," he contrasted "scientific theology," with which "agnosticism has no quarrel," with "Ecclesiasticism, or, as our neighbours across the Channel call it, Clericalism"; and his complaint against the latter's proponents was not that they reach substantive conclusions different from his own but that they maintain "that

Contrasts with atheism, Skepticism, Positivism

American Deists

The
agnosti-
cism
of the
Buddha

it is morally wrong not to believe certain propositions, whatever the results of strict scientific investigation of the evidence of these propositions." The second possibility, that of an agnosticism that is religious as opposed to secular, was realized perhaps most strikingly in the Buddha (Gautama). Typically and traditionally, the ecclesiastical Christian has insisted that absolute certainty about some minimum approved list of propositions concerning God and the general divine scheme of things was wholly necessary to salvation. Equally typically, according to the tradition, the Buddha sidestepped all such speculative questions. At best they could only distract attention from the urgent business of salvation—salvation, of course, in his own very different interpretation.

HISTORICAL ANTECEDENTS OF MODERN AGNOSTICISM

It is convenient to distinguish the antecedents of secular agnosticism from those of religious agnosticism.

Antecedents of secular agnosticism. The ancestry of modern secular and atheist agnosticism may be traced back to the Sophists and to Socrates in the 5th century BC; not, of course, the "Socrates" of Plato's *Republic*—the would-be founding father of an ideal totalitarian state—but the shadowy historical Socrates supposedly hailed by the oracle of Apollo's Delphi as the wisest of men—who knew what, and how much, he did not know. But the most important and immediate source of such agnostic ideas was surely Hume, while Hume's successor Kant may well be seen as the prime philosophical inspirer of religious reactions against them.

Huxley, as noted above, demanded that a thinker recognize and accept the limits of his knowledge. In taking it that these limits do not include either the findings of a general positive natural theology or the contents of a particular special divine revelation, Huxley was accepting a Humean critique. (It is significant that Huxley's study of Hume was the most sympathetic appraisal to be published in the 19th century.) Hume's critique is found in his *Enquiry Concerning Human Understanding* (first published in 1748 under another title), which attempts, in the manner of Locke and later Kant, to determine the limits of man's possible knowledge, and in his posthumous *Dialogues Concerning Natural Religion* (1779).

Two sections of the *Enquiry* refer directly to these limits: "Of a Particular Providence and of a Future State" and "Of Miracles." In the first, Hume starts from his basic Empiricist claims: that, generally, "matters of fact and real existence" cannot be known a priori (prior to and apart from experience); and that, particularly, one cannot know a priori that any thing or kind of thing either must be or cannot be the cause of any other thing or kind of thing. These considerations dispose of all the classical arguments for the existence of God other than the argument to design—that the structure and order of the universe and its constituents implies a design and a designer. But here, Hume urges, argument from experience can find no purchase because both the supposed effect, the universe as a whole, and the putative cause, God, are essentially unique and incomparable. Later, in his *Dialogues*, he develops the suggestion—which he acknowledges as stemming from the 3rd-century-BC philosopher Strato of Lampsacus, next but one after Aristotle as head of his Lyceum—that whatever order man discerns should be attributed to the universe itself and not to any postulated outside cause.

In the section "Of Miracles," Hume takes his stand on the agnostic principle: "A wise man . . . proportions his belief to the evidence." He then argues that no attempt to appeal to the alleged occurrence of miracles—conceived as authoritative endorsements by a power beyond and greater than nature—can succeed in establishing the truth of a claim to constitute special divine revelation. Hume's distinctive contribution here is methodological: the contention that the principles and presuppositions upon which the critical historian must rely, in first interpreting the remains of the past as historical evidence and in then building up from this evidence his account of what actually happened, are such as to make it impossible for him "to prove a miracle and make it a just foundation for any such system of religion."

In this two-phase attack, Hume challenged what was in his day, and long remained, the standard framework for systematic Christian apologetics. Indeed, the contrary contentions—of the possibilities, both of developing a positive natural theology and of establishing the authenticity of a supposed revelation by discovering endorsing miracles—were defined as essential and constitutive dogmas of Roman Catholicism by decrees of the first Vatican Council of 1869–70.

In view of the future history of Western thought, it must be emphasized that Hume's position, like Kant's, was (officially) that knowledge in this area is practically impossible. This thesis is stronger than that of those who simply confess that they just do not know:

The God-men say when die go sky
Through pearly gates where river flow,
The God-men say when die we fly
Just like eagle, hawk and crow—
Might be, might be; I don't know.

(Aboriginal song from the Northern Territory, Australia.)

Yet Hume's thesis was, on the other hand, weaker than that of his 20th-century neo-Humean successors, the logical positivists of the Vienna Circle, who held that any talk about a transcendent God must be "without literal significance." This view was presented brilliantly, and in an uncompromisingly drastic form, by A.J. Ayer in his *Language, Truth and Logic* (2nd ed., 1946). Similar conclusions were reached less high-handedly by several contributors to *New Essays in Philosophical Theology* (ed. by A. Flew and A. MacIntyre, 1955).

Antecedents of religious agnosticism. Looking backward, it is possible now to see what Hume himself did not know—that his attack on the possibility of a positive natural theology had to a considerable extent been anticipated by 14th-century Christian Scholastics: generally, by William of Ockham; and, with particular reference to the lack of a priori knowledge of causal relations, by Nicholas of Autrecourt.

The claims of Hume and Kant—and, indeed, those of the logical positivists and their successors—about the practical, or theoretical, impossibility of such knowledge should also be compared with the long traditions of "negative theology." Such a theology maintains that the nature of God passes so far beyond the comprehension of any creature that God must be characterized largely or entirely by indirection—as Infinite, as Incomparable, and so on. Thus Thomas Aquinas, the foremost Scholastic of the 13th century—who contrived on other occasions to tell his readers as much as his most practical church could wish about the deeds, plans, and demands of the Ineffable—nevertheless had his agnostic moments as well. But he did elaborate a doctrine of so-called analogical predication designed to show how it is possible for finite creatures to say and to understand something positive about God by means of comparisons with known entities or qualities. By contrast, the 12th-century philosopher Moses Maimonides, often dubbed anachronistically "the Jewish Aquinas," had been much more drastic than his successor, "the Christian Maimonides," in his insistence that everything that can be truly said about the Creator—not excluding the proposition that he exists—has to be construed as purely negative.

Although it is clearly possible to speak of a religious agnosticism without self-contradiction, the foregoing considerations suggest the difficulty of intermingling religious and agnostic concerns. The easiest case is that in which the religion is altogether without metaphysical content: thus, one of Huxley's biographers reports that the 19th-century Scottish sage Thomas Carlyle "taught him that a deep sense of religion was compatible with an entire absence of theology." The next simplest case is that in which worship is combined with a total noncommitment about the attributes of the object of worship:

He is not a male: He is not a female: He is not a neuter.
He is not to be seen: He neither is nor is not.
When He is sought He will take the form in which
He is sought.

It is indeed difficult to describe the name of the Lord.
(Poem from the Telugu, inscribed on a cult object in the Royal Ontario Museum.)

Tension
between
the
religious
and
agnostic

In its original setting this expression of a Hindu piety has power and charm. Yet its intellectual inadequacy becomes manifest when the doctrine of the Unknowable in the broad synthetic system of Herbert Spencer, a late-19th-century evolutionary philosopher, is recalled. For to affirm, as Spencer did, the existence of a being about whom absolutely nothing else can be said is a rather comical hypostatization (taking of an abstraction as real), which is surely indiscernible from affirming no being at all. Nor, perhaps, is it any great improvement to aver that much else can indeed be said about him, but only in words that here must bear an extraordinary meaning—unless, of course, those meanings can be specified. It was the suggestion that the goodness of God might thus be goodness in a quite unusual sense—what would elsewhere be called badness—that provoked the ire of John Stuart Mill, a mid-19th-century Empiricist, against certain developments from Sir William Hamilton's "Philosophy of the Unconditioned." Mill wrote: "I will call no being good, who is not what I mean when I apply that epithet to my fellow creatures."

The third, and surely the most promising, way in which the reconciliation may be attempted is by essaying some distinction between the essence or the internal nature of God and his external relations with the creation. It may then be suggested that, whereas man's knowledge of the former must be at least exiguous and at worst simply lacking, he can nevertheless know as much as he needs to know about the latter. As to the rest, he should be reverently agnostic.

INCOMPATIBILITY WITH FIDEISM

What cannot, however, by any means be squared with agnosticism in Huxley's sense are attempts to transmute the very limitations of human knowledge into grounds for accepting some wholly unevincenced faith. Such transmutations have been made in the interests of many mutually irreconcilable systems, and they apparently remain perennially attractive to thinkers with a different understanding of the ethics of belief.

St. Augustine of Hippo, near the end of the 5th century, felt the challenge of classical Skepticism in Cicero's *Academica* and *De natura deorum* ("On the Nature of the Gods") and gave his response in *Contra academicos* ("Against the Academics"). Skepticism, he thought, can be overcome only by revelation. The orthodox Muslim philosopher and mystic al-Ghazālī (late 11th century) deployed Skeptical arguments similarly, as a propaedeutic, or study preparatory to the acceptance of his rival revelation. With the rediscovery in the 16th century of the works of Sextus Empiricus, a course of Skepticism became commonly a preliminary to fideist commitment. Fideism is the thesis that truth in religion is accessible only to faith. The course persuaded the inquirer that reason cannot attain truth; yet certainty in true religious belief was still thought absolutely necessary for salvation. Martin Luther was speaking for his times (first half of the 16th century) when he thundered against the extremely cautious and restricted agnosticism of Desiderius Erasmus, foremost figure of the northern Renaissance: "Spiritus sanctus non est Scepticus" ("The Holy Spirit is not a Skeptic").

The only resort was, it seemed, faith: whether the easy-going Roman Catholic faith of the 16th-century Skeptic Michel de Montaigne; the polemical Counter-Reformation fervour of his contemporary Gentian Hervet, veteran of the Council of Trent and Latin translator of the *Adversus mathematicos* (1569; "Against the Pundits") of Sextus Empiricus; or, one century later, the vestigial Huguenot loyalty of Pierre Bayle—stocker of a great arsenal of secular argument, the *Dictionnaire historique et critique* (1695–97).

The decisive objection to any and every such rationally unfounded flight into faith was posed by John Locke, the 17th-century British Empiricist, who set a tone of coolly unfervent Anglicanism for the following century:

We may as well doubt of our being, as we can whether any revelation from God be true. So that faith is a settled and sure principle of assent and assurance, and leaves no room for doubt or hesitation. Only we must be sure that it be a divine revelation, and that we understand it right: else we

shall expose ourselves to all the extravagancy of enthusiasm, and all the error of wrong principles . . . (*An Essay Concerning Human Understanding*, Book IV, ch. xvi, 14).

Many thinkers have agreed that it is all very well to depreciate the potentialities of unaided natural reason and to insist that if man is to have any knowledge of God this must depend largely or wholly upon whatever special steps God may have taken to reveal himself; and they have also agreed that, if man's commitment of faith is not to be arbitrary and frivolous, then he clearly must have some good reason for believing, first, that there is a God who has so revealed himself, and, second, that his preferred candidate—and not one of its innumerable rivals—truly is that revelation.

These points are crucial—both for the appreciation of the history of ideas and for a reasonable contemporary understanding. Clearly, they were upheld by Aquinas, who in the *Summa contra gentiles*—before proceeding to present his own reasons for accepting Christianity, rather than Islām, as the authentic revelation—applied that same word frivolous to any such unsupportable commitment. Again, Judah ha-Levi, an early 12th-century Jewish poet and philosopher, has been authoritatively described as "concerned to bring men to a mystical and non-rational appreciation of religious truths" by his Skeptical attacks on the established Aristotelian natural theology. Yet ha-Levi's main work, entitled *Kuzari: The Book of Proof and Argument in Defence of the Despised Faith*, does in fact offer rational evidences of the truth of Judaism.

Skeptical propaedeutics to faith are now out of fashion. But the same challenge applies to all of the various responses to Kant's famous invitation: "I have found it necessary to deny *knowledge* in order to make room for *faith*" (Preface to the *Critique of Pure Reason*). Natural theology may, indeed, for Hume's reasons as reinforced by Kant, be impossible. The way of religious discovery may indeed be mystical experience, personal encounter with the divine Thou, or whatever else. But there is, and can be, no substitute for a man's having some sound grounds for identifying his experience not only as really mystical but also as experience of the real God; for holding his faith in some putative revelation not only to be real religious faith but also to be faith in a genuine revelation of the Real; and so on.

REJECTIONS OF THE AGNOSTIC PRINCIPLE

Anyone who insists on the foregoing touchstones may still be agnostic as well as religious. What cannot consist with agnosticism is a calculated commitment to faith seen as altogether without evidential warrant. The classic example of such commitment was provided in the 17th century by the Wager Argument of the French mathematician Blaise Pascal, who assumed, for the sake of the argument, that "reason can decide nothing here" and then urged that the only sane bet is Roman Catholicism; for we have nothing but this one short life to lose, and all eternity to win.

Pascal's Wager Argument is unsound because, on its own stated assumption of total and inescapable ignorance, the gambler is not entitled to limit the betting options to two—and to one particular two, at that. A similarly parochial inattention to the variety of candidacies for belief has characterized most fideists. Thus Søren Kierkegaard, an influential mid-19th-century Danish lay theologian, happily glorified the essential irrationality of religious faith, while taking it always that faith will, of course, be Protestant. Elsewhere, Pascal himself did notice, and tried to meet, some of the competition; his neglect here is the more remarkable because his wager was originally imported into Christendom from Islām (see Miguel Palacios, *Los precedentes de Pari de Pascal*). What makes it a landmark is that it constituted a direct, reasoned rejection of the agnostic principle—a rejection in which the reason proposed for believing was explicitly a motive for self-persuasion rather than some evidence of truth. Thus, when William James, a pre-World War I American psychologist and philosopher, in *The Will to Believe*, developed the best known systematic attack on that principle it was, rightly, Pascal whom he hailed as his first inspiration. James distinguished those hypotheses that, for any individual, represent psychologi-

Blaise
Pascal and
William
James

Locke's
definition
of faith

cally "live options" from those that do not, and he urged that, when evidential grounds are lacking, the choice may properly be determined by one's *passional nature*. For men often have to act on some unproved hypothesis, and sometimes such firm commitments may help to make the belief come true. Consider, for example, some belief that a man is trustworthy. The objections are that belief in the existence of God is clearly not of this case, and generally that to act decisively on some hypothesis does not require the agent to believe it as a known truth. (A.G.N.F.)

Atheism

The dialectic of the argument between forms of belief and unbelief raises questions concerning the most perspicuous delineation, or characterization, of atheism, agnosticism, and theism. It is necessary not only to probe the warrant for atheism but also carefully to consider what is the most adequate definition of atheism. This section will start with what have been some widely accepted, but still in various ways mistaken or misleading, definitions of atheism and move to more adequate formulations that better capture the full range of atheist thought and more clearly separate unbelief from belief and atheism from agnosticism. In the course of this delineation the section also will consider key arguments for and against atheism.

ATHEISM AS REJECTION OF RELIGIOUS BELIEFS

A central, common core of Judaism, Christianity, and Islām is the affirmation of the reality of one, and only one, God. Adherents of these faiths believe that there is a God who created the universe out of nothing and who has absolute sovereignty over all his creation; this includes, of course, human beings—who are not only utterly dependent on this creative power but also sinful and who, or so the faithful must believe, can only make adequate sense of their lives by accepting, without question, God's ordinances for them. The varieties of atheism are numerous, but all atheists reject such a set of beliefs.

Atheism, however, casts a wider net and rejects all belief in "spiritual beings," and to the extent that belief in spiritual beings is definitive of what it means for a system to be religious, atheism rejects religion. So atheism is not only a rejection of the central conceptions of Judeo-Christianity and Islām, it is, as well, a rejection of the religious beliefs of such African religions as that of the Dinka and the Nuer, of the anthropomorphic gods of classical Greece and Rome, and of the transcendental conceptions of Hinduism and Buddhism. Generally atheism is a denial of God or of the gods, and if religion is defined in terms of belief in spiritual beings, then atheism is the rejection of all religious belief.

It is necessary, however, if a tolerably adequate understanding of atheism is to be achieved, to give a reading to "rejection of religious belief" and to come to realize how the characterization of atheism as the denial of God or the gods is inadequate.

ATHEISM AND THEISM

To say that atheism is the denial of God or the gods and that it is the opposite of theism, a system of belief that affirms the reality of God and seeks to demonstrate his existence, is inadequate in a number of ways. First, not all theologians who regard themselves as defenders of the Christian faith or of Judaism or Islām regard themselves as defenders of theism. The influential 20th-century Protestant theologian Paul Tillich, for example, regards the God of theism as an idol and refuses to construe God as a being, even a supreme being, among beings or as an infinite being above finite beings. God, for him, is "being-itself," the ground of being and meaning. The particulars of Tillich's view are in certain ways idiosyncratic, as well as being obscure and problematic, but they have been influential; and his rejection of theism, while retaining a belief in God, is not eccentric in contemporary theology, though it may very well affront the plain believer.

Second, and more important, it is not the case that all theists seek to demonstrate or even in any way rationally to establish the existence of God. Many theists regard such

a demonstration as impossible, and fideistic believers (e.g., Johann Hamann and Søren Kierkegaard) regard such a demonstration, even if it were possible, as undesirable, for in their view it would undermine faith. If it could be proved, or known for certain, that God exists, people would not be in a position to accept him as their sovereign Lord humbly on faith with all the risks that entails. There are theologians who have argued that for genuine faith to be possible God must necessarily be a hidden God, the mysterious ultimate reality, whose existence and authority must be accepted simply on faith. This fideistic view has not, of course, gone without challenge from inside the major faiths, but it is of sufficient importance to make the above characterization of atheism inadequate.

Finally, and most important, not all denials of God are denials of his existence. Believers sometimes deny God while not being at all in a state of doubt that God exists. They either willfully reject what they take to be his authority by not acting in accordance with what they take to be his will, or else they simply live their lives as if God did not exist. In this important way they deny him. Such deniers are not atheists (unless we wish, misleadingly, to call them "practical atheists"). They are not even agnostics. They do not question that God exists; they deny him in other ways. An atheist denies the existence of God. As it is frequently said, atheists believe that it is false that God exists, or that God's existence is a speculative hypothesis of an extremely low order of probability.

Yet it remains the case that such a characterization of atheism is inadequate in other ways. For one it is too narrow. There are atheists who believe that the very concept of God, at least in developed and less anthropomorphic forms of Judeo-Christianity and Islām, is so incoherent that certain central religious claims, such as "God is my creator to whom everything is owed," are not genuine truth-claims; i.e., the claims could not be either true or false. Believers hold that such religious propositions are true, some atheists believe that they are false, and there are agnostics who cannot make up their minds whether to believe that they are true or false. (Agnostics think that the propositions are one or the other but believe that it is not possible to determine which.) But all three are mistaken, some atheists argue, for such putative truth-claims are not sufficiently intelligible to be genuine truth-claims that are either true or false. In reality there is nothing in them to be believed or disbelieved, though there is for the believer the powerful and humanly comforting illusion that there is. Such an atheism, it should be added, rooted for some conceptions of God in considerations about intelligibility and what it makes sense to say, has been strongly resisted by some pragmatists and logical empiricists.

While the above considerations about atheism and intelligibility show the second characterization of atheism to be too narrow, it is also the case that this characterization is in a way too broad. For there are fideistic believers, who quite unequivocally believe that when looked at objectively the proposition that God exists has a very low probability weight. They believe in God not because it is probable that he exists—they think it more probable that he does not—but because belief is thought by them to be necessary to make sense of human life. The second characterization of atheism does not distinguish a fideistic believer (a Blaise Pascal or a Kierkegaard) or an agnostic (a T.H. Huxley or a Leslie Stephen) from an atheist such as Baron d'Holbach or Thomas Paine. All believe that "There is a God" and "God protects humankind," however emotionally important they may be, are speculative hypotheses of an extremely low order of probability. But this, since it does not distinguish believers from nonbelievers and does not distinguish agnostics from atheists, cannot be an adequate characterization of atheism.

It may be retorted that to avoid apriorism and dogmatic atheism the existence of God should be regarded as a hypothesis. There are no ontological (purely a priori) proofs or disproofs of God's existence. It is not reasonable to rule in advance that it makes no sense to say that God exists. What the atheist can reasonably claim is that there is no evidence that there is a God, and against that background he may very well be justified in asserting that there is

Atheism
and
fideism

no God. It has been argued, however, that it is simply dogmatic for an atheist to assert that no possible evidence could ever give one grounds for believing in God. Instead, atheists should justify their unbelief by showing (if they can) how the assertion is well-taken that there is no evidence that would warrant a belief in God. If atheism is justified, the atheist will have shown that in fact there is no adequate evidence for the belief that God exists, but it should not be part of his task to try to show that there could not be any evidence for the existence of God. If the atheist could somehow survive the death of his present body (assuming that such talk makes sense) and come, much to his surprise, to stand in the presence of God, his answer should be, "Oh! Lord, you didn't give me enough evidence!" He would have been mistaken, and realize that he had been mistaken, in his judgment that God did not exist. Still, he would not have been unjustified, in the light of the evidence available to him during his earthly life, in believing as he did. Not having any such postmortem experiences of the presence of God (assuming that he could have them), what he should say, as things stand and in the face of the evidence he actually has and is likely to be able to get, is that it is false that God exists. (Every time one legitimately asserts that a proposition is false one need not be certain that it is false. "Knowing with certainty" is not a pleonasm.) The claim is that this tentative posture is the reasonable position for the atheist to take.

Burden-of-proof argument

An atheist who argues in this manner may also make a distinctive burden-of-proof argument. Given that God (if there is one) is by definition a very *recherché* reality—a reality that must be (for there to be such a reality) transcendent to the world—the burden of proof is not on the atheist to give grounds for believing that there is no reality of that order. Rather, the burden of proof is on the believer to give some evidence for God's existence; *i.e.*, that there is such a reality. Given what God must be, if there is a God, the theist needs to present the evidence, for such a very strange reality. He needs to show that there is more in the world than is disclosed by common experience. The empirical method, and the empirical method alone, such an atheist asserts, affords a reliable method for establishing what is in fact the case. To the claim of the theist that there are in addition to varieties of empirical facts "spiritual facts" or "transcendent facts," such as it being the case that there is a supernatural, self-existent, eternal power, the atheist can assert that such "facts" have not been shown.

Fallibilistic atheism

It will, however, be argued by such atheists, against what they take to be dogmatic aprioristic atheists, that the atheist should be a fallibilist and remain open-minded about what the future may bring. There may, after all, be such transcendent facts, such metaphysical realities. It is not that such a fallibilistic atheist is really an agnostic who believes that he is not justified in either asserting that God exists or denying that he exists and that what he must reasonably do is suspend belief. On the contrary, such an atheist believes that he has very good grounds indeed, as things stand, for denying the existence of God. But he will, on the second conceptualization of what it is to be an atheist, not deny that things could be otherwise and that, if they were, he would be justified in believing in God or at least would no longer be justified in asserting that it is false that there is a God. Using reliable empirical techniques, proven methods for establishing matters of fact, the fallibilistic atheist has found nothing in the universe to make a belief that God exists justifiable or even, everything considered, the most rational option of the various options. He therefore draws the atheistical conclusion (also keeping in mind his burden-of-proof argument) that God does not exist. But he does not dogmatically in a priori fashion deny the existence of God. He remains a thorough and consistent fallibilist.

ATHEISM AND METAPHYSICAL BELIEFS

Such a form of atheism (the atheism of those pragmatists who are also naturalistic humanists), though less inadequate than the first formation of atheism, is still inadequate. God in developed forms of Judaism, Christianity, and Islām is not, like Zeus or Wotan, construed in a

relatively plain anthropomorphic way. Nothing that could count as "God" in such religions could possibly be observed, literally encountered, or detected in the universe. God, in such a conception, is utterly transcendent to the world; he is conceived of as "pure spirit," an infinite individual who created the universe out of nothing and who is distinct from the universe. Such a reality—a reality that is taken to be an ultimate mystery—could not be identified as objects or processes in the universe can be identified. There can be no pointing at or to God, no ostensive teaching of "God," to show what is meant. The word God can only be taught intralinguistically. "God" is taught to someone who does not understand what the word means by the use of descriptions such as "the maker of the universe," "the eternal, utterly independent being upon whom all other beings depend," "the first cause," "the sole ultimate reality," or "a self-caused being." For someone who does not understand such descriptions, there can be no understanding of the concept of God. But the key terms of such descriptions are themselves no more capable of ostensive definition (of having their referents pointed out) than is "God," where that term is not, like "Zeus," construed anthropomorphically. (That does not mean that anyone has actually pointed to Zeus or observed Zeus but that one knows what it would be like to do so.)

In coming to understand what is meant by "God" in such discourses, it must be understood that God, whatever else he is, is a being that could not possibly be seen or be in any way else observed. He could not be anything material or empirical, and he is said by believers to be an intractable mystery. A nonmysterious God would not be the God of Judaism, Christianity, and Islām.

This, in effect, makes it a mistake to claim that the existence of God can rightly be treated as a hypothesis and makes it a mistake to claim that, by the use of the experimental method or some other determinate empirical method, the existence of God can be confirmed or disconfirmed as can the existence of an empirical reality. The retort made by some atheists, who also like pragmatists remain thoroughgoing fallibilists, is that such a proposed way of coming to know, or failing to come to know, God makes no sense for anyone who understands what kind of reality God is supposed to be. Anything whose existence could be so verified would not be the God of Judeo-Christianity. God could not be a reality whose presence is even faintly adumbrated in experience, for anything that could even count as the God of Judeo-Christianity must be transcendent to the world. Anything that could actually be encountered or experienced could not be God.

At the very heart of a religion such as Christianity there stands a metaphysical belief in a reality that is alleged to transcend the empirical world. It is the metaphysical belief that there is an eternal, ever-present creative source and sustainer of the universe. The problem is how it is possible to know or reasonably believe that such a reality exists or even to understand what such talk is about.

It is not that God is like a theoretical entity in physics such as a proton or a neutrino. They are, where they are construed as realities rather than as heuristically useful conceptual fictions, thought to be part of the actual furniture of the universe. They are not said to be transcendent to the universe, but rather are invisible entities in the universe logically on a par with specks of dust and grains of sand, only much, much smaller. They are on the same continuum; they are not a different kind of reality. It is only the case that they, as a matter of fact, cannot be seen. Indeed no one has an understanding of what it would be like to see a proton or a neutrino—in that way they are like God—and no provision is made in physical theory for seeing them. Still, there is no logical ban on seeing them as there is on seeing God. They are among the things in the universe, and thus, though they are invisible, they can be postulated as causes of things that are seen. Since this is so it becomes at least logically possible indirectly to verify by empirical methods the existence of such realities. It is also the case that there is no logical ban on establishing what is necessary to establish a causal connection, namely a constant conjunction of two discrete empirical realities. But no such constant conjunction can

God as "pure spirit"

God and theoretical entities

be established or even intelligibly asserted between God and the universe, and thus the existence of God is not even indirectly verifiable. God is not a discrete empirical thing or being, and the universe is not a gigantic thing or process over and above the things and processes in the universe of which it makes sense to say that the universe has or had a cause. But then there is no way, directly or indirectly, that even the probability that there is a God could be empirically established.

ATHEISM AND INTUITIVE KNOWLEDGE

The gnostic may reply that there is a nonempirical way of establishing or making it probable that God exists. The claim is that there are truths about the nature of the cosmos neither capable of verification nor standing in need of verification. There is, gnostics claim against empiricists, knowledge of the world that transcends experience and comprehends the sorry scheme of things entire.

Since the thorough probings of such epistemological foundations by David Hume and Immanuel Kant, scepticism about how, and indeed even that, such knowledge is possible is very strong indeed. With respect to knowledge of God in particular, both Hume and Kant provide powerful critiques of the traditional attempts to prove the existence of God (notwithstanding the fact that Kant remained a Christian). While some of the details of their arguments have been rejected and refinements rooted in their argumentative procedure have been developed, there is a considerable consensus among philosophers and theologians that arguments of the general type as those developed by Hume and Kant show that no proof of God's existence is possible. Alternatively, to speak of "intuitive knowledge" (an intuitive grasp of being or of an intuition of the reality of the divine being) is to make an appeal to something that is not sufficiently clear to be of any value in establishing anything.

Prior to the rise of anthropology and the scientific study of religion, an appeal to revelation and authority as a substitute for knowledge or warranted belief might have been thought to have considerable force. But with a knowledge of other religions and their associated appeals to revealed truth, such arguments are without probative force. Claimed, or alleged, revelations are many, diverse, and not infrequently conflicting; without going in a small and vicious circle, it cannot be claimed, simply by appealing to a given putative revelation, that the revelation is the "true revelation" or the "genuine revelation" and that others are mistaken or, where nonconflicting, mere approximations to the truth. Similar things need to be said for religious authority. Moreover, it is at best problematic whether faith could sanction speaking of testing the genuineness of revelation or of the acceptability of religious authority. Indeed, if something is a "genuine revelation," there is no using reason to assess it. But the predicament is that plainly, as a matter of anthropological fact, there is a diverse and sometimes conflicting field of alleged revelations with no way of deciding or even having a reasonable hunch which, if any, of the candidate revelations is the genuine article. But even if the necessity for tests for the genuineness of revelation is allowed, there still is a claim that clearly will not do, for such a procedure would make an appeal to revelation and authority supererogatory. It is, where such tests are allowed, not revelation or authority that can warrant the most fundamental religious truths on which the rest depend. It is something else—that which establishes the genuineness of the revelation or authority—that guarantees these religious truths (if such there be), including the proposition that God exists. But the question returns, like the repressed, what that fundamental guarantee is or could be. Perhaps such a belief is nothing more than a cultural myth. There is, as has been shown, neither empirical nor a priori knowledge of God, and talk of intuitive knowledge is without logical force.

If these considerations are near to the mark, it is unclear what it means to say, as some agnostics and even atheists have, that they are sceptical God-seekers who simply have not found, after a careful examination, enough evidence to make belief in God a warranted or even a reasonable belief. It is unclear what it would be like to have, or for

that matter fail to have, evidence for the existence of God. It is not that the God-seeker has to be able to give the evidence, for if that were so no search would be necessary, but that he, or at least somebody, must be able to conceive what would count as evidence if he had it so that he (and others) have some idea of what to look for. But it appears to be just that which cannot be done.

Perhaps there is room for the retort that it is enough for the God-seeker not to accept any logical ban on the possibility of there being evidence. He need not understand what it would be like to have evidence in this domain. But, in turn, when one considers what kind of transcendent reality God is said to be, there seems to be an implicit logical ban on there being empirical evidence (a pleonasm) for his existence. It would seem plausible to assert that there is such a ban, though any such assertion should, of course, be made in a tentative way.

Someone trying to give empirical anchorage to talk of God might give the following hypothetical case. (It is, however, important in considering the case to keep in mind that things even remotely like what is described do not happen.) If thousands of people were standing out under the starry skies and all saw—the thing went on before their very eyes—a set of stars rearrange themselves to spell out "God," they would indeed rightly be utterly astonished and think that they had gone mad. Even if they could somehow assure themselves that this was not in some way a form of mass hallucination—how they could do this is not evident—such an experience would not constitute evidence for the existence of God, for they still would be without a clue as to what could be meant by speaking of an infinite individual transcendent transcendent to the world. Such an observation (the stars so rearranging themselves), no matter how well confirmed, would not ostensibly fix the reference range of "God." Talk of such an infinite individual is utterly incomprehensible and has every appearance of being incoherent. No one knows what he is talking about in speaking of such a transcendent reality. All they would know is that something very strange indeed had happened. The doubt arises whether believers, or indeed anyone else in terms acceptable to believers, can give an intelligible account of the concept of God or of what belief in God comes to once God is de-anthropomorphized.

COMPREHENSIVE DEFINITION OF ATHEISM

Reflection on this should lead to a more adequate statement of what atheism is and indeed as well to what an agnostic or religious response to atheism should be. Instead of saying that an atheist is someone who believes that it is false or probably false that there is a God, a more adequate characterization of atheism consists in the more complex claim that to be an atheist is to be someone who rejects belief in God for the following reasons (which reason is stressed depends on how God is being conceived): for an anthropomorphic God, the atheist rejects belief in God because it is false or probably false that there is a God; for a nonanthropomorphic God (the God of Luther and Calvin, Aquinas, and Maimonides), he rejects belief in God because the concept of such a God is either meaningless, unintelligible, contradictory, incomprehensible, or incoherent; for the God portrayed by some modern or contemporary theologians or philosophers, he rejects belief in God because the concept of God in question is such that it merely masks an atheistic substance—e.g., "God" is just another name for love, or "God" is simply a symbolic term for moral ideals.

This atheism is a much more complex notion, as are its various reflective rejections. It is clear from what has been said about the concept of God in developed forms of Judeo-Christianity that the more crucial form of atheist rejection is not the assertion that it is false that there is a God but instead the rejection of belief in God because the concept of God is said not to make sense—to be in some important way incoherent or unintelligible.

Such a broader conception of atheism, of course, includes everyone who is an atheist in the narrower sense, but the converse does not obtain. Moreover, this conception of atheism does not have to say that religious claims are

Influence
of Hume
and Kant

Revelation
and
religious
authority

Reasons
for
rejecting
belief
in God

meaningless. The more typical and less paradoxical and tendentious claim is that utterances such as "There is an infinite, eternal creator of the universe" are incoherent and that the conception of God reflected in such a claim is unintelligible, and in that important sense the claim is inconceivable and incredible—incapable of being a rational object of belief for a philosophically and scientifically sophisticated person touched by modernity. It is this that is a central belief of many contemporary atheists. There are good empirical grounds for believing that there are no Zeus-like spiritual beings, and as this last, more ramified form of atheism avers, if there are sound grounds for believing that the nonanthropomorphic or at least radically less anthropomorphic conceptions of God are incoherent or unintelligible, the atheist has the strongest grounds for rejecting belief in God.

Atheism is a critique and a denial of the central metaphysical beliefs of systems of salvation involving a belief in God or spiritual beings, but a sophisticated atheist does not simply claim that all such cosmological claims are false but takes it that some are so problematical that, while purporting to be factual, they actually do not succeed in making a coherent factual claim. The claims, in an important sense, do not make sense, and while believers are under the illusion that there is something intelligible to be believed in, in reality there is not. These seemingly grand cosmological claims are in reality best understood as myths or ideological claims reflecting a confused understanding of their utterers' situation.

It is not a well-taken rejoinder to atheistic critiques to say, as have some contemporary Protestant theologians, that belief in God is the worst form of atheism and idolatry, since the language of Jewish and Christian belief, including such sentences as "God exists" and "God created the world," is not to be taken literally but symbolically and metaphorically. Christianity, as Reinhold Niebuhr, a theologian who defends such views, once put it, is "true myth." The claims of religion are not, on such account, to be understood as metaphysical claims trying to convey extraordinary facts but as metaphorical and analogical claims that are not understandable in any other terms. But if something is a metaphor it must at least in principle be possible to say what it is a metaphor of. Thus metaphors cannot be understandable only in metaphorical terms. There can be no unparaphrasable metaphors or symbolic expressions though, what is something else again, a user of such expressions may not be capable on demand of supplying that paraphrase. Moreover, if the language of religion becomes simply the language of myth and religious beliefs are viewed simply as powerful and often humanly compelling myths, then they are conceptions that in reality have only an atheistic substance. The believer is making no cosmological claim that the atheist is not; it is just that his talk, including his unelucidated talk of "true myths," is language that for many people has a more powerful emotive force.

Agnosticism has a parallel development to that of atheism. An agnostic, like an atheist, asserts either that he does not know that God exists—or, more typically, that he cannot know or have sound reasons for believing that God exists—but unlike the atheist he does not think that he is justified in saying that God does not exist or, stronger still, that God cannot exist. Similarly, while some contemporary atheists say that the concept of God in developed theism does not make sense and thus that Jewish, Christian, and Islāmic beliefs must be rejected, many contemporary agnostics believe that the concept of God is radically problematic. They maintain that they are not in a position to be able to decide whether, on the one hand, the terms and concepts of such religions are so problematic that such religious beliefs do not make sense or whether, on the other, though the talk is indeed radically paradoxical and in many ways incomprehensible, such talk has sufficient coherence to make reasonable a belief in an ultimate mystery. Such an agnostic recognizes that the puzzles about God cut deeper than perplexities concerning whether it is possible to attain adequate evidence for God's existence. Rather, he sees the need to exhibit an adequate nonanthropomorphic, extralinguistic referent for "God."

(This need not commit him to the belief that there are any observations independent of theory.) Believers think that, though God is a mystery, such a referent has been secured, though what it is remains a mystery. Atheists, by contrast, believe that it has not been, and indeed some of them believe that it cannot be, secured. To talk about mystery, they maintain, is just an evasive way of talking about what is not understood. Contemporary agnostics (those agnostics who parallel the atheists characterized above) remain in doubt and are convinced that there is no rational way of resolving the doubt about whether talk in a halting fashion of God just barely secures such reference or whether it, after all, fails and that nothing religiously acceptable is referred to by "God."

Intense religious commitment, as the history of fideism makes evident, has sometimes gone with deep scepticism concerning man's capacity to know God. It is agreed by all parties to the dispute between belief and unbelief that religious claims are paradoxical and that God is a mystery. Furthermore, criteria for what is meaningless and what is not or for what is intelligible and what is not are deeply contested. It is perhaps fair enough to say that there are no generally accepted criteria.

Keeping these diverse considerations in mind in the arguments between belief, agnosticism, and atheism, it is crucial to ask whether there is any good reason at all to believe that there is a personal creative reality that is beyond the bounds of space and time and transcendent to the world. Is there even a sufficient understanding of such talk so that such a reality can be the object of religious commitment? (One cannot have faith in or take on faith what one does not at all understand. People must at least in some way understand what it is that they are to have faith in to be able to have faith in it. If a person is asked to trust Irglig, he cannot do so no matter how strongly he wants to take something simply on trust.)

It appears to be a brute fact that there just is that indefinitely immense collection of finite and contingent masses or conglomerations of things and processes the phrase "the universe" refers to. People can come to feel wonder, awe, and puzzlement that there is a universe at all. But that fact, or the very fact that there is a world at all, does not license the claim that there is a noncontingent reality on which the world (the sorry collection of things entire) depends. It is not even clear that such a sense of contingency gives an understanding of what such a noncontingent thing could be. Some atheists think that the reference range of "God" is so indeterminate and the concept of God so problematical that it is impossible for someone fully aware of that reasonably to believe in God; believers, by contrast, think that, though the reference range of "God" is indeterminate, it is not so indeterminate and the concept of God so problematic as to make belief irrational or incoherent. It is known, they claim, that talk of God is problematic, but it is not known, and cannot be known, whether it is so problematic as to be without a religiously appropriate sense. Agnostics, in turn, say that there is no reasonable decision procedure. It is not known and cannot be ascertained whether or not "God" secures a religiously adequate referent. What needs to be kept in mind, in reflecting on this issue, is whether a "contingent thing" is a pleonasm and "infinite reality" is without sense and whether, when people go beyond anthropomorphism (or try to go beyond it), it is possible to have a sufficient understanding of what is referred to by "God" to make faith a coherent possibility.

Finally, it will not do to take a Pascalian or Dostoyevskian turn and claim that, intellectual absurdity or not, religious belief is necessary, since without belief in God morality does not make sense and life is meaningless. That claim is false, for even if there is no purpose to life there are purposes in life—things people care about and want to do—that can remain perfectly intact even in a godless world. God or no God, immortality or no immortality, it is vile to torture people just for the fun of it, and friendship, solidarity, love, and the attainment of self-respect are human goods even in an utterly godless world. There are intellectual puzzles about how people know that these things are good, but that is doubly true for the distinctive

Atheism
and
agnosticism

Problems
of the term
"God"

claims of a religious ethic. The point is that these things remain desirable and that life can have a point even in the absence of God. (K.E.N.)

BIBLIOGRAPHY

Nature worship: Apart from some older works about particular forms of nature worship, the most important discussions of this form of religion and the related nature mythology appear in journals. JAMES G. FRAZER, *The Worship of Nature* (1926), is a classic work mainly concerned with the worship of the heavens, the sun, and the earth; and *The Golden Bough*, 3rd ed. rev., 12 vol. (1907–15; abridged ed., 1922 and 1959), contains an important discussion of nature gods, especially vegetation gods, and their cults. Important references to the worship of nature may be found under various headings in *The Mythology of All Races*, ed. by LOUIS H. GRAY, 13 vol. (1916–32); and *The Encyclopaedia of Religion and Ethics*, ed. by JAMES HASTINGS, 13 vol. (1908–26, reprinted 1955).

Animism: The original and classic source is E.B. TYLOR, *Primitive Culture*, 2 vol. (1871 and later editions, reprinted 1958). For the "pre-animism" thesis, see R.R. MARETT, *The Threshold of Religion*, 4th ed. (1929). An extended analysis and review of theories may be found in ADOLF E. JENSEN, *Mythos und Kult bei Naturvölkern*, 2nd ed. (1960; Eng. trans., *Myth and Cult Among Primitive Peoples*, 1963); or for a short review, see E.E. EVANS-PRITCHARD, *Theories of Primitive Religion* (1965). Still to be recommended for an overview is ROBERT H. LOWIE, *Primitive Religion*, new ed. (1970). An ample source for the animism of China is the 5th volume of J.J.M. DE GROOT's monumental study, *The Religious System of China* (1907, reprinted 1969); and for Burma the best introduction is M.E. SPIRO, *Burmese Supernaturalism* (1967). Ethnographic studies of animistic peoples abound; for an annotated bibliography, see WILLIAM A. LESSA and EVON Z. VOGT, *Reader in Comparative Religion*, 2nd ed., pp. 640–645 (1965). A provocative consideration of the relation of animism to modern world views is presented in JACQUES MONOD, *Le Hasard et la nécessité* (1970; Eng. trans., *Chance and Necessity*, 1971).

Totemism: FRANZ BOAS, "The Origin of Totemism," *Am. Anthropol.*, 18:319–326 (1916), contains a variety of ideas and objects defined as totemism, and thus maintains little unity; A.P. ELKIN, "Studies in Australian Totemism: The Nature of Australian Totemism," *Oceania*, 4:113–131 (1933–34); E.E. EVANS-PRITCHARD, "Nuer Totemism," *Annali Lateran.*, 13:225–248 (1949), describes the manifestations of totemism combined with the conception of the spirit in the "Nilot" tribe; J.V. FERREIRA, *Totemism in India* (1965), a critical evaluation of hitherto existing works on totemism in general and that of India in particular; R. FIRTH, "Totemism in Polynesia," *Oceania*, 1:291–321, 377–398 vol. 1 (1930–31), a useful survey article; J.L. FISCHER, "Totemism on Truk and Ponape," *Am. Anthropol.*, 59:250–265 (1957), describes and interprets the highly contrasting forms of totemism found in Micronesia, using not only the unusual sociological-ideological organization but also containing psychological aspects. G. FOSTER, "Nagualism in Mexico and Guatemala," *Acta Am.*, 2:85–103 (1944), deals with important borderline cases of totemism with particular regard to the problem of personal totemism; J.G. FRAZER, *Totemism and Exogamy*, 4 vol. (1910) and *Totemica: A Supplement to Totemism and Exogamy* (1937), comprehensive and informative reference works although the hypotheses are now out of date; A.A. GOLDENWEISER, "Totemism: An Analytic Study," *J. Am. Folklore*, 23:179–293 (1910); "Totemism," *Encyclopaedia of the Social Sciences*, vol. 14 (1934); J. HAEKEL, "Der heutige Stand des Totemismusproblems," *Mitt. Anthropol. Ges. Wien*, 82:33–49 (1952), attempts to give a critical examination with concrete examples of the complex question in its various forms; CLAUDE LÉVI-STRAUSS, *Le Totémisme aujourd'hui* (1962; Eng. trans., *Totemism*, 1963), contains a detailed critical evaluation of existing hypotheses of Anglo-American and French authors; R. PIDDINGTON, *An Introduction to Social Anthropology* 1:200–206 (1950), offers a short but sufficient characterization of the totemic phenomena, the difficulty in defining it, its great variability, and some concrete examples.

Ancestor worship: J.T. ADDISON, *Chinese Ancestor Worship* (1925), descriptive information on traditional practices in China; E. BENDANN, *Death Customs* (1930, reprinted 1969), descriptive material useful in distinguishing between death cults and ancestor worship; R.F. FORTUNE, *Manus Religion* (1935, reprinted 1965), a detailed account, including information on the role of ancestor worship as a sanction for ethical behaviour; J.G. FRAZER, *The Belief in Immortality and the Worship of the Dead*, 3 vol. (1913–24, reprinted 1968), a classic work presenting extensive information on its subject among societies of the world; J.R. GOODY, *Death, Property and the Ancestors* (1962), a detailed account of mortuary customs of the Lodagaa of West Africa; B. MALINOWSKI, "Baloma, the Spirits of the Dead in the Trobriand Islands," in *Magic, Science and Religion and Other Essays* (1948),

Polytheism: S.G.F. BRANDON (ed.), *A Dictionary of Comparative Religion* (1970), contains articles on the various gods and also on theories, and these have bibliographical sections. A useful compendium is the *Larousse Encyclopedia of Mythology* (1959). One example of the numerous recent anthropological literature is G.E. SWANSON, *The Birth of the Gods: The Origin of Primitive Beliefs* (1960).

Pantheism and panentheism: CHARLES HARTSHORNE and W.L. REESE, *Philosophers Speak of God* (1953), offers an extensive historical exploration of pantheism, panentheism, and Classical Theism. The fundamental basis of panentheism is discussed not only in the epilogue of the above volume, but in many other works by CHARLES HARTSHORNE, including *The Divine Relativity* (1948) and *The Logic of Perfection* (1962). For the relation of mysticism to pantheism, see W.T. STACE, *Mysticism and Philosophy* (1960). For information concerning any of the philosophers mentioned, reference may be made to their individual entries in *The Encyclopedia of Philosophy*, 8 vol., ed. by PAUL EDWARDS (1967); the *Enciclopedia filosofica*, 6 vol., 2nd ed., ed. by G.C. SANSONI (1967); or the *Diccionario de filosofía*, 2 vol., ed. by JOSE FERRATER MORA (1965).

Religious dualism: UGO BIANCHI, *Il dualismo religioso: saggio storico ed etnologico* (1958), discusses the "dualistic area" extending from ancient Greece to Iran, east European folklore, north and Central Asia, and North America; see also his "Le dualisme en histoire des religions," *Revue de l'histoire des religions*, 159:1–46 (1961); and *Le origini dello gnosticismo* (1967), a collection of papers (in French, German, English, and Italian) presented at the Colloquium of Messina, April 1966, many of which are devoted to dualism in various religions. MIRCEA ELIADE, "Prolegomenon to Religious Dualism: Dyads and Polarities," *The Quest: History and Meaning in Religion*, ch. 8 (1969), is concerned not only with dualism proper but also with the functions of "duality"; his *De Zalmoxis à Gengis-Khan*, ch. 2–3 (1970), is a study of dualism in folklore and ethnology. SIMONE PETREMENT, *Le Dualisme dans l'histoire de la philosophie et des religions* (1946), and *Le Dualisme chez Platon, les Gnostiques et les Manichéens* (1947), are two important general surveys but do not sufficiently distinguish the different meanings of dualism in the philosophical and the religious-historical terminologies. For an analytic exposition of the Gnostic ideology, with modern analogies, see HANS JONAS, *The Gnostic Religion*, 2nd ed. (1963); for a discussion of the varieties of Iranian dualism, R.C. ZAEHNER, *Zurvan: A Zoroastrian Dilemma* (1955). JACQUES DUCHESNE-GUILLEMIN, *The Western Response to Zoroaster* (1958), deals with the history of the problem of Iranian dualism. Other works include: GEO WIDEN-GREN, "Der iranische Hintergrund der Gnosis," in *Zeitschrift für Religions- und Geistesgeschichte*, 4:97–114 (1952), on dualism in the Indian *Upanisads*; F.K. NUMAZAWA, *Die Weltanfänge in der japanischen Mythologie . . .* (1946), a comparative, ethnological appreciation of the Yin–Yang opposition; MARCEL GRIAULE and GERMAINE DIETERLEN, *Le Renard Pâle*, vol. 1, fasc. 1 (1965), an account of dualism in the ontology and the mythology of the Dogon of West Sudan; HELMER RINGGREN, "Dualism," *The Faith of Qumran*, ch. 2 (1963), a study of Qumranic dualism; and R.M. GRANT, *Gnosticism and Early Christianity*, rev. ed. (1966).

Monotheism: General works include: JOSIAH ROYCE, "Monotheism," in the *Encyclopaedia of Religion and Ethics*, vol. 8 (1928); "Monotheismus und Polytheismus," in *Religion in Geschichte und Gegenwart*, vol. 4 (1913); T.P. VAN BAAREN, *Doolhof der goden* (1960); G. VAN DER LEEUW, *Phänomenologie der Religion* (1933; Eng. trans., *Religion in Essence and Manifestation*, 2 vol., 1963); and R. OTTO, *Das Heilige* (1917; Eng. trans., *The Idea of the Holy*, 2nd ed., 1950). For primitive religions, see T.P. VAN BAAREN, *Menschen wie wir* (1964); and P. RADIN, *Monotheism Among Primitive Peoples* (1954); on the high gods, see H. ZWICKER, *Das Höchste Wesen* (1970); and E.O. JAMES, *The Concept of Deity* (1950), the only general systematic study of recent date treating the problems of monotheism. H.R. NIEBUHR, *Radical Monotheism and Western Culture* (1960), is a modern, incisive Protestant theological presentation of absolute monotheism.

Theism: The classic recent statement of God's transcendence is A.M. FARRER, *Finite and Infinite*, 2nd ed. (1959), a difficult but essential book; C.A. CAMPBELL, *On Selfhood and Godhood* (1957), is an exceptionally lucid presentation that allows for the distinctness of finite beings; see also further statements in WILLIAM TEMPLE, *Nature, Man and God* (1934); H.H. FARMER, *God and Men* (1947); and H.D. LEWIS, *Philosophy of Religion* (1965). A SETH PRINGLE-PATTISON presents the more traditional Idealist view in *The Idea of God in the Light of Recent Philosophy* (1920). An Idealism stressing the immediate awareness of other minds and of God is found in W.E. HOCKING, *The Meaning of God in Human Experience* (1912); a presentation similarly starting from Empiricism and science that culminates in a "Cosmic Teleology" is that of F.R. TENNANT, *Philosophical*

Theology, 2 vol. (1928–30). E.S. BRIGHTMAN, *The Problem of God* (1930), treats God as a limited being (finitism).

Deism: JOHN LELAND, *A View of the Principal Deistical Writers . . .*, 3rd ed., 3 vol. (1754; also 1837 ed.), the first historical account; FRITZ MAUTHNER, *Der Atheismus und seine Geschichte im Abendlande*, 4 vol. (1921–23), a complete history; ERNST CASSIRER, *Die Philosophie der Aufklärung* (1932; Eng. trans., *The Philosophy of the Enlightenment*, 1951), a description of Deism and its philosophical background; HAROLD G. NICOLSON, *The Age of Reason* (1960), on the nature of 18th-century Rationalism and its connection with Deism; JAMES COLLINS, *God in Modern Philosophy* (1959), a full history of Deism, here called “theism,” from Nicolas of Cusa to contemporary theological theories; JOHN ORR, *English Deism: Its Roots and Its Fruits* (1934); GOTTHARD V. LECHLER, *Geschichte des englischen Deismus* (1841), the first full history after the end of Deism; HERBERT OF CHERBURY, *De Veritate* (1624; Eng. trans. by MEYRICK H. CARRE, *On Truth*, 1937), the first English translation of the reputedly “first” classic expression of Deism; MARIO M. ROSSI, *La vita, le opere, i tempi di Edoardo Herbert di Chirbury*, 3 vol. (1947), and *Alle fonti del deismo e del materialismo moderno* (1942), two works that describe Herbert’s life and Deistic thought against the background of the history of Deism and the attitude of the church. DAVID HUME, *Dialogues Concerning Natural Religion*, 2nd ed. with suppl. (1947), the beginning of the Deist’s self-criticism; THOMAS PAINE, *The Age of Reason*, 3 pt. (1794–1811), the work most influential on the Deism of common people; JOHN S. SPINK, *French Free-Thought from Gassendi to Voltaire* (1960), on French Deism; HENRY E. ALLISON, *Lessing and the Enlightenment* (1966); IMMANUEL KANT, *Die Religion innerhalb der Grenzen der blossen Vernunft* (1793; Eng. trans., *Religion Within the Limits of Reason Alone*, 1947), the classic work of the last stage of German Deism; G.W.F. HEGEL, *Early Theological Writings*, trans. by THOMAS M. KNOX and RICHARD KRONER (1948), early writings to show Hegel’s indebtedness to Deistic polemics.

Agnosticism: The fundamental primary sources are T.H. HUXLEY, “Agnosticism” and “Agnosticism and Christianity” in his *Collected Essays*, vol. 5 (1894). Other basic sources are W.K. CLIFFORD, *The Ethics of Belief, and Other Essays* (1876, reprinted 1947); and LESLIE STEPHEN, *An Agnostic’s Apology, and Other Essays* (1893), which first appeared as an essay in 1876. An important classical antecedent is DAVID HUME, *An Enquiry Concerning Human Understanding* (1748), of which the best modern edition is that of C.W. HENDEL (1955). For a study of this, which was Hume’s first *Enquiry*, see ANTONY FLEW, *Hume’s Philosophy of Belief* (1961), which devotes special attention to its implications for religion. Religious agnosticism is treated in HENRY MANSEL, *The Limits of Religious Thought Examined in Eight Lectures* (1858). Notable secondary sources include LESLIE STEPHEN, *History of English Thought in the Eighteenth Century*, 2 vol. (1876), the best analytical study done at the time of Huxley and one that still deserves this high rating; R.F. FLINT, *Agnosticism* (1903); and R.A. ARMSTRONG, *Agnosticism and Theism in the Nineteenth Century* (1905); for a recent sympathetic biography, see CYRIL BIBBY, *T.H. Huxley: Scientist, Humanist, and Educator* (1959). Classic rejections

of agnosticism include BLAISE PASCAL, *Pensées* (1960), posthumous fragments given their definitive arrangement by L. LA-FUMA; and WILLIAM JAMES, “The Will to Believe,” in *The Will to Believe, and Other Essays in Popular Philosophy* (1897).

Atheism: The article “Atheism” in *The Encyclopaedia of Philosophy*, vol. 1, pp. 174–189 (1967, reissued 1972), and the article “Agnosticism” in the *Dictionary of the History of Ideas*, vol. 1, pp. 17–27 (1968), give sophisticated conceptual elucidations of the concept of atheism. See also *Encyclopaedia of Religion and Ethics*, vol. 2, pp. 173–190 (1922); *Reallexikon für Antike und Christentum*, vol. 1, cols. 866–870 (1950); *Die Religion in Geschichte und Gegenwart*, 3rd ed., vol. 1, cols. 670–678 (1957); GEORGE KLAUS and MANFRED BUHR (eds.), *Philosophisches Wörterbuch*, 6th rev. and enl. ed., vol. 1, pp. 125–129 (1969); *Enciclopedia filosofica*, 2nd ed., vol. 1, col. 557–562 (1968); and KAI NIELSEN, *Introduction to the Philosophy of Religion* (1982). A classic extended history of atheism is FRITZ MAUTHNER, *Der Atheismus und seine Geschichte im Abendland*, 4 vol. (1920–23, reissued 1963). See also JACOB PRESSER, *Das Buch “De tribus impostoribus”* (1926); JOHN MACK-INNON ROBERTSON, *A Short History of Freethought, Ancient and Modern* (1957, reissued 1972); HENRI BUSSON, *Le Rationalisme dans la littérature française de la Renaissance (1533–1601)*, new ed., rev. and augmented (1971); and CORNELIO FABRO, *God in Exile: Modern Atheism* (1968; originally published in Italian, 1961). Modern atheism is treated in CHARLES BRADLAUGH, *Champion of Liberty: Charles Bradlaugh* (1933); BARON D’HOLBACH, *The System of Nature* (1756–96, reissued 1970; originally published in French, 1770), and *Common Sense* (1795, reissued 1972; originally published in French, 1772); ARTHUR SCHOPENHAUER, *Complete Essays of Schopenhauer*, trans. by T. BAILEY SAUNDERS (1896); LUDWIG FEUERBACH, *The Essence of Christianity* (1854, reissued 1972, trans. of 2nd German ed.; originally published in German, 1841); FRIEDRICH NIETZSCHE, *Thus Spake Zarathustra* (1896; originally issued in German, 1883–92); KARL MARX and FRIEDRICH ENGELS, *On Religion* (1955); THOMAS H. HUXLEY, *Collected Essays*, vol. 5 (1894); and LESLIE STEPHEN, *An Agnostic’s Apology, and Other Essays* (1893), and *History of English Thought in the Eighteenth Century*, 3rd ed., 2 vol., (1902, reissued 1963). Powerful contemporary defenses of atheism, together with some religious responses, are given in NORBERT O. SCHEDLER (ed.), *Philosophy of Religion* (1974).

Contemporary analytical discussions of atheism include MICHAEL SCRIVEN, *Primary Philosophy* (1966); RICHARD ROBINSON, *An Atheist’s Values* (1964, reissued 1975); BERTRAND RUSSELL, *Why I Am Not a Christian, and Other Essays on Religion and Related Subjects* (1957); KAI NIELSEN, *Skepticism* (1973), and *Reason and Practice* (1971); SIDNEY HOOK, *The Quest for Being, and Other Studies in Naturalism and Humanism* (1961, reprinted 1971); and RONALD W. HEPBURN, *Christianity and Paradox* (1958, reissued 1968). Two anthologies that give the core debate between belief and unbelief are MALCOLM L. DIAMOND and THOMAS V. LITZENBURG, JR. (eds.), *The Logic of God* (1975); and ANTONY FLEW and ALASDAIR MACINTYRE and PAUL ROCOEUR, *The Religious Significance of Atheism* (1969); and MOSTAFA FAGHFOURY (ed.), *Analytical Philosophy of Religion in Canada* (1982).

Religious Experience

Religious experience is taken here to include such specific experiences as wonder at the infinity of the cosmos, the sense of awe and mystery in the presence of the holy, feelings of dependence on a divine power or an unseen order, the sense of guilt and anxiety accompanying belief in a divine judgment, and the feeling of peace that follows faith in divine forgiveness. Some thinkers also point to a religious aspect to the purpose of life and with the destiny of the individual. In the first sense, religious experience means an encounter with the divine in a way analogous to encounters with other persons and things in the world. In the second case, reference is made not to an encounter with a divine being but rather to the apprehension of a quality of holiness or rightness

in reality or to the fact that all experience can be viewed in relation to the ground from which it springs. In short, religious experience means both special experience of the divine or ultimate and the viewing of any experience as pointing to the divine or ultimate.

The first part of this article provides an overview of religious experience from a philosophical/psychological point of view. In the second part, the particular category of religious experience known variously as mysticism, enlightenment, or illumination is examined at some length, from a cross-cultural historical perspective. (See also RELIGIOUS AND SPIRITUAL BELIEF, SYSTEMS OF; RITES AND CEREMONIES, SACRED; SACRED OFFICES AND ORDERS.)

The nature and forms of religious experience

STUDY AND EVALUATION

"Religious experience" was not widely used as a technical term prior to the publication of *The Varieties of Religious Experience* (1902) by William James, an eminent U.S. psychologist and philosopher, but the interpretation of religious concepts and doctrines in terms of individual experience reaches back at least to 16th-century Spanish mystics and to the age of the Protestant Reformers. A special emphasis on the importance of experience in religion is found in the works of such thinkers as Jonathan Edwards, Friedrich Schleiermacher, and Rudolf Otto. Basic to the experiential approach is the belief that it allows for a firsthand understanding of religion as an actual force in human life, in contrast with religion taken either as church membership or as belief in authoritative doctrines. The attempt to interpret such concepts as God, faith, conversion, sin, salvation, and worship through personal experience and its expressions opened up a wealth of material for the investigation of religion by psychologists, historians, anthropologists, and sociologists as well as by theologians and philosophers. A focus on religious experience is especially important for Phenomenologists (thinkers who seek the basic structures of human consciousness) and Existentialist philosophers.

A number of controversial issues have emerged from these studies, involving not only different conceptions of

the nature and structure of religious experience but also different views of the manner in which it is to be evaluated and the sort of evaluation possible from the standpoint of a given discipline. Four such issues are basic: (1) whether religious experience points to special experiences of the divine or whether any experience may be regarded as religious by virtue of becoming related to the divine; (2) the kinds of differentia that can serve to distinguish religion or the religious from both secular life and other forms of spirituality, such as morality and art; (3) whether religious experience can be understood and properly evaluated in terms of its origins and its psychological or sociological conditions or is *sui generis*, calling for interpretation in its own terms; and (4) whether religious experience has cognitive status, involving encounter with a being, beings, or a power transcending human consciousness, or is merely subjective and composed entirely of ideas and feelings that have no reference beyond themselves. The last issue, transposed in accordance with either a Positivist outlook or some types of Empiricism, which restrict assertible reality to the realm of sense experience, would be resolved at once by the claim that the problem cannot be meaningfully discussed, since key terms, such as "God" and "power," are strictly meaningless.

Proponents of mysticism, such as Rudolf Otto, Rufus Jones, and W.T. Stace, have maintained the validity of immediate experience of the divine; theologians such as Emil Brunner have stressed the self-authenticating char-

Four basic
issues

acter of man's encounter with God; naturalistically oriented psychologists, such as Freud and J.H. Leuba, have rejected such claims, explaining religion in psychological and genetic terms as a projection of human wishes and desires. Philosophers such as William James, Josiah Royce, William E. Hocking, and Wilbur M. Urban have represented an idealist tradition in interpreting religion, stressing the concepts of purpose, value, and meaning as essential for understanding the nature of God. Naturalist philosophers, of whom John Dewey was typical, have focussed on the "religious" as a quality of experience and an attitude toward life that is more expressive of the human spirit than of any supernatural reality. Theologians Douglas Clyde Macintosh and Henry N. Wieman sought to build an "empirical theology" on the basis of religious experience understood as involving a direct perception of God. Unlike Macintosh, Wieman held that such a perception is sensory in character. Personalist philosophers, such as Edgar S. Brightman and Peter Bertocci, have regarded the person as the basic category for understanding all experience and have interpreted religious experience as the medium through which God is apprehended as the cosmic person. Existential thinkers, such as Søren Kierkegaard, Gabriel Marcel, and Paul Tillich, have seen God manifested in experience in the form of a power that overcomes estrangement and enables man to fulfill himself as an integrated personality. Process philosophers, such as Alfred North Whitehead and Charles Hartshorne, have held that the idea of God emerges in religious experience but that the nature and reality of God are problems calling for logical argument and metaphysical interpretation, in which emphasis falls on the relation between God and the world being realized in a temporal process. Logical Empiricists, of whom A.J. Ayer has been typical, have held that religious and theological expressions are without literal significance, because there is no way in which they can be either justified or falsified (refuted). On this view, religious experience is entirely emotive, lacking all cognitive value. Analytic philosophers following the lead of Ludwig Wittgenstein, an Austrian-British thinker, approach religious experience through the structure of religious language, attempting to discover exactly how this language functions within the community of believers who use it.

RELIGIOUS EXPERIENCE AND OTHER EXPERIENCE

Views of experience in general. Religious experience must be understood against the background of a general theory of experience as such. Experience as conceived from the standpoint of a British philosophical tradition stemming from John Locke and David Hume is essentially the reports of the world received through the senses. Experience, as a tissue of sensible content, was set in contrast to reason, understood as the domain of logic and mathematics. The mind was envisaged as a wax tablet on which the sensible world imprints itself; and the one who experiences is the passive recipient of what is given. It is possible to distinguish and compare these sensible items by means of understanding, but the data themselves are available only through experience—i.e., the sensation of things and reflection upon thought and mental activities, feelings, and desires. According to this classical empiricist view, all ideas, beliefs, and theories expressed in conceptual form are to be traced back to their origin in sense if they are to be understood and justified.

The above view of experience came under criticism from two sides. Immanuel Kant, an 18th-century German philosopher, who still retained some of the assumptions of the position he criticized, nevertheless declared that experience is not identical with passively received sensible material but must be construed as the joint product of such material and its being grasped by an understanding that thinks in accordance with certain necessary categories not derived from the senses. Kant opened the way for a new understanding of the element of interpretation in all experience, and his successors in the development of German Idealism, Johann Fichte, Friedrich Schelling, and G.W.F. Hegel, came to characterize experience as the many-sided reflection of man's multiple encounters with the world, other men, and himself.

A second attack on the classical conception came from U.S. Pragmatist philosophers, notably Charles Sanders Peirce, William James, and John Dewey, for whom experience was the medium for the disclosure of whatever there is to be encountered; it is far richer and more complex than a passive registry of sensible data. Experience was seen as a human activity related to the purposes and interests of the one who experiences, and it was understood as an interpreted product of multiple transactions between man and the environment. Moreover, stress was placed on the social and funded character of experience in place of the older conception of experience as a private content confined to the mind of an individual. On this view, experience is not confined to its content but includes modes or dimensions that represent frames of meaning—social, moral, aesthetic, political, religious—through which whatever is encountered can be interpreted. James went beyond his associates in developing the broadest theory of experience, known as radical empiricism, according to which the relations and connections between items of experience are given along with these items themselves.

Critics of the classical view of experience, while not concerned exclusively with religious experience, saw, nevertheless, that if experience is confined to the domain of the senses it is then difficult to understand what could be meant by religious experience if the divine is not regarded as one sensible object among others. This consideration prompted attempts to understand experience in broader terms. Cutting across all theories of experience is the basic fact that experience demands expression in language and symbolic forms. To know what has been experienced and how it is to be understood requires the ability to identify things, persons, and events through naming, describing, and interpreting, which involve appropriate concepts and language. No experience can be the subject of analysis while it is being had or undergone; communication and critical inquiry require that experiences be cast into symbolic form that arrests them for further scrutiny. The various uses of language—political, scientific, moral, religious, aesthetic, and others—represent so many purposes through which experience is described and interpreted.

Views of religious experience. Specifically religious experience has been variously identified in the following ways: the awareness of the holy, which evokes awe and reverence; the feeling of absolute dependence that reveals man's status as a creature; the sense of being at one with the divine; the perception of an unseen order or of a quality of permanent rightness in the cosmic scheme; the direct perception of God; the encounter with a reality "wholly other"; the sense of a transforming power as a presence. Sometimes, as in the striking case of the Old Testament prophets, the experience of God has been seen as a critical judgment on man and as the disclosure of his separation from the holy. Those who identify religion as a dimension or aspect of experience point to man's attitude toward an overarching ideal, to a total reaction to life, to an ultimate concern for the meaning of one's being, or to a quest for a power that integrates human personality. In all these cases, it is the fact that the attitudes and concerns in question are directed to an ultimate object beyond man that justifies their being called religious. All interpreters are agreed that religious experience involves what is final in value for man and concerns belief in what is ultimate in reality.

Because of their intimate relation to one another, the religious and the moral have often been confused. The problem has been intensified by many attempts—beginning with Kant's treatise on religion (1793)—to interpret religion as essentially morality or merely as an incentive for doing one's duty. Religion and morality are, however, usually taken to be distinguishable; religion concerns the being of a person, what he is and what he acknowledges as the worshipful reality, while morality concerns what the person does and the principles governing his relation to others. While it is generally acknowledged that religion must affect man's conduct in the world, some have maintained that there is no morality without religion, while others deny this claim on the ground that morality must remain autonomous and free of divine sanctions. Reli-

The expression and interpretation of experience

Sense experience and beyond

gious experience may be distinguished from the aesthetic aspect of experience in that the former involves commitment and devotion to the divine, while the latter is focussed on the appreciation and enjoyment of qualities, forms, and patterns in themselves, whether as natural objects or works of art. Anthropological studies have shown that primitive religions gave birth to many forms of art that, in the course of development, won independence as secular forms of expression. The problem of the relation between religion and art is posed in a particularly acute way when reference is made to religious art as a special form of the aesthetic. Since it is concerned with the holy and the purpose of human life as a whole, most scholars would hold that religious experience should be related in an intelligible way to all other experience and forms of experience. The task of tracing out these relationships belongs to theology and the philosophy of religion.

THE STRUCTURE OF RELIGIOUS EXPERIENCE

The self and the other. All religious experience can be described in terms of three basic elements: first, the personal concerns, attitudes, feelings, and ideas of the individual who has the experience; second, the religious object disclosed in the experience or the reality to which it is said to refer; third, the social forms that arise from the fact that the experience in question can be shared. Although the first two elements can be distinguished for purposes of analysis, they are not separated within the integral experience itself. Religious experience is always found in connection with a personal concern and quest for the real self, oriented toward the power that makes life holy or a ground and a goal of all existence. A wide variety of individual experiences are thus involved, among which are attitudes of seriousness and solemnity in the face of the mystery of human destiny; feelings of awe and of being unclean evoked by the encounter with the holy; the sense of a power or a person who both loves and judges man; the experience of being converted or of having the course of life directed toward the divine; the feeling of relief stemming from the sense of divine forgiveness; the sense that there is an unseen order or power upon which the value of all life depends; the sense of being at one with the divine and of abandoning the egocentric self.

In all these situations, the experience is realized in the life of an individual who at the same time has his attention focussed on an "other," or divine reality, that is present or encountered. The determination of the nature of this other poses a problem of interpretation that requires the use of symbols, analogies, images, and concepts for expressing the reality that evokes religious experience in an understandable way. Four basic conceptions of the divine may be distinguished: the divine as an impersonal, sacred order (Logos, Tao, *rita*, Asha) governing the universe and man's destiny; the divine as power that is holy and must be approached with awe, proper preparation, or ritual cleansing; the divine as all-embracing One, the ultimate Unity and harmony of all finite realities and the goal of the mystical quest; and the divine as an individual or self transcending the world and man and yet standing in relation to both at the same time.

The two most important concepts that have been developed by theologians and philosophers for the interpretation of the divine are transcendence and immanence; each is meant to express the relation between the divine and finite realities. Transcendence means going beyond a limit or surpassing a boundary; immanence means remaining within or existing within the confines of a limit. The divine is said to transcend man and the world when it is viewed as distinct from both and not wholly identical with either; the divine is said to be immanent when it is viewed as wholly or partially identical with some reality within the world, such as man or the cosmic order. The conception of the divine as an impersonal, sacred order represents the extreme of immanence since that order is regarded as entirely within the world and not as imposing itself from without. The conception of the divine as an individual or self represents the extreme of transcendence, since God is taken as not wholly identical with either the world or any finite reality within it. Some thinkers have described the

divine as wholly transcendent or "wholly other" than finite reality, some have maintained the total immanence of the divine, and still others claim that both concepts can be applied and therefore that the two characteristics do not exclude each other.

Social forms or expressions. Most enduring, historical religious traditions find their roots in the religious experience and insight of charismatic individuals who have served as founders; the sharing of their experience among disciples and followers leads to the establishment of a religious community. Thus, the social dimension of religion is a primary fact, but it need not be seen as opposed to religious experience taken as a wholly individual affair. There has been some difference of opinion on the point; Whitehead, for example, put emphasis on the "solitariness" of religious experience precisely in order to deny the claim of those who, like Émile Durkheim, a French sociologist, characterized religion as essentially a social fact. The social expression of religious experience results in the formation of specifically religious groups distinct from such natural groups as the family, the local society, and the state. Religious communities, including brotherhoods, mystery cults, synagogues, churches, sects, and monastic and missionary orders, serve initially to preserve and interpret their traditions or the body of doctrine, practices, and liturgical forms through which religious experience comes to be expressed. Such communities play a significant role in the shaping of religious experience and in determining its meaning for the individual through the structure of worship and liturgy and the establishment of a sacred calendar. Communities differ in the extent to which they stress the importance of individual experience of the divine, as distinct from adherence to a creed expressing the basic beliefs of the community. The tension between social and individual factors becomes apparent at times when the individual experience of the prophet or reformer conflicts with the norm of experience and interpretation established by the community. Therefore, although the religious community aims at maintaining its historic faith as a framework within which to interpret experience of the divine, every such community must find ways of recognizing both novel experience and fresh insight resulting from individual reflection and contemplation.

Objective "intention," or reference. Religious experience is always understood by those who have it as pointing beyond itself to some reality regarded as divine. For the believer, religious experience discloses something other than itself; this referent is sometimes described as the "intentional" object that is meant or aimed at by the experiencing person. Analysis of religious experience, interpretations placed upon it, and the beliefs to which it gives rise may result in the denial that there is any such reality to be encountered or that the assertion of it is justified by the experience in question. This conclusion, however, does not change the fact that all religious experience, whether that of the mystic who strives for unity with God or of the naturalist who points to a religious quality in life, purports to be experience "of" something other than itself. The question of the cognitive import or the objective validity of religious experience is one of the most difficult problems encountered in the philosophy of religion. In confronting the question, it is necessary to distinguish between various ways of describing the phenomena under consideration and the critical appraisal of truth claims concerning the reality of the divine made on the basis of these phenomena. Even if describing and appraising are not utterly distinct and involve one another, it is generally admitted that the question of validity cannot be settled on the basis of historical or descriptive accounts alone. Validity and cognitive import are matters calling for logical, semantic, epistemological, and metaphysical criteria—of the principles of rational order and coherence, meaning, knowledge, and reality—and this means that the appraisal of religious experience is ultimately a philosophical and theological problem. The anthropologist will seek to identify and describe the religious experience of primitive peoples as part of a general history and theory of man; the sociologist will concentrate on the social expression of religious experience and seek to

"Solitariness" and community

The three basic elements: subjective, objective, social

Cognitive import or objective validity

determine the nature of specifically religious groupings in relation to other groups—associations and organizations that constitute a given society; the psychologist will seek to identify religious experience within the life of the person and attempt to show its relation to the total structure of the self, its behaviour, attitudes, and purposes. In all these cases attention is directed to religious experience as a phenomenon to be described as a factor that performs certain functions in human life and society. As William Warde Fowler, a British historian, showed in his classic *Religious Experience of the Roman People* (1911), the task of elucidating the role of religion in Roman society can be accomplished without settling the question of the validity or cognitive import of the religious feelings, ideas, and beliefs in question. The empirical investigator, as such, has no special access to the critical question of the validity of religious experience.

The most radical form of the denial that religious experience has cognitive import is advanced by the Logical Positivists, who hold that all assertions or forms of expression involving a term such as "God" are meaningless because there is no way in which they can be verified or falsified.

Others who hold that religious utterance based on experience is without cognitive import regard it either as the expression of emotions or an indication that the person using religious language has certain feelings that are associated with religion. Those who follow the lead of Wittgenstein regard religious utterances as noncognitive but attempt to determine the way in which religious language is actually used within a circle of believers. Some psychologists have denied cognitive status to religious experience on the ground that it represents nothing more than man's projection of his own insecurity in the face of problems posed by life in the world and therefore has no referent beyond itself.

Immediacy and mediation. *Revelational and mystical immediacy.* Among defenders of the validity and cognitive import of religious experience, it is necessary to distinguish those who take such experience to be an immediate and self-authenticating encounter with the divine and those who claim that apprehension of the divine is the result of inference from, or interpretation of, religious experience. Two forms of immediacy may be distinguished: the revelational and the mystical (for a detailed treatment of the latter, see below *The experience of mysticism*). Christian theologians, such as Emil Brunner and H.H. Farmer, speak of a "divine-human encounter," and Martin Buber, a Jewish religious philosopher, describes religious experience as an "I Thou" relationship; for all three, religious experience means an immediate encounter between persons. The second form of the immediate is the explicitly mystical sort of experience in which the aim is to pass beyond every form of articulation and to attain unity with the divine.

Mediation through analysis and critical interpretation. A number of thinkers have insisted on the validity of religious experience but have denied that it can be understood as wholly immediate and self-supporting, since it stands in need of analysis and critical interpretation. Some, like Paul Tillich, hold that there are certain "boundary experiences," such as having an ultimate concern or experiencing the unconditional character of moral obligation, that become intelligible only when understood as the presence of the holy in experience. Others, such as H.D. Lewis and Charles Hartshorne, find the divine ingredient in the experience of the transcendent and supremely worshipful reality but demand that this experience be coherently articulated and, in the case of Hartshorne, supplemented by rational argument for the reality of the divine. Dewey envisaged a religious quality in experience pointing to God as an ideal that stands in active and creative tension with the actual course of events. Whitehead identified the presence of the divine with an apprehension of a "permanent rightness" in the scheme of things and based the validity of the experience on the claim that an adequate cosmology requires God as a principle of selection aiming at the realization of the good in the world process. James found the justification of religious experience in its consequences for the life of the individ-

ual: valid experience is distinguished by its philosophical reasonableness and moral helpfulness. Finally, some have sought to combine experience and interpretation by taking the traditional proofs of God's existence and pointing to their roots in the experience of perfection, of the contingency of one's own existence, and of the reality of purpose in human life. On this view, the arguments for the reality of God are not wholly formal demonstrations but rather the tracing out of intelligible patterns in experience.

Preparations for experience. Mystics, prophets, and religious thinkers in many traditions, both East and West, have been at one in emphasizing the need for various forms of preparation as a preliminary for gaining religious insight. The basic idea is that ordinary ways of looking at the world, dictated by the demands of everyday life, stand in the way of the understanding of religious truth; man must pass beyond these limitations by the disciplining of his mind and body. Three classic forms of preparation may be distinguished: first, rational dialectic for training the mind to reach insight (this explains why many mystical thinkers from the Pythagoreans to Nicholas of Cusa and Benedict de Spinoza were deeply involved in mathematics); second, moral preparation aiming at purity of heart, which was sometimes conjoined with bodily discipline, as in the Indian Yoga exercises; third, the use of drugs to expand the range of consciousness beyond that required for ordinary life. It is significant that the great mystics invariably regarded such preparation as necessary, but not sufficient, for experience. The self may be prepared, but the vision may not come; being prepared, as it were, establishes no claim on the divine. The experience described by St. John of the Cross, a 16th-century Spanish mystic, as "the dark night of the soul" points precisely to the experience of failure. The soul in this situation is convinced that God has abandoned it, cast it into darkness, perhaps forever. Mystics in the Taoist and Buddhist traditions have often emphasized the spontaneity of insight and the need to seek it through an "effortless striving" that combines the need to search with the awareness that the insight cannot be compelled. Zen Buddhists are fond of pointing to insights that are already possessed but not recognized as such until their holder is shaken loose from ordinary patterns of thought.

SITUATIONAL CONTEXTS AND FORMS OF EXPRESSION

Cultic and devotional. Religious experience receives its initial, practical expression in the forming of the cult that provides an orderly framework for the worship of the religious object. Worship includes expressions of praise, acknowledgments of the excellency of the divine, communion in the form of prayer, and the use of sacraments or visible objects that signify or represent the invisible sacred beyond them, feelings of joy and of peace expressed often in musical form, and sacrifice or the offering of gifts to the divine or in the name of the divine. Worship is ordered by means of liturgy directing the experience of the worshipper in patterns that combine the written word, the spoken word, and sacred music in a unity aimed at bringing him or her into the presence of the divine.

Life crises and rites of passage. Religious experience has to do with the quality and purpose of life as a whole and with the ultimate destiny of the person. Certain special times and events in the course of life present themselves as occasions that are set apart and celebrated, because they direct man's thought to the divine and the sacred with peculiar forcefulness. These occasions, called life crises, are regarded as dangerous because they are transitional from one stage of life to another and open to view the relation of life as a whole to its sacred ground. Pregnancy and birth, the naming of a child, being initiated into the community—sometimes called "puberty rites"—the choice of a vocation, the celebration of marriage, and the time of death are experienced as special events distinct from the routine happenings of secular life. These events represent "crises"—i.e., turning points—when man's relation to the sacred becomes a matter of special concern. As Gerardus van der Leeuw, a Dutch phenomenologist and historian of religions, points out, these transitional times are occasions for celebration in every culture because they mark the

Three forms of preparation: rational dialectic, moral purification, drugs

Religious
experience
and secular
life

death of one stage and the birth of another in a universal cycle of life.

Sacred and secular. The marking off of these crisis occasions from the routine events of daily life points to the all-important distinction between the sacred and the secular. As directed toward the sacred, religious experience finds expression in the specifically religious form of the cult and in the cycle of sacred life. There is, however, a secular as well as a sacred life, and, since religious experience concerns the whole of life, the religious meaning must be related to all the dimensions of secular life—political, economic, moral, technological, and other. The relationship is twofold; on the one hand, there is the bearing of the conception of the divine on standards of behaviour, and, on the other, there is the influence that the religious meaning has upon one's general attitude toward life. The sacred, thus, makes its impact on the secular by providing principles that are to govern the relations between persons and by holding before men a vision of the divine that gives purpose to life as a whole. Although the sacred retains its dynamism by becoming related to secular life, there is the constant danger that it will lose itself in the secular, unless specifically religious forms of life are preserved. The existence in every society of secret and mystery cults, of sacred brotherhoods, of groups of disciples devoted to holy men, of monastic orders, and, on the broadest scale, of established churches and denominations, points to the need felt to retain the sacred as a special domain that can neither be merged into nor contained within secular society.

Verbal, conceptual, and symbolic. In all of the world religions, religious experience receives its most enduring expression in the form of sacred scriptures and the body of commentary through which they are interpreted. Mythological and symbolic forms of expression are older than conceptual forms and systems of doctrine. Myth takes the form of a story and represents the imaginative use of materials drawn from sensible experience in order to express a religious meaning surpassing the sensible world. Myths of creation in many religions give ample evidence of this imaginative function. The task of the theologian using conceptual tools is to elucidate the thought content of the myth and other primary forms of religious expression—legend, parable, confession, lamentation, prophetic vision—and thereby reduce the degree of dependence on the sensible and imaginative elements. It is important to distinguish devotional and liturgical expressions from the theological use of language. Creeds, confessions, psalms and hymns of praise, litanies and scriptures containing a record of the lives and experiences of sacred persons, all give immediate expression to the primary experience upon which a religious tradition is founded. Systems of theology and religious philosophy make their appearance when it becomes necessary to conceptualize and express consistently the body of belief about the divine, the world, and man implied in this primary experience. Tension exists between religious experience and theological expression at two points: first, the pietistic and evangelical spirit in religion, as seen, for instance, in some forms of Protestant Christianity, and the *bhakti* devotional movement in Hinduism, seeks to preserve the primacy of experience at the expense of theology; and, second, those who acknowledge the indispensability of theology will also demand that its formulations remain in accord with the experience it is meant to express and interpret.

TYPES OF RELIGIOUS EXPERIENCE AND PERSONALITY

The personal character of religious experience makes it essential to understand its varieties as manifested in different types of personality and the functions they perform. The mystic, a reflective and contemplative type, shuts out the world and all distracting influences in order to reach true selfhood through purification and enlightenment. Although mysticism has social implications, the mystic is primarily an individualist, whereas the prophet, a person of intense but intermittent experience, sees himself called to be a spokesman for the divine to the community or all mankind, and regards his own experience as a message that enables him to interpret the past and the future in the light of the divine will. The priest is a mediator be-

tween man and the divine, and his main function is the proper ordering of worship through liturgical forms. By contrast with the prophet, whose insight is spontaneous, the priest attains the authority of his office through education and training; as guardian of the tradition, he must assume administrative responsibilities in addition to his role as spiritual adviser; thus he is both active and contemplative. The reformer is a figure who stands within a religious tradition and seeks to transform or revitalize it in the light of his own experience and insight. The reforms intended may be moral, intellectual, or ecclesiastical, depending on the particular genius of the individual. Common to all reformers is the conviction that some valid and essential feature of traditional faith has been ignored or distorted and that these deficiencies must be overcome if the religion is to be purified. It is characteristic of the reformer to be actively engaged in bringing about the reforms indicated by his renewing experience. The monk or member of a religious order is in search of a special or sacred place set apart from secular life within which a religious life can be lived and moral and religious demands fulfilled to a greater degree than is possible in the world. Different orders stress different aspects of experience: some emphasize ascetic practices and self-discipline; others are devoted to the preservation of learning and the development of theology; still others make missionary zeal uppermost, and the members are impelled by their own experience to seek to convert others. The forerunner of the monk, who lives in a community governed by rule, was the hermit or religious recluse, the type for whom solitary existence, preferably in deserts and barren places, is necessary for communion with the divine and self-purification. The saint is a figure venerated by the religious community as one who embodies perfection in some form. The saint may have been a martyr, exhibiting perfection in faith; a person possessed of intensified capacity for experience and communion with the divine; or one who achieves to a supreme degree the moral and spiritual ideals of the beatific life. The theologian has the task of expressing the historic faith of a community concerning the divine (*theos*) in rational or conceptual form (*logos*). The content of his thought, though handed on to him in its essentials by the tradition, will depend on his own experience and his insight into the special relevance of that tradition for his time. The theologian both interprets and reinterprets. The founder, as might be expected, surpasses all others in importance. The founder's experience forms the basis of his own authority and the substance of the religion he establishes. The intensity of his experience and the effect it has upon his personality are decisive factors determining the response of his initial followers and disciples. There is reason to believe that the founders of the great religions, such as Moses, Buddha, and Jesus, did not intend to fill this role; the founding of the religion in each case was the result of the impact of their personalities and of the profundity of their experience on those who gathered around them. (J.E.Sm.)

and Jesus

The experience of mysticism

Mysticism, a quest for a hidden truth or wisdom ("the treasure hidden in the centres of our souls"), in the 20th century is undergoing a renewal of interest and understanding and even a mood of expectancy similar to that which had marked its role in previous eras. Such a mood stems in part from the feeling of alienation that many persons experience in the modern world. Put down as a religion of the elite, mysticism (or the mystical faculty of perceiving transcendental reality) is said by many to belong to all men, though few use it. The British author Aldous Huxley has stated that "a totally unmythical world would be a world totally blind and insane," and the Indian poet Rabindranath Tagore has noted that "Man has a feeling that he is truly represented in something which exceeds himself."

NATURE AND SIGNIFICANCE

The goal of mysticism is union with the divine or sacred. The path to that union is usually developed by following

four stages: purgation (of bodily desires), purification (of the will), illumination (of the mind), and unification (of one's will or being with the divine). If "the object of man's existence is to be a Man, that is, to re-establish the harmony which originally belonged between him and the divinized state before the separation took place which disturbed the equilibrium" (*The Life and Doctrine of Paracelsus*), mysticism will always be a part of the way of return to the source of being, a way of counteracting the experience of alienation. Mysticism has always held—and parapsychology also seems to suggest—that the discovery of a nonphysical element in man's personality is of utmost significance in his quest for equilibrium in a world of apparent chaos.

Mysticism's apparent denial, or self-negating, is part of a psychological process or strategy that does not really deny the person. In spite of its lunatic fringe, the maturer forms of mysticism satisfy the claims of rationality, ecstasy, and righteousness.

There is obviously something nonmental, alogical, paradoxical, and unpredictable about the mystical phenomenon, but it is not, therefore, irrational or antirational or "religion without thought." Rather, as Zen (Buddhist intuitive sect) masters say, it is knowledge of the most adequate kind, only it cannot be expressed in words. If there is a mystery about mystical experience, it is something it shares with life and consciousness. Mysticism, a form of living in depth, indicates that man, a meeting ground of various levels of reality, is more than one-dimensional. Despite the interaction and correspondence between levels—"What is below is like what is above; what is above is like what is below" (*Tabula Smaragdina*, "Emerald Tablet," a work on alchemy attributed to Hermes Trismegistus)—they are not to be equated or confused. At once a praxis (technique) and a gnosis (esoteric knowledge), mysticism consists of a way or discipline.

Mysticism and religion

The relationship of the religion of faith to mysticism ("personal religion raised to the highest power") is ambiguous, a mixture of respect and misgivings. Though mysticism may be associated with religion, it need not be. The mystic often represents a type that the religious institution (e.g., church) does not and cannot produce and does not know what to do with if and when one appears. As William Ralph Inge, an English theologian, commented, "institutionalism and mysticism have been uneasy bedfellows." Although mysticism has been the core of Hinduism and Buddhism, it has been little more than a minor strand—and, frequently, a disturbing element—in Judaism, Christianity, and Islam. As the 15th- to 16th-century Italian political philosopher Niccolò Machiavelli had noted of the 13th-century Christian monastic leaders St. Francis and St. Dominic, they had saved religion but destroyed the church.

The founders of religion may have been incipient or advanced mystics, but the inner compulsions of their experience have proved less amenable to dogmas, creeds, and institutional restrictions, which are bound to be outward and majority oriented. There are religions of authority and the religion of the spirit. Thus, there is a paradox: if the mystic minority is distrusted or maltreated, religious life loses its sap; on the other hand, these "peculiar people" do not easily fit into society, with the requirements of a prescriptive community composed of less sensitive seekers of safety and religious routine. Though no deeply religious person can be without a touch of mysticism, and no mystic can be, in the deepest sense, other than religious, the dialogue between mystics and conventional religionists has been far from happy. From both sides there is a constant need for restatement and revaluation, a greater tolerance, a union of free men's worship. Though it validates religion, mysticism also tends to escape the fetters of organized religion.

RELATION OF MYSTICAL EXPERIENCE TO OTHER KINDS OF EXPERIENCE

Mysticism shares a common world with magic, theurgy (power of persuading the supernatural), prayer, worship, religion, metaphysics (transcendent levels of reality), and even science. It may not be always easy to distinguish

mysticism from these but its approach and emphasis are different. Though there is an element of magic, psychism, and the occult in much of what passes for mysticism, it is not to be equated with a science of the unseen or with voices and visions. Powers of the occult (or *siddhis*) are viewed as real, but they can also be dangerous and are not of interest to genuine mystics, who have warned against their likely misuse.

Prayer and worship may form part of mysticism, but they are viewed as means and not as essence; also, they are usually continuations of sensory experience, whereas mysticism is a pure unitary consciousness, or a union with God. As for science, it is analytic and discursive and expresses its findings in precise and abstract formulas; mysticism, however, like poetry, depends more on paradoxes and an unusual use of language. Philosophies may lead to or follow from mysticism, but they are not the same. Nature mysticism is another prominent variant, to which poets and artists are particularly prone. This has often been described or dismissed as pantheism (the divine in all), though it is perhaps other than a simple assertion of identity.

Aesthetic mysticism

Emotionalism and purified emotion are quite different. Emotionalism, a kind of unsuccessful ecstasy, may arise from unpurged elements in the being; it could also be a concession or inability to hold the flow or touch from above. The natural state of man and, even more, that of the true mystic is serene and not agitated, not at the mercy of what the medieval mystical book *The Cloud of Unknowing* calls "monkey tricks of the soul." "Be still, and still, and know." Mysticism, among the many forms of experience, confirms the claims of religion and is viewed as providing a foretaste of the life after death.

DEFINITIONS OF MYSTICISM AND MYSTICAL EXPERIENCE

Differences between mysticism and similar phenomena.

To define is to limit, and no single definition will cover every aspect of mysticism. Some have objected to the word itself and believed that "enlightenment" or "illumination" might be better. Though they meet, mysticism has to be distinguished from prophetic religions as well as from shamanism (a belief system built around psychic transformations). Working through chosen individuals—not necessarily saints and chosen for no other reason than God's will—prophetic religions emphasize action to a far greater extent than most forms of mysticism, with its penchant for inwardness and the beyond. Though in ecstasy the barriers seem to disappear, in prophetism God and man are rarely identified. Shamanism, a technique of ecstasy generally found in Siberia and Central Asia but with parallels in primitive society, provides a sort of correspondence with the purgative stage of mysticism (in which physical needs are negated). The closeness to paranormal (or supernatural) phenomena seems more pronounced, however, in shamanism. Both the shaman and the mystic, as communicants with a world beyond normal experience, reveal an identity of goal, if not of practice and content.

Basic patterns. Paradigmatic pronouncements in regard to mysticism pose problems of their own. The classic Indian formula—"that thou art," *tat tvam asi* (*Chândogya Upaniṣad*, 6.9)—is hedged in with the profoundest ambiguity. The difficulty reappears in the thought of the medieval Christian mystic Meister Eckhart, who had the church raising questions for such unguarded statements as "The knower and the known are one. God and I, we are one in knowledge" and "There is no distinction between us."

Mysticism may be defined as the belief in a third kind of knowledge, the other two being sense knowledge and knowledge by inference. Adolf Lasson has written:

The essence of Mysticism is the assertion of an intuition which transcends the temporal categories of the understanding. . . . Rationalism cannot conduct us to the essence of things; we therefore need intellectual vision.

This same view was held by the 3rd-century-AD Greek philosopher Plotinus. But the pattern misses the other dominant quality of mystical experience—love, or union through love. The medieval, theistic view of mysticism (as of religious life) was that it was "a stretching out of the

Mysticism as a third kind of knowledge

soul into God through the urge of love, an experimental knowledge of God through unifying love." Its other name was joy, and the endeavour of the mystic to grasp the divine essence or ultimate reality helped him to enjoy the blessedness of actual communion with the highest. This was considered both a science and an art. As a science (*i.e.*, intuitive knowledge, or the "science of ultimates"), mysticism is viewed as being able to help in "the overcoming of creatureliness," and also as being able to maintain "the tendency to stress up to an extreme and exaggerated point the non-rational aspect of religion."

Reality, a kingdom of values, is viewed not as a faceless infinite, an impersonal something or somewhat. If not an ego, it is a being, and most mystics would call it God. Mysticism arises when man tries to bring the urge toward a communion with God—a "Being conceived as the supreme and ultimate reality," according to the British scholar William Ralph Inge—toward a higher consciousness and being in relation with the other contents of his mind and total personality, when he tries to realize the presence of the living God in the soul and in nature or, more generally, in the attempt to realize (in thought and feeling) the immanence of the temporal in the eternal. A 19th-century scholar, Otto Pfeleiderer, indicated that religious mysticism is "the immediate feeling of unity of the self with God; it is nothing, therefore, but the fundamental feeling of religion, the religious life at its very heart and centre." Against such exclusive concentration the British writer Richard Nettiesship suggests a corrective element, that of wholeness and symbolism. "Mysticism is the consciousness that everything that we experience is an element, and only an element, in fact, *i.e.* that in being what it is, it is symbolic of something else."

Introvertive mysticism. Certain forms of mysticism, however, would seem to strive toward a naked encounter with the Whole or All, without and beyond symbols. Of this kind of direct apprehension of the absolute, introvertive mysticism offers examples from different times and traditions. Instead of looking out, the gaze turns inward, toward the unchanging, the undifferentiated "One without a second." The process by which this state is attained is by a blotting out or suppression of all physical sensations—indeed, of the entire empirical content of consciousness. *Cittavṛttinirodha* ("the holding or stopping of the mind stuff") was how the 2nd-century-BC Indian mystic Patañjali described it. The model of introvertive mysticism comes from the *Māṇḍūkya Upaniṣad*:

Unitary
conscious-
ness—
One
without a
second

The Fourth, [aspect of self] say the wise, . . . is not the knowledge of the senses, nor is it relative knowledge, nor yet inferential knowledge. Beyond the senses, beyond the understanding, beyond all expression is The Fourth. It is pure unitary consciousness wherein [all] awareness of the world and of multiplicity is completely obliterated. It is ineffable peace. It is the supreme good. It is One without a second. It is the Self. (From *The Upanishads, Breath of the Eternal*; trans. by Swami Prabhavananda and Frederick Manchester.)

Other definitions and experiences of mysticism. Such undifferentiated unity or union between the individual and the supreme self is unacceptable to certain traditions and temperaments. The Jewish philosopher Martin Buber emphasized an "I-Thou" relationship: "All real living is meeting," and one Thou cannot become It. But even his own "unforgettable experience" of union he would explain as "illusory." With a wider range, a British scholar, R.C. Zaehner, has tried to establish different kinds, or types, of mysticism: of isolation, the separation of spirit and matter, eternity from time; pantheistic, or "pan-enhenic," in which the soul is the universe—all creaturely existence is one; the theistic, in which the soul feels identified with God; and the beatific, with its hope of deification when "the perishable puts on the imperishable."

Definitions of mysticism include a bewildering variety, ranging from the biological through the psychological to the theological. The origin of the word and certain of its features strongly suggest the possibility that mysticism is the science of a hidden life. But there is also a growing belief among 20th-century scholars that "the people of the hidden" should not remain hidden too long and should come out in the open, befitting an era of "open

development" and "open realization." Some 20th-century scientists, among them physicists, biologists, and paleontologists, have shown a marked mystical bias. A biologist, Ludwig von Bertalanffy, has confessed to "peak experiences" of a great unity and liberation from ego boundary: "In moments of scientific discovery I have an intuitive insight into a grand design." He finds no necessary opposition between the rational way of thinking and intuitive experience culminating in what the mystics have tried to express. Both have their place and may coexist. Earlier there had been a sharp dichotomy between scientific and mystical knowledge. The logic of levels may never be amenable to analysis or intellectual understanding, but that is not to deny the role of reason.

Attitudes toward mysticism since the middle of the 20th century have been considerably modified by an awareness of subliminal consciousness, extrasensory perceptions, and, above all, an evolutionary perspective. The Roman Catholic paleontologist Teilhard de Chardin asked if in an expanding universe mysticism would not burst the limits of narrow cults and religious rigidity and move toward an ecumenical future. In a larger view, mysticism has not so much to be defined as renewed and redefined.

20th-
century
views of
mysticism

UNIVERSAL TYPES OF MYSTICAL EXPERIENCE

Intellectual and contemplative forms. Mystical experience, which is centred in a seeking for unity, admits of wide variations but falls into recognizable types: mild and extreme, extrovertive and introvertive, and theistic and nontheistic. Another well-known typology—corresponding to the faculties of thinking, willing, and feeling—employs the Indian formula, the respective ways of knowledge (*jñāna*), works (*karma*), and devotion (*bhakti*). Claims have been made on behalf of each, though maturer mystics have tried to accord to each its place and also to arrive at a synthesis, as in the *Bhagavadgītā* (Hindu sacred scripture). Depending on the powers of discrimination, the intellectual or the contemplative type tries to reach the Highest, the One, or the Godhead behind God. In its approach toward the supreme identity it tends to be chary of multiplicity, "to deny the world that it may find reality." Plotinus was "ashamed of being in the body." In the 17th century, Spinoza's nondenominational concept of intellectual love of God revealed a sense of aloofness or isolation reminiscent of the ancient Hindus.

Man, however, does not live by thought alone; to live is to work, and faith without works is dead. The mystic injunction is that works should be done in a spirit of nonattachment, with the ego sense (I, the doer) taken away. In a larger sense, not merely the doing of religious chores but all activity is offered to the Supreme. All life, according to many mystics, turns into a sacrament. "All life is *yoga* (meditation practice)."

Devotional forms. For the emotional type of person there is the mysticism of love and devotion. A theistic attitude, or devotional mysticism, depends upon mutual attraction. In the words of a Sūfi poet, "I sought Him for thirty years, I thought that it was I who desired Him, but no, it was He who desired me." The path of devotion includes the rituals of prayer, worship, and adoration, which—if done with sincerity, inwardness, and understanding—can bring some of the most rewarding treasures of the religious life, including ecstasy (or *samādhi*). There is a paradox and a danger here: the paradox of avoiding the loss of personality, the danger of self-indulgence.

Ecstatic and erotic forms. Also, in an unpurified medium, the experiences may and do give rise to erotic feelings, a fact observed and duly warned against by the wiser spirits and the Fathers of the Church. (Zen Buddhism avoids both the overly personal and erotic suggestions.) Sometimes the distinction between *eros* (Greek: "erotic love") or *kāma* (Sanskrit: "sexual love") and *agapē* (Greek: "a higher love") or *prema* (Sanskrit: "higher love") can be thin. In the Indian tradition the Vaiṣṇava (devotional) and Tantric (sexual) experiments were, in their apparently different ways, bold and honest attempts at sublimation, though the majority of these experiments turned out to be failures and disasters.

The same fate is likely to overtake the craze for

Use of
drugs as
aids to
visionary
experience

psychedelic drugs and pharmacological aids to visionary experience—practices that are by no means new. A yogic writer, Patañjali, speaks of the use of *auṣadhi* (a medicinal herb) as a means to yogic experience, and the Vedas (Hindu scriptures) and *Tantras* (Hindu occultic writings) refer to wine as part of worship and the initiatory rites. The Greek Mysteries (religions of salvation) sometimes used sedatives and stimulants. Primarily meant to remove ethical, social, and mental inhibitions and to open up the subconscious no less than the subliminal, these techniques, as a rule, were frowned upon, even though those who took the help of such artificial aids had undergone prior training and discipline.

A whole new life-style and vocabulary have developed around medicinal mysticism in the 20th century. Peyote, mescaline, hashish, marijuana, *Cannabis indica*, LSD, and other similar products have become familiar to much of the world's population. The visions induced by such aids at best resemble the extrovertive type and cannot be easily equated with genuine mystical experience. According to taste, temperament, and tradition, the experience—a parody of creative spontaneity—may come from unexpected sources. In any case, utilizing such medicinal aids rarely achieves union with Self or God, and no permanent change of personality (in the mystical sense) has been known to occur.

GOAL OF MYSTICAL EXPERIENCE AND MYSTICISM

Experience of the divine or sacred. The goal of mysticism is "ghostly," a state or condition in which the soul is "one'd with God," according to the Western medieval work *The Cloud of Unknowing*. This "one-ing" is because all men, according to mystics, are called to their origin. Self-realization is basically one in intent with the injunctions of the Greek Mysteries: "Know thyself." This knowing, union, or communion with the divine and the sacred is of the essence of the ascent of man. As the only answer to the problem of identity, mystics look upon it as the final end, the *summum bonum*. At the journey's end waits the knowledge by identity. The direct, intuitive perception is more akin to revealed religion than to science and philosophy, though it is of itself a science, and philosophies spring from as well as lead to it.

Union with the divine or sacred. In the movement toward the goal there are, naturally, stages and processes, marked differently in different traditions. The discipline of prayer, purification, and contemplation culminates in the highest wordless union with the divine and the ultimate. As the process unfolds itself along the mystic way, an alteration of personality—a conversion, if not reintegration—occurs. The unregenerate "old man" (in Christianity) is replaced by the new being. The "twice born" (in Hinduism) becomes more than a metaphor or sacrosanct social arrangement. There is a change of level and mind. One of the aims or methods of mysticism is to make possible this change and conversion, a shift from the profane to the sacred, from "here" to "there": "Lead me from the unreal to the real, from darkness to light, from death to immortality" (*Bṛhadāraṇyaka Upaniṣad*). Before the transition, or the "great passage," is completed, however, the individual or pilgrim feels successively or simultaneously his oneness with nature, with people, and with things—an extension of awareness or expanded selfhood to which no limits can be assigned. Cosmic consciousness is thus a stage in a progressive self-discovery.

Experience of the universal. The nature of the goal, however, introduces a paradox. Like every other aim and activity, mysticism operates in a historical context. Yet, sooner or later, it also tends to reveal a timeless stance. The mystic is both in and out of time. The eternal now is a kind of release from the temporal order. Such a release may lead to a shift from the local to the universal, to a growing sense of unity of all experience. Though not a declared or conscious aim, this result could be looked upon as a not unworthy goal as well as a pragmatic standard.

To cure man of a provincialism of the spirit, from which more people suffer than either know or admit it, is one of the goals of a mysticism that has come of age. The true mystic is a cosmopolitan. In man's many-sided growth

toward the real, a sane and mature mysticism leads to an ecumenical insight and obligation. Local colour, particulars, and uniqueness will not cease, but, in the perspective of the future and of wholeness, the universal alone will have survival value.

Experience of oneness with people. The apotheosized (divinized) field of consciousness is mysticism's ultimate goal and gift to the life of an evolving humanity. It alone is fitted to mediate between the anguish of existence and the serenity of essence, between *samsāra* ("cycle of birth and rebirth") and *Nirvāṇa* (the State of Bliss). According to an American Roman Catholic mystic, Thomas Merton, "The spiritual anguish of man has no cure but mysticism."

Though the mystic goal may seem to be tied to a transcendent reality, this does not mean a sundering of all relations and responsibilities. On the contrary, it is the guarantee of a set of altered relationships and a rehabilitation of what may be called the higher reason. Intuitions that sink into private fancy and morbidity have a short life to live. As for the mystic's "yonder," it is not spatially or posthumously remote but rather refers to a different order of reality and consciousness. The healthier forms of mysticism do not abjure action or the claims of love. It is an ancient maxim that one becomes what one loves. This is how the psychic birth repeats itself in the mystic soul, as stated, for example, by Meister Eckehart, a medieval German mystic: "It is more worthy of God that he should be born spiritually of every virgin, or of every good soul, than that he should have been born physically of Mary."

The mystic is not always amorous of the beyond, leaving an unredeemed world to its own ways. Not escape but, rather, victory is mysticism's inner urge and promise. The more sober among the mystics do not merely withdraw; they also return to the base and attempt the ancient alchemy, the transformation of men. A solitary salvation does not satisfy either head or heart.

MYSTICAL RELATIONSHIP BETWEEN MAN AND THE SACRED

Nature of the relationship. Within man is the soul of the holy, said Ralph Waldo Emerson in the 19th century. This is true of society, too. As the French sociologist Émile Durkheim saw it, the sacred is but a personified society. Mysticism, one might say, is the art and science of the holy. Theologically, it is but "the experience of the Holy Ghost, . . . the realization of the Spirit of Holiness." As the opposite of the profane and as a distinct and irreducible quality of the religious and mystical life, the sacred has always existed. It is indeed a mark of the real, and, when the German theologian Rudolf Otto isolated the sacred as a "quite distinctive category" of mystical apprehension, he had no lack of evidence. The emphasis, however, was not unanimously accepted. Some, like Inge, thought the sacred might as well be elicited from such ultimate values as "truth, goodness, and beauty."

According to the respective world view, the interpretation or emphasis varies, but the universal core remains unaffected. The sacred is in its own way a coherent system, though not rational. The dualists no less than the theists insist on the unqualified and irreducible "otherness," the unbridgeable gulf, even when one speaks of union or communion. It is the distance that preserves the sacred.

Christian mystics, who often speak of "union with God," generally do not imply identity with the divine, since this might lead to heresy. The 16th-century Spanish mystic St. Teresa of Avila could write with impunity: "It is plain enough what unity is—two distinct things becoming one." But most others could not be so plain and had to use special strategy to cover up traces of possible deviation from what was permissible. Even if there had been a semblance of interpenetration between man and the divine, there could be no substantial identity. "Each of these," wrote the medieval Dutch mystic Jan van Ruysbroeck, "keeps its own nature. There is here a great distinction, for the creature never becomes God, nor does God ever become the creature." The same doctrine is preached in the Middle Ages by the mystic Heinrich Suso:

In this merging of itself in God the spirit passes away and yet not wholly; for it receives indeed some attribute of God, but it does not become God by nature. It is still something

that has been created out of nothing, and continues to be this everlastingly.

Identification of man with the divine, according to many the heart of mysticism, raises problems from other points of view as well. Pantheism, which asserts that all is God (or Nature), and God (or Nature) is all, is looked upon as a false doctrine in many religions. To John Calvin's leading question—"The Devil also must be God, substantially?"—the unsuspecting Spanish theologian and physician Michael Servetus had answered smilingly: "Do you doubt it?" The opinion cost him his life. The Hindus' *Upaniṣads*, however, insist on this identity in passage after passage. Closely looked at, this may not be simple pantheism but an identity in difference, a paradox present in even Vedānta (a Hindu monistic system). Islām has been fiercely critical of these claims of oneness and the medieval mystic al-Ḥallāj had to pay with his life (922) for making the unorthodox announcement of his identity with the divine: "*Anā al-ḥaqq*" ("I am the Truth"). He was not the only one to speak in this manner. The more moderate Maḥmūd Shabestārī had reported an experience (c. 1320):

In God there is no duality. In that presence "I" and "we" and "you" do not exist. "I" and "you" and "we" and "He" become one. Since in the unity there is no distinction, the Quest and the Way and the Seeker become one.

But Muslim theologians as a rule tended to dismiss those who "boasted of union with the Deity" as merely "babblers." In the Jewish tradition, it is generally considered improper and indecorous for any man to give a personal account of his own mystical experience.

Behind these and other interpretations, the reality of the sacred—and its persistent ambiguity—appears to be too true to be denied or ignored. Awe may or may not be the best part of man, but without it a necessary dimension is left out of the image of man, the dimension of what Otto called the *mysterium tremendum et fascinans* ("the mystery that repels and attracts"). The mystics are loath to leave this dimension out and, directly or indirectly, insist on its inclusion. The reason was suggested in the 5th–4th centuries BC by the Greek philosopher Plato, who maintained that the divine was the head and root of man. The mystic's is the eye, the third eye, with which the world beholds itself and knows itself divine. Though the vision is partial and passes away, there could be an ideal state of unbroken awareness of the Real Presence, an epiphany (manifestation).

According to the mystical point of view, the rational content of religion is not enough; it is not of the essence of religion. The sense of the holy, the mark of man's encounter with the "other," is usually invested with an ethical aura or undertone. This is how most people understand it. But this lowers its potency considerably. There is clearly an overplus, below good and evil and beyond good and evil. The numinous (spiritual) is not altogether free of the ominous. Thus, though the holy may be discussed, it cannot be well defined. It can, however, be experienced and evoked, as part of that wordless mystery that man must face—even if he is not able to explain satisfactorily—in his journey toward the real. This may happen early or late in his mystical journey, and the notion of evolution may not be applied to it uniformly.

The holy is not always and altogether a pleasant experience. Often shrouded in a fear that is more than fear, it is an inward dread and shuddering. The holy as awe-inspiring can be found in the Indian pantheon in such figures as Rudra and Kālī, the dark and wrathful faces of the divine, in which—in a collapse of finitude—majesty and unapproachability are inexplicably blended. The feeling of being consumed in the presence of the divine is a profound expression of man's relation to the holy. As for the ultimate mystical identity with the Supreme, Self, God, or the Unknowable, that also confirms the nonrational and suprarational nature of the experience in which ego, logic, and grammar are shattered alike. A frightful and traumatic adventure, not unlike the Greek Mystery rites, it can erupt at every crisis, break through an insulated universe. A clergyman cited by William Starbuck, an American psychologist of religion, spoke of having experienced

a [silent] presence [in the night], all the more felt because it was not seen. I could not any more have doubted that *He* was there than that I was. Indeed, I felt myself to be, if possible, the less real of the two.

Diminution apart, the holy generally gives rise to a sense of energy and urgency, which may take different forms. At a higher level, the consuming fire of love reported by mystics could be an extension or refinement of the same energy, for "Love is nothing else than quenched Wrath." The "nothing else" may be an exaggeration, but such paradoxes of the religious life—e.g., the unity of opposites—meet man at every turn. The void in Buddhism, like the nothing in Western mysticism, may be a numinous ideogram of the "wholly other."

Means and modes of the relationship. As means to meet the divine, some mystics have taken recourse to fasting, breath control, meditation, ecstasy, simplification, autosuggestion, and monoideism (absorption in a single idea). Rituals, in some cases, provide contact. An old method is the *via negativa* ("negative way"): "the emptier your mind, the more susceptible are you to the working of the presence." In other words, the impediments have to be removed. Among other indirect—but no less effective—means would be the shock therapy of the blood-curdling images that one notes in Tibetan iconography and symbology, which have their links with the archaic and the chthonian (infernal). On more negotiable levels, works of art—as far apart as Sung (Chinese) paintings, Gothic cathedrals, medieval temple architecture in India, the Egyptian Sphinx, music such as the *Missa Solemnis* or Sanskrit (Hindu) hymns—are accredited conductors of the numinous. Darkness, solitude, silence, and emptiness are sometimes enough for the sensitive soul, and the doors of perception open to a wider world beyond. A wide stretch of land or cranes flying against a cloudy sky were enough to throw the 19th-century Indian saint Ramakrishna into transport. But, always, it is less the object than something seen through the object, a bodiless presence, that forms the essence. Without symbols in which the holy is embodied, the experience of the holy vanishes.

Though it creates a sense of awe and exaltation, the idea of the holy also produces a mood of dependence, leading to action aimed at appeasing the deity or the powers behind the universe. At first, the policy of appeasement may have been inspired by fear and hope of reward. But, since the deity is not ultimately malevolent, it could also evolve into an idea of grace. Mystical theology, both in the East and in the West, has sometimes been divided over the issue whether the union with the divine is the result of one's unaided effort or supernatural grace.

The approaches to the divine or sacred are various rather than uniform. Moving through physical, intellectual, devotional, and symbolic rituals and disciplines, it moves toward the ultimate goal: the annihilation of the self, *unio mystica* ("mystical union") in Western Christianity, *mokṣa* ("salvation") in Hinduism, Nirvāṇa (the State of Bliss) in Buddhism, and *fanā* ("the snuffing out of self") in Islām. Though the words differ, the experiences are perhaps allied, if not the same. In a Ṣūfī (Islāmic mystical) poem the divine voice speaks exultantly:

Annihilate yourself gloriously and joyously in Me, and in Me you shall find yourself; so long as you do not realize your nothingness, you will never reach the heights of immortality. The description could as well be applied to the Buddhist *śūnyatā* ("void") and the self-negating of the Christian mystics.

The ultimate has been, as a rule, thought of as something "other" and apart, even if in mysticism what is sought is union or unity. Hierophany (manifestation of the holy) implies a choice and a distinction: between that which manifests the sacred and that which does not. Also, though a hierophany may represent a historic event that does not minimize its larger validity (and in any culture there may be local as well as general hierophanies), a hierarchy is not unlikely. On occasions, the sacred may manifest itself in something profane. Ideally, to a mystic, "the integrated quality of the cosmos is itself a hierophany." From this follows the possibility of consecrating the whole of life, so that by sacramental transformation, at any moment, "the

The *via negativa*

The dimension of attraction and repulsion

The various approaches to the divine

flash of a trembling glance" may be inserted into the great time and project the man amphibian (having dual life) into eternity. Deification, without doubt one of the goals of the mystical life and a fundamental concept of orthodox Christendom, is part of the dialectics of the sacred. The alchemic undertone, in the man-God idea, has never wholly been extinguished. But, as part of the continuing paradox, one should also mention a resistance to the sacred. Depending on the ambivalence of the response to the sacred, which at once repels and attracts, the resistance is ultimately a flight from reality.

SEMANTICS AND SYMBOLISM IN MYSTICAL EXPERIENCE

Union of opposites. Mystical experience is flanked with a communication hazard, a "polar identity." The linguistic liberties and extravagances are part of the logical impossibility of having to describe one order of experience in terms of another. Hence, the rhetoric of mysticism is largely one of symbols and paradoxes. The most striking of the strategies, as the medieval Christian scholar Nicholas of Cusa put it, is *coincidentia oppositorum* ("union of opposites"). Since the opposites coincide without ceasing to be themselves, this also becomes an acceptable definition of God, or the nature of the Ground. God, said Heraclitus, is day and night, summer and winter, war and peace, and satiety and hunger—all opposites. A 5th- to 6th-century-AD Christian mystical writer called Dionysius the Areopagite advised people to

strip off all questions in order that we may attain a naked knowledge of that Unknowing and that we may begin to see the supressential Darkness which is hidden by the light that is in existent things.

This use of language or view of things is obviously not normal.

Old myths and archetypes are full of examples of such dichotomy. The Zoroastrian tradition has Ormazd (the Good Lord) and Ahriman (the Lie); the Gnostic myth speaks of Christ and Satan as brothers; and the same idea is found in the Vedas, where the *suras* ("good spirits") and *asuras* ("bad spirits") are shown to be cousins. In a different context there is the androgyne ("man-woman"), the *ardhanārīśvara* in Indian myth. As for the Hindu *jīvanmukta*, the liberated individual, he is liberated from duality. This is also part of what the Lord Kṛṣṇa (Krishna) said, when he asked the hero Arjuna to rise above the three *guṇas* ("modes"). The Tantras refer to the union of Śiva (a Hindu god) and Śakti (Śiva's consort) in one's own body and consciousness and provide appropriate practices to this end. The Chinese had their Yang and Yin (opposites), the Tibetans their Yab and Yum (opposites), and Buddhism its *saṃsāra* and *Nirvāṇa* as aspects of the Same. In *Prajñāpāramitā*, a Mahāyāna (northern Buddhist) text, the Illumined Ones are supposed to engage in a laughter in which all distinctions cease to exist.

Emptiness and fullness. Mystical experience permits complementary and apparently contradictory methods of expression: *via affirmativa* ("affirmative way," or fullness) as well as *via negativa* ("negative way," or emptiness). For fullness and freedom both are needed. This is because the reality affirmed contains its own opposite. In fact, the apparent negations—*neti-neti*, ("not this, not that") of the *Upaniṣads*, the *śūnyatā* ("void") of the Buddhists, or the Darkness beyond Light of Dionysius—perform a double function. They state a condition of being as well as its utter freedom from every determination. As Dionysius explains it, "While God possesses all the attributes of the universe, being the universal Cause, yet in a stricter sense He does not possess them, since He transcends them all." The "negative way," a way of turning the back upon the finite, is part of an old, positive, verified insight, at once the last freedom and, as far as many men are concerned, perhaps a lost freedom.

Symbolism of divine messengers. Experiences relating to these realities could not at any time have been common or widespread and must have come mainly through consecrated channels: yogis (Hindu meditation practitioners), gurus (Hindu teachers), prophets, mystics, saints, and spiritual masters of the inner life. This channelling through human agents has given rise to a host of divine messengers:

a hierarchy of angels, intermediaries, and incarnations, singly or in succession. This manner of approaching or receiving the divine or holy is the justification of avatars (incarnations of God) and the man-God in various religions. "God was made man in order that man might be made God."

The mystical experience is a renovation of life at its root; that is, of the forgotten language of symbols and symbolism. The mystic participates in two worlds at once, the profane and the sacred. Rituals and ceremonies become the means of integration with a higher reality and consciousness. But symbols cannot be deliberately manufactured, nor do they make an arbitrary system. "Being for ever communicating its essence" is the source of their abundance, potency, and unity. Even a nontheistic mysticism, such as Buddhism, has deployed symbols freely, of which perhaps the most well-known is the formula *om maṇi padme hūṃ* ("the jewel in the lotus").

Symbols point beyond themselves, participate in that to which they point, open up levels of reality that are otherwise closed to man, unlock dimensions and elements of the soul that correspond to reality and cannot be produced intentionally or invented. Symbols may be inner or outer. To some, nature symbolism comes easily.

Symbolism of love and marriage. A far more risky but inescapable mode of symbolism than pantheism has been the use of the analogy of human love and marriage. Not all the mystics have been deniers or champions of repression. The soul, it may be added, is always feminine. The Christian mystics St. Bernard and St. John of the Cross, the Islamic Sūfī poets, and the Hindu Dravidian and Vaiṣṇava saints could teach lovers. Not only the church but the faithful are viewed to be among Christ's brides and speak the language of love. "O that you would kiss me with the kisses of your mouth!" The speaker is the bride, thirsting for God. St. Bernard has shown that through carnal, mercenary, filial, and nuptial love the life of man moves toward the mystery of grace and union.

The hermeneutics (critical interpretation) of "the Bridegroom-Word" is that "the soul's return is her conversion to the Word, to be reformed through Him and to be conformed to Him." In the West, the roots of the tradition go back to the Song of Solomon in the Bible, not, perhaps, the best of models. The Hindu *līlās* ("love plays") of Rādhā and Kṛṣṇa have been freely misunderstood in spite of the repeated disclaimer that the events described are not facts but symbols. The charge of immorality has been loudest against the Tantras, which had made a subtle, bold, and strict experiment in sublimation, whose inner sense may fail to be intelligible even to those who are attracted by it. That the marriage symbol should find a readier response among the brides of Christ is only to be expected. In *The Interior Castle*, St. Teresa has been fairly outspoken: "He has bound Himself to her as firmly as two human beings are joined in wedlock and will never separate Himself from her." But this was not a monopoly of nuns. The medieval theologian Richard of Saint-Victor has described as well as explained the "steep stairway of love" made up of betrothal, marriage, wedlock, and fruitfulness. In a slightly different set of symbols, St. John of the Cross states that after the soul has driven away from itself all that is contrary to the divine will, it is "transformed in God by love."

Symbolism of the journey. Another prominent mystical symbol is the way, quest, or pilgrimage. Having lost the paradise of his soul, man, as the 16th-century physician and alchemist Paracelsus says, is a wanderer ever. A Christian monk, St. Bonaventure, has written about the mind's journey to God, and an English mystic, Walter Hilton, has described the Christian journey thus:

Right as a true pilgrim going to Jerusalem, leaveth behind him his house and land, wife and child, and maketh himself poor and bare from all that he hath, that he may go lightly without letting: right so, if thou wilt be a ghostly pilgrim, thou shalt make thyself naked from all that thou wouldst be at Jerusalem, and at none other place but there. (From *The Ladder of Perfection*.)

According to the Sūfis, the pilgrim is the perceptive or intuitional sense of man. Aided by attraction, devotion,

Participation in two worlds at once

The notion of the "stairway of love"

Role of symbols and paradoxes

and elevation, the journey leads, by way of many a wine shop (divine love), to the tavern (illumination), "the journey to God in God." In his *Conference of the Birds*, the 12th-century Persian Šūfi 'Aṭṭār refers to the seven valleys en route to the king's hidden palace: the valleys of quest, love, knowledge, detachment, unity, amazement, and, finally, annihilation. Others have gone further and spoken of "annihilation of annihilation." In the symbolic universe, denudation may be viewed as a way of fullness.

Men are called to the journey inward or upward because of a homing instinct. Eckehart put the matter simply: earth cannot escape the sky. All men are called to their origin, which implies God's need of man. A mutual attraction, the tendency toward the Divine cannot be stifled indefinitely, since it returns after every banishment. For some, paradise is not enough; it is too localized and perhaps perishable. They strain toward eternity, a leap beyond history into the incommunicable forever. A white radiance to some, to others it is "a ring of pure and bright light." The Veda speaks of the *kālahahaṃsa* ("the swan of time") winging back to the sky and nest, eternity.

Essentially a way of return, *ricorso*, the final aim of mysticism is transfiguration. But

by what alchemy shall this lead of mortality be turned into that gold of divine Being? But if they are not in their essence contraries? If they are manifestations of one Reality, identical in substance? Then indeed a divine transmutation becomes conceivable. (From Sri Aurobindo, *The Life Divine*.)

This is a clue to the Vedas, those hymns to the mystic fire and the inner sense of sacrifice, burning forever on "the altar Mind." Hence the abundance of solar and fire images: birds of fire, the fire of the sun, and the isles of fire. The symbol systems of the world religions and mysticisms are profound illuminations of the human-divine mystery. Be it the cave of the heart or the lotus of the heart, "the dwelling place of that which is the Essence of the universe," the third eye, or the eye of wisdom—the symbols all refer back to the wisdom entering the aspiring soul on its way toward progressive self-understanding. "I saw my Lord with the Eye of the Heart. I said, 'Who art Thou?' and he answered, 'thou'." Throughout the ages man, *homo symbolicus*, has been but exploring the endless miracle of being. Mystical experience is a living encyclopaedia of equations and correspondences, pointer readings that partly reveal and partly conceal.

PSYCHOLOGICAL ASPECTS OF MYSTICISM

Awareness. Mysticism has been accused of passing off psychological states for metaphysical statements. But the psychological base has never been questioned seriously. It would, however, be proper to call it autology (the science of self). If the word psychology is to be retained, it must be in the original sense of the word now discarded. The contrast between the old and the new has been well expressed by the Russian philosopher P.D. Ouspensky:

Never in history has psychology stood at so low a level, lost all touch with its origin and meaning, perhaps the oldest science and, unfortunately, in its most essential features, a forgotten science, the science of [man's] possible evolution.

Mysticism is that science in which the psychology of man mingles with the psychology of God. The major change or orientation is from the level of the profane to the sacred, an awareness of the divine in man and outside. The source and goal of such a psychology was revealed in the 18th-century Methodist leader John Wesley's dying words: "The best of all is this, that God is with us."

A mark of the mystic life is the great access of energy and enlarged awareness, so much so that the man who obtains the vision becomes, as it were, another being. Mansions of the mind, *maqām* (Arabic: "place"), and *bhūmi* (Sanskrit: "land"), open up to the gaze of the initiate, a wayfarer of the worlds. This means a renewal or conversion until one knows that the earth alone is not man's teacher. The mystic begins to draw his sustenance from supersensuous sources. He has "drunk the Infinite like a giant's wine," and a hidden bliss, knowledge, and power begin to sweep through the gates of his senses.

Role of identification. The state of energizing is facilitated by controlled attention. It is customary to fix the

mind on some object or idea, some focus of contemplation. According to the Indian formula, to worship God one must become like him (*devam bhutva devam yajet*). Exercises, physical no less than mental, including methods of worship and prayer, have been developed to this end until one becomes what one contemplates. The ranges and creative aspects of the mind are part of the psychology of the mystics and one of the oldest traditions of mankind. The old Indian psychology divided consciousness into three provinces: waking state (*jāgrat*), dream state (*svapna*), and sleep state (*susupti*), and added a fourth (*turiya*), which is the consciousness of man's pure self-existence or being. The fourfold scale represents the degrees of the ladder of being by which man climbs back to the source, the absolute divine. The change, from "here" to "there," is not an uneventful process. There come dry periods, deviations, violent alterations, and temptations. If there are raptures and blue heavens, there are python agonies and absolute abandonments, howling deserts and "dark nights of the soul" to go through. Tears of joy, horripilation (bristling of the hair), stigmata (bodily marks or pains), and parapsychological phenomena have been known to develop.

The earlier phases of a naturalistic psychology had no qualms in relegating most of these experiences to the scrap heap of obsolete and archaic vanities, disorders, and morbidities—in a word, hallucination. One reason for such overall denigration was that complacent aliens to the mystical life did not care to distinguish between abnormal and supernormal phenomena. To them all were the same, at best some kind of religious sport. An American Quaker philosopher, Rufus Jones, has noted that psychology, as 20th-century man knows it, is empirical and possesses no ladder by which it can transcend the empirical order.

According to mystics, most men live in a prison, the walls thick with ego, the senses, and restricting interests. But some prisoners develop a passion to scale the walls and move toward an unvalled horizon, an adventure of ideas, if nothing more. Thus, the hypothesis that there might be cherubs and seraphs (angels of knowledge and of love) who call and guide men in the upward way is difficult to ignore. But if the distinction between love and knowledge is at all valid, the achievements of men would seem to be the products of love, since, as Aristotle maintained, the intellect by itself moves nothing. Without "the driving and drawing that we feel in the heart," mysticism would lack power and might sink into quiescence, as has sometimes happened. To will what the Supreme wills is the supreme secret, the *primum mobile*. "Nothing burns in hell but self-will" (*Theologia Germanica*, ch. 34). The mystic approaches this knowledge and mobility even when he is compelled to withdraw from society for long or short periods. But withdrawal without return is not complete. As scientists of the psyche, the mystics insisted on the primacy of the inner factors. Modern psychoanalysis claims to have made available to man's knowledge areas of darkness beneath the conscious levels. However revealing these evidences of the ape and the tiger, psychoanalysis is debarred from understanding the superconscious, and it is viewed by mystics as being less than correct in its reading of the irrational in man. The inescapable pessimism of the psychoanalytic conclusion stands in contrast to the possibilities of self-development and sublimation to which mystics have always pointed.

Among other discoveries on the mystical way is that of ambivalence, or the alternate ways of looking at the world: temporal as against eternal. The double vision characterizes the saint whose life forms a point of intersection between time and timelessness. Mystical psychology assumes a transcendental faculty, in the hiddenness, beyond the threshold. It is committed to a breakthrough and could never have sustained itself without constant verification. In many ways a guarded secret, meant for the competent few, the experiment has hazards and could upset any but the most disciplined. The rousing of energy, the infusion of grace, and confrontation of the levels of reality create tensions and difficulties. Hence, the insistence on moderation and balance on all hands. "The higher the love, the greater the pain," a voice had consoled a 13th-century German mystic, Mechthild von Magdeburg. "Believe me,

Indian
states of
conscious-
ness

Solar
and fire
symbolism

children," wrote a 14th-century German mystic, Johann Tauler, "one who would know much about these matters would often have to keep to his bed, for his bodily frame could not support this."

These upheavals of "mystic ill health" are part of a developing consciousness that has to move through and adjust to habits of inertia and resistance in the system and to an inability to support the emerging powers and their demands. A little imbalance now and then should take no one by surprise. The possibility of ranges of consciousness without thinking is one of the basic premises of yogic or mystical psychology. It constitutes a confutation of the formula of the 17th-century French philosopher René Descartes: *cogito ergo sum* ("I think; therefore, I am"). Being can exist without *cogito* (or *ratio*, "reason") in a direct awareness of things that is the function of intuition, *prajñā*.

thinking

SYSTEMATIC EXPOSITION OF MYSTICAL EXPERIENCE

Attempts of mystics to record the nature of their experiences. The theory or interpretation of mysticism is not mysticism. Generally, there are two sides to the theory: philosophical and practical. There may be another: confessional and justificatory. Though some mystics have been content to record what happened, others have worked out manuals of praxis (techniques), or *sādhāna*. As a rule, mystical method, experience, and exegesis cannot be sharply set apart from one another. However ineffable, raids on the inarticulate and expositions of the same have not ceased. The expositions have formed part of a particular framework of culture, tradition, and temperament. The 8th- to 9th-century-AD Indian philosopher Śaṅkara and the 16th-century Spanish mystic St. John of the Cross are not likely to talk in the same tone or accent. However universal in intent, all expositions tend to be localized.

The study of comparative mysticism as well as the spirit of the age make it possible and perhaps mandatory for modern man to move toward an open and untethered mysticism, the "ocean of tomorrow." Indications of this change in attitude and emphasis are not wanting, especially in the 20th-century writings of the Indian mystic philosopher Sri Aurobindo and Teilhard de Chardin, who represent something totally new but allied. R.C. Zaehner has explained that both, though unknown to each other, not only accepted the theory of evolution, but enthusiastically acclaimed it, indeed were almost obsessed with it. Both were profoundly influenced by Bergson, both were deeply dissatisfied with organized religion, and both were vitally concerned not only with individual salvation or "liberation," but also with the collective salvation of mankind.

The value and meaning of mystical experience. Among the attempts to explain the value and meaning of mystical experience, a few features may be indicated. Claimed to be a guarantee for order and reconciliation, mysticism does not take away mystery from the world, nor is it essentially irrational. Though in their penchant for the beyond or God-intoxication some mystics have inclined to reject the world, the maturer variety has not divided the world of spirit and matter but has tried to mediate between spirit and matter with the help of emanations, correspondences, and a hierarchy of the real. As a giver of life, mysticism is meant to fulfill and not to destroy. Thus, it need not be world negating.

Pointing to a scale of senses and levels of mind, mysticism provides an escape from a life of uninspired existence. It magnifies man and gives him a hope and destiny to fulfill. With its abiding sense of the "more," mysticism may be called the religion of man or the religion of maturity. It offers not irrational developments or inducements but the working out of inherent potentials. Evolution, according to mystics, is not yet ended.

The mystical life is not for those who are well adjusted and other oriented. In Ramakrishna's homely phrase, at some point or other one has to "take the plunge." A change so radical calls for a kind of attention other than what most people seem prepared to give. To make it his supreme business one must have a call to holy living. He who seeks the divine must consecrate himself to God and to God only.

Problems of communication and understanding. The problem of communication, of tidings from another country, is obvious. Transvaluation of values is not easy to accept, adjust to, or express. The dialogue between mystical and other pursuits is an unsolved problem. After he had undergone a spiritual experience, the 13th-century Christian philosopher St. Thomas Aquinas is reported to have said, "I have seen that which makes all that I have written and taught look small to me. My writing days are over." This, from the author of the voluminous *Summa theologica* ("Summary of Theology"), is not without its importance.

Even if it is difficult to describe visions and dangerous to systematize, the direction in which mysticism points is clear: relational transcendence. The 20th-century crises and the mass media suggest the possibility of a mysticism brought up to date that will serve "the Creative Intention that past ages have called God." Whether it comes through symbols, systems, paradigmatic examples, or extreme situations, there will probably always be some response to the call of the real.

MYSTICISM AS A SOCIAL FACTOR

Mystical experience is no doubt solo, the experience of a singular person. But more than "a flight of the alone to the Alone," it could also be a redemption of solitude no less than of society. In the mystic experience, as Jakob Böhme said, the world is not destroyed but remade. At times a protest against heteronomy (*i.e.*, external authority and ecclesiastical machinery), mysticism has expressed itself in diverse backgrounds and flourished during dark periods of history.

Because of its other-worldly bias, the belief still persists that the solitary mystic, absorbed in a vertical relation with God or reality, owes no social responsibility. Altogether an outsider, he has deliberately undergone a civil death. This is not an ideal or wholly accurate picture. "A Mystic who is not of supreme service to the Society is not a Mystic at all" (from preface to R.D. Ranade, *Mysticism in Maharashtra*). According to Zen Buddhism, the great contemplative—even when "sitting quietly, doing nothing"—has been a man of action, perhaps the only kind of action that leaves no bitter residue behind. The less extravagant forms of mysticism represent attitudes and principles of charity, detachment, and dedication, which should guide the relation of the individual to the group. The mystics have fought the inner battle and won, creating themselves and their world.

Mysticism proves the individual's capacity to rise above the conditioning factors of nature, nurture, and society and to transform collective life, though this has not been generally recognized. With a hidden and potent force, mystics have tried, as best as circumstances permitted, to mend the universal ill. As in the classic resolve of the *bodhisattva* ("buddha-to-be"), they have looked forward to universal enlightenment. If the attempt by mystics to create a new order or a better society has failed, the incapacity or defection of the majority may be the reason for the failure.

"Revolution" is a word too often profaned. The change suggested is mainly, if not wholly, from without. In such contrived salvation by compulsion, the inner core is hardly touched. "But it is an eternal law that there can be no compulsion in the realm of the spirit. It is essentially a world of free creative choices" (Rufus Jones, *Some Exponents of Mystical Religion*). Mystics insist on a change of consciousness, a slower and more difficult process, and also on a scrupulous equation between ends and means. Impatience, deviations, and subterfuges in this respect can be costly, ironic, and instructive. According to mystics, the individuals who will most help the future of humanity will be those who recognize the unfinished and ultimate revolution—the evolution of consciousness—as the destiny and therefore the great need of all men as of society.

Holiness does not mean a retreat from or a rejection of the world. To be a mystic or a seer is not the same thing as being a spectator on the fence. As the Swedish secretary-general of the United Nations, Dag Hammarskjöld, proved with his life, in the modern era the road to holiness

The mystic
as a man
of action
"doing
nothing"

necessarily passes through the world of action. Many with a mystical frame of mind look beyond what mystics call quasi-revolutions to a great life—an entire civilization, the civilization of consciousness. The need of synthesis places its stake on the future and the All.

The outcome of the world, the gates of the future, the entry into the super-human—these are not thrown open to a few of the privileged nor to one chosen people to the exclusion of all others. They will open only to an advance of *all together*. (From Teilhard de Chardin, *The Phenomenon of Man*.)

According to mystics, here may be the outline of a revolution whose message has reached but a few. The hope of a Kingdom of Heaven within man and a City of God without remains one of mysticism's gifts to what many mystics view as an evolving humanity. (S.Gh.)

The nature of religious experience: WILLIAM JAMES, *The Varieties of Religious Experience* (1902), a classic philosophical and psychological study; RUDOLF OTTO, *Das Heilige*, 9th ed. (1922; Eng. trans., *The Idea of the Holy*, 1923; 2nd ed., 1950), a study of the nonrational in religious experience; J.M. MOORE, *Theories of Religious Experience, with Special Reference to James, Otto and Bergson* (1938); JAMES A. MARTIN, JR., *Empirical Philosophies of Religion* (1945); and C.C.J. WEBB, *Religious Experience* (1945), contain valuable appraisals and good bibliography; H.E. BRUNNER, *Wahrheit als Begegnung* (1937; Eng. trans., *The Divine-Human Encounter*, 1943); and MARTIN BUBER, *Ich und Du* (1923; Eng. trans., *I and Thou*, 1937 and 1970), express the view that authentic religion is based on personal encounter between man and God; JOHN DEWEY, *A Common Faith* (1934), argues for the "religious" in experience; E.S. BRIGHTMAN, *A Philosophy of Religion* (1940), represents the Personalist view that personhood is the most basic quality of reality; W.E. HOCKING, *The Meaning of God in Human Experience* (1912, reprinted 1963); J.E. SMITH, *Experience and God* (1968), emphasize the experiential basis of the question of God; and ALISTER HARDY, *The Spiritual Nature of Man: A Study of Contemporary Religious Experience* (1979), a collection of 3,000 personal reports.

Religious experience and other experience: H.D. LEWIS, *Our Experience of God* (1959); and J.E. SMITH, *Religion and Empiricism* (1967), deal with the bearing of different conceptions of experience on religion; JOSIAH ROYCE, *The Sources of Religious Insight* (1912); W.G. DE BURGH, *From Morality to Religion* (1938); and PAUL TILLICH, *Morality and Beyond* (1963), treat the relation between religion and morality; GERARDUS VAN DER LEEUW, *Vom Heiligen in der Kunst* (1957; Eng. trans., *Sacred and Profane Beauty*, 1963), treats the relation between art and religion.

The structure of religious experience: JOHN MACMURRAY, *The Structure of Religious Experience* (1936, reprinted 1971); J.B. PRATT, *The Religious Consciousness* (1920); PAUL TILLICH, *The Dynamics of Faith* (1957); and A.N. WHITEHEAD, *Religion in the Making* (1926), deal with psychological, theological, and metaphysical aspects; JOACHIM WACH, *The Sociology of Religion* (1944), is an indispensable study of the social expression of religious experience; WILLIAM A. CHRISTIAN, *Meaning and Truth in Religion* (1964); F. FERRE, *Basic Modern Philosophy of Religion* (1967); NINIAN SMART, *Philosophers and Religious Truth* (1964); and J.E. SMITH, *Reason and God* (1961), deal with the issue of the cognitive import of religious experience; J.H. LEUBA, *The Psychology of Religious Mysticism* (1925), argues against its cognitive import; W.E. HOCKING, *Science and the Idea of God* (1944); W.T. STACE, *Religion and the Modern Mind* (1960); and H.N. WIEMAN, *The Wrestle of Religion with Truth* (1927), discuss the relation between religion and science; J. MACQUARRIE, *God-Talk* (1967); I.T. RAMSEY, *Christian Discourse* (1965) and *Models and Mystery* (1964), represent the linguistic approach to religious experience; MIRCEA ELIADE, *Le Mythe de l'éternel retour* (1949; Eng. trans., *Cosmos and History: The Myth of the Eternal Return*, 1954; rev. ed., 1965) and *The Sacred and the Profane: The Nature of Religion* (1959), interpret religious experience through myth, symbol, and ritual.

Situational contexts and forms of expression: EVELYN UNDERHILL, *Worship* (1936, reprinted 1957), invaluable for the meaning of worship and its forms; P. EDWALL *et al.* (eds.), *Ways of Worship* (1951), treats the liturgies of the major Christian communities; EMILE DURKHEIM, *Les Formes élémentaires de la vie religieuse* (1912; Eng. trans., *The Elementary Forms of the Religious Life*, 1915, paperback 1961), presents the "group theory" of religion; C.C.J. WEBB, *Group Theories of Religion and the Individual* (1916), a critique of Durkheim; MIRCEA ELIADE, *Birth and Rebirth* (1958); ARNOLD VAN GENNEP, *Les Rites de passage* (1909; Eng. trans. 1960); and GERARDUS VAN DER LEEUW, *Phänomenologie der Religion* (1933; Eng. trans., *Religion in Essence and Manifestation*, 1938), on initiation rites and the cycle of sacred life; JOACHIM WACH, *The Sociology of Religion* (1944), the best source for the relation between religious and nonreligious groupings.

Types of religious experience and personality: GERARDUS VAN DER LEEUW, *Religion in Essence and Manifestation* (op. cit.); and JOACHIM WACH, *The Sociology of Religion* (1944) and *Types of Religious Experience* (1951), invaluable for the analysis of religious roles and personalities; ALFRED GUILLAUME, *Prophecy and Divination Among the Hebrews and Other Semites* (1938); RUDOLF OTTO, *Religious Essays* (1931); and JOHN SKINNER, *Prophecy and Religion* (1922; paperback ed., 1961), deal with the meaning of prophecy in the Semitic traditions.

Mystical experience: RICHARD M. BUCKE, *Cosmic Consciousness: A Study in the Evolution of the Human Mind* (1905, many later editions), introduced two important ideas as one, ideas that would recur, with modifications, in later writings. RUFUS M. JONES, *Studies in Mystical Religion* (1908, reprinted 1970), provided a balanced and liberal attitude that emphasized its experiential quality, its value as a practical guide, and the presence of a mystical brotherhood through the centuries. EVELYN UNDERHILL, *Mysticism*, 12th ed. rev. (1957), has been a pioneer work, though its insistence on the Mystic Way has been questioned. REYNOLD A. NICHOLSON, *The Mystics of Islam* (1913, reprinted 1966), is one of the earliest studies in Sūfism that still holds interest. SRI AUROBINDO, *The Synthesis of Yoga* (first published, serially, 1914–21, later in book form), with much collateral illumination, explains the idea of Integral Yoga. HENRI BERGSON, *Les Deux sources de la morale et de la religion*, 3rd ed. (1932; Eng. trans., *Two Sources of Morality and Religion*, 1935), forms part of a general thesis on creative evolution and, paradoxically, on the need for mysticism in an age of mechanization. GERSHOM G. SCHOLEM, *Major Trends in Jewish Mysticism*, 3rd rev. ed. (1954), clearly brings out the distinction that the concept of union is not an essential of mystical experience as understood in the Jewish tradition. ALDOUS HUXLEY, *The Perennial Philosophy* (1946), is an anthology with sophisticated, sometimes cynical, commentary with an ascetic bias. JACQUES DE MARQUETTE, *Introduction to Comparative Mysticism* (1949), is a fair and straightforward survey in which its relevance to modern life and thought is brought out and an awareness of possibilities hinted at. R.C. ZAEHNER, *Mysticism, Sacred and Profane* (1957), beginning as a caveat against the use of drugs for transcendental experience, goes on to make critical distinctions between four types of mysticism. D.T. SUZUKI, *Mysticism: Christian and Buddhist* (1957), offers a sympathetic study of contrasts as well as some resemblances between two traditions. RADHAKAMAL MUKERJEE, *The Theory and Art of Mysticism* (1960), is an overall study, particularly good with regard to the Eastern material. WALTER T. STACE, *Mysticism and Philosophy* (1960), is balanced and analytic but singles out introverted mysticism as more genuine and superior. SIDNEY SPENCER, *Mysticism in World Religion* (1963), is a helpful anthology with a reliable introduction to the field of comparative mysticism. PIERRE TEILHARD DE CHARDIN, *Le Phénomène humain* (1955; Eng. trans., *The Phenomenon of Man*, 1959), though its scientific accuracy has been questioned, its poetic and impassioned attempt to mediate between religious insights and a hope for man and the future has made it the object of much attention. See also LOUIS DUPRÉ, *The Deeper Life: An Introduction to Christian Mysticism* (1981); and RICHARD WOODS, *Mysterion: An Approach to Mystical Spirituality* (1981).

Religious Symbolism and Iconography

Symbolism, the basic and often complex artistic forms and gestures used as a kind of key to convey religious concepts, and iconography, the visual, auditory, and kinetic representations of religious ideas and events, have been utilized by all the religions of the world.

In the 20th century the symbolical character of religion has often been stressed over attempts to present religion rationally. The symbolic aspect of religion is even considered by some scholars of psychology and mythology as the main characteristic of religious expression. Scholars of comparative religions, ethnologists, and psychologists have gathered and interpreted a great abundance of material on the symbolical aspects of religion, especially in relation to Eastern and primitive religions. In recent Christian theology and liturgical practices another revaluation of religious symbolical elements has occurred.

The importance of symbolical expression and of the pictorial presentation of religious facts and ideas has been confirmed, widened, and deepened both by the study of primitive cultures and religions and by the comparative study of world religions. Systems of symbols and pictures that are constituted in a certain ordered and determined relationship to the form, content, and intention of presentation are believed to be among the most important means of knowing and expressing religious facts. Such systems also contribute to the maintenance and strengthening of the relationships between man and the realm of the sacred or holy (the transcendent, spiritual dimension). The symbol is, in effect, the mediator, presence, and real (or intelligible) representation of the holy in certain conventional and standardized forms.

THE NATURE OF RELIGIOUS SYMBOLS AND SYMBOLIZATION

The word symbol comes from the Greek *symbolon*, which means contract, token, insignia, and a means of identification. Parties to a contract, allies, guests, and their host could identify each other with the help of the parts of the *symbolon*. In its original meaning the symbol represented and communicated a coherent greater whole by means of a part. The part, as a sort of certificate, guaranteed the presence of the whole and, as a concise meaningful formula, indicated the larger context. The symbol is based, therefore, on the principle of complementation. The symbol object, picture, sign, word, and gesture require the association of certain conscious ideas in order to fully express what is meant by them. To this extent it has both an esoteric and an exoteric, or a veiling and a revealing, function. The discovery of its meaning presupposes a certain amount of active cooperation. As a rule, it is based on the convention of a group that agrees upon its meaning.

Concepts of symbolization. In the historical development and present use of the concepts of symbolization, a variety of categories and relationships must necessarily be differentiated. Religious symbols are used to convey concepts concerned with man's relationship to the sacred or holy (e.g., the cross in Christianity) and also to his social and material world (e.g., the *dharma-cakra*,

or wheel of the law, of Buddhism). Other nonreligious types of symbols have achieved increasing significance in the 19th and 20th centuries, especially those dealing with man's relationship to and conceptualization of the material world. Rational, scientific-technical symbols have assumed an ever increasing importance in modern science and technology. They serve partly to codify and partly to indicate, abbreviate, and make intelligible the various mathematical (e.g., =, equality; ≡, identity; ~, similarity; ||, parallel; or <, less than), physical (e.g., ~, alternating

current), chemical (e.g., , benzene ring), biological

(e.g., ♂, male; ♀, female), and other scientific and technical relationships and functions. This type of "secularized" symbol is rooted, to a degree, in the realm of religious symbolism. It functions in a manner similar to that of the religious symbol by associating a particular meaning with a particular sign. The rationalization of symbols and symbolical complexes as well as the rationalization of myth have been in evidence at least since the Renaissance.

The concept of the religious symbol also embraces an abundantly wide variety of types and meanings. Allegory, personifications, figures, analogies, metaphors, parables, pictures (or, more exactly, pictorial representations of ideas), signs, emblems as individually conceived, artificial

symbols with an added verbal meaning, and attributes as a mark used to distinguish certain persons all are formal, historical, literary, and artificial categories of the symbolical. If one looks for a definable common denominator for the various types of symbols, one could perhaps choose the term "meaning picture" or "meaning sign" to best describe the revealing and at the same time the concealing aspects of religious experience. The symbol (religious and other) is intended primarily for the circle of the initiated and involves the acknowledgment of the experience that it expresses. The symbol is not, however, kept hidden in meaning; to some extent, it even has a revelatory character (*i.e.*, it goes beyond the obvious meaning for those who contemplate its depths). It indicates the need for communication and yet conceals the details and innermost aspects of its contents.

Varieties and meanings associated with the term symbol. Different forms and levels of the experience of and relationship to reality (both sacred and profane) are linked with the concepts of symbol, sign, and picture. The function of the symbol is to represent a reality or a truth and to reveal them either instantaneously or gradually. The relationship of the symbol to a reality is conceived of as somewhat direct and intimate and also as somewhat indirect and distant. The symbol is sometimes identified with the reality that it represents and sometimes regarded as a pure transparency of it. As a "sign" or "picture" the representation of the experience of and relationship to reality has either a denotative or a truly representative meaning. The doctrine of the eucharistic (sacramental) presence of Christ in the teachings of Eastern Orthodoxy, Roman Catholicism, and the Protestant Reformers concretely demonstrate the various and extensive levels of symbolical understandings. These levels extend all the way from the concept of physical identity in the transubstantiation theory of Roman Catholicism (in which the substance of breadness and wineness is believed to be changed into the body and blood of Christ, though the properties of the elements remain the same) through Luther's Real Presence theory (in which Christ is viewed as present, though the question of how is not answered because the question of why he is present is considered more important), and Zwingli's sign (symbolic or memorial) theory, to the concept of mere allusion. The concept of the symbol, however, includes all these interpretations.

Furthermore, a symbol in its intermediary function has aspects of epistemology (theory of knowing) and ontology (theory of being). As a means of knowledge, it operates in a characteristically dialectical process of veiling and revealing truths. It fulfills an interpretative function in the process of effectively apprehending and comprehending religious experience. In doing so, the word, or symbol—with its meaning, contextual use, relationship to other types of religious expression, and interpretative connection with the various forms of sign, picture, gesture, and sound—plays an important part in the process of symbolical perception and reflection. Although the symbol is an abbreviation, as a means of communication it brings about—through its connection with the object of religion and with the world of the transcendent—not only an interpretative knowledge of the world and a conferral or comparison of meaning to life but also a means of access to the sacred reality. It may possibly even lead to a fusion, or union of some sort, with the divine. To this extent, the sacrament of the Lord's Supper, the liturgical and ritualistic mystery in Christianity—with its many symbolical signs, pictorial representations, significant actions, interpretative words, and various levels of approach to the divine reality—is an example of a highly developed form of a complex symbolic action. Here, the concept of analogy is important; the symbol functions in these ways because it has an analogous cognitional as well as existential relationship to that which it signifies.

The symbolic process. To trace the origin, development, and differentiation of a symbol is a complicated process. Almost every symbol and picture in religion is at first either directly or indirectly connected with the sense impressions and objects of man's environment. Many are derived from the objects of nature, and others are arti-

ficially constructed in a process of intuitive perception, emotional experience, or rational reflection. In most cases, the constructions are again related to objects in the world of sense perception. A tendency toward simplification, abbreviation into signs, and abstraction from sense objects is quite evident, as well as a tendency to concentrate several processes into a single symbol. A good example of this last tendency may be seen in ancient Christian portrayals of the triumphant cross before a background of a star-filled heaven that appear in the apses of many basilican churches. In these representations the Crucifixion, Resurrection, Ascension, exaltation, and Transfiguration of Christ are joined to apocalyptic concepts (centring on sudden interventions by God into history) inherent in the doctrine of the Last Judgment. An excellent example of such an apse mosaic is to be found in the S. Apollinare in Classe, near Ravenna (in Italy). On the other hand, there is a tendency to accumulate, combine, multiply, and differentiate symbolical statements for the same thought or circumstance, as seen, for example, on the sarcophagi (stone coffins) of late Christian antiquity—especially in Ravenna. Here, the same idea is symbolically expressed in various manners; *e.g.*, by means of persons, objects, animals, and signs, all appearing side by side.

The forms and figures of symbolical thought can change into exaggerations and rank growths, however, and lead to transformations and hybrids—figures with several heads, faces, or hands—as exemplified in the statues and pictorial representations of the deities of India (*e.g.*, the multi-armed goddess Kālī) and of Slavic tribes (*e.g.*, the four-headed Suantevitus). The meaning of individual symbols can change and even be perverted. The lamb that in ancient Christian art symbolizes Christ may also symbolize the Apostles or mankind in general. The dove may symbolize the Holy Spirit or the human soul. The wheel or circle can symbolize the universe, the sun, or even the underworld. The encyclopaedic Christian allegorism (symbolism) of the Middle Ages offers many interesting examples, as noted in the writings of Isidore of Seville, a 6th- to 7th-century Spanish theologian, and Rabanus Maurus, a 9th-century German abbot and encyclopaedist.

The foundations of the symbolization process lie in the areas of the conscious and the unconscious, of experience and thought, and of sense perception, intuition, and imagination. From these arises the structure of religious symbolism. Sensation and physiological and psychological processes participate in the formation of the symbol structure. Extraordinary religious experiences and conditions, visions, ecstasy, and religious delirium brought about by intoxication, hallucinogenics, or drugs that produce euphoria and changes in consciousness must also be taken into consideration. The symbol itself, however, is intended as an objective concentration of experiences of the transcendent world and not as a subjective construction of a personally creative process. In cultic and mystical visions and trances, the forms and processes of the external world and of the religious tradition are condensed and combined with mythical images and historical events and take on a life of their own. The process of rational conceptualization and structuralization, however, also plays a part in the origin and development of many symbols. There is a correlation between sense perception, imagination, and the work of the intellect.

Symbols in the religious consciousness. The formation of religious symbols that occur when unconscious ideas are aroused or when a process of consciousness occurs is principally a matter of religious experience. Such symbols usually become intellectual acquisitions, and, as religious concepts are further elaborated upon, the symbols may even finally become subjects of major theological questions. In Christian theology, for example, summaries of dogmatic statements of faith are called symbols (*e.g.*, the Apostles', Nicene, and Athanasian creeds and the confessional books of Protestantism, such as the Augsburg Confession of Lutheranism). This particular use of the term symbol is exceptional, however.

In the development of the symbol, religious experience, understanding, and logic are all connected, but each places different accents on the individual categories and species

Denotative and cognitive aspects

The foundations of the symbolization process

Development and differentiation of a symbol

Religion
as both
origin and
product of
symbols

of symbol. Occasionally, religion is regarded as the origin and the product of certain established (or fundamental) symbols. In such cases the outcome of the process of the structuralization of religious consciousness would then be the establishment of a symbol that is generally applicable to a particular historical species of religion. Conversely, one could ask whether the experience and establishment of an individual or collective symbol by a creative personality or a community is not itself the establishment of a religion. If so, the classical symbol that was developed at the time of the foundation of any one particular religion would then be constitutive for its origin and further development (e.g., the T'ai Chi or the combination of Yin and Yang for the Chinese, the cross for the Christian religion). In any event, the symbol belongs to the essence of man's coming of religious consciousness and to the formation of history's institutional religions. It plays a fundamental and continual part in the further growing of such religions and in the mental horizons of their followers.

THE RELATION OF THE SYMBOL AND THE SACRED

Symbols as the incarnate presence of the sacred or holy. Whatever the experience of reality that lies behind the religious symbol may be, it is above all the experience of the sacred or holy, which belongs essentially to any concept of religion. The historical study of religions has shown that it is fundamentally the symbol that mediates and forms for man's religious consciousness the reality and the claim of the holy. Religion is a system of relationships, a system of reciprocal challenges and responses the principal correspondents of which are the sacred or holy and man. Though there are many forms of experience in which the sacred or holy is distinctly known and felt, the experience is often acquired in worship, in which this system of relationships is realized and continually renewed and in which the sacred or holy supposedly makes itself present. The details of worship serve to objectify and regulate in a perceptual and material manner the presupposed presence of the sacred or holy, of which the symbol and the picture are intended to be its materialization. In its material manifestation the sacred or holy is adapted to man's perceptual and conceptual faculties. Viewed from the aspect of its holiness, the symbol originates in a process of mediation and revelation, and every encounter with it is supposed to bring about a renewed actualization and a continual remembrance of this revelation.

Incarnation
and
identity

The actualization of the presence of the holy by means of symbolic representation can, in extreme cases, lead to an identification of the physical manifestations with the spiritual power symbolized in them. The symbol, or at least an aspect of it, is then viewed as the incarnated presence of the holy. The sacred stone, animal, plant, and drum and the totem symbol or the picture of ancestors all represent the sacred or holy and guarantee its presence and efficacy. The origin of many such symbols clearly indicates the identity that was presumed to have existed between the symbol and the sacred or holy. The Greek god Dionysus as a bull, the Greek goddess Demeter as an ear of corn, the Roman god Jupiter as a stone, the Syrian god Tammuz-Adonis as a plant, and the Egyptian god Horus as a falcon all are viewed as manifestations of the deities that were originally identified with these respective objects of nature.

Symbols as indicators of the sacred or holy. The symbol is understood to have a referential character. It refers to the reality of the sacred or holy that is somewhat and somehow present. When the symbol is an indicator of the sacred or holy, a certain distance exists between them, and there is no claim that the two are identical. Short of actual identification, various degrees of intensity exist between the symbol and the spiritual reality of the sacred or holy. The symbol is a transparency, a signal, and a sign leading to the sacred or holy. The objects, gestures, formulas, and words used in meditation—for example, the Buddhist *mudrās* (gestures), *pratimās* (images), *mantras* (magic formulas)—and in mysticism—for example, the crystal or the shoemaker's ball in the contemplative experience of Jacob Böhme, a 16th- to 17th-century German cobbler and mystic; the navel in Omphalism (a method

[called Hesychasm] of contemplating the navel in order to experience the divine light and glory in medieval Greek Christian mysticism of the monks of Mt. Athos); and the pictures of the deity in the language of Hindu, Islāmic, and medieval Christian mysticism—all of these are truly symbols, but nonetheless they have at most only an indirect mediating relationship to the divine, a purely noetic (intellectually abstract) significance with regard to the reality and presence of the sacred or holy.

Symbols of sacred time and space. The symbolical forms of representation of the sacred or holy are to be understood as references to or transparencies of the sacred or holy. The sacred manifests itself in time and space, so that time and space themselves become diaphanous indications of the holy. The holy place—a shrine, forest grove, temple, church, or other area of worship—is symbolically marked off as a sacred area. The signs, such as a stake, post, or pillar, that delimit the area themselves are endowed with sacred symbolic meanings, which often can be noted by their particular designs. The ground plan of the sacred building and its orientation, walls, roof, and arches are all utilized to symbolize the sacred or holy. Pre-historic places of worship—e.g., Stonehenge (in England) and other megaliths of Europe and the shrines and holy places of ancient Egypt, Babylon, China, and Mexico—were invested with symbolical meanings.

Sacred places are often pictorial reflections of the universe and its design and partake of its holiness. The domes of Christian churches are symbols of heaven, the altar a symbol of Christ, the Holy of Holies of the Temple in Jerusalem a symbol of Yahweh, the Holy of Holies in Shintō shrines (*honden*) a symbol of the divinity, and the prayer niches in mosques a symbol of the presence of Allāh. In many instances shoes may not be worn on holy ground (e.g., Shintō temples), and hands and feet are to be washed before entering into a holy place. The woodwork of demolished Shintō shrines, when taken to private homes, makes the sacred or holy present in the homes of pious Japanese families.

Time as a transparent symbol of the sacred may be represented by means of the cycle of the sacred year and its high points—e.g., New Year's (as in ancient Near Eastern religions), the times of sowing and reaping, and the solstices and equinoxes. Or the lapse of time may be represented in signs and pictures. Cosmic, mythical, and liturgical time and destiny are portrayed, for example, in the Buddhist symbol of the wheel of life, *bhava-cakra*, with its causal chain of human deeds and succession of existences, entwined by the claws of a devouring monster; the figures of Aion (Time) in late Greco-Roman and Persian antiquity show a figure with a winged lion's head standing on a globe and encircled by a snake. Time itself, its course, division, and fixed points, is both an allusion and the bearer and mediator of the sacred or holy.

Ceremonial and ritualistic objects as indicators or bearers of the sacred or holy. Liturgical and ceremonial objects can also indicate or lead to the sacred or holy. Not only holy pictures and symbols (e.g., the cross in Christianity or the mirror in Japanese Shintō) but also lights, candles, lamps, vessels for holy materials, liturgical books, holy writings, vestments, and sacred ornaments are indicators of the sacred or holy. Liturgical vestments and masks are intended to transform the wearer, to remove him from the realm of the this-worldly, and to adapt him to the sphere of the sacred or holy; they help him to come into contact with the divine—for example, by obscuring his sexual characteristics. The vestments may be covered with symbols, such as those worn by Arctic shamans (medicine men with psychic transformation abilities). They are signs of the function of the wearer and his relationships to the sacred or holy and to the profane world. Such vestments are frequently derived from those of rulers or from ceremonial court dress; e.g., Japanese Shintō and Roman Catholic and Eastern Orthodox Christianity. They are supposed to create a fitting atmosphere of solemnity and dignity. In Western Christianity, the liturgical vestments have a very specific symbolism: the alb (a tunic) symbolizes purity of heart; the stole, the raiment of immortality; and the chasuble (an outer eucharistic, or holy communion,

The
cycle
of the
sacred
year

vestment), the yoke of Christ. The liturgical vestments of the Eastern Christian churches have a similar symbolism. The ritual headdress and the crown express the sacred dignity of the wearer. The vestments of the various religious orders (Oriental and Occidental) express the holiness of the members of the community, their nearness to the sacred or holy, and the significance of religious life for them. In the reception ritual of Jainism and Buddhism, the monastic vestments are put on as a sign of an entrance in a new state of life. This ritual in Jainism resembles that of a wedding ceremony. The taking over of the monastic garb is an essential part of becoming a *sādhu*. The monks of the Jainistic Śvetāmbara sect wear five objects (e.g., shells) as symbols of the five monastic virtues. In early Christianity the white baptismal vestment was a symbol of rebirth, new life, and innocence.

Other relations between the symbol and the sacred. The sacred or holy as represented or manifested in the symbol has, generally speaking, a sanctifying function (elevating one to a closer relationship to the sacred or holy) and an exorcising function (decreasing or eliminating those aspects that hinder one's relationship to the sacred or holy). Remembrance (*anamnēsis*) and imitation (*mimēsis*) are the analogous and associative means of representing the reality and indestructibility of the sacred or holy and its power, which defends, protects from injury, bans evil, and guarantees salvation. Symbolic signs and pictures (e.g., masks; sex, animal, or plant symbols, such as the skulls or horns of animals) are placed on houses and sacred places to make present the saving and sanctifying power of the sacred or holy.

RELATION OF RELIGIOUS SYMBOLISM AND ICONOGRAPHY TO OTHER ASPECTS OF RELIGION AND CULTURE

Relation to myth and ritual. The symbol has a long-established relationship with myth (sacred stories that define the human condition and man's relation to the sacred or holy). Often containing a collection of symbolic forms, actions, expressions, and objects, myths describe gods, demons, men, animals, plants, and material objects that are themselves bearers of symbolical meanings and intentions. Thus, it is sometimes difficult to distinguish between a myth and a coherent complex of symbols brought together in story form. Examples are myths of cosmogony (origin of the world), theogony (origin of the gods), and anthropogony (origin of man). The details and contexts of religious teaching, dogma, and theology also produce or form symbolic values or refer to traditional symbolic representations. Symbol structures and pictorial representations are brought into connection with dogma and theological statements—e.g., the Buddhistic *karma-saṃsāra* (law of cause and effect and reincarnation) theory and the *bodhisattva* (buddha-to-be) theory or the Christian teaching of the Last Judgment, punishment of sin, hell and purgatory, and eternal reward (Paradise). In worship, individual actions and objects used in the ritual are given a symbolic meaning that transcends their immediate practical purpose. Magic, in its ritual, also uses various formations of symbols, pictures, and symbolical actions that may be seen as parallels to the distinctively religious use of symbols.

Relation to meditation and mysticism. The spiritualization of religious experience in forms of meditation and mysticism assimilate and rework the existing symbols and pictures of an older historical period of religion, giving to some symbols a higher value and placing others in the centre of focus. At the same time it develops new forms the appearances of which stem especially from the visionary experiences of the mystic and from his need for a suitable means of expression and from the objects of meditation training; e.g., holy sounds and words (*om*), the lotus flower, the *vajra* (ritual object shaped like a thunderbolt), and the wheel in Buddhist meditations or the ladder, the heart, and the letters IHS (the first three letters of the Greek word for Jesus) in Christian mysticism. In contemplation, colours, forms, sounds, signs, and pictures become ways and means of penetrating to the centre of the mystical union. Jacob Böhme's work is characteristic of the development of an especially rich mystical language

of symbols. Mysticism supplies conventional and customary religiosity with new pictures and symbols.

Relation to the social realm. The field of symbolism and iconography shows a strong interdependence that existed between religion and other areas of culture that were later to become autonomous and profane (or secularistic). The social domain under the influence of religion develops its own symbolism for expressing its values and objectives. Conversely, religion often draws its symbols and pictorial forms from the social, political, and economic domains. Persons (e.g., king, father, mother, child, slave, brother) and conditions and structures in society and the state (e.g., government, a people, family, marriage, occupation) all receive meaning as symbolical and pictorial motifs in myth and cult. Examples of such motifs are throne, crown, sceptre, standard, arms, instruments, the figures of the father, mother, and child, and symbols of familial relationships. The morals, law, administration of justice, and the customs and habits of a society contain religious symbols and symbolical actions, as in the anointing of a king and in the administering of the oath or ordeal or in the observance of traditions and customs associated with birth, marriage, and death.

Relation to the literary and visual arts. Religious symbols and pictures may be identical with, related to, or similar to those of language (metaphors) and to pictorial expressions in prose and poetry. They are related in allegory, parable, fairy tales, fables, and legends in which they can appear in a form that is closely related to that of religious symbolism. Religious symbols are used in the plastic arts, in architecture, and in music. Symbols also have been developed in those arts and then introduced into religion. A few examples of such symbols are house, room, door, column, sound, harmony, and melody (as when Christ was viewed as the "new melody" in the words of Clement of Alexandria, a 2nd-century philosophical theologian). Here, also, the interdependence and the continual reciprocal influence of religion and culture may be observed.

Relation to other areas of culture. The formation of religious symbols and pictures has been stimulated by numerous other areas of human culture—such as the philosophy of nature, the natural sciences (especially botany and zoology), alchemy, and medicine (including anatomy, physiology, pathology, and psychiatry). In the works of Jacob Böhme, alchemy (e.g., the elements, fire, salt, sulfur, mercury, tincture, gold, essence, the philosopher's stone, and the transmutation) found an all-inclusive symbolical use; and in the works of Robert Fludd, an English physician and mystical philosopher of the 16th and 17th centuries, medical, cosmological, alchemical, and theological (esoteric religious) symbols were fused together (e.g., the contrast of light and darkness and the idea of man as a microcosm). Symbols, also religious and mythological (such as signs of astral gods for the planets in astronomy), have achieved new importance in the conceptual presentations of distinctively scientific systems; e.g., in physics, cosmology, psychiatry, and psychology. Even spaceships bear symbolic or mythical names. Psychoanalysis and depth psychology have reevaluated the role of the religious symbols and have used them in interpreting psychological processes, such as in the works of the Swiss psychiatrist Carl Jung. Jung interprets religious processes as symbolic ones and emphasizes the growing of individual and social symbols in the unconscious. According to his interpretations, many of the symbols, transforming the archaic libido into other functions, come out of dream experiences in a kind of intuition or revelation. Important symbols are duality (male-female, animus-anima), trinity, and quaternity.

Changes in symbolical relations and meanings. Symbols emerge and disappear and change in their value and function. Although symbols have a tendency to be normative, stable, and to have a fixed meaning value, the demise of old symbols and the genesis of new ones or changes in the meaning of existing symbols nevertheless occur. Many ancient Christian symbols (e.g., the fish) had long lost their recognition value or had been pushed into the background. With the renewal of ancient Christian

Reciprocal influences of culture and religion

Relationship of symbolism and doctrine

Relationship of religious symbolism to scientific symbols

symbolism in modern times, they have had a re-evaluation. The triangle and the eye as recently used in Christianity are relatively new symbols for God. The old and formerly very meaningful religious symbolism of the axe and hammer has almost disappeared. The symbolism of kingship and sovereign authority has, on the other hand, been maintained in religious language and in the religious conceptual framework, although the political structures from which it originated have disappeared or lost their relevance. The disintegration of individual symbols and the change in the emphasis on the role of symbolism in general are partly consequences of cultural, intellectual, social, and economic transformations.

MODES OF SYMBOLIC EXPRESSION

In the long history of the forms of symbolical expression a narrower (exclusive) and broader (inclusive) idea of what a symbol is has gradually evolved. This evolution is reflected in the various manners of symbolical expression that may influence and combine with one another. Many scholars question whether a picture or a verbal expression, for example, strictly corresponds to the idea of a symbol. Just as the ideology and terminology of the ancient Greek mystery (salvatory) religions distinguished between that which is shown and seen (*deiknymenon*), that which is done (*drömenon*), and that which is said (*legomenon*), so also can one make distinctions among three types of symbols: the visual symbol, the symbolical action that is dramatically enacted in worship, and the linguistic symbol, which includes music and other sounds. Viewed in these various aspects, the complex character of the symbol becomes apparent.

Diagrammatic and emblematic. Symbolic representations are usually depicted in diagrammatic or ideographic modes as signs, abbreviations, images, and objects of all kinds that indicate a larger context. In this category belong the simplified or abstract forms of objects of nature or other objects and geometrical forms, as well as colours, letters, and numbers. The circle, the disk, the rosette, or the swastika, for example, may symbolize the sun, universe, or a star. The square and the cross may symbolize the Earth or the four cardinal points; the wreath, the labyrinth, the spiral, the plait, and the knot may indicate eternity, the flow of time, or a magical spell.

Ornamental designs in primitive artwork, those of the American Indians, for example, frequently have a symbolical meaning and embody fundamental figures, such as the straight line, circle, rectangle, rhombus, or ellipse. The cross in its varying forms: the Latin (+), Tau (T), ankh (⚡), Saint Andrew's (X), and the forked (Y) may symbolize man and his extremities. Among various peoples and in different religions a number of basic colours have at times different and sometimes even opposite meanings. White, for example, may signify joy and festivity or death and sadness. Red has the most pronounced symbolical value: it refers to the liturgical, priestly sphere and also to life and death. In Christianity, colour symbolism is associated with the sacred year; in Buddhism with the picture of the universe, the regions of which are classified according to particular colours; and in the religion of the Maya of Mexico and Central America with the four world directions—east (red), north (white), west (black), and south (yellow). The symbolism of metals and precious stones also is related to their colours (*e.g.*, emerald with green).

The symbolism of the letters of the alphabet varies according to the alphabet (*e.g.*, A and Ω in Greek or A to Z in English) and is often connected with magic and prophecy—which is also true of the symbolism of numbers. In the picture writing of hieroglyphic systems and in the ideographic (idea-sign) writing of earlier times there is a direct relation between the word-sign and the object to which it refers. In alphabetic writing, numbers and letters are interchangeable if the letter has a number value, as, for example, in Greek and Hebrew alphabets. In some religions, the world of the gods is arranged according to a number system; *e.g.*, into enneads (nines), triads (threes), or dyads (pairs). The idea of oneness was then extended to a numerically arranged pantheon. Gnosticism (a Hellenistic esoteric dualistic system) and Kabbala (a Jewish

esoteric mystical system) developed number symbolisms. The letters received a symbolic character in two ways: first, as components of a word for which they stood—*e.g.*, the Hebrew tetragram (four-letter) YHWH (Yahweh) for God, the Latin IOM for Jupiter Optimus Maximus (Jupiter the Best and Greatest), and the Greek IHS for Jesus—or, second through their numerical value, as in A and Ω, the beginning and end of the Greek alphabet, signifying Christ. They then became means of abbreviation—signs possessing a specific content and meaning.

Pictorial. Pictorial symbolism in its many forms is a further development of nonrepresentational, ideographic symbolism and also, to some extent, its origin. In depicting the world of nature, pictorial symbolism captures and mediates the religious experience of reality. The picture shows plainly and clearly the rich and intricate connections of its symbolic content. It may present a part for a whole (a head, a hand, a foot, or an eye for a complete figure) or the whole itself. Symbolic expression of religious experience by means of painting has had a long history.

Sculptural representations of the sacred or holy have their origin in cult. They range from Stone Age idols to the sacred sculpture of early Mesopotamian and Egyptian cultures, from the statues and reliefs of Greco-Roman gods, divinized heroes, and their deeds to the symbolic sculpture of India with its Hindu gods and demons, from the sacred sculpture of China and Japan with their respective pantheons to that of Mahāyāna (Greater Vehicle) Buddhism with its *bodhisattvas* (buddhas-to-be), saints, and spirits. These sacred figures, which may appear in statue or relief form, are sculptured out of various materials. The reliefs on the interiors and exteriors of temples have a decorative function similar to that of wall painting. They narrate a myth or tell a sacred history. Particular parts of the body and symbolical objects may also be sculpturally represented. They may be the male and female sexual organs (*e.g.*, the *linga-yoni* in Hinduism); the hand of Sabazius, a Greek god sometimes identified with Dionysus (the god of wine), whose hand is portrayed as raised in blessing and encircled by a number of rather bizarre appendages; and human limbs used as votive offerings for the cure of the part of the body represented. Representative symbolic sculpture tends either to simplify the figure in an abstract, geometrical, or expressionistic style or to imitate nature realistically.

Gestural and physical movements. Gestures and bodily movements play an important part in religious ritual and in the religious conduct of man. Such behaviour derives its meaning from its relationship to the holy.

In proceeding to and from a holy place, a worshipper generally proceeds according to certain symbolic patterns: rectilinear, circular, and vertical. Rectilinear movement to and from a holy place is intended to gradually prepare the worshipper for the spatial encounter with the holy and after the encounter to remove him from the sacred sphere. Special streets for processions often are marked off or built to a temple or holy place, such as in ancient Egypt, Mesopotamia, and China. The great procession from Athens to Eleusis for participants in the mysteries possessed a symbolic meaning. Worshippers not only enter a holy place but may also walk around it. Rectilinear and circular movement thus complement each other. Movement to and from a holy place may also be vertical as well as horizontal, as to and from a holy place on top of a mountain or pyramid. All these various types of movement give expression to the symbolism of the holy way or path.

The sacred dance combines rectilinear and circular movements and may also include hopping, jumping, and hand movements. Hand and finger movements in temple dances in Indian and other Asian cultures are strictly regulated and have a precise symbolic meaning. The liturgical dance in a rudimentary form was maintained for a long time in Christianity, as has been the procession. Dancing has not only a significative but also a magical function. It seeks to enchant the holy power.

Hand movements are widely used in ritual and liturgical actions; the touching of holy objects, materials, or men is performed according to a canon (rule) that precisely reg-

Sacred figures in sculptured or relief forms

Symbolism of hand movements

ulates these gestures and their accompanying prayers and blessings. The gesture of blessing may imitate a symbolic form, such as that of the cross in Christianity. Here the position of the fingers is regulated and has a special meaning, as is also true in the Hindu and Buddhist practice of meditation (*mudrās*). Stroking, thrusting, striking, pushing, waving, and hand clapping also can be symbolical gestures. By raising his hands in prayer, the worshipper approaches the realm of the heavenly gods; by kneeling, the realm of the underworld. This apparently was the original meaning of kneeling before it became an expression of humility. The bow as an intimated genuflection generally indicates respect. The kiss and the embrace—and sometimes also the actions of breathing or spitting upon someone or anointing a person with spittle—were originally magical manipulations; in later usage, they indicated union with or a strengthening of the community or the transferral or communication of power. The holy kiss, whether practiced or only verbally depicted, plays an important part in many religions. Standing is a posture of respect; sitting expresses the reception and acceptance of the sacred word or teaching. It is also the position for meditation as it is practiced in Buddhist monasteries. Symbolic gestures may be either individually or collectively performed.

Verbal symbolism. Gestures are usually accompanied by words. The spoken and written word in religion generally is not thought of primarily as symbolic but rather as a form of rational communication, of communication of thought. Despite its predominantly rational character in modern times, however, language does develop expressions that extend into the area of the symbolical. In its origin, language most likely was richly symbolical. Linguistic symbolism, however, has always had a certain tendency toward rational transparency and logical coherence, and thus words, objects, and pictures—in their origin as symbols—are very closely related. The visual value of the object and picture is later translated into language and enhanced by it.

Linguistic symbolism generally is metaphorical; the allegory, a particular development of the metaphor, symbolically represents an idea by means of a coherent complex of metaphors. Specific genres of narration and literature, such as myth, belong in this category. In a figurative, interpretative, and cryptic sense, names and metaphors denote the person or thing in question. God sometimes is metaphorically called a “spring” or a “rock”; Christ, “the Beloved”; Mary (the mother of Jesus), “the Rose”; and Vardhamāna Malāvira (the founder of Jainism) and the Buddha (Siddhārtha Gautama, the founder of Buddhism) are called “the Conqueror.”

Symbolic syllables and names

Individual syllables or sounds may also have a symbolic quality. The *om*, which is used to introduce the holy texts of Hinduism and is a meditation syllable used in Buddhism, provides one example. Understood magically as an emanation of the divine, the word or a name or a part of a word can become an independent hypostatized (substantial) object, a representation, or even the incarnation of the divine, such as the Logos (Word) in the Gospel According to John or *hū* (“he”) and *al-ḥaqq* (“the truth”) in Islāmic mysticism or the name Metatron in Kabbala. A holy writing or book in its entirety may represent the divine in the same way, as the Bible in Christianity, the Qurʾān in Islām, and the *Ādi Granth* in Sikhism.

Musical symbolism. Music, like the word, also may have symbolic meaning. The basic elements out of which musical symbolism is built are sounds, tones, melodies, harmonies, and the various musical instruments, among which is the human voice. Sound effects can have a numinous (spiritual) character and may be used to bring about contact with the realm of the holy. A specific tone may call one to an awareness of the holy, make the holy present, and produce an experience of the holy. This may be done by means of drums, gongs, bells, or other instruments. The ritual instruments can, through their shape or the materials from which they are made, have symbolic meaning. The Uitoto in Colombia, for example, believe that all the souls of their ancestors are contained in the ritual drums.

The relationship between religious ideas and music is of special importance when the sacred word is set to music or when the music supports or interprets the sacred word by orchestral accompaniment. Medieval and modern Christianity in the West has made important contributions in this area. The symbolic word may be enriched, intensified, and increased in meaning when it is given a musical form. In the medieval technique of motet composition, different but parallel texts from the Bible or the liturgy would be simultaneously sung in various voices to appropriate but different melodies. This is an example of the structuralization of symbols into a coherent whole, a process that may sometimes also be encountered in the visual arts.

Conjunction and combination of various modes. In ritual, liturgy, liturgical and devotional art, and in religious literature and experience, many different types of symbolical expression are frequently combined. Pictorial art may be symbolically interpreted or its present meaning may be reinforced by the addition of a verbal explanation or possibly even by music. In ritual, symbolical words, tones, noises, gestures, signs, odours (e.g., the odour of the sacrifice or the fragrance of incense as an expression of prayer and offering), colours, and pictures are combined. Pictorial art often depicts religious texts and ideas; in so doing it not only uses the human form but also objects of nature, scenery, sacred architecture, and particular symbols. A picture or sign on an emblem often receives its interpretation by the inscription of a verbal explanation. Conversely, in an illustration of religious texts, the picture or sign interprets the text. Over against verbal and musical symbols stands the sacred value of silence. It may indicate devotion, contemplation, or the presence of God.

ICONS AND SYSTEMS OF ICONOGRAPHY

Throughout the history of their development, religious iconography and symbolism have been closely interrelated. Many religious symbols can be understood as conceptual abbreviations, simplifications, abstractions, and stylizations of pictures or of pictorial impressions of the world of sense objects that are manifested in iconographic representations. In conceiving, describing, and communicating the experience of reality, the realistic picture and the non-representational sign both have as their primary function the expression of this experience in religious terms. In religious pictures that are of a compound or complex nature, particular symbols occasionally reappear. These pictures may also include other types of symbolic representation, such as words, tones, gestures, rituals, and architecture.

Iconographic forms. *Temples and other sacred places.* The architectural iconography of sacred buildings and places of worship is a field of its own. The place of worship, insofar as it is understood as the image of the universe and its centre, must be architecturally patterned according to a specific design of the universe. The place of worship may be considered to be the navel of the world; e.g., the *omphalos*, a round stone in the temple at Delphi (in Greece), the holy stone in the Church of the Holy Sepulchre, in Jerusalem, or the rock in the temple area of the Dome of the Rock (Mosque of Omar), in Jerusalem. A holy place usually is built around these holy points.

The cross-shaped ground plan of the Christian transept church is sometimes interpreted as an architectural portrayal of the crucified Christ, the apse with its altar representing Christ's head. The holy place as a structural creation together with its natural setting may create an idyllic or overwhelming effect, evoking in the beholder an experience of religious awe or devotion. The Shintō and Buddhist temples of Japan and the beauty of the landscape in which they are set, the mountain temples of ancient Greece, and Christian churches and chapels built in such dramatic settings as Le Mont-Saint-Michel in France all inspire a sense of wonderment. The Buddhist temple in all the splendour and richness of its form, trappings, and surroundings or the *stūpa* (a building containing relics of the Buddha) represents the presence of the Buddha.

Great importance, therefore, is often attached to the exterior form of the holy place, and its construction is governed by a canon of symbolical and iconological principles. The individual parts of the building—the walls,

Relationship of symbolism to experience

Triumphant cross, symbolizing Christ, before a star-filled heaven, the eternal, surrounded by the symbolic words or letters IΧΘΥΣ (ichthys; fish), ΣΑΛΥΣ ΜΟΝΔΙ (salvation of the world), and Α and Ω (Alpha and Omega; beginning and end); one set of symbols bringing together several Christian ideas of the relationship between man and God, the temporal and eternal, earth and heaven, the transfiguration and ascension of Christ, the Last Judgment. Apse mosaic in the church of S. Apollinare in Classe, near Ravenna.

Avalokitesvara, the compassionate *bodhisattva*, shown as a composite figure with eleven heads and eight arms, symbolic of his ability to sense man's needs everywhere in the universe. In the Rijksmuseum voor Volkenkunde, Leiden, The Netherlands. Height 35 cm.

The symbol: unity and multiplicity

Two-headed Janus, who sees forward and backward, personification of the month of January; romanesque high-relief sculpture of stone. In the Museo del Duomo, Ferrara, Italy.

Buddha's footprint, the "sign of a grand man," containing the symbols of the swastika, the wheel of the law, the *tri-ratna* (the "three jewels" of the Buddhist creed), and the lotus. Stone relief from Gandhara, 2nd century AD. In the Prince of Wales Museum of Western India, Bombay.

The Trinity represented by Christ as man, the Holy Spirit as a dove, and God as a hand; Armenian miniature of the baptism of Jesus, 1273. In the Topkapı Museum, Istanbul. 16 × 11 cm.

Symbols of space and time

"The Skies," watercolour copy of a Navajo sand painting. Four holy plants radiate from the central four storm figures. The dawn, midday, evening, and night skies are shown in the east, south, west, and north. Paired guardians in the east are a medicine pouch and a bat. In the Museum of Navaho Ceremonial Art, Santa Fe, New Mexico.

Bhava-cakra ("wheel of life," circle of existences), Tibetan *tanka*, probably 19th century. In the Newark Museum, New Jersey. 109.2 × 86.3 cm.

Cathedral of Notre Dame, Chartres, France, completed mid-13th century. The nave and apse form a cross; the steeple and bell tower may be interpreted symbolically as the "fingers of God."

Borobudur stupa, Buddhist monument in central Java, built in the form of a *mandala*, late 8th century. The surrounding galleries are decorated with reliefs representing scenes of the life and religious development of the Buddha.

Stonehenge, circular earthwork and stone religious site, Wiltshire, England; late Neolithic to Early Bronze Age (1800–1400 BC).

Poseidon, Apollo, and Artemis, detail from the marble east frieze of the Parthenon, Athens, c. 440 BC. In the Acropolis Museum, Athens. Height 109.2 cm.

The sacred or holy in the image of man, animals, and plants

Horus as a falcon, Egyptian bronze, 26th dynasty to Ptolemaic dynasty (7th–3rd centuries BC). In the Brooklyn Museum, New York. Height 28.8 cm.

Buddha Amitabha and two Bodhisattvas on lotus blossoms, the "Amida-Trias." Japanese bronze known as the Tachibana Shrine, 7th–8th century. In the Horyu-ji, Nara Prefecture, Japan.

"Tree of Jesse," symbolizing Jesus' descent from the house of David, illuminated page from Rabanus Maurus's *De laudibus sanctae crucis*, from Anchin, mid-12th century. In the Bibliothèque Municipale de Douai, France. 29 × 20 cm.

The four Evangelists represented by their symbols—Matthew by a man, Mark by a lion, Luke by an ox, and John by an eagle—illuminated page (f.27v) from the Book of Kells, Hiberno-Saxon, 8th century. In Trinity College Library, Dublin.

Symbols from the realm of family and society

Krsna (right) with his beloved, Rādhā, painting in the Kangra style from India, 18th century. In the Prince of Wales Museum of Western India, Bombay.

The child Krsna, bronze from India, 16th–17th century. In the Detroit Institute of Arts. Height 11.4 cm.

The warring archangel, shown in "St. Michael Triumphant Over the Devil," bronze by Sir Jacob Epstein, 1959. Coventry Cathedral, England. Height 7.6 m.

Christ enthroned as Lord of All (Pantocrator), with the explaining letters IC XC, symbolic abbreviation of "Iesous Christos." Mosaic in the cathedral of Monreale, Palermo.

"The Virgin Adoring the Child," painting by Fra Filippo Lippi, c. 1460. In the Staatliche Museen Preussischer Kulturbesitz, West Berlin. 127 × 116.8 cm.

columns, ceilings, vaults, and towers—usually have pictorial and symbolic functions. Generally, the ceiling or vault presents a picture of heaven. Special accent is placed on the portals and the paths leading to them, on the position of the tables of offering, altars, sacred pictures, and relics. The bell tower, or campanile, is characteristic of Christian churches and is popularly interpreted as the finger of God. Ancient Christian basilicas (large, roofed buildings, generally with aisles) were viewed as images of the heavenly Jerusalem. The pictorial aspect of the place of worship extends not only to the building in the entirety of its architectural form but also to the painted, sculptured, and mosaic artwork that decorates it. The exteriors of Hindu and Buddhist holy places, such as the famous terrace temple of Borobudur on Java, and the pediments and friezes of Greek temples utilize an abundance of figures and reliefs representing scenes from myth and sacred history. The facades of Egyptian temples are covered with tableaux of the gods and depictions of ritual ceremonies. The facades and portal walls and sometimes the outside walls of Christian churches portray the main figures and events in the history of salvation, legends of the saints, and the Last Judgment. Inside the holy place, this pictorial and interpretative function is continued in the figures and scenes on its walls, capitals, and vaults. The adytum (sanctuary), the apses, and the altar may be decorated with symbols or pictures of the divinity or of other gods and saints.

Icons and images. Pictures are the main subject matter of iconography, which also includes free-standing sculptured forms and reliefs. Free-standing figures or statues are important in ritual as well as in partly serving magical purposes, which cannot always be separated from religious ritual. Such figures, which later became objects of personal devotion and meditation, include representations of the gods and demons in various prehistoric religions and of Buddha, Christ, and the various Buddhist and Christian saints. Generally, Judaism, Islām, and ancient Shintō have rejected any representation of the divine.

Painted or sculptured tableaux of historical or mythical events originally belonged in a ritual setting. The function of a wall painting, wall or floor mosaic, or relief was or is to establish the ritual actions as authentic reenactments of their mythical or historical prototype and to make these mythical or historical events continually present. These tableaux also may be found on the interiors and sometimes the exteriors of houses and on cemetery monuments. They are made to serve private devotion and a personal confession of faith. In the form of a framed picture, Oriental roll picture, print, or book illustration, such an iconographic tableau contains religious information, mediates, and stimulates contemplation and devotion.

Iconographic themes. In the religions of highly developed cultures and in the universal religions, complicated systems of iconography have been developed. In the course of time, however, these systems have been subject to change. Icons (images) may depict the divine in its oneness and in the plurality of its differentiations, emanations, and incarnations, as well as man in his various relationships to the sphere of the holy. They may also depict the world as the stage of divine action, as the realm of the diabolical, or as the battleground of these two warring forces. They may portray evil, the diabolical, and the Satanic (the negatively sacred); or, more positively, they may depict the offer of salvation, redemption, and damnation. Furthermore, icons may portray the ritual means of attaining salvation or moral relationships and duties. Icons may borrow from myths and other religious narrative material to depict the historical past and the present, as well as the future and the afterlife. Icons, finally, may represent religious doctrine and the theological treatment of dogmatic themes, as well as other religious beliefs, religious experiences, and conceptions of a more individualistic nature.

Iconographic types. There are many fundamentally different points of departure in the ways of conceiving the contents of religious pictures and of forming them. These differences, which go back to very early times, continue to exist side by side throughout the history of religions, some dominating at one time while others recede in importance.

Anthropomorphic motifs. The object that generally is

depicted in religious pictures or sculpture is an anthropomorphic (human-form) representation. Man is shown as the image and likeness of the holy and as engaging in typically religious behaviour; conversely, the divine appears with anthropomorphic characteristics. This tendency is found quite early in the history of religions. Examples include the religious pictures used in ancestor worship; the spirit and soul idols of various primitive cultures in animism; the fetish, or charm, figures of West African fetishism; and the magical objects of hunter and agrarian cultures. This type of anthropomorphism reaches its high point in the ritual and mythical pictures of the great polytheistic religions and is especially characteristic of ancient Greek religion and also of Jainism in its pictures of the Tirthankaras (saviours).

In universal religions, such as Buddhism and Christianity, anthropomorphic pictures of the divine were maintained despite criticism. They were not intended to be interpreted realistically but rather as symbolically representing the divine. Buddhism adapted the gods and anthropomorphic myths of the then popular Asian religions and developed the figure of the *bodhisattva* (buddha-to-be) to represent the attainment of Nirvāṇa (the state of extinction or bliss). In Christianity, the picture of Christ usually serves as a representation of the divine. God the Father also is anthropomorphically depicted, usually as an old man wearing papal or imperial insignia. Individual parts of the body may be depicted and serve as symbols of the divine: e.g., the hand of God may stand for Christ, the creative power of God, God's covenant with man, or for God's fidelity and truth; the phallus or foot may symbolize Śiva (a Hindu god). Man may be portrayed as a miniature copy of the universe or as the recipient of salvation and also the bearer of the divine, as in the Christian iconography of Mary and the saints.

Theriomorphic, or zoomorphic, motifs. Besides animal demons in primitive religions and totemism (a belief system and social system based on animal symbolism), animal images frequently occur in other more sophisticated religions. The animal form as a representation of the divine (theriomorphism, or zoomorphism) is characteristic of polytheism. It has been maintained in Hinduism, to some extent in Buddhism, and occasionally in Christianity. Besides the theriomorphic (animal-form) representations of the holy (e.g., the ancient Egyptian gods and animals that are symbols of the divine or the lamb symbolizing Christ in Christianity), there are also theriomorphic (animal-form) pictures of the universe and its powers and of the world of the demons. In many religions the animal kingdom is depicted as a part of creation, as in the portrayals of creation in ancient Greek myths and in the Bible. Animals also play important roles in allegories. Various forms of the shepherd-flock motif have been developed to describe God's relationship to man.

Besides being represented in human form, the Christian Evangelists Mark, Luke, and John are symbolically depicted in animal form (lion, ox, and eagle, respectively). Byzantine iconography sometimes depicts St. Christopher (patron of travellers) with a dog's head. Parts of animals (skulls, horns, wings, and feet) also serve as symbols of the power of the divine or diabolical.

Phytomorphic motifs. Phytomorphic, or plant-form, representations of the divine also are rich in diverse examples and often enigmatic. Holy plants and plants considered to be divine are represented in connection with gods in human form. The god sometimes is the plant itself, as the Egyptian god Nefertum is the lotus, or begets the plant, as the Egyptian Osiris or the Greek Demeter as deities of corn, or the deity comes forth from the plant, as the Egyptian goddess Hathor from the sycamore or the *bodhisattva* from the lotus, or the god unites with or is transformed into the plant, as the Greek heroine Daphne changed into the laurel tree, which thus became sacred to Apollo. The genealogy of Christ from "the root of Jesse," the father of the Israelite king David, is represented as a tree the last blossom of which is Christ. The biblical story of creation describes the vegetative surroundings of man and his dependence on plants (e.g., the tree of knowledge). The tree of life, the world tree, and the primeval cosmic

Importance of human forms in representations of the holy

Pictorial representations of myths and historical events

Plants as representations of the holy

plant all have characteristics related to the nature and origin of the cosmos.

The grapevine is a prominent ritual motif. It is found, for example, in representations of Dionysus and Christ. Painted and sculptured leaf, flower, and plant motifs decorate Christian churches and many religious and funeral monuments. Plants bound into a wreath symbolically promise victory over death and the joys of heaven. In such instances, the simple forms of nature may sometimes be depicted in a nonrepresentational and ultimately abstract and stylized manner.

Hybrid motifs. In religious iconography, anthropomorphic, theriomorphic, and phytomorphic motifs may be combined. The result of this fusion of forms may be seen in the numerous hybrid figures of primitive culture (e.g., totem poles, *uli* figures of New Ireland, and ancestral tablets). Such combined motifs occur also in ancient Near Eastern figures of winged demons with human heads and animal bodies or in winged beings with animal heads and human bodies and in the winged Greek goddesses, as well as in the winged protectresses of the dead in ancient Egypt and the angels and demons in Christian art. In Christianity, the snake in the Garden of Eden is sometimes portrayed with a human head (the face of Satan). In the Middle Ages, representations of the living cross with its arms depicted as hands appear. The cross also has been combined with various other anthropomorphic and phytomorphic elements.

A composite picture of plants, animals, and men together with other natural objects and architectural structures often becomes a sacred scenic background against which the mythical and ritual action takes place. Such scenic depictions were developed in Hellenism and adopted by early Christianity. Paradise scenes including plants, animals, men, Christ, and the saints are later enriched by symbolic and diagrammatic elements. Renaissance painting and East Asian Buddhist and Taoist art also use such combinations when depicting sacred, mythological, and allegorical scenes.

Chrematomorphic motifs. Objects that are used, or chrematomorphic objects, provide another form of pictorial representation. Holy objects, especially those used in worship, fall in this category. The holy book, the cross, the throne and other insignia of power and majesty, lights, lamps, and canopies become representatives of the holy. Garments also may have a symbolic meaning of their own apart from their wearer, as, for example, the veil or the blue mantle of Mary as symbols for the tent of heaven.

Absence of representational forms. The absence of an expected object, person, plant, or animal in a picture or the absence of all pictorial representation may also represent the holy or divine. In the Holy of Holies of the Jewish Temple in Jerusalem there was no picture of Yahweh in or on the ark of the Covenant, although it was supposed to be a sort of portable throne for God. Ancient Christian art often depicted an empty throne on which perhaps lay a folded purple robe or a book (*hetoimasia*) as a symbol of the invisible presence of God. In mosques the empty prayer niche (*mihrāb*), which is oriented toward Mecca, represents the presence of Allāh. Buddha apparently was not iconically represented in early Buddhist art in accordance with the theory of "emptiness" (*śūnya*) and the radically negative transcendence of the aim of salvation, Nirvāṇa. The rejection of a picture as a means of representing the holy also is a symbolical way of positively asserting the presence of God.

Hostility toward and prohibition of pictures are found in ancient Shintō, Judaism, Islām, the various radical movements (i.e., the iconoclasts, or image destroyers) of 8th-century Christianity that were influenced by Islām, and, centuries later, in some elements of Reformed Protestantism.

INFLUENCE OF MAN'S ENVIRONMENT ON RELIGIOUS SYMBOLISM AND ICONOGRAPHY

Influences from nature. The main streams of the influence from nature are derived from man's experience of nature itself, his position in the universe, and his attempt to master his world in religious terms. Man's sense of

the holy influences the way he perceives and understands nature. The space that surrounds man provides him with the dimensional coordinates of his religious experience. Height, depth, breadth, direction, proximity, and distance are the spatial forms in which the holy manifests itself. The holy may reside on a mountaintop, in heaven, in a chasm, in the underworld, in watery depths, or in a desert. The holy way or path provides man with his direction to the divine and a means of approaching it. The spatial position of the holy and the direction to it may also be abstractly expressed—e.g., by means of symbolical numbers or coordinates. The infinity of space may be represented by geometrical and linear figures.

Emptiness or fullness may characterize the utilization of spaces and surfaces that are usually intended for the reception of symbols and signs. Works of art may be totally absent in certain architectural structures; or all available space may be filled with a dense profusion of all kinds of figures and objects, all of which may sometimes be encircled by an ornamental network or web of branches, vines, leaves, and blossoms; an example of such embellishment is Islāmic art. The ebb and flow of, time and things, the flow of water, and the cyclic recurrence of time are pictorially expressed—in symbols such as the wheel, spiral, wave, and circle. Time appears as the god of destiny—*kāla* in ancient Indian and Zurvān in ancient Persian religions. In late antiquity time takes the form of a demon entwined with snakes (Aion). The snake biting its own tail, the ring, and the spiral are frequently recurring symbols of fate and eternity; in Christianity, eternity is represented by the Λ and Ω , and the wreath.

Other physical, chemical, and physiological facts of nature also serve as sources of symbolic and iconographic concepts. Examples include the experiences of seeing, hearing, tasting, smelling, and touching; the myriad forms of plant and animal life; heaven and its astral and meteorological phenomena, which may be represented realistically or abstractly through symbols or personifications; and the colours and various colourful natural occurrences such as the rainbow (often symbolizing God or Christ) or the sunrise and sunset or minerals and precious stones. In the depiction of natural happenings, plant, animal, and human forms may blend into one another, as in the symbolic circle of the Mesopotamian god Tammuz in which the tree of life is combined with figures of fertile wild and domestic animals and the figure of a shepherd. All these symbols represent the preservation and regeneration of life. They also represent nature as a holy power.

Another area of nature symbolism is that of the microcosm and macrocosm of heaven and Earth. Heaven and Earth are depicted as a dually or polarly related pair, which generally are theistically personified as a man and a woman. These roles may sometimes be reversed, as in ancient Egypt: the heavenly divinity a goddess, Nut, and the Earth divinity a god, Geb. In Greek myths on the origin of the gods (theogony), the world of the gods and man results from such pairing. Mother Earth is a central figure of many myths: she is the mistress of fertility and death.

Influence of human relationships. Another group of pictures and symbols that are especially significant in depicting the relationship of God and man are those drawn from the area of family and social relationships, especially the roles of the father and mother. These relationships to some extent are determined by the structure of the society and its economy. The mother image is closely bound up with Earth symbolism, vegetation, agriculture, fertility, the reappearance of life, and the lunar cycle. The father image usually is associated with the sphere of heaven, authority, dominion, age, wisdom, and struggle. Love, betrothal, marriage, sexual union, family, and friendship also are significant in symbolization. The relationships between brothers and sisters are of importance, especially in the structure of religious communities and in the various fraternal groups and secret organizations of modern societies. The images of the child, the subject, or slave again indicate man's relationship to God; those of the ruler, king, or master express the power and authority of the deity. Even the structure of the world of the gods is explained in terms of family.

Depiction of the presence of the holy by non-representation

The importance of social relationships in concepts of the holy

Symbolism of sex and the life cycle. The symbols of sexuality and the life cycle perform a function similar to those of time and eternity in the higher religions. They indicate the permanence of the cycle of sexual functions and the return and renewal of individual and collective physical life. The endless renewal of life is variously represented. It may be as realistic depictions or diagrammatic and stylized abbreviations of man and woman, god and goddess, masculine and feminine animals in the act of love and sexual union, as in reliefs on Hindu temples, or as depictions of sex characteristics (e.g., in Indian *linga-yoni* symbolism). The theme of renewal also may be depicted in representations of woman with emphasis on her function as mother, as in the nursing-mother figures of ancient Greece. The life cycle also is represented by figures portraying the ages of man or by depictions of pain and suffering, as in pictures of the Buddha's death, which also indicate his breaking out of the endless chain of existence.

Cultural influences. Other cultural, political, social, and economic institutions and conventions also influence religious symbolism and iconography. Work and leisure, war and peace, and the myriad things associated with them—occupations, positions in society, classes and their functions, the tools of domestic and professional life, technical equipment, forms of international relations and strife—all play an important part in man's interpretation and understanding of religious reality and hence in his symbolization of this experience. Hunters, farmers, shepherds, warriors, artisans, and merchants and their activities are represented in religious pictures and appear in the verbal symbolism of religion. In the universal and missionary religions, such as Buddhism, Christianity, and Islam, the believer is summoned to take up spiritual arms and fight for salvation. In Judaism, Christianity, and the religion of ancient Rome, the relationship between God and man is regulated according to the model of a peace treaty. In ancient German and Indian religions the military virtues of loyalty, duty, and comradeship are stressed. Man's religious activities may also be expressed in terms of play and sport, training, competition, and victory.

Conceptual influences. Ideas, theories, and structured systems of thought also are incorporated into religious symbolism. Abstract ideas—such as wholeness, unity, and the absolute—and the power of the spirit are concretely expressed in religious terms. The idea of unity plays an important part in expressing the oneness of the divinity. Mathematical principles expressed in number symbolisms are used to organize the world of the gods, spirits, and demons, to describe the inner structure of man, and to systematize mythology and theology. The concepts of duality or polarity find expression as the body and soul of man: the divine pair; the syzygy (paired emanations) in Gnosticism; the dualism of God and the devil, of good and evil; and, finally, as the two natures of Christ. The number three, or triplicity, is represented in divine triads, the trinity, and the body-soul-spirit structure of man; as is number four, or quaternity, in the four cardinal points, the picture of the cosmic whole, the divine quaternity. Time and eternity may be expressed in abstract symbolical terms as well as concretely in picture form.

INFLUENCE OF RELIGION ON SYMBOLISM AND ICONOGRAPHY

Religious figures and spiritual authorities themselves form a vast complex of symbols: gods, saviours, redeemers, heroes, the avatars (incarnations) and the Īśvaras (manifestations) of Hinduism, the heroes and gods of epics, the founders, lawgivers, saints, and reformers of the great religions. The biblical prophets, apostles, and evangelists and the Christian saints are characterized by a very complicated system of symbols. Theologians, mystics, and contemplatives may also be symbolically and pictorially represented; the doctors (teachers) of Roman Catholicism and Eastern Orthodoxy and fathers of the early church have standard iconic forms, attributes, and symbols (e.g., St. Augustine is represented by the heart; St. Jerome by the lion). Persons connected with ritual and representatives of the religious institution (e.g., hierarchs, priests, assistants in the liturgy, male and female dancers, and musicians)

may also be symbolically and iconographically depicted.

The offering, the place of offering, the altar and its trappings, the instruments that prepare and destroy the offering, the fire that consumes it, the liquids and drinks used in the rite, the sacred meal, and the rites of communion all are objects of iconography and symbolism. The offering symbolizes the idea of submission to the ideals of a religion, the giving up of valuables and possessions for religious purposes and for the service of human brotherhood, and the giving up of one's life for religion.

A religious community recognizes itself and its ideas by symbols. Examples are the *yin-yang* (union of opposites) symbol bound by the circle of stability (*'ai-chi*) in Chinese universalism; the swastika in Hinduism and Jainism; the wheel of the law in Buddhism; the *khandā* (two swords, dagger, and disk) in Sikhism; the star of David or *menora* (candelabrum) in Judaism; and the cross in its various forms in Christianity.

CONCLUSION

The further development of symbolism and iconography in the higher religions of the modern world is an open question. During much of the 20th century in the Christian communities, revivals of the liturgical traditions and of ritual symbolism were in progress, though criticized vigorously by many theologians. Liturgical symbolism became valued anew and stabilized. Theological systems, like that developed by Paul Tillich, were based on the concept of the symbol. On the other hand, during the 1960s some indifference toward symbols and pictures developed because of an emphasis on the moral and social tasks of religion. Symbols, myths, pictures, and anthropomorphic ideas of God were rejected by many theologians, and philosophical structures (e.g., the theory of the demythologization of the Bible, or the "God-is-dead" theology) became substitutes for them. In the great non-Christian religions, this process seems to be less acute. Within the horizons of a secularized, skeptical, and agnostic society, religious symbols seem to be dispensable, but nonetheless a new and increasing interest in symbols was appearing, especially among the younger generations who came into contact with both Eastern and Western religious and cultural traditions with their rich sources of symbolic images and modes of thinking. Thus, a resurgence of an understanding for the specific values of symbolism and iconography has been recognized in the latter part of the 20th century, in spite of all apparently opposite trends.

Rembrandt

For most modern observers Rembrandt Harmenszoon van Rijn remains synonymous with 17th-century Dutch painting, and his art has attained a kind of universal familiarity and popularity. Yet the biblical scenes and the self-portraits that today form the hallmark of his art were by no means typical of Dutch pictures then; more commonly, his contemporaries produced landscapes, still lifes, or genre scenes of daily life that never held great interest for Rembrandt. In his own era Rembrandt achieved greatest fame as the most fashionable portrait painter of Amsterdam during the 1630s, but he was eventually eclipsed even during his own lifetime by younger rivals, including some of his own students. Another major field of accomplishment lay in the medium of etching. Rembrandt commanded high prices for his prints even during his lifetime, and his technical mastery had a lasting effect on printmakers for centuries.

Rembrandt, self-portrait, oil on canvas, c. 1661–62. In the Iveagh Bequest, Kenwood House, London.

If any quality typified the works of this great artist, especially in his youth, that quality would be a personal ambition to rival the dominant artists of Europe, particularly Peter Paul Rubens from nearby Antwerp. But the tides of fashion in Holland and Rembrandt's own temperament seem to have frustrated much of his ambition and left him increasingly isolated and idiosyncratic in his final years. There is actually a kernel of truth to the apocryphal legend of Rembrandt's rejection by the leading patrons of Amsterdam, although this loss of favour was gradual and never total. As a result of his increasing isolation, however, Rembrandt achieved a particular personal independence that doubtless contributed to his distinctive and evocative suggestion of the timeless human world of quiet yet deep emotional states. The silent human figure remained the central subject of Rembrandt's art and contributed to the sense of a shared dialogue between viewer and picture, which still is the foundation of Rembrandt's greatness as well as of his popularity today.

Early years in Leiden. Rembrandt's youth does not help much to explain either the derivation or the character of his art. The artist was born on July 15, 1606, in the university city of Leiden. His father, Harmen Gerritszoon van Rijn, was a miller, a reasonably prosperous man; the family of his mother, Neeltje van Zuytbroeck, were

bakers, but more important, they remained Catholics at a time when Leiden had adopted the Protestant creed. Indeed, Rembrandt's father was the only member of his family who became a Calvinist rather than remaining a Catholic. According to a Leiden chronicle written during the artist's lifetime (by Jan Orlers, 1641), the young Rembrandt was sent to a Latin school and directed toward the local university, the very first to have been established in Holland (1575) and a major centre of learning. But because the young man's proclivities led toward art, he was apprenticed during the period 1619–22 to the local painter Jacob Isaacszoon van Swanenburg. Little of the work of van Swanenburg can be identified today, and his art seems to have left scant influence on Rembrandt, but the fact that he, too, was a Catholic might have affected the choice of van Swanenburg as a master. Moreover, van Swanenburg's father had also been a highly successful painter in Leiden and had trained Rubens' master, Otto van Veen. Thus, this tutor held out a potential set of connections for the young Rembrandt.

But Rembrandt's chief training came from the Amsterdam painter Pieter Lastman (1583–1633), who had spent time in Italy (1603–1606/07) and had returned to Amsterdam to become the leading painter of biblical, mythological, and historical pictures. Although Rembrandt seems to have spent only about half a year with Lastman around 1623, he fully absorbed the lessons of his master. From Lastman he learned the importance of painting lofty subjects in a broad format with careful attention to the ancient costumes, dramatic gestures, and compositional groupings of the full-length figures. The earliest Rembrandt pictures, including "Stoning of Saint Stephen" (1625), "Palamedes Before Agamemnon" (1626), and "Baptism of the Eunuch" (1626), clearly derive closely from both the themes and the pictorial formulas of Lastman. The baptism of the eunuch, for example, had already been painted by Lastman in a broad format a few years before (1623; Karlsruhe); Rembrandt's version of the scene from Acts is transposed into a vertical format, but it retains most of the same figures, costumes, and accessories, yet condensed into a tighter, more dramatically lighted mass. Another close comparison of both theme and form is provided by Lastman's 1622 panel and Rembrandt's denser, vertical 1626 panel of the same subject, "Balaam's Ass and the Angel." Recent research links the "St. Stephen" and the "Palamedes" with commissions from the young Rembrandt in Leiden by a local humanist named Petrus Scriverius, whose estate cites two large pictures by Rembrandt; otherwise the early patrons of these pictures are unknown today.

The early Rembrandt paintings already reveal the artist's ambition to rival the leading painters in Europe. Not only did he concentrate on the most learned and morally serious subjects but he also strove for the historically plausible settings and costumes that distinguished the pictures of Lastman and such painters in Rome as the German émigré Adam Elsheimer. Also evident in these early paintings are Rembrandt's nascent fascination with dramatic personal responses and with spotlight effects of light and shadow. If anything, these elements came to dominate his art in the succeeding decade. In particular, Rembrandt's exposure to a group of artists from nearby Utrecht led to an abrupt emulation of their sharply drawn chiaroscuro, or painting in light and dark. These Utrecht painters, led by Gerrit van Honthorst, had recently returned from Rome, and their art enjoyed not only local popularity but also strong favour in the courts of northern Europe. Hence, when Rembrandt painted such religious works as "The Presentation in the Temple" (c. 1627–28) or "Christ at Emmaus" (1628), he sought to emulate the drama of lighting and gesture of Elsheimer, Caravaggio, and, now,

Apprenticeship with Pieter Lastman

van Honthorst and to place himself firmly into the international world of art. A measure of the self-concept of Rembrandt around this time is the small but dramatic "Young Painter in the Studio" (c. 1629), which shows a full-length shadowy figure of an artist situated against the back wall and dwarfed by a massive panel lying on its easel in the foreground. This panel, seen from behind, lies in shadow, with only its near edge glowing with light. The overall effect is one of heroic confrontation within the very act of creation.

That Rembrandt had attained eminence as an artist by the end of the 1620s can be discerned from a famous reference, dating from 1629/30, in the autobiography of Constantijn Huygens, the secretary of the Prince of Orange. Huygens singles out Rembrandt as well as his young Leiden friend and colleague, Jan Lievens (1607–74), for special praise in terms of their future promise as artists. Rembrandt is lauded for his penetration to the essence of his subjects and for his effects in small format. In particular, the 1629 panel "Judas Returning the Thirty Pieces of Silver" is held up as a model for moving gesture and emotion, worthy of the finest works of Italy or even of antiquity. Huygens' chief regret is that Rembrandt and Lievens never traveled to Italy for further study of the past masters.

Only in recent years has Lievens begun to receive attention commensurate with that paid to Rembrandt, although the careers of the two artists developed in tandem for many years. Lievens, too, journeyed from Leiden to Amsterdam for a two-year apprenticeship (1618–19) with Lastman. Indeed, it may well have been the example of Lievens that led Rembrandt to study with Lastman, and the influence of Lievens remained essential. Probably through Lievens came the exposure to Utrecht painting, which was to influence Rembrandt's art. In the late 1620s Lievens' art so closely resembled Rembrandt's that scholars are still debating the proper attribution of some panels. For example, Lievens' "Capture of Samson" (c. 1627–28; Amsterdam) appears to have been the stimulus for Rembrandt's "Capture of Samson" (1628), and both works emulate the same subject as painted by Rubens (1610; London) and circulated throughout Europe in prints from an engraved version. In similar fashion Rembrandt and Lievens maintained a pictorial dialogue concerning the subject of the raising of Lazarus, beginning with Rembrandt's c. 1630 panel (Los Angeles), followed by Lievens' 1631 canvas (Brighton) and etching, and ending with Rembrandt's masterful, dramatic, and large etching of about 1632. Rembrandt even seems to have predated some of his works to make them seem earlier than the comparable Lievens compositions. In 1632, however, Lievens departed for England, where he most likely became acquainted with Anthony Van Dyck, whose art redirected his own and led him to a later career in Antwerp between 1635 and 1644 before he returned to Amsterdam.

As part of the same ambition to paint historical pictures, both Rembrandt and Lievens also experimented with studies of heads, or what the Dutch call *tronies*. Often these figures wear exotic millinery and receive dramatic poses and lighting, but they are not portraits. Rather, they seem to have served as possible models or practice pieces for the character heads to be included within larger histories. Many of the pictures with the same models that were known in the 19th century as Rembrandt's "father" or "mother" are actually such studies of heads, with special attention to the rendition of stuffs, of lighting, and of facial expressions or features. Many of the early self-portraits also seem to have been variants of the *tronies* formula, in which Rembrandt simply used his own features in lieu of those of another model and dressed himself up in military or fashionable garb: plumed hats, golden chains, armour gorgets. Some of the heads of the older models reappear virtually without change on the numerous prophets and apostles (including the luminous 1630 "Jeremiah") that Rembrandt produced in 1630–31 in his later years in Leiden; this was a kind of picture that he left off doing until his final decade in the 1660s.

Rembrandt already enjoyed the attention of pupils and followers during his early years. His first disciple was Ger-

rit Dou, who emulated still another category of pictures from Rembrandt's oeuvre: his genre scenes, or depictions of everyday activities. Rembrandt had already created such scenes in his 1626 "Music Lesson," a work that also features archaic costumes and suggestions of lustfulness. Dou, also a Leiden native, the son of a glass engraver, became a pupil of Rembrandt in 1628 and continued this kind of subject but with overtones of seriousness and moral instruction and with an enamel-like fineness on a minute scale that was highly prized by collectors.

Having attracted the attention of the influential Huygens at court in The Hague, Rembrandt made inroads with the ruling House of Orange, chiefly with Prince Frederick Henry, for whom he painted in 1632–33 two scenes of Christ's Passion, the "Raising of the Cross" and the "Descent from the Cross" (both in Munich) as well as a portrait of the princess Amalia van Solms that was to have been the pendant of a van Honthorst portrait of Frederick Henry. The Passion scenes were ordered for the Prince by Huygens and are closely linked to the model of Rubens, again known to Rembrandt chiefly through an engraving. At the time Rubens was the leading artistic force in Europe, and as a cultivated diplomat as well as a consummate painter he was especially favoured at princely courts. Thus, to emulate Rubens' "Descent from the Cross" for his own princely patron was for Rembrandt the highest act of artistic self-assertion. Rembrandt even went so far as to produce his own 1633 etching of his picture in emulation of Rubens. One striking feature about both of Rembrandt's Passion scenes is that the artist gave his own features to participants within the scene; in the "Raising of the Cross" he even employed modern dress and a focused light to underscore this personal involvement, meant perhaps to express his own meditative spirituality.

The letters from Rembrandt to Huygens concerning the Passion series survive, and they document a second phase of artistic production between 1636 and 1639, when three more pictures were made for Frederick Henry. The letters document the progressive disenchantment with Rembrandt by Huygens and the Prince, but one of them also contains a rare personal testimonial from Rembrandt concerning his artistic aims. The letter underscores the artist's commitment to evoking "the greatest and most natural emotion" for his religious subjects. In this respect he is close to Rubens, who also was dedicated to the evocation of energy, drama, and emotion. Rembrandt's works in comparison present less of the heroism and beauty of Rubens' scenes but emphasize instead dramatic nocturnal lighting, humble figures, and intimate, lifelike reactions of his religious actors. These were basically the same elements that Huygens had already singled out for praise in Rembrandt's earlier pictures, and they continued to inform his religious art during the 1630s.

Early years in Amsterdam. Rembrandt moved to Amsterdam in late 1631. He already had a dealer in that city, Hendrick Uylenburgh, and his prospects at court were eclipsed by the domination of van Honthorst. Thus, the prosperity of Amsterdam, a capital of capitalism and a virtual city-state, drew him inexorably. In part through his introductions from Uylenburgh, Rembrandt quickly became one of the most fashionable and well-paid portraitists in Amsterdam. He was able to impress the regents of his adopted city, that clan of mercantile patricians who formed the centre of political power and influence. A mark of Rembrandt's early success was his commission to paint "Anatomy Lesson of Dr. Nicolaes Tulp" (1632), a commemoration of the annual anatomic demonstration to the city's guild of surgeons by its praelector, or chief surgeon. This large-scale group portrait by Rembrandt has been justly celebrated ever since for its departure from the rule of showing a coordinated row of portrait heads. In contrast Rembrandt animated his subjects through a pyramidal composition and his mastery of dramatic lighting to focus attention on the actual process of the lecture itself. At the same time he enlivened the faces of the listeners with a rich variety of expressions of attention, investing them with the same suggestive pictorial psychology that would remain his trademark. Many of the same features can be found in Rembrandt's portraits of individuals or

Tulp"

of husbands and wives painted shortly after his arrival in Amsterdam. Although Rembrandt had painted very few portraits while at Leiden, his first four years in Amsterdam brought him some 50 portrait commissions, most of them quite well paid. Inasmuch as Nicolaes Tulp was not only a surgeon but also an alderman and a member of the Amsterdam town council, he was an influential man within the regents' group. Also popular with the regents was Uylenburgh, the art dealer with whom Rembrandt lived briefly and also entered into commercial partnership. Many of Rembrandt's portrait sitters (e.g., Marten Looten, 1632) appear to have been Mennonites, religious conservatives, whom he met through Uylenburgh and who were well connected with the Amsterdam regents.

Rembrandt also portrayed a number of religious leaders of Holland during his first decade in Amsterdam: the Remonstrant Johannes Uytenbogaert (1633 panel and 1635 etching), the Calvinist Johannes Elison (1634), and the Mennonite Cornelis Anslø (1641 double portrait panel and etching). This last figure was a renowned preacher, and Rembrandt's portrayal emphasizes Mennonite reliance on the spoken word. In general his renditions take up the traditional challenge to the pictorial arts to render life without the aid of the spoken or the written word, as if in response to the challenge written in verse by the greatest of 17th-century Dutch poets, Joost van den Vondel:

That's right, Rembrandt, paint Cornelis's voice!
His visible self is second choice.
The invisible can only be known through the word.
For Anslø to be seen, he must be heard.

Yet, in addition to these portraits and the numerous pendant pairs of portraits during these early Amsterdam years, Rembrandt also clearly yearned for recognition, after the model of Rubens, as a painter of both mythologies and biblical stories. Around the time of his move from Leiden he produced his most extensive group of mythologies, beginning with "Andromeda" (c. 1630), which stresses the pathos rather than either the beauty or the heroism of the nude victim. A large "Pluto and Proserpina" (c. 1632) was clearly made for Frederick Henry at the same time as the Passion pictures, and both its scale and its frenetic energy attest to its relationship to the idiom of Rubens, although the refined execution still harks back to the Leiden of Dou. More typical, however, of Rembrandt's tendency to demythologize is the way he renders such subjects as "Rape of Europa" (c. 1632) or "Rape of Ganymede" (1635). The former places a seraglio of exotically clad, small-scale women in front of a shoreline that includes a Dutch harbour scene. The latter scene is even more prosaic, showing a mewling toddler instead of the seductively beauteous youth of legend. Not only is the eagle elevating the child upward against a leaden-gray sky but also the frightened boy urinates reflexively in his horror. The artist seems almost to have taken pains to violate conventions of beauty and decorum in such a work, as if to engage in persiflage rather than homage to the classical heritage. Scholars still debate whether this work holds Neoplatonic significance as a mythic analogue to the union of the Christian soul with the divine or whether its irreverence lies closer to the homophilic traditions of the subject.

Rembrandt's masterpiece of mythology followed a year later: "Danaë" (1636). Again, the artist avoided the standard formulation of the subject; instead of the shower of golden rays or coins that signal the arrival of Jupiter in his metamorphosed state, this picture simply bathes the heroine in a rich, luminous light. The "Danaë" also provided Rembrandt with the occasion for one of his most splendid nudes (reworked during the 1650s). He portrays the young woman waiting expectantly for her approaching lover despite the mournful, bound cupid above her head. The theory has been advanced that this was the large-scale picture sent as an unsolicited gift to Huygens and referred to in Rembrandt's letters: "My lord, hang this piece in a strong light and so that one can stand a distance from it, then it will show at its best."

If Rembrandt's mythologies reveal a turn toward the unconventional, his biblical subjects offer a range of themes and stagings. His paintings include a number of unusual subjects from the Old Testament, drawn from the story of

Samson in the Book of Judges or from the Book of Daniel. One large picture of this kind is "Belshazzar's Feast" (c. 1635), a work filled with Oriental costumes, dramatic gestures, and horror-stricken facial expressions. (In addition, the presence of accurate Hebrew orthography testifies to Rembrandt's connections with the Sephardic Jewish community of Amsterdam through yet another religious leader, Menasseh ben Israel, an ecumenical and millenarian author. Rembrandt also etched a portrait of Menasseh in 1636.) Some of the same vitality and energy informs Rembrandt's "Sacrifice of Isaac" (1635; Leningrad), where the angel's sudden intervention stills the hand of Abraham and causes the fatal knife to hang suspended in midair, giving the scene photographic immediacy. What is striking about the Leningrad picture is that it has a slightly modified mate in Munich, inscribed with the ambiguous signature *Rembrandt verandert en overgeschildert* ("Rembrandt altered and overpainted"), suggesting that the documented Uylenburgh workshop practice of copying works in stock might well have been a practice of Rembrandt's own store of pictures during the 1630s.

Another feature of Rembrandt's output during the 1630s is his development of ambitious etchings of biblical subjects. A beginning to this trend may already be seen in the 1633 "Descent from the Cross," adapted from the painting for Frederick Henry, and in the mid-1630s Rembrandt and Uylenburgh seem to have had the ambition to create a series of large etchings at premium prices. One etching, "Christ Before Pilate" (1636), was carefully modeled in advance in an oil sketch of grays and browns (1634). Another oil sketch on canvas, "John the Baptist Preaching" (c. 1634), was never completed as a print. Its broad expanse of figures in picturesque costumes against a ruined setting still recalls the formulas of Lastman, who had died in 1633. Another ambitious etching that shows an ostentatious mastery of rich, dark tones is the 1634 "Annunciation to the Shepherds." Here Rembrandt once more added a native Dutch element in transforming the shepherds into cowherds, who evince their own primal fear before the glowing angelic apparition. The character of experimentation that would typify Rembrandt's etchings emerges from this print in the conscious reversal of lights and darks. Here the forms and highlights come forward out of the dense, dark lines, partly through relative lightness and partly through actual removal of lines with a burnisher. This technique, which creates the effect of light emerging out of darkness, became a hallmark of some of Rembrandt's most moving late religious prints.

Some of Rembrandt's finest pupils can be documented in Amsterdam in the late 1630s: Govert Flinck from Kleve, Jacob Backer of Harlingen, and Ferdinand Bol of Dordrecht. Flinck (1615–60) in particular may well have reproduced several of Rembrandt's pictures for collectors or else collaborated with him in the workshop. But the replication of Rembrandt's formulas for historical pictures, portraiture, and *tronies* remained a staple of his pupils for many years to come.

Rembrandt married on June 22, 1634. His bride was Saskia Uylenburgh (born in 1612), the cousin of Hendrick Uylenburgh and the daughter of the burgomaster of Leeuwarden. Saskia brought a substantial dowry as well as patrician status with her, so this marriage represented a substantial climb in social status for Rembrandt. At the time of their marriage Rembrandt's court connections with The Hague were at their zenith; hence, the match might have seemed well balanced. One of Saskia's cousins and her guardian when the couple first met was the Reformed clergyman Johannes Cornelisz. Sylvius, whose posthumous etched portrait of 1646, emerging dynamically out of an illusionistic oval window frame, offers one of Rembrandt's most moving likenesses. Yet Saskia herself was to be the subject of the largest number of single portraits during the 1630s. Rembrandt posed her in mythological dress, particularly in the flower-draped abundance of the goddess Flora (1634), and in formal attire with fastidious profile. But he also delighted in using her as his subject in a cluster of spontaneous domestic drawings, such as those catching her leaning out of a window or lying in bed. Some of the unhappy biographical data make the

scenes in bed poignant: Saskia lost three children before the birth of a son, Titus, in 1641. Saskia herself died only a year later.

With his marriage Rembrandt seemed to be at the summit of his potential, and his self-portraits of the 1630s radiate confidence and prosperity. The climax of this trend is the stately, pyramidal self-portrait of 1640, which at once borrows its nonchalant pose upon a balustrade from Titian's portrait, then thought to be the poet Ariosto, plus its rich costume and golden colour harmonies from Raphael's portrait of the quintessential courtier Baldassare Castiglione. Both of these pictures had passed through prosperous Amsterdam's art market in recent days, a fact which gave support to Rembrandt's response to Huygens that he need not go to Italy to study the great masters. In addition, this image after the Renaissance model shows not only Rembrandt's successful assimilation of the forms but also the courtier aspirations of Raphael, Titian, and, most recently, Rubens himself. Just as he had previously done with the Anso portrait, Rembrandt also issued an etched version of this self-portrait on a stone sill in 1639.

If the velvet berets and fur-trimmed coats show Rembrandt to be a man luxuriating in his successes, a unique double portrait of Rembrandt and Saskia (c. 1635–36) seems to offer an ironic and reflective gaze at his life. Here, too, an etching echoes the subject of the painting, but in the 1636 etched double portrait Rembrandt shows himself at work, drawing as he looks up at the viewer. In the Dresden painting Saskia sits on the lap of a foppishly dressed Rembrandt, who gaily holds up a flagon of ale as he twists to offer a silly grin out of the picture. This tavern setting at once indulges a current "Arcadian" fashion for showing fashionable ladies as courtesans (yet another incarnation of the goddess Flora, with whom Rembrandt had already identified Saskia) as well as draws upon the pictorial tradition of the Prodigal Son with the tavern harlots. It is worth noting that the lavish dress of this couple offers an echo of the finery in the Kassel profile of Saskia, but here the suggestion of loose living and of future repentance from the Prodigal Son analogy also sounds a note of self-criticism.

As if to underscore the conspicuous consumption of the Dresden double portrait, Rembrandt purchased a large house in 1639 on the Jodenbreestraat. (This house is still known as the Rembrandt House, and today many of his etchings are kept there as a memorial.) In the same year Rembrandt painted a full-length portrait identified as Andries de Graeff, the brother of a leading Amsterdam patrician, Cornelis de Graeff, and son of the recent burgo-master, Jacob de Graeff. Cornelis' brother-in-law and fellow patrician, Frans Banning Cocq, headed the civic guard that was to grant Rembrandt the commission for what is one of his grandest and most famous pictures: the group portrait nicknamed the "Night Watch" (Amsterdam).

The "Night Watch"

The proper title of the "Night Watch" ought to be "The Militia Company of Captain Frans Banning Cocq." Executed between 1640 and 1642, it was one of six such group portraits of militia companies designed for the new hall of the Kloveniersdoelen, the musketeer branch of the civic militia (alongside crossbowmen and archers). Two of the other group portraits were painted by Rembrandt's pupil Flinck, and a third was entrusted to his emulator Backer. Most of the sitters in the "Night Watch" lived near one another in the drapers' section of Amsterdam and were men of wealth, headed by Banning Cocq and his lieutenant Willem van Ruytenburgh. These are the two striding figures who lead the march in the spotlighted foreground of the large painting. Like the anatomy lesson group portrait of a decade earlier, Rembrandt's militia group portrait differs from other Dutch instances by showing the entire scene animated and energized into a single, dynamic action. Emerging from in front of a large triumphal arch, the militia company seems to be setting out on a specific mission, evoking the glory days of the Dutch Revolution at the end of the preceding century. Scholars have debated whether in fact a specific ceremonial event was commemorated by this picture, such as the triumphal entry of the dowager French queen-mother, Marie de Médicis, in September 1638, one of the first state occasions

for the young Dutch Republic. In any case, the militia company's action elicits comparison of the armed guards at the city gates in a past era with the present protection of the city's independence and privilege by her own citizens. Thus did Rembrandt in this largest of his pictures (even though trimmed seriously on its left side; originally about 4½ × 5 metres) fuse history and portraiture, action and description. In the process he realized within an authentic Dutch pictorial tradition the same glories that Rubens had rendered in his equestrian portraits of reigning princes.

Experimentation and exploration. The contradictory experiences of Saskia's death and the completion of the "Night Watch" in 1642 produced a watershed in Rembrandt's life and artistic career. His connections at court had come to nothing late in the 1630s, and during the decade of the 1640s neither the sitters for his portraits nor the documented owners of his pictures reveal the kinds of social eminence of those of a decade earlier after his sudden arrival in Amsterdam (except for a couple of later submissions of religious pictures in 1646 to the court in The Hague). Legend has it that Rembrandt's patronage suffered on account of the boldness of invention in a work like the "Night Watch"; while this is mere fable, the taste, especially in portraits, for greater refinement and detail of execution was exactly the opposite of Rembrandt's own developing predilection. If he had delighted in the meticulous in his earlier portraits and in the later Leiden histories, Rembrandt now experimented with bolder brush strokes and stronger shadows with dark backgrounds. His followers, chiefly Bol, Flinck, and Backer, were becoming more successful and popular than their master, even among the highest levels of patronage.

Another cluster of talented pupils worked with Rembrandt around 1640: Gerbrand van den Eeckhout (1621–74) from Amsterdam; Carel Fabritius (1622–54), later a leading painter in Delft; and Samuel van Hoogstraten (1627–78) of Dordrecht, later better known for his art theory, *Inleyding tot de hooge school der schilderkonst* (1678; "Introduction to the High School of Painting"). Each of these made his own variation on the theme of the master, by adding colour to the history groups (van den Eeckhout), by working with a lighter background and experimenting with perspective effects (Fabritius), and by producing illusionistic experiments (van Hoogstraten).

Rembrandt's pupils

Rembrandt's art in general took on a more private and modest ambition during the 1640s. One measure of this development is provided by the comparison between his landscapes of the succeeding decades. During the 1630s the chief landscape efforts by Rembrandt took the form of paintings, which often show stormy skies and blasted trees. These wild pieces of nature respond to a heritage of powerful, stormy vistas, represented by several Rubens landscapes with narratives and in Dutch art by Hercules Seghers. During the early 1640s, however, Rembrandt turned increasingly to images with a more local, Dutch flavour, and he increasingly produced drawings and etchings rather than paintings of such scenes. Examples include the painted "Landscape with a Stone Bridge," the filigree etching of the Amsterdam skyline (c. 1641), the etched "Windmill" (1641), and several etched "Cottages" (1641/42). A climax of landscape etching was produced in 1643 with the "Three Trees." Here a stormy sky at the upper left provides the dramatic contrasts of light and dark that had characterized painted landscapes, but the silhouetted trees of the hillside offer a topographic complement to a rural Dutch scene dotted with miniature windmills and human figures at their labours (including a lonely artist at the upper right, sketching on top of the hill!). This is a virtuoso performance that includes reworkings of the plate in drypoint for the delicate clouds.

Dutch scenes

One cliché of scholarship avers that this turn toward landscapes in both drawings and etchings indicates Rembrandt's desire to find a peaceful alternative to the stresses in his life. More likely, these works meant a shift of marketing strategy away from the portraits and the kinds of histories that had been his staples during the halcyon days of the 1630s. When Rembrandt now created biblical histories, he omitted the Old Testament topics that had fascinated him earlier in favour of more conventional

themes from the infancy or mission of Christ. Some of the pictures, such as the 1648 "Christ at Emmaus" (Paris), already exemplify the quiet dignity and human vulnerability of Rembrandt's later spirituality, but a number of his other pictures exist in several versions, many of which were doubtless copies by associates, such as van den Eeckhout. Quite a few other paintings show sentimental single figures of young girls or old, bearded men without any of the force of the earlier figures and without their refined technique.

This fallow period of paintings is accompanied by a relative silence in the documents concerning Rembrandt during the 1640s. The exceptions are unpleasant. Despite Rembrandt's posthumous tribute to Saskia's former guardian, Sylvius, in the 1646 etching, the Uylenburghs made legal inquiries concerning Rembrandt's administration of Saskia's estate. In addition Rembrandt was having an affair with Titus' nurse, Geertghe Dirckx, but at the end of the decade she sued him for breach of promise of marriage. The episode dragged on and ended badly, with a cash settlement by Rembrandt, followed by the commitment of Geertghe to a reformatory and her early death in 1656.

In light of the importance of painted portraits and the relative scarcity of etched portraits in Rembrandt's output, it surely must be significant that in the late 1640s and the 1650s the artist produced a series of spectacular etched likenesses of friends and associates: the landscape painter Jan Asselijn (c. 1647), the Jewish physician Ephraim Bonus (1647), the patrician and then burgomaster Jan Six (1647), the printseller Clement de Jonghe (1651), the municipal auctioneer Pieter Haaringh (1655), and the apothecary Abraham Francen (c. 1657). The personal nature of some of these etchings emerges when viewed against the fact that Rembrandt filed for bankruptcy in 1656, for Francen, an art collector, stood by Rembrandt during his financial crises, while Haaringh must have been the auctioneer of Rembrandt's goods in the winter of 1655/56. But the interest in these plates is not just biographical; they are among the richest and most complex of Rembrandt's etched work. The "Jan Six," in particular, is worked up with meticulous care; velvety darks, reworked in drypoint to allow the subtlest nuances, are broken only by the glaring white of the paper for the light-filled window where the elegant young man stands. A decade later this same formula with a window was repeated in the Francen etching. Similar control of lights emerging out of darks can be found in the portrait of Bonus. In many of these portraits numerous details in the plates were reworked to produce subsequent states, and both etching and drypoint were combined with burnishing to alter the linear or tonal qualities of figures and settings.

Etchings of religious subjects also came to occupy increasing importance in the output of Rembrandt in the later 1640s and early 1650s. The largest, most celebrated religious etching, now known as the "Hundred Guilder Print" because of its high prices, was produced over an extended period of time, c. 1643–49, and it shows the full richness of Rembrandt's etching technique and experimentation. The subject, as in many of the paintings of the 1640s, is Christ's ministry—healing the sick, receiving the little children, and preaching to the multitude. It is spread out across a huge wall like the one for the "Night Watch" or the multi-figural biblical episodes of the 1630s (e.g., the "Doubting Thomas," 1634). In this large print, almost 30 × 40 centimetres, there are enormous variations in the techniques of different segments, creating a range of lights and darks, of descriptive detail or sketchiness, and of narrative focus. At the centre of the entire composition, almost dissolving in his delicately worked halo before the dark wall, is the tall figure of Christ. Rembrandt had made a number of painted sketches for the face of Christ from a single model, possibly a young Jewish man from his neighbourhood; replicas of these sketches doubtless served the same purpose as the *tronies* of the 1630s, that is, as models for biblical histories, and the 1656 inventory of Rembrandt's collection lists three such heads, two by him. This is also the same Christ featured in the 1648 "Christ at Emmaus," where the quiet and reflec-

tive apostles take the place of the crowd of the "Hundred Guilder Print."

The human component of religious stories became an increasing concern of the artist, and some of his most moving visions were developed in etchings of the early 1650s. As if a complement to the "Hundred Guilder Print," the etching of "Christ Preaching" (c. 1652), known as "La Petite Tombe," carries out the same theme within a more intimate and structured space, now marked by deep, dark passages of drypoint. Other etchings carry to the ultimate Rembrandt's fascination with figures emerging out of darkness. In contrast, however, to the drama of earlier biblical etching experiments, such as the 1634 "Annunciation to the Shepherds," these are sombre, meditative environments of quiet inwardness, such as the "Adoration of the Shepherds" (with lamp, c. 1654; at night, c. 1652). Most of these nocturnal visions concern themselves with the issue of divine revelation as a personal epiphany, often around the body of Christ in either infancy or Passion: "Entombment" (c. 1654) and "Descent from the Cross" (c. 1654), plus the dark "Presentation in the Temple" (c. 1654). In addition Rembrandt produced a pair of large-scale etchings that he reworked almost continuously during the mid-1650s as a kind of meditative exercise that produced increasingly focused attention on the figure of Christ and on the spiritual content of the scene—at the expense of the narrative richness of the earlier states. These two prints also depict key moments of Christ's Passion: "The Three Crosses" (1653; four states) and "Christ Presented to the People" (1655; six states). Most scholars seem to think that Rembrandt continued to work on the plate of the "Three Crosses" until around 1660, after which time he abandoned this most widespread and easily available of mediums entirely, except for a single commissioned portrait of 1665.

The other chief burst of pictorial activity during the 1650s was a continuation of the interest in landscape in both etching and painting. Again, most of the etchings show local, Dutch rural settings of gabled cottages and farm buildings, but some reflect renewed interest in monumental or picturesque buildings, such as towers or obelisks. One masterwork of etching is the oblong 1651 panorama, known as the "Goldweiger's Field," which was actually the estate, near Haarlem, of Christoffel Thijsz., the man who had sold Rembrandt his house 12 years earlier and was thus his creditor. Like the rendition of the delicate skyline of Amsterdam a decade earlier, this print has a refined sense of spatial gradation achieved through scale, tonal change (including rich foreground drypoint accents), and a curving perspective; its broad format replicates in etching the formulas used in Dutch landscape paintings by artists such as Jan van Goyen. In paintings Rembrandt's landscapes ("The Mill"; "River Landscape with Ruins") incorporate the bluer skies and more careful structures of the Italianate Dutch landscape painters, one of whom, Asselijn, was the subject of a portrait etching of about 1647.

After a gap of nearly a decade Rembrandt also returned to self-portraits at the end of the 1640s, including his final etched self-portrait, which shows him emerging out of the shadows as he draws beside a window (1648; five states). This is a fleshier figure than the jaunty courtier of 1639, but the presence of his own portrait amid those of his friends and patrons might point to a renewed confidence. At a time when portrait patrons began to return Rembrandt also produced some self-portraits, notably the large, three-quarter-length 1652 likeness.

Rembrandt's art of the 1640s did not inspire many pupils or followers, although Nicolaes Maes of Dordrecht (1634–93) seems to have apprenticed in the early 1650s and to have assimilated some of the single figure types of young or old women in ruddy colours, but used in this case for moralizing on their behaviour.

Beginning in 1653 the documents reveal a steadily worsening financial picture for Rembrandt, and in 1656, after transferring most of his assets to Titus, he applied for bankruptcy. Because of the auction of his possessions an inventory of his collections was drawn up in 1656 prior to liquidation. Analysis of his collections reveals not only quite a number of his own works, including many

The

portraits

landscapes and animal pictures, but also a vast collection of prints and drawings by other artists, usually mounted in books. Of the Dutch masters owned by Rembrandt, Seghers and Lievens predominate, but the Fleming Adriaen Brouwer, the Dutchman Jan Porcellis, and numerous Italians are also present. The variety of other items, including *naturalia*, Orientalia, and weapons, have been related to the contemporary princely tradition of the encyclopaedic collection, or *Kunst- und Wunderkammer* (arts and natural wonders room), a kind of personal museum. Here, as in the very subjects of his pictures and his early education in Leiden, Rembrandt is seen as a cosmopolitan, learned, and ambitious individual with broad interests.

Final years. Rembrandt's fame extended far beyond Holland. His "Aristotle Contemplating the Bust of Homer" (1653) was produced for a Sicilian, Don Antonio Ruffo. The imaginative classical subject, incorporating the worlds of philosopher, poet, and prince into a single work, seems to have been Rembrandt's own idea. This work not only seems to glow with its own inner light, coming out of a murky darkness, but it also shows Rembrandt's strength at painting character heads in meditative reverie. In 1660 Ruffo asked for a companion picture, and Rembrandt delivered an "Alexander" along with a "Homer" (1663; preserved only in a fragment).

Closer to home Rembrandt received an important large commission for another anatomy lesson by Dr. Jan Deyman (fragment, 1656). The well-known "Syndics of the Drapers' Guild" (1662) was a final group portrait, painted for the sampling officials closely connected with the musketeers' company shown in the "Night Watch." This work is at once filled with the lively animation of Rembrandt's other groups, but it conforms more closely to the conventions of clustered yet balanced rows of posed heads that were the rule for such assignments.

The grandest commissions in Amsterdam, however, were the pictures for the new and grand Town Hall, and these were going to Rembrandt's circle—to Lievens, Bol, and especially Flinck, rather than to Rembrandt himself. Rembrandt's only venture, "The Conspiracy of Julius Civilis" (fragment, c. 1661–62), depicted a heroic moment of Dutch revolt against the ancient Romans rendered as a nocturnal dinner oath by suffused candlelight. But Rembrandt's painting of the one-eyed chief conspirator, Julius Civilis, and his coarse band was only briefly hung in 1662 and never paid for, probably because it lacked the proper heroic decorum to be found in works by Flinck and Bol. Thus, two decades after the triumph of the Kloveniersdoelen militia commissions shared with his former students Rembrandt lost out to them on the success and the rewards of his hometown's principal adornment.

Rembrandt did share his later years with someone: Hendrickje Stoffels (c. 1615–63) had become his live-in companion after Geertghe Dirckx, and she was even more featured as his subject than Saskia had been. The full-bodied nude of the 1654 "Bathsheba" has traditionally been identified with Hendrickje and accords well with her numerous portraits and studies (e.g., "Woman Bathing," 1655). In 1654, shortly before she bore a daughter, Cornelia, Hendrickje was officially censured by the church council for living in sin. At the same time Titus, who held Rembrandt's assets in his name, became the subject of numerous portraits before he predeceased his father in 1668, just prior to his 27th birthday.

Despite financial strains and lack of prominent commissions Rembrandt was able to summon his energies in his final decade of creativity to produce the kinds of soulful pictures for which he is best loved today. He returned to biblical histories but gave them the portrait-like, stilled power of personality that was already present in the "Aristotle." Beginning with "Jacob Blessing the Sons of Joseph" (1656), family drama became the subject, as it did for the "Return of the Prodigal Son." In this later work, unfinished at Rembrandt's death, the sombre figures seem to emerge with their own glow out of a gloomy background, and each turns his gaze inward in quiet reflection. Some works so closely resemble portraits that their religious identity is submerged or even lost; such is the case of the "Jewish Bride" (c. 1664; Amsterdam), where the husband's

tender embrace of his wife dominates over the thickly painted exotic, rich, gold and vermillion costumes of the figures. A rare family portrait in modern costume from the late 1660s (Braunschweig) shows close affinity with the Amsterdam couple and prompts the question of whether the couple of the "Jewish Bride" might not be biblical but rather a costumed double portrait in historical guise, akin to the portrait of the musketeers of the "Night Watch."

Personal isolation and internal anguish dominate Rembrandt's interpretations of other historical figures: "Peter Denying Christ" (1660) and "Lucretia" (1664, 1666). A series of half-length, portrait-like apostles of 1661, especially the "Self Portrait as the Apostle Paul" (1661), completes the overlap between contemporary individuals and historical subjects in Rembrandt's oeuvre. These were painted at the same time as the "Homer" and the "Alexander" exported to Ruffo in Sicily and culminate the *tronies* tradition of model heads of historical figures.

In light of his own financial woes during this later period, Rembrandt could not sustain a large workshop or circle of pupils. Yet Aert de Gelder of Dordrecht (c. 1645–1727) spent at least a couple of years with Rembrandt around 1660 after training initially with van Hoogstraten. De Gelder, too, chiefly created half-length historical pictures in the manner of Rembrandt in the 1660s, and his "Self-Portrait as the Painter Zeuxis" (1685; Frankfurt) has been related to the late, laughing self-portrait by Rembrandt (c. 1668–69; Cologne), where the aged artist seems to smirk at his destiny as well as at the stern figure alongside him.

Rembrandt was not without patrons for portraits during his final decade, and some of his most moving likenesses were produced then with the kind of stillness and empathy that he also brought to his single-figure, biblical characters. Included among his sitters were the wealthy Trip family, also originally from Dordrecht and patrons of Bol. Rembrandt had painted mother and daughter of the Elias Trip clan in 1639, and in 1661 he painted Elias' brother, Jacob, and his wife, Marguerite de Geer. Most other sitters for the late works of Rembrandt are unknown, except for the classicizing artist Gerard de Lairesse (1665) and the religious poet Jeremias de Decker (1666), a close friend. Yet there are impressive but anonymous pendants (especially in New York and Washington) plus a family group (Braunschweig) showing thick, colourful impasto applied with a palette knife.

Finally, the last dozen years of his life were a fertile period for self-portraits. In addition to using his face for St. Paul in the apostles series of 1661, Rembrandt shows himself in another larger half-length portrait of around that time (Kenwood House) with palette in hand and two large arcs on the background to record his mastery of geometry (possibly also an allusion to the hemispheres of a world map in the conventions of Dutch cartography). Two further canvases record the artist in his final year, 1669. The first (London) presents the pyramidal dignity of his early maturity; the second (The Hague) combines an exotic turban, as seen in the early *tronies*, with a dispassionate, almost clinical directness in recording his firm gaze amidst his sagging flesh.

Rembrandt died on Oct. 4, 1669, and was buried in Amsterdam's Westerkerk.

Reputation. With the ascendancy of a classicizing taste for clear compositions and handsome protagonists, Rembrandt was eclipsed even during his lifetime by his own pupils, particularly by Flinck and Bol. After an ambitious period, when he emulated the models of Lastman, van Honthorst, and Rubens, Rembrandt himself gave up the attempt to follow international currents, although he never renounced the serious themes of biblical subjects. Rembrandt has been lauded for his spiritual qualities, and his art shows contact with orthodox Calvinists as well as with Mennonites, Remonstrants, and even Jews in tolerant Amsterdam. Although he enjoyed patrician patronage from the de Graeff circle and painted important group portraits throughout his career, his art never held sway at the peak of Amsterdam fashion after the 1630s, though it never was fully eclipsed.

Rembrandt was never really forgotten, but he was eagerly rediscovered by artists during the 19th century, who found

in his works echoes of many of their own Romantic strivings for independent formal means and experiments with the depiction of character and passion. His etchings, which continued to exert considerable influence over later practitioners of that medium, such as Giovanni Castiglione in 17th-century Genoa or Giovanni Battista Tiepolo in 18th-century Venice, also came back into prominence with the etching revival in the mid-19th century. His emphasis on the natural rather than the beautiful accorded well with the credo of a painter such as Courbet, who strove to be "modern" in protest against French academic training. Thus, Rembrandt acquired the mantle of the Romantic hero—of the individual following his own inner light.

The
issue of
attribution

Modern scholarship has followed several leads in evaluating Rembrandt. Debates continue over precisely which works belong to him and which can be assigned to pupils, followers, imitators, or even later forgers. Scientific investigations in the laboratory have added to the data necessary for drawing such conclusions, but the recent studies of Rembrandt's pupils have at once given their own characters sharper focus while also serving as a reminder of how little one can define their precise relationship to Rembrandt while they were working in his studio. The study of workshop working method remains a crucial task for sorting out authentic Rembrandt paintings or drawings from the inauthentic works or works that seem to have at least partial contributions from his students. This latter category—consisting of works formerly ascribed to Rembrandt but not yet fully attributable to the defined oeuvres of his individual students—remains a growing corpus that will occupy scholars for years to come.

The integration of Rembrandt's works into a larger and longer visual tradition has also been a recent project of scholarship, which has determined that many of Rembrandt's religious subjects conform to earlier models, especially from Dutch prints. In addition, the less familiar Dutch tradition of ambitious historical pictures for town halls, palaces, and wealthy patrons has been clarified, in light of which Rembrandt no longer seems like quite such an anomaly.

Finally, major discoveries concerning Rembrandt's relationship to his patrons and to contemporary politics, economics, and social structure in Amsterdam have provided insights into this artist's role within the culture of his day. It is now possible to compare his achievement with that of rivals and colleagues, such as Lievens, Flinck, and Bol, by considering patrons and status as well as by drawing on modern evaluations of their respective ambitions. In this light the fact that Rembrandt was himself a collector and a student of past art from both Italy and Holland acquires greater meaning, even as it dispels the persistent myth of the isolated genius.

Thus, the current image of Rembrandt ties him more closely to his environment in various ways: through working method, favoured subjects, and patronage within the Dutch urban culture. Without denying the creativity and the distinctive personal sensitivity that has always been the basis of Rembrandt's popularity, modern interest focuses on Rembrandt and his art in terms of their meaning for 17th-century Holland, for it is only by comparing his accomplishments to those of his fellow artists that one can truly grasp the achievement of this beloved Dutch master.

MAJOR WORKS

Paintings

PORTRAITS: "Self Portrait" (c. 1628; Rijksmuseum, Amsterdam); "Self-Portrait" (1629; Isabella Stewart Gardner Museum, Boston); "Old Woman Praying" (c. 1630; Residenz Gallery, Salzburg, Austria); "Old Man with a Gold Chain" (c. 1631; Art Institute of Chicago); "Nicolaes Ruts" (1631; Frick Collection, New York City); "Amalia van Solms" (1632; Jacquemart-André Museum, Paris); "Anatomy Lesson of Dr. Nicolaes Tulp" (1632; Mauritshuis, The Hague); "Marten Looten" (1632; Los Angeles County Museum of Art); "Johannes Uytenbogaert" (1633; private collection, England); "Johannes Elison" (1634; Museum of Fine Arts, Boston); "Saskia as Flora" (1634; Hermitage, Leningrad); "Saskia in Profile" (c. 1634; State Art Collections, Kassel, W.Ger.); "Rembrandt and Saskia as the Prodigal Son" (c. 1635–36; Picture Gallery, Dresden, E.Ger.); "Andries de Graeff" (1639; State Art Collections, Kassel); "Self-Portrait" (1640; National Gallery, London); "Cornelis Anso

and Aeltje Schouten" (1641; Picture Gallery, Dahlem Museums, West Berlin); "The Militia Company of Captain Frans Banning Cocq" ("Night Watch," 1642; Rijksmuseum); "Self-Portrait" (1652; Kunsthistorisches Museum, Vienna); "Anatomy Lesson of Dr. Jan Deyman" (1656; Rijksmuseum); "Self-Portrait" (1658; Frick Collection); "Self-Portrait as the Apostle Paul" (1661; Rijksmuseum); "Self-Portrait" (c. 1661–62; The Iveagh Bequest, Kenwood House, London); "Syndics of the Drapers' Guild" ("De Staalmeeesters," 1662; Rijksmuseum); "The Jewish Bride" (c. 1664; Rijksmuseum); "Gerard de Lairese" (1665; Lehman Collection, Metropolitan Museum of Art, New York City); "Jeremias de Decker" (1666; Hermitage); "Family Group" (c. 1666–68; Herzog Anton Ulrich Museum, Braunschweig, W.Ger.); "Laughing Self-Portrait" (c. 1668–69; Wallraf-Richartz Museum, Cologne); "Self-Portrait" (1669; National Gallery, London); "Self-Portrait" (1669; Mauritshuis).

RELIGIOUS PAINTINGS: "Stoning of St. Stephen" (1625; Museum of Fine Arts, Lyon); "Balaam's Ass and the Angel" (1626; Cognac-Jay Museum, Paris); "Baptism of the Eunuch" (1626; St. Catherine's Convent National Museum, Utrecht, Neth.); "Presentation in the Temple" (c. 1627–28; Hamburg Gallery); "Christ at Emmaus" (c. 1628; Jacquemart-André Museum); "Capture of Samson" (c. 1628; Picture Gallery, Dahlem Museums); "Judas Returning the Thirty Pieces of Silver" (1629; private collection, England); "Raising of Lazarus" (c. 1630; Los Angeles County Museum of Art); "Jeremiah Lamenting the Destruction of Jerusalem" (1630; Rijksmuseum); "Raising of the Cross" (c. 1633; Alte Pinakothek, Munich); "Descent from the Cross" (c. 1633; Alte Pinakothek); "Christ Before Pilate" (1634; National Gallery, London); "John the Baptist Preaching" (c. 1634; Picture Gallery, Dahlem Museums); "Belshazzar's Feast" (c. 1635; National Gallery, London); "Sacrifice of Isaac" (1635; Hermitage); "Sacrifice of Isaac" (1636; Alte Pinakothek); "Holy Family with Angels" (1645; Hermitage); "Christ at Emmaus" (1648; Louvre, Paris); "Bathsheba" (1654; Louvre); "Jacob Blessing the Sons of Joseph" (1656; State Art Collections, Kassel); "Peter Denying Christ" (1660; Rijksmuseum); "Return of the Prodigal Son" (Hermitage).

HISTORY AND MYTHOLOGY: "Palamedes Before Agamemnon" (1626; Municipal Museum [De Lakenhal], Leiden, Neth.); "Andromeda" (c. 1630; Mauritshuis); "Pluto and Proserpina" (c. 1632; Picture Gallery, Dahlem Museums); "Rape of Europa" (c. 1632; private collection, New York City); "Rape of Ganymede" (1635; Picture Gallery, Dresden); "Danaë" (1636; Hermitage); "Aristotle Contemplating the Bust of Homer" (1653; Metropolitan Museum of Art); "Conspiracy of Julius Civilis" (c. 1661–62; National Museum, Stockholm); "Homer" (1661/63; Mauritshuis); "Lucretia" (1664; National Gallery of Art, Washington, D.C.); "Lucretia" (1666; Minneapolis Institute of Arts, Minnesota).

LANDSCAPES: "Landscape with Storm" (c. 1638; Herzog Anton Ulrich Museum, Braunschweig, W.Ger.); "Landscape with Good Samaritan" (1638; Czartoryski Collection, Cracow, Pol.); "Landscape with a Stone Bridge" (c. 1638; Rijksmuseum); "Mill" (c. 1650; National Gallery of Art, Washington, D.C.); "Winter Landscape" (c. 1650/55; State Art Collections, Kassel).

GENRE, FIGURES: "Music Lesson" (1626; Rijksmuseum); "Young Painter in the Studio" (c. 1629; Museum of Fine Arts, Boston); "Woman Bathing (Hendrickje Stoffels?)" (1655; National Gallery, London).

Etchings

"Self-Portrait" (1629); "Raising of Lazarus" (c. 1632); "Descent from the Cross" (1633); "Annunciation to the Shepherds" (1634); "Johannes Uytenbogaert" (1635); "Christ Before Pilate" (1636); "Menasseh ben Israel" (1636); "Self-Portrait with Saskia" (1636); "Self-Portrait" (1639); "Cornelis Anso" (1641); "Skyline with Amsterdam" (c. 1641); "Windmill" (1641); "Three Trees" (1643); "Johannes Cornelisz. Sylvius" (1646); "Jan Asseijn" (c. 1647); "Ephraim Bonus" (1647); "Jan Six" (1647); "Self-Portrait by a Window" (1648); "Christ Healing the Sick (The Hundred Guilder Print)" (c. 1643–49); "Goldweiger's Field" (1651); "Clement de Jonghe" (1651); "Christ Preaching" (c. 1652); "Three Crosses" (1653ff); "Adoration of the Shepherds" (c. 1652/54); "Entombment" (c. 1654); "Descent from the Cross" (c. 1654); "Christ Presented to the People" (1655ff); "Abraham Fransen" (c. 1657).

Drawings

"Self-Portrait" (c. 1627–28; British Museum, London); "Seated Old Man" (c. 1631; Print Room, Dahlem Museums); "Woman Bathing" (c. 1631; British Museum); "Saskia Looking out of a Window" (c. 1635; Boymans-van Beuningen Museum, Rotterdam); "Study After Leonardo da Vinci's 'Last Supper'" (c. 1635; British Museum); "Woman Carrying Child" (c. 1636; Pierpont Morgan Library, New York City); "Saskia in Bed" (c. 1635–38; State Graphics Collection, Munich); "Rear View of Woman in North Holland Costume" (c. 1638; Teylers Museum, Haarlem, Neth.); "Portrait of Titia van Uylenburg" (1639; National Museum, Stockholm); "Youth Pulling a Rope" (c. 1645;

Rijksmuseum); "Standing Male Nude" (c. 1646; Albertina, Vienna); "View of River IJ near Amsterdam" (c. 1649-50; Chatsworth Settlement); "View of Amstel River" (c. 1648-50; Print Room, Rijksmuseum); "View of Haarlem" (c. 1651; Boymans-van Beuningen Museum); "Lion" (c. 1650-52; Louvre); "Ruins of Old Town Hall in Amsterdam" (1652; Rembrandt House Museum, Amsterdam); "Four Orientals Beneath a Tree" (c. 1655; British Museum); "Sleeping Woman" (c. 1655; British Museum); "Woman at Window" (c. 1655; Louvre); "Nathan Admonishing David" (c. 1655-56; Metropolitan Museum of Art); "Row of Windmills" (c. 1655; Print Collection, State Art Museum, Copenhagen); "Anatomy Lesson of Dr. Jan Deyman" (c. 1656; Print Room, Rijksmuseum); "Portrait of a Man" (c. 1655-60; Louvre); "Female Nude on a Stool" (c. 1658; Art Institute of Chicago); "Christ on the Mount of Olives" (c. 1656-58; Hamburg Gallery); "Study for the Conspiracy of Julius Civilis" (1661; State Graphics Collection, Munich).

BIBLIOGRAPHY

Biographical works and documents: C. HOFSTEDE DE GROOT, *Die Urkunden über Rembrandt (1575-1721)*, new ed. (1906), a basic source that contains all documents concerning Rembrandt known at the time of publication, with annotations; ARNOLD HOUBRAKEN, *De Grootte schouburgh der nederlantsche konstschilders en schilderessen*, 3 vol. (1718-21, reissued 1976), a long biography containing many anecdotes as well as facts that became the basis for 18th- and 19th-century criticism of Rembrandt's works; BOB HAAK, *Rembrandt: His Life, Work, and Times* (1969; originally published in Dutch, 1968), an illustrated biography with a discussion of the period in Dutch history, including documents concerning Rembrandt's life; OTTO BENESCH, *Rembrandt: Werk und Forschung* (1935, reissued 1970), a detailed analysis of Rembrandt's life and oeuvre, including a bibliography; CHRISTOPHER WHITE, *Rembrandt and His World* (1964), a study of the artist's life and environment, and *Rembrandt* (1984), a later general study that draws on recent research; KENNETH CLARK, *An Introduction to Rembrandt* (1978), a biography for the general reader; CHRISTIAN TÜMPER, *Rembrandt in Selbstzeugnissen und Bilddokumenten* (1977), a study of biographical and autobiographical documents; WALTER L. STRAUSS and MARJON VAN DER MEULEN (comps.), *The Rembrandt Documents* (1979), a collection of primary records; and JACOB ROSENBERG, *Rembrandt, Life and Work*, 2nd rev. ed. (1964, reissued 1980), a survey and catalog. See also GARY SCHWARTZ, *Rembrandt: His Life, His Paintings: A New Biography with All Accessible Paintings Illustrated in Colour* (1985; originally published in Dutch, 1984).

Analytical catalogs: (Paintings): C. HOFSTEDE DE GROOT, "Rembrandt" in vol. 6 of his *Catalogue Raisonné of the Works of the Most Eminent Dutch Painters of the Seventeenth Century*, trans. from German, 8 vol. (1907-27, reissued in 3 vol., 1976); KURT BAUCH, *Rembrandt Gemälde* (1965); and A. BREDIUS, *Rembrandt: The Complete Edition of the Paintings*, 4th ed., revised by HORST GERSON, trans. from Dutch (1971), a book in which the authors reject a number of works that are generally attributed to the artist and provide an understanding of many aspects of the artist's personality and oeuvre. See also J. BRUYN *et al.*, *A Corpus of Rembrandt Paintings: Stichting Foundation Rembrandt Research Project* (1982-), a multivolume work, of which two volumes had appeared by 1986 covering the years 1625 to 1634.

(Engravings): LUDWIG MÜNZ (ed.), *Rembrandt's Engravings: Reproductions of the Whole Original Etched Work*, complete ed., 2 vol. (1952); ARTHUR M. HIND, *A Catalogue of Rembrandt's Engravings*, 2nd ed., 2 vol. (1923, reprinted in 1 vol., 1967); GEORGE BIÖRKLUND and OSBART H. BARNARD, *Rembrandt's Engravings, True and False: A Summary Catalogue*, 2nd rev. ed. (1968), with a discussion of the various states of the works; and CHRISTOPHER WHITE and KAREL G. BOON, *Rembrandt's Engravings: An Illustrated Critical Catalogue*, 2 vol. (1969). (*Draw-*

ings): BEN BROOS, *Rembrandt en tekenaars uit zijn omgeving* (1981); and OTTO BENESCH, *The Drawings of Rembrandt*, enl. ed., edited by EVA BENESCH, 6 vol. (1973).

Critical studies: SEYMOUR SLIVE, *Rembrandt and His Critics, 1630-1730* (1953), a study of critical and biographical works on the artist; EGBERT HAVERKAMP-BEGEMANN, "The Present State of Rembrandt Studies," *Art Bulletin*, 53:88-104 (March 1971), an overview of modern scholarship; JAN A. EMMENS, *Rembrandt en de regels van de kunst* (1968, reissued 1979), a work demolishing the image of Rembrandt that was created by the 17th-century classicistic critics and that continued to influence scholarship well into the 20th century, with a summary in English; OTTO BENESCH, "Rembrandt," vol. 1 of his *Collected Writings*, 4 vol., edited by EVA BENESCH (1970-73), a collection of articles; JULIUS S. HELD, *Rembrandt's Aristotle: And Other Rembrandt Studies* (1969), a collection of the author's iconological studies of Rembrandt; HORST GERSON, *Rembrandt Paintings*, trans. from Dutch (1968, reprinted 1978), a general discussion of Rembrandt's development and position in Dutch art, including a catalog of the paintings; CHRISTOPHER WHITE, *Rembrandt as an Etcher: A Study of the Artist at Work*, 2 vol. (1969), a discussion that emphasizes the artist's technique and the connections between the etchings, drawings, and paintings; OTTO BENESCH, *Rembrandt as a Draughtsman* (1960), an introduction commenting upon the discovered additions to the artist's drawing oeuvre; CHRISTOPHER WHITE, *The Drawings of Rembrandt*, 2nd ed. (1966); and CHRISTOPHER WRIGHT, *Rembrandt, Self-Portraits* (1982), an illustrated interpretation of the self-portraits. Other studies include H. VAN DE WAAL, *Steps Towards Rembrandt: Collected Articles 1937-1972*, trans. from Dutch (1974); and EGBERT HAVERKAMP-BEGEMANN, *Rembrandt, the "Nightwatch"* (1982).

Rembrandt's interests, influences, and contemporaries: R.W. SCHELLER, "Rembrandt en de encyclopedische verzameling," *Oud-Holland*, 84(2-3):81-147 (1969), an interpretation of Rembrandt's art collecting, with a summary in English; KENNETH CLARK, *Rembrandt and the Italian Renaissance* (1966), a discussion of antique and Renaissance influences on Rembrandt's style; WERNER SUMOWSKI (ed.), *Gemälde der Rembrandt-Schüler* (1983-), a multivolume analytical catalog of paintings of the Rembrandt school, of which two volumes were published by 1986, and his *Drawings of the Rembrandt School*, trans. from German (1979-), another multivolume work, of which nine volumes are available; WOLFGANG STECHOW, "Some Observations on Rembrandt and Lastman," *Oud-Holland*, 84(2-3):148-162 (1969); RUDOLF H. FUCHS, *Rembrandt in Amsterdam* (1969; originally published in Dutch, 1968), essays on the artist's connections with the city and with the art of his contemporaries; *Geschildert tot Leyden anno 1626* (1976), an exhibition catalog of works by the artist and his contemporaries; A.B. DE VRIES, MAGDI TÓTH-UBBENS, and W. FROENTJES, *Rembrandt in the Mauritshuis: An Interdisciplinary Study*, trans. from Dutch (1978), an analysis of several works of Rembrandt in conjunction with works of his contemporaries in The Hague museum; ALBERT BLANKERT, *Ferdinand Bol (1616-1680): Rembrandt's Pupil* (1982; originally published in Dutch, 1976); and ALBERT BLANKERT *et al.*, *The Impact of a Genius: Rembrandt, His Pupils and Followers in the Seventeenth Century: Paintings from Museums and Private Collections* (1983), and *Gods, Saints, & Heroes: Dutch Painting in the Age of Rembrandt* (1980), exhibition catalogs. See also *Rembrandt After Three Hundred Years: An Exhibition of Rembrandt and His Followers* (1969), a catalog, containing a discussion on Rembrandt as a teacher in the introduction written by EGBERT HAVERKAMP-BEGEMANN, and, published in conjunction with the exhibition, a symposium of the same title edited by DEIRDRE C. STAM (1973); and ERNST VAN DE WETERING, "Studies in the Workshop Practice of the Early Rembrandt" (Thesis, Ph.D.—University of Amsterdam, 1986).

(L.A.Si.)

Reproduction and Reproductive Systems

In a general sense reproduction is one of the most important concepts in biology: it means making a copy, a likeness, and thereby providing for the continued existence of species. Although reproduction is often considered solely in terms of the production of offspring in animals and plants, the more general meaning has far greater significance to living organisms. To appreciate this fact, the origin of life and the evolution of organisms must be considered. One of the first characteristics of life that emerged in primeval times must have been the ability of some primitive chemical system to make copies of itself. At its lowest level, therefore, reproduction is chemical replication. As evolution progressed, cells of successively higher levels of complexity must have arisen, and it was

absolutely essential that they had the ability to make likenesses of themselves. In unicellular organisms, the ability of one cell to reproduce itself means the reproduction of a new individual; in multicellular organisms, however, it means growth and regeneration. Multicellular organisms also reproduce in the strict sense of the term—that is, they make copies of themselves in the form of offspring—but they do so in a variety of ways, many involving complex organs and elaborate hormonal mechanisms.

For a depiction of some of the structures that make up the human reproductive system, shown in relation to other parts of the gross anatomy, see the colour Trans-*vision* in the *Propædia*: Part Four, Section 421.

The article is divided into the following sections:

General features of reproduction 609	External genitalia
The nature of reproduction 609	Structures of the sperm canal
Levels of reproduction	Accessory organs
Natural selection and reproduction	The female reproductive system 653
The process of fertilization 612	External genitalia
Maturation of the egg	Internal structures
Events of fertilization	The menstrual cycle
Biochemical analysis of fertilization	Menopause
Plant reproduction 615	Diseases of the human reproductive system 658
Plant reproductive systems 615	Genetic and congenital abnormalities
General features of asexual systems	Functional genital disorders
General features of sexual systems	Infectious diseases spread by sexual contact
Bryophyte reproductive systems	Other infections affecting the reproductive system
Tracheophyte reproductive systems	Structural changes of unknown causes
Variations in reproductive cycles	Tumours
Physiology of plant reproduction	Human reproduction from conception to birth 664
Pollination 624	The normal events of pregnancy 664
Types: self-pollination and cross-pollination	Initiation of pregnancy
Agents of pollen dispersal	Diagnosis of pregnancy

The nature of seeds and fruits	normal pregnancy
Form and function	Abnormal changes in pregnancy 672
Agents of dispersal	Ectopic pregnancy
Germination	Abortion
Animal reproduction 636	Systemic diseases and pregnancy
Reproductive systems of invertebrates 637	Diseases of pregnancy
Gonads, associated structures, and products	Parturition: the process of birth 680
Mechanisms that aid in the union of gametes	The stages of labour
Parthenogenesis	Relief of pain in labour
Provisions for the developing embryo	Natural childbirth
Reproductive systems of vertebrates 642	Operative obstetrics
Gonads, associated structures, and products	Accidents during labour
Adaptations for internal fertilization	Puerperium or period of involution 684
Role of gonads in hormone cycles	Lactation
Provisions for the developing embryo	Weaning and the cessation of lactation
The human reproductive system 650	Bibliography 686
The male reproductive system 651	

GENERAL FEATURES OF REPRODUCTION

The nature of reproduction

LEVELS OF REPRODUCTION

Molecular replication. The characteristics that an organism inherits are largely stored in cells as genetic information in very long molecules of deoxyribonucleic acid (DNA). In 1953, it was established that DNA molecules consist of two complementary strands, each of which can make copies of the other. The strands are like two sides of a ladder that has been twisted along its length in the shape of a double helix (spring). The rungs, which join the two sides of the ladder, are made up of two terminal

bases. There are four bases in DNA; thymine, cytosine, adenine, and guanine. In the middle of each rung a base from one strand of DNA is linked by a hydrogen bond to a base of the other strand. But they can only pair in certain ways: adenine always pairs with thymine, and guanine with cytosine. This is why one strand of DNA is considered complementary to the other.

The double helices duplicate themselves by separating at one place between the two strands and becoming progressively unattached. As one strand separates from the other, each acquires new complementary bases until eventually each strand becomes a new double helix with a new com-

plementary strand to replace the original one. Because adenine always falls in place opposite thymine and guanine opposite cytosine, the process is called a template replication—one strand serves as the mold for the other. It should be added that the steps involving the duplication of DNA do not occur spontaneously; they require catalysts in the form of enzymes that promote the replication process.

Molecular reproduction. The sequence of bases in a DNA molecule serves as a code by which genetic information is stored. Using this code, the DNA synthesizes one strand of ribonucleic acid (RNA), a substance that is so similar structurally to DNA that it is also formed by template replication of DNA. RNA serves as a messenger for carrying the genetic code to those places in the cell where proteins are manufactured. The way in which the messenger RNA is translated into specific proteins is a remarkable and complex process. (For more detailed information concerning DNA, RNA, and the genetic code, see the articles BIOCHEMICAL COMPONENTS OF ORGANISMS: *Nucleic acids*; GENETICS AND HEREDITY: *The gene*).

The ability to synthesize enzymes and other proteins enables the organism to make any substance that existed in a previous generation. Proteins are reproduced directly; however, such other substances as carbohydrates, fats, and other organic molecules found in cells are produced by a series of enzyme-controlled chemical reactions, each enzyme being derived originally from DNA through messenger RNA. It is because all of the organic constituents made by organisms are derived ultimately from DNA that molecules in organisms are reproduced exactly by each successive generation.

Cell reproduction. The chemical constituents of cytoplasm (that part of the cell outside the nucleus) are not resynthesized from DNA every time a cell divides. This is because each of the two daughter cells formed during cell division usually inherits about half of the cellular material from the mother cell (see CELLS: *Cell division*), and is important because the presence of essential enzymes enables DNA to replicate even before it has made the enzymes necessary to do so.

Cells of higher organisms contain complex structures, and each time a cell divides the structures must be duplicated. The method of duplication varies for each structure, and in some cases the mechanism is still uncertain. One striking and important phenomenon is the formation of a new membrane. Cell membranes, although they are very thin and appear to have a simple form and structure, contain many enzymes and are sites of great metabolic activity. This applies not only to the membrane that surrounds the cell but to all the membranes within the cell. New membranes, which seem to form rapidly, are indistinguishable from old ones.

Thus, the formation of a new cell involves the further synthesis of many constituents that were present in the parent cell. This means that all of the information and materials necessary for a cell to reproduce itself must be supplied by the cellular constituents and the DNA inherited from the parent cell.

Binary fission. Of the various kinds of cell division, the most common mode is binary fission, the division of a cell into two separate and similar parts. In bacteria (prokaryotes) the chromosome (the body that contains the DNA and associated proteins) replicates and then divides in two, after which a cell wall forms across the elongated parent cell. In higher organisms (eukaryotes) there is first an elaborate duplication and then a separation of the chromosomes (mitosis), after which the cytoplasm divides in two. In the hard-walled cells of higher plants, a median plate forms and divides the mother cell into two compartments; in animal cells, which do not have a hard wall, a delicate membrane pinches the cell in two, much like the separation of two liquid drops. Budding yeast cells provide an interesting exception. In these fungi the cell wall forms a bubble that becomes engorged with cytoplasm until it is ultimately the size of the original cell. The nucleus then divides, one of the daughter nuclei passes into the bud, and ultimately the two cells separate.

In some instances of binary fission, there may be an unequal cytoplasmic division with an equal division of

the chromosomes. This occurs, in fact, in a large number of higher organisms during meiosis—the process by which sex cells (gametes) are formed: originally each chromosome of the cell is in a pair (diploid); during meiosis these diploid pairs of chromosomes are separated so that each sex cell has only one of each pair of chromosomes (haploid). During the two successive meiotic divisions involved in the production of eggs, a primordial diploid egg cell is converted into a haploid egg and three small haploid polar bodies (minute cells). In this instance the egg receives far more cytoplasm than the polar bodies.

Multiple fission. Some algae, some protozoans, and the true slime molds (Myxomycetes) regularly divide by multiple fission. In such cases the nucleus undergoes several mitotic divisions, producing a number of nuclei. After the nuclear divisions are complete, the cytoplasm separates, and each nucleus becomes encased in its own membrane to form an individual cell. In the Myxomycetes, the fusion of two haploid gametes or the fusion of two or more diploid zygotes (the structures that result from the union of two sex cells) results in the formation of a plasmodium—a motile, multinucleate mass of cytoplasm. The nuclei are in a syncytium, that is, there are no cell boundaries, and the nuclei flow freely in the motile plasmodium. As it feeds, the plasmodium enlarges, and the nuclei divide synchronously about once every 24 hours. The plasmodium may become very large, with millions of nuclei, but, ultimately, when conditions are right, it forms a series of small bumps, each of which becomes a small, fruiting body (a structure that bears the spores). During this process the nuclei undergo meiosis, and the final haploid nuclei are then isolated into uninucleate spores (reproductive bodies).

Many algae (e.g., the Siphonales and related groups) are multinucleate. In most instances the nuclei are in one common cytoplasm within a large and elaborate organism surrounded by a hard cell wall. As the wall becomes extended, the nuclei, which wander freely in the central cavity, undergo repeated mitoses. Again, either during the formation of zoospores (asexual reproductive cells) or after meiosis during gamete formation, a massive progressive division occurs. The most unusual of such organisms is the marine alga *Acetabularia*; many nuclei stay clumped together in one compound nucleus in the rootlike base, which often is as much as two inches (five centimetres) away from the tip of the plant. The compound nucleus breaks up just before gamete formation, and the minute individual nuclei undergo meiosis and wander to the elaborate tip structures, where they are released as uninucleate gametes.

Syncytial organisms raise the question of whether or not cells, in the strict sense, are necessary for the development of large organisms. Syncytia are also found in animals—e.g., in the early stages of development of fishes and insects—and in the voluntary muscles of man. The proposal of the 19th-century botanist Julius von Sachs is generally considered a satisfactory answer to this question; he suggested that the important matter was the existence not of a cell membrane but of a certain amount of cytoplasm surrounding a nucleus and acting as a unit of metabolism, which he called an energid. Cell reproduction, therefore, might be considered a special case of energid reproduction.

Reproduction of organisms. In single-celled organisms (e.g., bacteria, protozoans, many algae, and some fungi), organismic and cell reproduction are synonymous, for the cell is the whole organism. Details of the process differ greatly from one form to the next and, if the higher ciliate protozoans are included, can be extraordinarily complex. It is possible for reproduction to be asexual, by simple division, or sexual. In sexual unicellular organisms the gametes can be produced by division (often multiple fission, as in numerous algae) or, as in yeasts, by the organism turning itself into a gamete and fusing its nucleus with that of a neighbour of the opposite sex, a process that is called conjugation. In ciliate protozoans (e.g., *Paramecium*), the conjugation process involves the exchange of haploid nuclei; each partner acquires a new nuclear apparatus, half of which is genetically derived from its mate. The parent cells separate and subsequently reproduce by

dium

Mitosis
and
meiosis

Vegetative
repro-
duction

binary fission. Sexuality is present even in primitive bacteria, in which parts of the chromosome of one cell can be transferred to another during mating.

Multicellular organisms also reproduce asexually and sexually; asexual, or vegetative, reproduction can take a great variety of forms. Many multicellular lower plants give off asexual spores, either aerial or motile and aquatic (zoospores), which may be uninucleate or multinucleate. In some cases the reproductive body is multicellular, as in the soredia of lichens and the gemmae of liverworts. Frequently, whole fragments of the vegetative part of the organism can bud off and begin a new individual, a phenomenon that is found in most plant groups. In many cases a spreading rhizoid (rootlike filament) or, in higher plants, a rhizome (underground stem) gives off new sprouts. Sometimes other parts of the plant have the capacity to form new individuals; for instance, buds of potentially new plants may form in the leaves; even some shoots that bend over and touch the ground can give rise to new plants at the point of contact (see below *Plant reproductive systems*).

Among animals, many invertebrates are equally well endowed with means of asexual reproduction. Numerous species of sponges produce gemmules, masses of cells enclosed in resistant cases, that can become new sponges. There are many examples of budding among coelenterates, the best known of which occurs in freshwater *Hydra*. In some species of flatworms, the individual worm can duplicate by pinching in two, each half then regenerating the missing half; this is a large task for the posterior portion, which lacks most of the major organs—brain, eyes, and pharynx. The highest animals that exhibit vegetative reproduction are the colonial tunicates (e.g., sea squirts), which, much like plants, send out runners in the form of stolons, small parts of which form buds that develop into new individuals. Vertebrates have lost the ability to reproduce vegetatively; their only form of organismic reproduction is sexual.

In the sexual reproduction of all organisms except bacteria, there is one common feature: haploid, uninucleate gametes are produced that join in fertilization to form a diploid, uninucleate zygote. At some later stage in the life history of the organism, the chromosome number is again reduced by meiosis to form the next generation of gametes. The gametes may be equal in size (isogamy), or one may be slightly larger than the other (anisogamy); the majority of forms have a large egg and a minute sperm (oogamy). The sperm are usually motile and the egg passive, except in higher plants, in which the sperm nuclei are carried in pollen grains that attach to the stigma (a female structure) of the flower and send out germ tubes that grow down to the egg nucleus in the ovary. Some organisms, such as most flowering plants, earthworms, and tunicates, are bisexual (hermaphroditic, or monoecious)—i.e., both the male and female gametes are produced by the same individual. All other organisms, including some plants (e.g., holly and the ginkgo tree) and all vertebrates, are unisexual (dioecious): the male and female gametes are produced by separate individuals.

Some sexual organisms partially revert to the asexual mode by a periodic degeneration of the sexual process. For instance, in aphids and in many higher plants the egg nucleus can develop into a new individual without fertilization, a kind of asexual reproduction that is called parthenogenesis.

Partheno-
genesis

Life-cycle reproduction. Although organisms are often thought of only as adults, and reproduction is considered to be the formation of a new adult resembling the adult of the previous generation, a living organism, in reality, is an organism for its entire life cycle, from fertilized egg to adult, not for just one short part of that cycle. Reproduction, in these terms, is not just a stage in the life history of an organism but the organism's entire history. It has been pointed out that only the DNA of a cell is capable of replicating itself, and even that replication process requires specific enzymes that were themselves formed from DNA. Thus, the reproduction of all living forms must be considered in relation to time; what is reproduced is a series of copies that, like the sequence of individual frames

of a motion picture, change through time in an exact and orderly fashion.

A few examples serve to illustrate the great variety of life cycles in living organisms. They also illustrate how different parts of the life cycle can change, and the fact that these changes are not confined solely to adult structures. One variation is that of minimum size—that is to say, the differences in the sizes of gametes (mature sex cells) and asexual bodies. An even greater variation in life cycles, however, involves maximum size; there is an enormous difference between a single-celled organism that divides by binary fission and a giant sequoia. Size is correlated with time. A bacterium requires about 30 minutes to complete its life history and divide in two (generation time); a giant sequoia bears its first cones and fertile seeds after 60 years. Not only is the life cycle of the sequoia 10,000,000 times longer than that of the bacterium, but the large difference in size also means that the tree must be elaborate and complex. It contains different tissue types that must be carefully duplicated from generation to generation.

Life cycles of plants. Most life histories, except perhaps for the simplest and smallest organisms, consist of different epochs. A large tree has a period of seed formation that involves many cell divisions after fertilization and the laying down of a small embryo in a hard resistant shell, or seed coat. There then follows a period of dormancy, sometimes prolonged, after which the seed germinates, and the adult form slowly emerges as the shoots and roots grow at the tips and the stem thickens. In some trees the leaves of the juvenile plant have a shape that is quite different from that of the taller, more mature individuals. Thus, even the growth phase may be subdivided into epochs, the final one being the flowering or gametebearing period. Some of the parasitic fungi have much more complex life histories. The wheat rust parasite, for example, has alternate hosts. While living on wheat, it produces two kinds of spores; it produces a third kind of spore when it invades its other host, the barberry, on which it winters and undergoes the sexual part of its life cycle.

In plants, variations in the epochs of the life cycle are often centred around the times of fertilization and meiosis. After fertilization the organism has the diploid number of chromosomes (diplophase); after meiosis it is haploid (haplophase). The two events vary in time with respect to each other. In some simple algae (e.g., *Chlamydomonas*), for example, most of the cycle is haploid; meiosis occurs immediately after fertilization. Yet in other algae, such as the sea lettuce (*Ulva*), two equal haploid and diploid cycles alternate. The outward morphological structures of mature *Ulva* are indistinguishable; the two cycles can be differentiated only by the size of the cell or nucleus, those of the haploid stage being half the size of those of the diploid stage.

In many of the higher algae, there is a progressive diminution of the haplophase and an increase in the importance of the diplophase, a trend that is especially noticeable in the evolution of the vascular plants (e.g., ferns, conifers, and flowering plants). In mosses, the haplophase, or gametophyte, is the main part of the green plant; the diplophase, or sporophyte, usually is a sporebearing spike that grows from the top of the plant. In ferns, the haplophase is reduced to a small, inconspicuous structure (prothallus) that grows in the damp soil; the large sporebearing fern itself is entirely diploid. Finally, in higher plants the haploid tissue is confined to the ovary of the large diploid organism, a condition that is also prevalent in most animals.

Life cycles of animals. Invertebrate animals have a rich variety of life cycles, especially among those forms that undergo metamorphosis, a radical physical change. Butterflies, for instance, have a caterpillar stage (larva), a dormant chrysalis stage (pupa), and an adult stage (imago). One remarkable aspect of this development is that, during the transition from caterpillar to adult, most of the caterpillar tissue disintegrates and is used as food, thereby providing energy for the next stage of development, which begins when certain small structures (imaginal disks) in the larva start growing into the adult form. Thus, the butterfly undergoes essentially two periods of growth and

Metamor-
phosis

development (larva and pupa-adult) and two periods of small size (fertilized egg and imaginal disks). A somewhat similar phenomenon is found in sea urchins; the larva, which is called a pluteus, has a small, wartlike bud that grows into the adult while the pluteus tissue disintegrates. In both examples it is as if the organism has two life histories, one built on the ruins of another.

Another life-cycle pattern found among certain invertebrates illustrates the principle that major differences between organisms are not always found in the physical appearance of the adult but in differences of the whole life history. In the coelenterate *Obelia*, for example, the egg develops into a colonial hydroid consisting of a series of branching *Hydra*-like organisms called polyps. Certain of these polyps become specialized (reproductive polyps) and bud off from the colony as free-swimming jellyfish (medusae) that bear eggs and sperm. As with caterpillars and sea urchins, two distinct phases occur in the life cycle of *Obelia*: the sessile (anchored), branched polyps and the motile medusae. In some related coelenterates the medusa form has been totally lost, leaving only the polyp stage to bear eggs and sperm directly. In still other coelenterates the polyp stage has been lost, and the medusae produce other medusae directly, without the sessile stage. There are, furthermore, intermediate forms between the extremes.

NATURAL SELECTION AND REPRODUCTION

The significance of biological reproduction can be explained entirely by natural selection (see EVOLUTION, THE THEORY OF: *Natural selection*). In formulating his theory of natural selection, Charles Darwin realized that, in order for evolution to occur, not only must living organisms be able to reproduce themselves but the copies must not all be identical; that is, they must show some variation. In this way the more successful variants would make a greater contribution to subsequent generations in the number of offspring. For such selection to act continuously in successive generations, Darwin also recognized that the variations had to be inherited, although he failed to fathom the mechanism of heredity. Moreover, the amount of variation is particularly important. According to what has been called the principle of compromise, which itself has been shaped by natural selection, there must not be too little or too much variation: too little produces no change; too much scrambles the benefit of any particular combination of inherited traits.

Of the numerous mechanisms for controlling variation, all of which involve a combination of checks and balances that work together, the most successful is that found in the large majority of all plants and animals—i.e., sexual reproduction. During the evolution of reproduction and variation, which are the two basic properties of organisms that not only are required for natural selection but are also subject to it, sexual reproduction has become ideally adapted to produce the right amount of variation and to allow new combinations of traits to be rapidly incorporated into an individual.

The evolution of reproduction. An examination of the way in which organisms have changed since their initial unicellular condition in primeval times shows an increase in multicellularity and therefore an increase in the size of both plants and animals. After cell reproduction evolved into multicellular growth, the multicellular organism evolved a means of reproducing itself that is best described as life-cycle reproduction. Size increase has been accompanied by many mechanical requirements that have necessitated a selection for increased efficiency; the result has been a great increase in the complexity of organisms. In terms of reproduction this means a great increase in the permutations of cell reproduction during the process of evolutionary development.

Size increase also means a longer life cycle, and with it a great diversity of patterns at different stages of the cycle. This is because each part of the life cycle is adaptive in that, through natural selection, certain characteristics have evolved for each stage that enable the organism to survive. The most extreme examples are those forms with two or more separate phases of their life cycle separated by a metamorphosis, as in caterpillars and butterflies; these

phases may be shortened or extended by natural selection, as has occurred in different species of coelenterates.

To reproduce efficiently in order to contribute effectively to subsequent generations is another factor that has evolved through natural selection. For instance, an organism can produce vast quantities of eggs of which, possibly by neglect, only a small percent will survive. On the other hand, an organism can produce very few or perhaps one egg, which, as it develops, will be cared for, thereby greatly increasing its chances for survival. These are two strategies of reproduction; each has its advantages and disadvantages. Many other considerations of the natural history and structure of the organism determine, through natural selection, the strategy that is best for a particular species; one of these is that any species must not produce too few offspring (for it will become extinct) or too many (for it may also become extinct by overpopulation and disease). The numbers of some organisms fluctuate cyclically but always remain between upper and lower limits. The question of how, through natural selection, numbers of individuals are controlled is a matter of great interest; clearly, it involves factors that influence the rate of reproduction.

The evolution of variation control. Because inherited variation is largely handled by genes in the chromosomes, organisms that reproduce sexually require a single-cell stage in their life cycle, during which the haploid gamete of each parent can combine to form the diploid zygote. This is also often true in organisms that reproduce asexually, but in this case the asexual reproductive bodies (e.g., spores) are small and hence are effectively dispersed.

The amount of variation is controlled in a large number of ways, all of which involve a carefully balanced set of factors. These factors include whether the organism reproduces asexually or sexually; the mutation (gene change) rate; the number of chromosomes; the amount of exchange of parts of chromosomes (crossing over); the size of the individual (which correlates with complexity and generation time); the size of the population; the degree of inbreeding versus outbreeding; and the relative amounts and position of haploidy and diploidy in the life cycle. It is clear, therefore, that the mode of reproduction influences the amount of variation and vice versa; the two together permit natural selection to operate, and selection in turn modifies the mechanisms of reproduction and variation.

(J.T.Bo.)

The process of fertilization

Fertilization, the completion of the cycle of sexual reproduction, may be formally defined as the union of a spermatozoal nucleus, of paternal origin, with an egg nucleus, of maternal origin, to form the primary nucleus of an embryo. In all organisms the essence of fertilization is, in fact, the fusion of the hereditary material of two different sex cells, or gametes, each of which carries half the number of chromosomes typical of the species. The most primitive form of fertilization, found in micro-organisms and protozoans, consists of an exchange of genetic material between two cells.

The first significant event in fertilization is the fusion of the membranes of the two gametes resulting in the formation of a channel that allows the passage of material from one cell to the other. Fertilization in advanced plants is preceded by pollination, during which pollen is transferred to, and establishes contact with, the female gamete or macrospore (see below *Pollination*). Fusion in advanced animals is usually followed by penetration of the egg by a single spermatozoon. The result of fertilization is a cell (zygote) capable of undergoing cell division to form a new individual.

The fusion of two gametes initiates several reactions in the egg. One of these causes a change in the egg membrane(s), so that the attachment of and penetration by more than one spermatozoon cannot occur. In species in which more than one spermatozoon normally enters an egg (polyspermy), only one spermatozoal nucleus actually merges with the egg nucleus. The most important result of fertilization is egg activation, which allows the egg to

Efficiency
of repro-
duction

Formation
of the
zygote

undergo cell division. Activation, however, does not necessarily require the intervention of a spermatozoon; during parthenogenesis, in which fertilization does not occur, activation of an egg may be accomplished through the intervention of physical and chemical agents. Invertebrates such as aphids, bees, and rotifers normally reproduce by parthenogenesis.

In plants certain chemicals produced by the egg may attract spermatozoa. In animals, with the possible exception of some coelenterates, it appears likely that contact between eggs and spermatozoa depends on random collisions. On the other hand, the gelatinous coats that surround the eggs of many animals exert a trapping action on spermatozoa, thus increasing the chances for successful sperm-egg interaction.

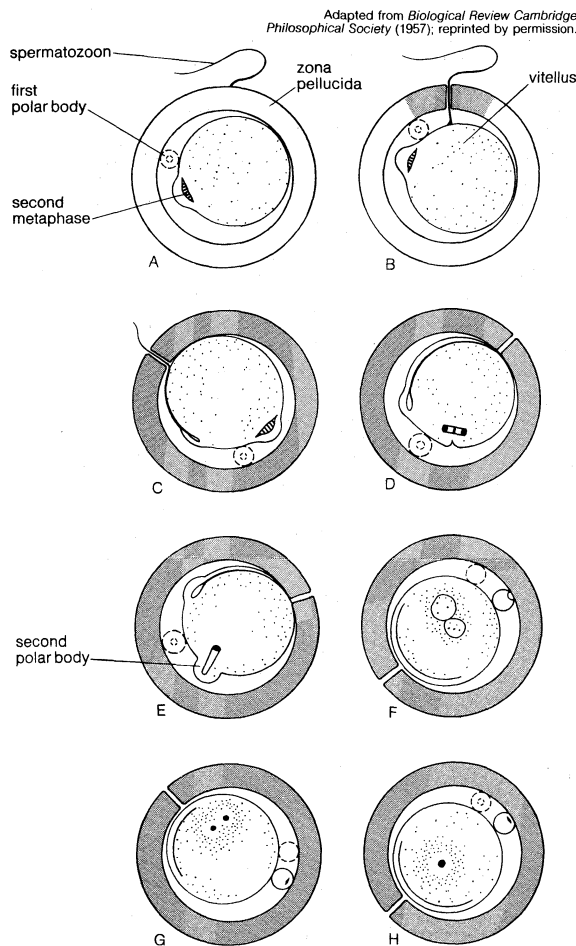

Figure 1: Steps in fertilization in the rat egg. (A–C) Entrance of spermatozoon; shading denotes zona reaction. (D, E) Completion of meiotic division. (F) Pronuclear development. (G) Reappearance of chromosome group. (H) First cleavage metaphase.

The eggs of marine invertebrates, especially echinoderms, are classical objects for the study of fertilization. These transparent eggs are valuable for studies observing living cells and for biochemical and molecular investigations because the time of fertilization can be accurately fixed, the development of many eggs occurs at about the same rate under suitable conditions, and large quantities of the eggs are obtainable. The eggs of some teleosts and amphibians also have been used with favourable results, and techniques for fertilization of mammalian eggs in the laboratory may allow their use even though only small numbers are available.

MATURATION OF THE EGG

Maturation is the final step in the production of functional eggs (oogenesis) that can associate with a spermatozoon and develop a reaction that prevents the entry of more than one spermatozoon; in addition, the cytoplasm of a

mature egg can support the changes that lead to fusion of spermatozoal and egg nuclei and initiate embryonic development.

Egg surface. Certain components of an egg's surface, especially the cortical granules, are associated with a mature condition. Cortical granules of sea urchin eggs, aligned beneath the plasma membrane (thin, soft, pliable layer) of mature eggs, have a diameter of 0.8–1.0 micron (0.0008–0.001 millimetre) and are surrounded by a membrane similar in structure to the plasma membrane surrounding the egg. Cortical granules are formed in a cell component known as a Golgi complex, from which they migrate to the surface of the maturing egg.

The surface of a sea urchin egg has the ability to affect the passage of light unequally in different directions; this property, called birefringence, is an indication that the molecules comprising the surface layers are arranged in a definite way. Since birefringence appears as an egg matures, it is likely that the properties of a mature egg membrane are associated with specific molecular arrangements. A mature egg is able to support the formation of a zygote nucleus; *i.e.*, the result of fusion of spermatozoal and egg nuclei. In most eggs the process of reduction of chromosomal number (meiosis) is not completed prior to fertilization. In such cases the fertilizing spermatozoon remains beneath the egg surface until meiosis in the egg has been completed, after which changes and movements that lead to fusion and the formation of a zygote occur.

Egg coats. The surfaces of most animal eggs are surrounded by envelopes, which may be soft, gelatinous coats (as in echinoderms and some amphibians) or thick membranes (as in fishes, insects, and mammals). In order to reach the egg surface, therefore, spermatozoa must penetrate these envelopes; indeed, spermatozoa contain enzymes (organic catalysts) that break them down. In some cases (*e.g.*, fishes and insects) there is a channel, or micropyle, in the envelope, through which a spermatozoon can reach the egg.

The jelly coats of echinoderm and amphibian eggs consist of complex carbohydrates called sulfated mucopolysaccharides; it is not yet known if they have a species-specific composition. The envelope of a mammalian egg is more complex. The egg is surrounded by a thick coat composed of a carbohydrate protein complex called zona pellucida. The zona is surrounded by an outer envelope, the corona radiata, which is many cell layers thick and formed by follicle cells adhering to the oocyte before it leaves the ovarian follicle.

Although it once was postulated that the jelly coat of an echinoderm egg contains a substance (fertilizin) thought to have an important role not only in the establishment of sperm-egg interaction but also in egg activation, fertilizin now has been shown identical with jelly-coat material, rather than a substance continuously secreted from it. Yet there is evidence that the egg envelopes do play a role in fertilization; *i.e.*, contact with the egg coat elicits the acrosome reaction (described below) in spermatozoa.

EVENTS OF FERTILIZATION

Sperm-egg association. The acrosome reaction of spermatozoa is a prerequisite for the association between a spermatozoon and an egg (Figure 2), which occurs through fusion of their plasma membranes. After a spermatozoon comes in contact with an egg (2A), the acrosome, which is a prominence at the anterior tip of the spermatozoa, undergoes a series of well-defined structural changes. A structure within the acrosome, called the acrosomal vesicle (labelled a), bursts, and the plasma membrane (labelled s) surrounding the spermatozoon fuses at the acrosomal tip with the membrane surrounding the acrosomal vesicle to form an opening (2B). As the opening is formed, the acrosomal granule (labelled g), which is enclosed within the acrosomal vesicle, disappears. It is thought that dissolution of the granule releases a substance called a lysin, which breaks down the egg envelopes, allowing passage of the spermatozoon to the egg. The acrosomal membrane region opposite the opening adheres to the nuclear envelope of the spermatozoon and forms a shallow outpocketing, which rapidly elongates into a thin tube, the acrosomal

Figure 2: A diagrammatic representation of successive states of the sperm penetration in the egg of *Saccoglossus*.

From Colwin and Colwin, *Journal of Cell Biology*, vol. 19 (December 1963)

tubule (labelled *t*) that extends to the egg surface and fuses with the egg plasma membrane (2C, 2D). The tubule thus formed establishes continuity between the egg and the spermatozoon and provides a way for the spermatozoal nucleus to reach the interior of the egg. Other spermatozoal structures that may be carried within the egg include the midpiece and part of the tail; the spermatozoal plasma membrane and the acrosomal membrane, however, do not reach the interior of the egg. In fact, whole spermatozoa injected into unfertilized eggs cannot elicit the activation reaction or merge with the egg nucleus. As the spermatozoal nucleus is drawn within the egg, the spermatozoal plasma membrane breaks down; at the end of the process, the continuity of the egg plasma membrane is re-established. This description of the process of sperm-egg association, first documented for the acorn worm *Saccoglossus* (phylum Enteropneusta), generally applies to most eggs studied thus far.

During their passage through the female genital tract of mammals, spermatozoa undergo physiological change, called capacitation, which is a prerequisite for their participation in fertilization; they are able to undergo the acrosome reaction, traverse the egg envelopes, and reach the interior of the egg. Dispersal of cells in the outer egg envelope (corona radiata) is caused by the action of an enzyme (hyaluronidase) that breaks down a substance (hyaluronic acid) binding corona radiata cells together. The enzyme may be contained in the acrosome and released as a result of the acrosome reaction, during passage of the spermatozoon through the corona radiata. The reaction is well advanced by the time a spermatozoon contacts the thick coat surrounding the egg itself (zona pellucida). The pathway of a spermatozoon through the zona pellucida appears to be an oblique slit.

Association of a mammalian spermatozoon with the egg surface occurs along the lateral surface of the spermatozoon, rather than at the tip as in other animals, so that the spermatozoon lies flat on the egg surface; several points of fusion occur between the plasma membranes of the two gametes (*i.e.*, the breakdown of membranes occurs by formation of numerous small vesicles).

Specificity of sperm-egg interaction. Although fertilization is strictly species-specific, very little is known about the molecular basis of such specificity. The egg coats may have a role. Among the echinoderms solutions of the jelly coat clump, or agglutinate, only spermatozoa of their own species. In both echinoderms and amphibians, however,

slight damage to an egg surface makes fertilization possible with spermatozoa of different species (heterologous fertilization); this procedure has been used to obtain certain hybrid larvae.

The eggs of ascidians, or sea squirts, members of the chordate subphylum Tunicata, are covered with a thick membrane called a chorion; the space between the chorion and the egg is filled with cells called test cells. The gametes of ascidians, which have both male and female reproductive organs in one animal, mature at the same time; yet self-fertilization does not occur. If the chorion and the test cells are removed, however, not only is fertilization with spermatozoa of different species possible, but self-fertilization also can occur.

Prevention of polyspermy. Most animal eggs are monospermic; *i.e.*, only one spermatozoon is admitted into an egg. In some eggs, protection against the penetration of the egg by more than one spermatozoon (polyspermy) is due to some property of the egg surface; in others, however, the egg envelopes are responsible. The ability of some eggs to develop a polyspermy-preventing reaction depends on a molecular rearrangement of the egg surface that occurs during egg maturation (oogenesis). Although immature sea urchin eggs have the ability to associate with spermatozoa, they also allow multiple penetration; *i.e.*, they are unable to develop a polyspermy-preventing reaction. Since the mature eggs of most animals are fertilized before completion of meiosis and are able to develop a polyspermy-preventing reaction, specific properties of the egg surface must have differentiated by the time meiosis stops, which is when the egg is ready to be fertilized.

In some mammalian eggs defense against polyspermy depends on properties of the zona pellucida; *i.e.*, when a spermatozoon has started to move through the zona, it does not allow the penetration of additional spermatozoa (zona reaction). In other mammals, however, the zona reaction either does not take place or is weak, as indicated by the presence of numerous spermatozoa in the space between the zona and egg surface. In such cases the polyspermy-preventing reaction resides in the egg surface. Although the eggs of some kinds of animals (*e.g.*, some amphibians, birds, reptiles, and sharks) are naturally polyspermic, only one spermatozoal nucleus fuses with an egg nucleus to form a zygote nucleus; all of the other spermatozoa degenerate.

Formation of the fertilization membrane. The most spectacular changes that follow fertilization occur at the egg surface. The best known example, that of the sea urchin egg, is described below. An immediate response to fertilization is the raising of a membrane, called a vitelline membrane, from the egg surface. In the beginning the membrane is very thin; soon, however, it thickens, develops a well-organized molecular structure, and is called the fertilization membrane. At the same time an extensive rearrangement of the molecular structure of the egg surface occurs. The events leading to formation of the fertilization membrane require about one minute.

At the point on the outer surface of the sea urchin egg at which a spermatozoon attaches, the thin vitelline membrane becomes detached. As a result the membranes of the cortical granules (*cg*, see Figure 2F) come into contact with the inner aspect of the egg's plasma membrane and fuse with it, the granules open, and their contents are extruded into the perivitelline space; *i.e.*, the space between the egg surface and the raised vitelline membrane. Part of the contents of the granules merge with the vitelline membrane to form the fertilization membrane; if fusion of the contents of the cortical granules with the vitelline membrane is prevented, the membrane remains thin and soft. Another material that also derives from the cortical granules covers the surface of the egg to form a transparent layer, called the hyaline layer, which plays an important role in holding together the cells (blastomeres) formed during division, or cleavage, of the egg. The plasma membrane surrounding a fertilized egg, therefore, is a mosaic structure containing patches of the original plasma membrane of the unfertilized egg and areas derived from membranes of the cortical granules. The events leading to the formation of the fertilization membrane are accompanied by a change of the

Roles of the egg surface and coats

Effects on membrane properties

electric charge across the plasma membrane, referred to as the fertilization potential, and a concurrent outflow of potassium ions (charged particles); both of these phenomena are similar to those that occur in a stimulated nerve fibre. Another effect of fertilization on the plasma membrane of the egg is a several-fold increase in its permeability to various molecules; this change may be the result of the activation of some surface-located membrane transport mechanism.

Formation of the zygote nucleus. After its entry into the egg cytoplasm, the spermatozoal nucleus, now called the male pronucleus, begins to swell, and its chromosomal material disperses and becomes similar in appearance to that of the female pronucleus. Although the membranous envelope surrounding the male pronucleus rapidly disintegrates in the egg, a new envelope promptly forms around it. The male pronucleus, which rotates 180° and moves towards the egg nucleus, initially is accompanied by two structures (centrioles) that function in cell division. After the male and female pronuclei have come into contact, the spermatozoal centrioles give rise to the first cleavage spindle, which precedes division of the fertilized egg. In some cases fusion of the two pronuclei may occur by a process of membrane fusion; in this process, two adjoining membranes fuse at the point of contact to give rise to the continuous nuclear envelope that surrounds the zygote nucleus.

BIOCHEMICAL ANALYSIS OF FERTILIZATION

Many of the early studies on biochemical changes occurring during fertilization were concerned with the respiratory metabolism of the egg. The results, however, were deceiving; the sea urchin egg, for example, showed an increased rate of oxygen consumption as an immediate response to either fertilization or parthenogenetic activation, in apparent support of the idea that the essence of fertilization is the removal of a respiratory or metabolic block in the unfertilized egg. Extensive comparative studies have shown that the increased rate of oxygen consumption in fertilized sea urchin eggs is not a general rule; indeed, the rate of oxygen consumption of most animal eggs does not change at the time of fertilization and may even temporarily decrease.

At the time of fertilization the egg contains the components required to carry out protein synthesis, and hence development, through an early embryonic stage called the blastula. Most immediate post-fertilization protein synthe-

sis is directed by molecules of ribonucleic acid, known as messenger RNA, that were formed during oogenesis and stored in the egg. In addition, protein synthesis up to the blastula stage (up to a much earlier stage in the mammalian embryo) is directed by the cell components called ribosomes, which are present in the unfertilized egg; new ribosomes, as well as molecules of another type of RNA involved in protein synthesis, and called transfer RNA, are synthesized at a later stage in embryonic development (gastrulation). Eggs fertilized and allowed to develop in the presence of the antibiotic actinomycin, which suppresses RNA synthesis, not only reach the blastula stage but their rate of protein synthesis is the same as that in untreated embryos.

Unfertilized sea urchin eggs, as well as those of other marine animals studied thus far, have a very low rate of protein synthesis, suggesting that something in the unfertilized egg inhibits its protein synthesizing machinery. Since the rate of protein synthesis increases immediately following fertilization, it may depend on some change in, or removal of, an inhibitor. In the sea urchin egg, for example, the low efficiency of the protein synthesizing apparatus apparently depends on certain properties of the ribosomes. Most of the ribosomes found in an unfertilized sea urchin egg are single ribosomes (so-called monosomes); soon after fertilization, however, the single ribosomes interact with messenger RNA molecules thus giving rise to the polyribosomes, which are the active units in protein synthesis. This process also occurs in eggs of a few other marine animals that have been studied. The protein-synthesizing inefficiency of unfertilized sea-urchin-egg ribosomes is caused by an inhibitor that is associated with them and interferes with the binding of messenger RNA molecules to the ribosomes; the inhibitor is removed almost immediately following fertilization, perhaps by enzymatic breakdown.

It thus appears that at least in the sea urchin egg the overall rate of protein synthesis is controlled at the ribosome level and that the first step in the activation of protein synthesis following fertilization is the "turning on" of the ribosomes.

In vertebrates such as amphibians, activation of protein synthesis takes place at the onset of egg maturation, apparently initiated by the action of a hormone, progesterone. The effect of progesterone is not mediated by the nucleus but is a direct effect on the cytoplasm.

PLANT REPRODUCTION

Plant reproductive systems

In plants, as in animals, the end result of reproduction is the continuation of a given species, and the ability to reproduce is, therefore, rather conservative, or given to only moderate change, during evolution. Changes have occurred, however, and the pattern is demonstrable through a survey of plant groups. Reproduction is basically either asexual or sexual. Asexual reproduction in plants involves a variety of widely disparate methods for creating new plants identical in every respect to the parent plant. Sexual reproduction, on the other hand, depends on a complex series of basic cellular events, involving chromosomes and their genes, that take place within an elaborate sexual apparatus evolved precisely for the creation of new plants in some respects different from the two parents that played a role in their production. (For an account of the common details of asexual and sexual reproduction and the evolutionary significance of the two methods see above *The nature of reproduction*.)

In order to describe the modification of reproductive systems, plant groups must be identified. One convenient classification of organisms sets plants apart from lower forms such as bacteria, algae, fungi, and protozoans. Under such an arrangement, the plants, as separated, comprise two great divisions (or phyla)—the Bryophyta (mosses and liverworts) and the Tracheophyta (vascular plants).

The vascular plants include four subdivisions: the three entirely seedless groups are the Psilopsida, Lycopsidea, and Sphenopsida; the fourth group, the Pteropsida, consists of the ferns (seedless) and the seed plants (gymnosperms and angiosperms).

A comparative treatment of the two patterns of reproductive systems will introduce the terms required for an understanding of the survey of those systems as they appear in selected plant groups.

GENERAL FEATURES OF ASEXUAL SYSTEMS

Asexual reproduction involves no union of cells or nuclei of cells and, therefore, no mingling of genetic traits, since the nucleus contains the genetic material (chromosomes) of the cell. Only those systems of asexual reproduction that are not really modifications of sexual reproduction are considered below. They fall into two basic types: systems that utilize almost any fragment or part of a plant body; and systems that depend upon specialized structures that have evolved as reproductive agents.

Reproduction by fragments. In many plant groups, fragmentation of the plant body, followed by regeneration and development of the fragments into whole new organisms, serves as a reproductive system. Fragments of the plant bodies of liverworts and mosses regenerate to form new plants. In nature and in laboratory and greenhouse culture, liverworts fragment as a result of growth; the growing

Two basic
asexual
processes

fragments separate by decay at the region of attachment to the parent. During prolonged drought, the mature portions of liverworts often die, but their tips resume growth and produce a series of new plants from the original parent plant.

In mosses, small fragments of the stems and leaves (even single cells of the latter) can, with sufficient moisture and under proper conditions, regenerate and ultimately develop into new plants.

It is common horticultural practice to propagate desirable varieties of garden plants by means of plant fragments, or cuttings. These may be severed leaves or portions of roots or stems, which are stimulated to develop roots and produce leafy shoots. Naturally fallen branches of willows (*Salix*) and poplars (*Populus*) root under suitable conditions in nature and eventually develop into trees. Other horticultural practices that exemplify asexual reproduction include budding (the removal of buds of one plant and their implantation on another) and grafting (the implantation of small branches of one individual on another).

Reproduction by special asexual structures. Throughout the plant kingdom, specially differentiated or modified cells, groups of cells, or organs have, during the course of evolution, come to function as organs of asexual reproduction. These structures are asexual in that the individual reproductive agent develops into a new individual without the union of sex cells (gametes). A number of examples of special asexual agents of reproduction from several plant groups are cited in this section.

Airborne spores characterize most nonflowering land plants, such as mosses, liverworts, and ferns. Although the spores arise as products of meiosis, a cellular event in which the number of chromosomes in the nucleus is halved, such spores are asexual in the sense that they may grow directly into new individuals, without prior sexual union.

Among liverworts, mosses, lycopods, ferns, and seed plants, few to many celled, specially organized buds, or gemmae, also serve as agents of asexual reproduction.

The vegetative, or somatic, organs of plants may, in their entirety, be modified to serve as organs of reproduction. In this category belong such flowering-plant structures as stolons, rhizomes, tubers, corms, and bulbs, as well as the tubers of liverworts, ferns, and horsetails, the dormant buds of certain moss stages, and the leaves of many succulents (Figure 3). Stolons are elongated runners, or horizontal stems, such as those of the strawberry, which root and form new plantlets when they make proper contact with a moist soil surface. Rhizomes, as seen in iris, are fleshy, elongated, horizontal stems that grow within or upon the soil. The branching of rhizomes results in multiplication of the plant. The enlarged, fleshy tips of subterranean rhizomes or stolons are known as tubers, examples of which are potatoes. Tubers are fleshy storage stems, the buds ("eyes") of which, under proper conditions, can develop into new individuals. Erect, vertical, fleshy, subterranean stems, which are known as corms, are exemplified by crocuses and gladioli. These organs tide the plants over periods of dormancy and may develop secondary cormlets, which give rise to new plantlets. Unlike the corm, only a small portion of the bulb, as in lilies and the onion, represents stem tissue. The latter is surrounded by the fleshy, food-storage bases of earlier formed leaves. After a period of dormancy, bulbs develop into new individuals. Large bulbs produce secondary bulbs through development of buds, resulting in an increase in number of individuals.

GENERAL FEATURES OF SEXUAL SYSTEMS

In most plant groups both sexual and asexual methods of reproduction occur. Some species, however, seem secondarily to have lost the capacity for sexual reproduction. Such cases are described below (see *Variations in reproductive cycles*).

The cellular basis. Sexual reproduction at the cellular level generally involves the following phenomena: the union of sex cells and their nuclei, with concomitant association of their chromosomes, which contain the genes, and the nuclear division called meiosis. The sex cells are called gametes, and the product of their union is a zygote. All gametes are normally haploid (having a single set of

Loomis, Copyright 1952, © 1957, 1962 by Holt, Rinehart and Winston, Inc., reproduced by permission of Holt, Rinehart and Winston, Inc.

chromosomes) and all zygotes, diploid (having a double set of chromosomes, one set from each parent). Gametes may be motile, by means of whiplike hairs (flagella) or of flowing cytoplasm (amoeboid motion). In their union, gametes may be morphologically indistinguishable (*i.e.*, isogamous) or they may be distinguishable only on the criterion of size (*i.e.*, heterogamous). The larger gamete, or egg, is nonmotile; the smaller gamete, or sperm, is motile. The last type of gametic difference, egg and sperm, is often designated as oogamy. In oogamous reproduction, the union of sperm and egg is called fertilization. Isogamy, heterogamy, and oogamy are often considered to represent an increasingly specialized evolutionary series (Figure 4).

From P.B. Weisz, *The Science of Biology*, 3rd ed. (1967), used with permission of McGraw-Hill Book Company

Figure 4: Patterns of fertilization based on gamete types. In isogamy and heterogamy all gametes are motile; in oogamy only the smaller is motile, and moves to the larger.

In the plants included in this article—bryophytes (mosses and liverworts) and tracheophytes (vascular plants)—sexual reproduction is of the oogamous type, or a modification thereof, in which the sex cells, or gametes, are of two types, a larger nonmotile egg and a smaller motile sperm. These gametes are often produced in special containers called gametangia, which are multicellular. In cases in which special gametangia are lacking, every cell produces a gamete. In oogamy, the male gametangia are called antheridia and the female oogonia or archegonia. A female gametangium with a sterile cellular jacket is called an archegonium although, like an oogonium, it produces eggs. In most of the plants dealt with in this article the eggs are produced in archegonia and the sperms in antheridia with surface layers of sterile cells.

The plant basis. Individual plants may be either bisexual (hermaphroditic), in which male and female gametes are produced by the same organism, or unisexual, producing either male or female gametes but not both. A bisexual individual, however, is not necessarily capable of fertilizing its own eggs. In certain ferns, for example, male gametes of one individual are not compatible with the female gametes of the same individual, so that cross-fertilization (with another individual of the species) is obligatory. This situation, of course, is similar in adaptive significance to cross-pollination (which leads to cross-fertilization) among seed plants.

Among the liverworts, mosses, and vascular plants, the life cycle involves two different phases, often called generations, although only one plant generation is, in fact, involved in one complete cycle. This type of life cycle is often said to illustrate the “alternation of generations” in which a haploid individual (*i.e.*, with one set of chromosomes), or tissue, called a gametophyte, at maturity produces gametes that unite in pairs to form diploid (*i.e.*, containing two sets of chromosomes) zygotes. The latter develop directly into individuals, or tissues, called sporophytes, in which the nuclei of certain fertile cells, called spore mother cells, or sporocytes, give rise to haploid spores (sometimes called meiospores). These spores are lightweight and are borne by air currents; they germinate to form the haploid, sexual, gamete-producing phase, usually designated the gametophyte.

There are several variations in the above described life cycle. The haploid gametophyte and sporophyte may be free-living, independent plants (*e.g.*, certain algae and yeasts), in which case the life cycle is said to be diplobiontic; or the sporophyte may be physically attached to the gametophyte, as it is in liverworts and mosses. By contrast, the gametophytic phases develop as parasites on the sporophytes of the seed plants, as in certain algae. In further variation, the alternating phases may be similar morphologically except for the type of reproductive cells, gametes or spores they produce (isomorphic life cycle); or they may be strikingly dissimilar, as in some algae, mosses, ferns, and seed plants (heteromorphic life cycle). Only heteromorphic life cycles occur in liverworts, mosses, vascular plants, and certain fungi.

The differences between the gametophyte and sporophyte are often great, especially those of the diplobiontic types, so that the alternates seem to be two different, unrelated individuals rather than different manifestations of the same organism.

BRYOPHYTE REPRODUCTIVE SYSTEMS

Liverworts and hornworts. The plant bodies of liverworts and hornworts represent the gametophytic (sexual) phase of the life cycle, which is dominant in these plants. In the liverworts, the sporophyte is borne upon or within the gametophyte but is transitory. Liverwort and hornwort plants, depending on the species, may be bisexual or unisexual, and the sex organs may be distributed on the surface (*Riccia*, *Ricciocarpus*, *Sphaerocarpus*, *Pellia*) or localized in groups and borne on special branches (antheridiophores and archegoniophores) as in *Marchantia*; the sperms are biflagellate (Figure 5).

Release of the mature sperm and the process of fertilization require moisture in the form of heavy dew or raindrops. In all but a few genera (*Riccia*, *Ricciocarpus*),

Figure 5: Archegonia and antheridia in the liverwort *Marchantia*.

From (top) Botany, 3rd ed. by Carl L. Wilson and Walter E. Loomis, Copyright 1952, © 1957, 1962 by Holt, Rinehart and Winston, Inc., reproduced by permission of Holt, Rinehart and Winston, Inc.; (bottom) T.E. Weir et al., Botany (1967), John Wiley & Sons, Inc.

the developing sporophytes are actively photosynthetic—*i.e.*, capable of utilizing light energy to form organic substances. They are, however, dependent on gametophytic tissues for water (and the inorganic salts dissolved in it) and probably derive and utilize in their nutrition some organic substances manufactured by the gametophytes. Liverwort spores are meiospores; *i.e.*, they arise by meiosis from cells called sporocytes.

The sporophytes may consist almost completely of fertile (sporogenous) tissues (*Riccia*, *Oxymitra*), or they may contain sterile cells (nurse cells or elaters) among the developing spores. In *Marchantia* and *Porella*, a sterile foot and seta, or stalk, are present; the foot anchors the spore-bearing capsule (sporangium) to the gametophyte and also probably serves an absorptive function. The seta connects the foot and capsule. The elongation of the seta raises the capsule from its protective envelopes, thus, placing it in a favourable position for spore dispersal. The capsules of liverworts may shed their spores only by decay of the capsule wall and gametophytic tissues (*Riccia*, *Oxymitra*), or they may open irregularly or into two or four segments.

Spore germination in some species may occur immediately after deposition if the spores are in a favourable environment; or, as in other species, the spores may require a period of dormancy before germination.

Mosses. In mosses, as in liverworts and hornworts, the leafy shoots belong to the gametophytic phase and produce sex organs when they mature (Figure 6). The leafy shoots (often called gametophores, because they bear the sex organs) arise from a preliminary phase called the protonema, the direct product of spore germination. Filamentous, straplike, or membranous, it grows along the soil surface. A protonema of a moss may proliferate, apparently indefinitely, under favourable conditions and thus increase the population of leafy shoots that arise as buds. Under adverse conditions, certain buds and branches of the protonema may thicken their walls and thus serve to tide the species over an unfavourable growing period.

The antheridia and archegonia may be borne at the tips (apices) of the main shoots or on special, lateral branchlets. Both bisexual and unisexual leafy shoots occur, de-

pending on the species. In a number of mosses (*Mnium*, *Polytrichum*, *Funaria*), the sexually mature shoots become recognizable through the production of special, prominent leaves that form an apical cup around the sex organs. If brightly coloured, the cup is often flowerlike. In species with bisexual leafy gametophores, the archegonia and antheridia may be present on the same apex (as can be seen, for example, in *Bryum*) or at the apices of separate branches as is exemplified in the moss *Funaria*.

The archegonia and antheridia of mosses are large enough in many species to be just barely visible to the unaided eye. The jacket cells of the antheridia are often coloured bright orange or rust; their sperm are biflagellate. As in liverworts and hornworts, rains and even heavy dews evoke the liberation of sperm and the opening of the mature archegonia so that fertilization may be accomplished.

The moss sporophyte, which is attached to the gametophyte, photosynthesizes during much of its development and is more or less self-supporting. It is, to a certain degree, dependent upon the gametophyte for nutrients such as water and mineral salts and, in some cases, even for elaborated foods.

After elongation of the moss sporophyte has ceased, the distal portion (farthest away) enlarges to form the capsule (sporangium), or spore-bearing region. The spores (meiospores), which arise by meiosis, are shed from the capsules gradually through a variety of mechanisms. After the operculum (cover) of the capsule has been shed, its mouth is usually partially closed by the peristome (teeth) and sometimes by associated structures. These teeth absorb moisture, and their resultant swelling and contraction open spaces through which the spores are shed.

TRACHEOPHYTE REPRODUCTIVE SYSTEMS

Spore plants. In liverworts, hornworts, and mosses, the dominant phase in the life cycle is the sexual gametophyte. In the tracheophytes (vascular cryptogams and seed plants), on the other hand, the sporophyte is the dominant phase in the life cycle. The gametophytes of the vascular

cryptogams mature after the spores that initiated them have been shed from the parent plant, so that the gametophytes are free-living. In the seed plants the gametophytes mature as parasites on the sporophytes.

Psilopsids. The trilobed sporangia of the whisk fern *Psilotum*—not a true fern but a psilopsid—are borne terminally on short lateral branches. During development, some of the potentially spore-bearing tissue is used as nutrient by the sporocytes as they complete the meiotic divisions that result in colourless kidney-shaped spores. The latter, which are shed as the sporangia open along three lines, germinate and slowly develop into cylindrical, sparingly branched gametophytes, about 0.5 to two millimetres (0.02 to 0.08 inch) in diameter and several millimetres long. They presumably derive nourishment from decaying matter and occur in humus-rich soil, in rock fissures, or among roots on the trunks of tree ferns. The cells of the gametophyte contain fungal structures (hyphae) that probably are involved in some type of nutritional relation with the gametophyte.

The gametophytes are bisexual and the sperms multiflagellate. The embryonic sporophyte is not easily distinguished from the gametophyte that bears it. At first anchored to the gametophyte by an absorptive foot, the sporophyte ultimately becomes separated from both the foot and the gametophyte.

Lycopoids. In the genus *Lycopodium*, the sporangia are closely associated with the leaves. In some species (*L. lucidulum*), the sporangium-bearing leaves (sporophylls) occur in zones among the vegetative portions of the stems. In most, however, the sporophylls occur in specialized compressed stems, called cones, or strobili (Figure 7). Each sporophyll is associated with one yellow to orange, kidney-shaped sporangium.

From *Biological Science: An Inquiry into Life*, 2nd ed. (1968); Harcourt Brace Jovanovich, Inc., New York; by permission of the Biological Sciences Curriculum Study

Figure 7: Sporangial protection of a club moss and a horsetail.

In several species the spores develop rapidly on the soil surface into ovoid-cylindrical gametophytes about two to three millimetres (0.08 to 0.12 inch) long, with green lobes and colourless bases; they usually contain a fungus. In other species, development of a colourless gametophyte is slow, so that at maturation, which may require up to eight years, the fleshy gametophyte will have become buried in successive layers of humus. These subterranean gametophytes, which contain fungi, are long-lived and are larger (up to two centimetres) than the surface types.

The gametophytes of *Lycopodium* are bisexual, although the antheridia and archegonia may develop into separate groups. The sperms are biflagellate and apparently more than one egg of the same gametophyte may be fertilized.

The zygote divides at a right angle to the long axis of the archegonium. The inner cell gives rise to the embryo, which thus is oriented as if it will develop within the gametophyte; it turns 180° during later development, however, and the axis grows vertically outward from the gametophyte.

In contrast to *Lycopodium*, all *Selaginella* sporophytes have sporophylls localized in strobili, and all species of *Selaginella* are heterosporous: that is, they produce spores of two sizes, the larger designated as megaspores and the smaller as microspores. The megaspores develop into female gametophytes and the microspores into male gametophytes. Accordingly, strobili bear megasporophylls that contain megasporangia, which will produce megaspores, and microsporophylls that contain microsporangia, which will yield microspores. Although the evolutionary origin

The heterosporous condition

of two kinds of spores (dimorphism) is unknown, the development of megaspores in living plants suggests that differences in nutrition in the two kinds of sporangia are significant. In a microsporangium, most of the microsporocytes undergo meiosis, forming four spores each; by contrast, all but one or, occasionally, several of the sporocytes in the megasporangium do not complete development. As a result, only four megaspores usually mature in such a sporangium, enlarging as they become gorged with the nutrients made available by disintegration of the other cells. The megaspores, accordingly, are much larger than microspores, although both contain stored food. Both types of spores are thick walled, and both have prominent three-part (triradial) ridges.

Unlike the homosporous spores of most liverworts, hornworts, mosses, ferns, and *Lycopodium*, the spores of *Selaginella* begin to develop into gametophytes before they have been shed from their sporangia and attain maturity on a suitable, moist substrate.

The microscopic male gametophyte is composed essentially of a single antheridium, which produces biflagellate sperm. The female gametophyte, which protrudes after the megaspore wall cracks open in the region of the triradial ridge, consists of vegetative cells, has several archegonia at maturity, and usually has three groups of rhizoids. Both male and female gametophytes lack the chlorophyll (green pigment) necessary for photosynthesis; they utilize nutrients stored in the spores.

After fertilization, one zygote of each female gametophyte develops into an embryonic sporophyte. There is considerable variation in details of development among the species of *Selaginella*. In some, the spores may develop mature gametophytes before they are shed from their sporangia, and fertilization may occur, so that female gametophytes with embryos may be found in the strobili (compressed stems, or cones). The megaspores of *Selaginella*, containing female gametophytes with still-attached juvenile sporophytes, have the superficial appearance of germinating seeds, from which, however, they differ in many significant respects.

Isoetes, like *Selaginella*, is monoecious and heterosporous. Most of the leaves are fertile; some bear one large megasporangium each, and others support a single microsporangium on the inner surface of a spoonlike leaf base. The microsporangia can produce enormous numbers of microspores—as many as 1,000,000—and the megasporangia give rise to 50 to 300 megaspores. The spores are liberated as the older sporophylls decay. Unlike those of *Selaginella*, the spores of *Isoetes* do not germinate until they have been shed from their sporangia. The unisexual gametophytes are much like those of *Selaginella*, but the sperm are multiflagellate. The embryonic sporophyte is nourished by food stored in the megaspore and transported through a massive foot.

Sphenopsids. The perennial sporophytes of horsetails (*Equisetum* species) produce strobili once during every growing season. They may be borne at the tips of green shoots (*E. hyemale*, *E. kansanum*); at the tips of non-green shoots that become green after the spores have been shed (*E. fluviale*, *E. sylvaticum*); or on special nongreen branches that wither and die after the spores have been shed (*E. arvense*, *E. talmateia*). The appendages of the strobilus are often called sporangiophores and have been considered to be both stem branches and of leafy origin; in the latter case, they are called sporophylls (Figure 7). Each sporangiophore bears a number of fingerlike sporangia, which produce large numbers of thin-walled, green spores. The outermost wall layer of the spore breaks down into four appendages, which, by their sensitivity to moisture, coil and uncoil, thereby disseminating the spores.

The spores of *Equisetum* germinate rapidly and grow into green, pincushion-like gametophytes anchored to the surface by rhizoids. Apparently, two types of gametophytes are produced from the homosporous spores; some mature slowly, are smaller than others, and always produce antheridia, never archegonia. Others are larger and hermaphroditic, producing archegonia at first and, later, antheridia. The ratios of male to hermaphroditic gametophytes vary among species but are relatively uniform

within a species. The ratios are altered by changes in environmental conditions; for example, at certain temperatures (e.g., 32° C, or 90° F) only male gametophytes develop from the spores of five species; whereas at 15° C (59° F) approximately 50 percent are male and 50 percent hermaphroditic gametophytes.

Self-fertilization of hermaphroditic gametophytes can occur, and several sporophytes may be produced on one gametophyte. The embryo consists of an absorptive foot, a primary root or radicle, and a shoot with whorled appendages.

Ferns. As they mature, many fern sporophytes begin to produce spores in clusters of sporangia on the undersurfaces of their vegetative "leaves." Others produce their sporangia on highly modified leaves or portions thereof.

The site of origin of the sporangia is the receptacle; the latter, with its groups of sporangia, is called a sorus. In many ferns each sorus is covered with a special outgrowth, the indusium; in others, the sporangia are covered during development by the margin of the leaf. In a few ferns (e.g., *Polypodium*), the sori remain uncovered.

In primitive ferns, such as *Ophioglossum* and *Botrychium*, the spores are borne upon a specialized axis, the fertile spike. The sporangia of such primitive ferns are massive, with several layers of cellular walls, and produce an indefinite but large number of spores. In most other ferns, the sporangia are smaller, long stalked, with single-layered walls and a definite number of spores. The spores of the latter are shed explosively by breakage and shrinking as the sporangia open and then slam shut.

Most ferns produce one kind of spore (homospory), but a few genera of aquatic and amphibious ferns (*Marsilea*, *Salvinia*, and *Azolla*) produce two kinds (heterospory), small microspores and much larger megaspores. In either case, after being shed from the parent sporophyte, the spores that have suitable environmental conditions germinate and develop into the gametophytic phase. The ribbonlike, filamentous or heart-shaped gametophytes of most ferns contain chlorophyll, are anchored to some surface—moist soil, moist rocks, or tree bark—by unicellular root-like rhizoids, and rarely exceed one-half inch (13 millimetres) in diameter. In a few ferns (*Ophioglossum*, *Botrychium*, and certain species of *Schizaea*), the gametophytes are subterranean, lack chlorophyll, are cylindrical or tuberous, and contain the filamentous structures (hyphae) of an associated fungus.

Fern gametophytes, often called prothalli (singular, prothallus) are one cell layer thick except in the centre. Most fern prothalli are bisexual—i.e., have both male (antheridia) and female (archegonia) sex organs, which develop usually on the undersurface of the prothallus.

Although the eggs of several archegonia may be fertilized, only one zygote usually develops into a juvenile sporophyte. The latter consists of an absorbing foot; a primary root, or radicle, which promptly penetrates the surface; a prominent first leaf; and a rudimentary, slowgrowing stem. As the juvenile sporophyte becomes established, the parental gametophyte dies. The series of leaves formed from the stem of the juvenile sporophyte gradually attain the form and vein pattern that characterize the mature sporophyte.

In most ferns, the antheridia appear before the archegonia and continue to develop as the latter mature; furthermore, the archegonial necks curve toward the mature antheridia so that fertilization can readily occur. Both gametes may be derived from one individual, or from different individuals. In the bracken fern (*Pteridium aquilinum*), although the gametophytes are bisexual, self-incompatibility factors reduce self-fertilization. In *Onoclea sensibilis*, the gametophytes are unisexual in early development, thus favouring cross-fertilization; but, later, the gametophytes become bisexual so that, if cross-fertilization fails, the species can still be maintained.

Seed plants. In the two great groups of seed plants, gymnosperms and angiosperms, the sporophyte is the dominant phase in the life cycle, as it is also in the vascular cryptogams; the gametophytes are microscopic parasites on the sporophytes (Figure 8).

In the gymnosperms, the seeds occur individually, ex-

Homo-
spory and hetero-
spory in

posed at the ends of stalks, sometimes in whorls on an axis, or on the scales of a cone, or megastrobilus. In angiosperms, or flowering plants, by contrast, the seeds are enclosed during development in a structure variously termed a pistil or carpel, which is sometimes considered to represent an enfolded megasporophyll.

A number of parts of the reproductive process are common to both angiosperms and gymnosperms: (1) they produce seeds at maturity; (2) the megasporangium, unlike that of heterosporous seedless plants, is covered by one or two cellular layers called integuments and is termed an ovule; (3) there is a minute passageway, or micropyle, through the integuments; (4) the ovule matures as a seed; (5) only one megasporocyte is present and undergoes meiosis in the megasporangium to produce four megaspores, only one of which usually is functional; (6) the megaspore is never discharged from its megasporangium and ovule; (7) one female gametophyte is produced within each megasporangium and ovule; (8) the microspores begin their development into male gametophytes while still enclosed in the microsporangia; (9) as they mature, the male gametophytes, which are contained within the microspore wall and are termed pollen grains, develop a tube that conveys sperm to the egg cell; (10) union of sperm and egg and development of an embryonic sporophyte from the zygote occur within the female gametophyte (sometimes called the "embryo sac"), which is covered by the remains of the megasporangium and by integuments; (11) as the embryo develops, the ovule matures as a seed.

In contrast to this impressive list of similarities are important differences, which, in addition to seed position, serve to distinguish angiosperms from gymnosperms. The reproductive cycle in most angiosperms is completed quicker than that in gymnosperms, and the gametophytes are smaller and simpler and, unlike those of most gymnosperms, lack archegonia. The pollen in angiosperms is transferred to the surface of the megasporophyll, whereas in gymnosperms it is brought to the micropyle of the ovule itself. Two sperm are involved in the sexual union in angiosperms: one unites with the egg to form a zygote; the other unites with two nuclei of the female gametophyte to form the primary endosperm nucleus. The latter divides to form a postfertilization storage tissue, which serves as a food source for the embryo; the embryo of gymnosperms is nourished by the somatic (nonreproductive) tissues of the female gametophyte. The angiosperm ovule increases to mature seed size after fertilization, whereas in gymnosperms, this enlargement occurs prior to fertilization.

The general features of the reproduction of seed plants having now been summarized, certain special aspects of

the reproduction in representative seed plants are described below.

Gymnosperms. The cycads are slow-growing dioecious gymnosperms, the microsporangia (potential pollen) and megasporangia (potential ovules) occurring on different individual sporophytes. In all cycads except the genus *Cycas*, the ovules are borne on megasporophylls in megastrobili; in *Cycas* the ovules develop on individual, leaflike megasporophylls in what is regarded as a primitive arrangement. The microspores of all cycads develop in microstrobili.

The microspores reach the three-celled stage of development of the male gametophyte before they are shed as pollen grains from the microsporangia. At this time, elongation of the megastrobilus separates the megasporophylls, and the wind-borne pollen grains have access to the micropyles of the ovules. At the time of pollination each ovule exudes a mucilaginous droplet, the pollination droplet, through the micropyle; some of the pollen grains become engulfed in this droplet and are drawn into the ovule.

The interval between pollination and fertilization is several months in cycads. The sperm are multiflagellate and are among the largest (about 300 microns, or 0.01 inch) in the plant kingdom. Each pollen tube may contain from two to 22 sperm, depending on the genus. The pollen tubes, which develop from the pollen grains, work their way through the megasporangium of the ovule to the archegonia of the female gametophyte. Fertilization of the eggs of the several archegonia is followed by the early development of several embryos (polyembryony), only one of which survives in the mature seeds. Cycad embryos produce two seed leaves, or cotyledons. The seeds are brightly coloured (yellow or scarlet) and covered by an outer fleshy layer and a stony layer of the integument. The seeds of some cycads (e.g., *Cycas*) may germinate in the megastrobilus without a period of dormancy.

The maidenhair tree, or ginkgo (*Ginkgo biloba*), is sometimes classified with the conifers (see below) or separately in a group of which it is the sole living representative. The mature ginkgo (sporophyte) produces microstrobili and ovules each spring as the buds unfold. They occur on the spur shoots among the bases of the young leaves. The ginkgo, like the cycads, is strictly dioecious, so that some trees produce ovules and others produce pollen. The ovules occur in pairs at the tips of stalks that emerge among the leaf bases.

Ginkgo pollen, like that of pines, is four-celled at the time of pollination (spring season), which is accomplished by wind. Development of male and female gametophytes is similar to that in cycads, and the sperm are also multiflagellate. The female gametophyte, within the ovule of *Ginkgo*, is unique among seed plants in containing chlorophyll. The ovules enlarge tremendously after pollination, and as the seeds mature the integument differentiates into several coats, of which a stony layer and outer fleshy layer are most prominent. The latter becomes mottled, purplish green and foul smelling. Its tissues may cause nausea or skin eruptions in man. The inner tissues of the seed (the embryo and the female gametophyte) are palatable and prized among some peoples. Fertilization often occurs after the ovules have fallen from the trees, three or four months after pollination. The ginkgo embryo has two cotyledons.

The sporophytes of most of the species of living conifers, like those of the ginkgo, are woody trees at maturity. They usually grow for a number of years beyond the seedling stage before they mature and produce seeds.

The sporophyte of a typical conifer, such as a pine, may become a large tree. Unlike the cycads and ginkgo, a pine is monoecious, both microstrobili and megastrobili occurring on the same tree. At the beginning of each growing season, the microstrobili enlarge and emerge from their bud scales; they are borne at the base of the terminal bud, which is destined to develop into the current season's growth. The megastrobili, by contrast, arise singly or in a whorl near the apex of the current season's growth.

The microstrobili are called simple strobili because the microsporangia are borne in pairs on the appendages (microsporophylls) that emerge from the axis of the strobilus. The megastrobili, however, are compound, for the ovules

Events
in the
reproductive
process

System of
the ginkgo

are borne in pairs upon the upper (adaxial) surface of scales, which, in turn, are borne on bracts attached to the megastrobilus.

The pollen of pine, four-celled when shed, is characterized by two lateral, air-filled "wings," enlarged cavities between two layers of the pollen-grain wall. The pollen is produced in large amounts and may be transported great distances by air currents. During the time of pollination, the ovuliferous scales on the megastrobili separate slightly, and pollen can be trapped in the pollination droplet of the micropyles of the ovules. Pollen grains that make contact with a droplet are transferred by its subsequent contraction through the micropyle and to the surface of a small depression (pollen chamber) at the tip of the megasporangium.

As the pollen grain germinates, forming a tube that works its way through the megasporangium, it arrives at the female gametophyte as the latter matures its several archegonia. The pollen tubes discharge their sperm nuclei into the archegonia, and fertilization is accomplished. As in the cycads and ginkgo, the zygotes of several archegonia may initiate embryogeny. Furthermore, in pine and certain other conifers, the young embryos may form several embryos. At maturity of the seed, however, only one embryo is normally present, embedded in the remains of the female gametophyte and megasporangium, all surrounded by the seed coat (the former integument).

The reproductive process in pine occupies two full growing seasons: ovules pollinated in the spring of a given year do not mature as seeds until the late summer of the next year. The interval between pollination and fertilization is about 14 months.

Among the numerous other gymnosperm species are many different reproductive processes. Some gymnosperms, for example, are dioecious, with microstrobili and megastrobili being borne on separate plants, as in junipers (*Juniperus*), plum yews (*Cephalotaxus*), yews (*Taxus*), and podocarps (*Podocarpus*). Furthermore, in larches (*Larix*) and other groups the pollen grains lack wings. The pollen grains in larches become attached at pollination to a special receptive enlargement of the integument. In podocarps, the megasporangium bulges through the micropyle at pollination and receives the pollen directly. The interval between pollination and fertilization may be as short as four to five weeks in firs (*Abies*). The number of ovules formed on the ovuliferous scale varies, as does the number of microsporangia on the microsporophyll. There may be only one ovule in a megastrobilus, as in some junipers, and the megastrobili may become fleshy, also in junipers. In yews the solitary ovules are terminal on dwarf shoots; each ovule is surrounded by a cuplike structure called an aril, which becomes fleshy and brightly coloured as the seed matures. The number of sperm produced in each male gametophyte varies also—from two in pine to 20 in some cypresses (*Cupressus*).

The genera *Ephedra*, *Gnetum*, and *Welwitschia*, which are often grouped together in one category (Gnetales, or Gnetophyta), differ among themselves and from other gymnosperms with respect to several details of reproduction. The microsporangia and ovules of both *Ephedra* and *Welwitschia* are produced in compound strobili; those of *Gnetum* are borne in a series of whorls on elongated axes sometimes called misleadingly "inflorescences." The ovules of these genera, unlike those of other gymnosperms, have two integuments instead of one, as in angiospermous ovules. Archegonia are present in the female gametophytes of *Ephedra*, but only eggs occur in those of *Gnetum* and *Welwitschia*. The sperm, like those of the conifers, lack flagella.

Angiosperms. Although the angiosperms are known as flowering plants, they are difficult to distinguish from gymnosperms solely on the basis of bearing flowers, for, like the strobilus, a flower is a compressed stem, with crowded, spore-bearing appendages. The occurrence of coloured petals and attractive scents is not essential and is by no means characteristic of all flowers. The most important distinguishing feature separating flowering plants from gymnosperms is that the ovules of flowering plants

Figure 9: Gross morphology of the flower.

are produced within enclosed containers called carpels (Figure 9).

Flowers may occur singly at the ends of stems (e.g., tulip, poppy, rose), or they may be grouped in various clusters or inflorescences (gladiolus, sunflower, delphinium, and yucca).

An individual flower may be complete, in that a given floral receptacle produces sepals (often greenish and leaf-like), petals (often white or coloured other than green), stamens, and a pistil (or pistils). The sepals are collectively known as the calyx, and the petals as the corolla; the calyx and corolla comprise the perianth. If sepals or petals are lacking, the flower is said to be incomplete. Although incomplete, a flower that has both stamens and a pistil is said to be perfect; lacking either of these parts, it is imperfect.

In practice, groups of solitary flowers are not easily distinguished from inflorescences; the latter seemingly evolved from a system of branches, each with a terminal, solitary flower. The inflorescence may be few flowered or have up to 6,000,000 flowers, as in certain palms. Inflorescences vary also in their position, being terminal, axillary, or intercalary. Terminal inflorescences are at the tips of the major or dominant branches; axillary ones are at the tips of axillary, or side, branches. In intercalary inflorescences, the stem continues beyond the inflorescence, which may result in alternating fertile and sterile areas of the axis.

Inflorescences can be distinguished by their growth patterns as determinate or indeterminate. In determinate inflorescences the first formed flower at the tip of the dominant stem matures first, and younger flowers develop on lower lateral branches; the cyme of the forget-me-not (*Myosotis*) is a typical example. In indeterminate inflorescences the growing region of the axis functions for extended periods so that as the older flowers mature and set fruit near the base of the inflorescence axis, younger buds develop and continue to expand into flowers at the apex. This is exemplified in the spikes of yucca and the racemes of delphinium, in which the youngest flowers are farthest away from the root. Other types of indeterminate inflorescences include umbels and capitula, or heads. The youngest flower is terminal or central in umbels and in heads.

The head is the type of inflorescence that characterizes the composite, or aster family. It may be few to many flowered and usually has at its base one or more series of leaflike bracts. The small individual flowers arise in spiral order on the receptacle, the youngest being at the centre. The basal calyx of each flower, known as a pappus, is bristle-like, scaly, or feathery and borne at the top of the ovary. The corolla, formed of the petals, may be: (1) tubular, with five petal lobes, sometimes split open; (2) ligulate, or tonguelike, with a very short basal tube; or

clusters

Repro-
ductive
variations
in gymno-
sperms

(3) bilabiate, with the tube split into two tips. In some genera, all of the flowers are ligulate, whereas in others, the marginal flowers are ligulate (ray flowers) and the others tubular or all are tubular. The marginal ray flowers are either female (pistillate) or sterile. The tubular flowers are characterized by male and female parts: five united pollen-bearing stamens and a pistil, which matures as a one-seeded fruit (achene).

The position of the floral organs with reference to each other and to the tip of the floral receptacle varies in different flowers; in some, the perianth (sepals and petals) and stamens are attached to the receptacle below the pistil; such flowers are hypogynous (*e.g.*, buttercup and magnolia). In others (rose, cherry, peach), the perianth and stamens are borne on the rim of a concave structure in the depression of which the pistil is borne; such flowers are perigynous. Finally, there are flowers in which the ovary is enclosed by a tissue composed of the fused bases of the perianth and stamens (apple, pear, aster); the blossom seems to arise upon or above the ovary and is called epigynous.

The stamen, seemingly the equivalent of the gymnospermous microsporophyll, consists of an anther (a group of two to four microsporangia) borne at the tip of a blade stalk, or filament. The pistil, most often composed of an enlarged basal ovary, a columnar style, and distal stigma, is the ovule-producing organ of the flower. It is often considered to have evolved from enfolded megasporophyll or some other ovuliferous structure with enclosed ovules (angiospermy); alternatively, it is thought to have arisen from the cuplike bracts of extinct seed-bearing plants on which the leafy bracts grew together and thus enclosed the ovules.

There may be one or more pistils on the floral receptacle, depending on the species. Furthermore, pistils may be simple (composed of one ovule-bearing unit, megasporophyll, or carpel) or compound (composed of more than one carpel). Compound pistils are thought to have arisen as a result of crowding of simple pistils on the floral axis; for example, variation in the degree of fusion may be observed in members of the saxifrage family. The ovary—which matures as the fruit—usually reveals by the number of ovule-containing chambers (locules) the number of carpels it contains. The stigma is a specially adapted portion of the pistil modified for the reception of pollen. It may be feathery and branched or elongated, as in such wind-pollinated flowers as those of the grasses, or it may be compact and with a sticky surface. The ovary may contain one ovule (*e.g.*, buckwheat, avocado), a few ovules (*e.g.*, grape, bean) or a large number of ovules (tobacco, begonia, snapdragon).

In some angiosperms (*e.g.*, corn, hickory, walnut, pecan, oak) both types of imperfect flower are borne on the same plant, which is, therefore, called monoecious. By contrast, staminate flowers may occur on one plant and pistillate flowers on another, as in willows, poplars, and mulberries, which are said to be dioecious. In common parlance (and unfortunately in some botanical textbooks) staminate flowers and plants that bear them are often designated “male,” and pistillate flowers and the plants that bear them are called “female.” This may be traced back at least as far as to the time of Linnaeus (1753), who interpreted stamens and pistils as sex organs. Comparative morphology indicates clearly, however, that stamens and pistils are the spore-bearing structures of the sporophyte and not actually the gamete-bearing organs of the gametophyte. The terms “male” and “female,” applied to angiosperm plants and their flowers, is often condoned because the gametophytic phase is so condensed in angiosperms. The designations suggest to the uninitiated, however, that pollen grains and sperm, on the one hand, and eggs and ovules, on the other, are identical, which is not the case.

Among the vast number of species of angiosperms there is considerable variation in floral organization. The perianth may be absent or present; clearly differentiated as calyx and corolla (*e.g.*, pea); or the perianth segments may be similar (magnolia, tulip tree). The number of stamens and pistils may be large and separately attached to the receptacle in a spiral pattern (buttercup), or the numbers may be reduced and the attachment cyclic or whorled

(lily). The stamens may be fused together by their anthers (daisy) or their filaments (peas, beans). The filaments may be petallike (water lilies) or stalklike. Opening of the anther may be by longitudinal or transverse fissures or by terminal pores.

The reproductive cycle in angiosperms can be traced from before the shedding of pollen (Figure 10). The microspores begin their development of male gametophytes, which in-

volves formation of a small generative cell and a tube cell. The generative cell may divide to form two sperm before the pollen grain (developing male gametophyte) is shed, or while the pollen tube is growing during germination. The pollen grains of angiosperms have variously, and often elaborately, ornamented walls characteristic of the species.

Pollination in angiosperms is the transfer of the pollen grains from the anther of a stamen to the stigma of a pistil.

The pistil of a flower may receive pollen from the stamens of the same flower, in self-pollination (*e.g.*, peas and tomatoes). In many other flowers, however, pollen from one or more flowers is transferred to the stigmas of other flowers. A number of specialized relationships have evolved between floral organization and animal pollinators such as insects. (See below *Pollination* for a complete treatment of the processes and mechanisms of pollination in plants.)

In the majority of angiosperms one megasporocyte develops in the megasporangium (often called the nucellus) of the ovule, and a tetrad of megaspores is formed as a result of meiosis. Three megaspores (nearest the micropyle) degenerate; only one enlarges, and then undergoes divisions to form the eight-nucleate, seven-celled female gametophyte (“embryo sac”). Of the three cells of this gametophyte near the micropyle, one functions as an egg. As the pollen tube discharges its contents into the female gametophyte, the egg nucleus is fertilized by one of the sperm, the other unites with the two nuclei (polar nuclei) within the large central cell of the female gametophyte. The resultant nucleus, which has three sets of chromosomes, is the primary endosperm nucleus. This process, double fertilization, occurs only in angiosperms.

Both pollination and fertilization stimulate cell division in the ovary, ovules, and zygotes, all of which enter upon a period of rapid enlargement. In most angiosperms, the primary endosperm nucleus divides to form endosperm tissue, the cells of which become filled with stored food, such as starches, oils, and proteins. As the rate of embryonic development decreases, the seeds of most angiosperms enter a period of dormancy, accompanied by dehydration and hardening of the integuments, which form seed coats.

At this period, the enlarged ovary (and sometimes adjacent structures) matures as fruit. (Further discussion of the form, function, and development of seeds and fruits is presented below, in the section *Seed and fruit*.)

Angiosperm seeds may germinate as soon as they reach maturity, or they may undergo various kinds of dormancy. In some cases (e.g., coconut) the embryo is rudimentary and undifferentiated when the seed is shed, so that a period of preparation, or after-ripening, is required. In other types of dormancy, germination is retarded by the hardness and impermeability of the seed coat or by special requirements of light, temperature, and moisture.

Some representative variations occur in the reproductive process of angiosperms. In violets (*Viola*), in addition to the ordinary flowers produced first during the usual flowering season, less conspicuous flowers later develop; called cleistogamous flowers, they do not open but are self-pollinated, thus insuring augmentation of the population during a period less favourable for the usual blossoms.

The pollen grains of most angiosperms separate from each other, but in some cases (e.g., *Rhododendron*) they remain attached in original groups of four, called tetrads. The very tiny pollen grains of orchids, certain mimosas, and milkweeds are clustered in waxy masses called pollinia (singular pollinium).

A number of variations in pattern of development of the female gametophyte occur in various angiosperms; for example, in certain species of evening primrose (*Oenothera*), the female gametophyte contains only four nuclei, whereas, in *Peperomia*, as many as 16 may be present. In lily, all four megaspore nuclei are involved in the formation of the female gametophyte.

Pollen may germinate immediately after contact with a stigma (sugar cane), within five minutes (corn), in two hours (beet), or after one or two days. The pollen grains of most plants produce only one pollen tube, but ten or more pollen tubes have been observed to develop from one pollen grain in plants of the mallow family. The pollen tubes usually enter through the micropyle (porogamy), but they may also enter through the base of the ovule (chalazogamy).

The interval between pollination and fertilization varies. It may be as long as 12 to 14 months in certain species of oak, five to seven months in witch hazel; two to 20 weeks among the orchids; three to four hours in lettuce and as little as 15 to 45 minutes in dandelions.

The postfertilization endosperm fails to develop in orchid seeds but is present at least during early embryogeny in most others. The endosperm may arise by nuclear divisions and become cellular as nuclear divisions terminate, or its development may involve both nuclear and cell divisions from the beginning. In a number of cases (e.g., legumes) the embryo consumes the endosperm during its development, resulting in mature seeds with massive embryos and no endosperm. Most angiosperm embryos have two seed leaves (are dicotyledonous), some have one lateral cotyledon (are monocotyledonous), and a few (e.g., *Degeneria*) have three to four cotyledons.

In seed germination, the cotyledons may remain below the soil surface within the seed (hypogean germination) and may function in digesting and absorbing endosperm (corn), may serve as sources of stored food themselves (pea), or may rise above the soil surface (epigeal germination) by elongation of the hypocotyl, the embryonic axis between the root, the growing stem, or epicotyl. Cotyledons that emerge above the soil may wither and drop off as their food is used (e.g., bean), or they may persist and function as photosynthetic leaves (e.g., castor bean).

An even greater range of variation occurs in angiospermous fruits. The fruit may arise from one pistil (simple or compound) of one flower (i.e., the simple fruits of pea and peach), from several pistils of one flower (i.e., the aggregate fruits of strawberry and raspberry), or from the pistils of several flowers (i.e., the multiple fruits of pineapple, mulberry, and corn). Simple fruits may be dry (legumes) or fleshy (peach, apple, tomato) at maturity. Dry fruits may open (dehiscent; many legumes) or remain closed about the seed (be indehiscent; grasses and sunflower).

The manner of ovular attachment is known as placenta-

tion. The ovary may contain one to many ovules, which may be attached to the ovary wall (parietal placentation) or to the central axis (axial, or free-central placentation). Despite these and other variations in the morphology of flower parts, the reproductive process is, with minor diversities, remarkably uniform.

VARIATIONS IN REPRODUCTIVE CYCLES

The life cycles and reproductive processes described above characterize the vast majority of their respective plant groups.

Among the liverworts it has been demonstrated that small fragments of the stalk of the sporophyte are capable of regenerating diploid gametophytes. In the mosses, both haploid and diploid apospory have been experimentally evoked. As in the liverworts, injury and regeneration of fragments of the sporophytic seta result in diploid gametophytes. By contrast, fragments of moss leaves, stems, and rhizoids (and even the sterile tissues of the sex organs) can regenerate haploid gametophytes.

In certain strains of mosses, the gametophyte can give rise to clusters of presumably haploid sporophytes without the functioning of gametes; such apogamous formation of sporophytes may also be chemically induced (by application of a solution containing a specific amount of chloral hydrate to both the protonema and leafy shoots).

Among the vascular plants both natural and induced apogamy and apospory are known. In certain ferns, gametophytes may develop at the leaf margins or in sori from transformed sporangia. Certain other ferns reproduce apogamously in nature; thus, for example, in the holly fern (*Cryptium falcatum*), the gametophytes give rise directly to sporophytes by nuclear and cell division on vegetative cells of the gametophyte. In almost every group, however, variations of the usual reproductive process occur. These may involve substitution of asexual reproduction for sexual or the direct production of plants by cells other than the usual ones (apomixis). Apomictic phenomena—which are in the strictest sense asexual—include apospory, in which the gametophyte phase is produced without the need of spores, and apogamy, in which the sporophyte phase is produced without the need of gametes, or sex cells.

Apogamy may be induced in normally sexual ferns by withholding water from the gametophytes, which prevents the liberation and functioning of sperm. Similarly, when gametophytes are grown in inorganic culture media supplemented by a variety of sugars, they produce sporophytes apogamously. Colourless roots removed from the bracken fern (*Pteridium aquilinum*) have been induced to develop diploid gametophytes aposporously, as have the injured juvenile leaves of a number of ferns.

Apomictic phenomena occur also among many angiosperms. In some species, haploid sporophytes may develop either from the unfertilized egg or from some other cell of the gametophyte. Such apogamy occurs, for example, after stimulation of one species with the pollen of a related one (e.g., *Solanum nigrum* by the pollen of *S. luteum*). Apogamy involving an unfertilized egg (a phenomenon termed parthenogenesis) occurs in certain orchids. Male parthenogenesis, or the production of a sporophyte from a sperm, has been detected in tobacco hybrids. Finally, a form of haploid apogamy is known in which a cell of the female gametophyte other than an egg may develop into an embryo.

In certain species of hawkweed, the embryo develops from a certain cell of the ovule or the megasporangium. In others, the female gametophyte is diploid through an impairment of the meiotic process; in this case, the egg (diploid parthenogenesis) or one of the related cells may form an embryo. In citrus trees a number of embryos (polyembryony) arise from diploid cells of the megasporangium or integuments.

PHYSIOLOGY OF PLANT REPRODUCTION

The maturation of sporophytes and gametophytes, as manifested by their ability to produce spores and gametes respectively, involves both internal and environmental factors. With respect to the former, the organism must have completed a certain minimum period of vegetative devel-

Apogamy,
apospory,
and
apomixis

Effects of
light and
tempera-
ture

oment before environmental factors are able to stimulate formation of spores and gametes.

Among environmental factors affecting reproduction, the duration, intensity, and quality of light, as well as temperature, have primary roles; for example, the liverwort *Marchantia polymorpha* continues in the vegetative state indefinitely under daily fluorescent illumination of 16 hours. Control plants exposed to daily incandescent lighting of 16 hours become sexually mature after 30 days. Addition of the sugar sucrose hastens the development of the sexual phase, an indication that chemical factors also play a role. In hornworts (e.g., *Anthoceros* and *Phaeoceros*), antheridia develop under daily light periods (photoperiods) of four to 12 hours; none develop when the plants are illuminated for longer periods.

Temperature also affects sexual maturation. In mosses, for example, initiation of sex organs in bacteria-free laboratory cultures of *Funaria* occurs at 10° C (50° F) when cultures are illuminated six, 12, or 20 hours daily. On the other hand, the moss *Polytrichum* is seemingly not affected by duration of light but forms sex organs best at 21° C (70° F).

Among vascular cryptogams little is known about the various environmental factors that affect development of sex organs in nature, and, except for certain ferns and horsetails, experimental studies of rigidly controlled laboratory cultures are lacking. It has been shown that laboratory cultures of gametophytes of certain horsetails derived from single spores produce sex organs 40 to 60 days after the spores germinate. In horsetails generally, conditions favouring vegetative growth evoke a preponderance of initially female gametophytes; less favourable conditions induce the production of male gametophytes.

Considerable information is available about the physiology of reproduction in ferns, especially with respect to the gametophyte generation. Spore germination occurs if adequate moisture is present and in temperatures between 15° and 35° C (59° and 95° F). The spores germinate and the young gametophytes do best under neutral or slightly acid conditions. Most fern spores require light for germination. Some fern spores remain viable for as long as 20 years.

Spores germinating in darkness or in the absence of blue wavelengths of light remain in the protonemal, or filamentous, condition. Growth to the mature gametophyte requires light of blue wavelengths in most species.

An interesting aspect of fern reproductive physiology was the discovery that antheridial production is under hormonal control. Several types of antheridium-evoking substances (hormones) have been recognized, and there is some evidence that they are specific. The sperm of ferns are attracted chemically to the vicinity of the maturing archegonia, where they become trapped in extruded mucilage. Although only one sporophyte usually develops on a gametophyte, as many as five may be induced to form if the gametophyte is repeatedly exposed to sperm.

The preceding paragraphs, dealing with vascular cryptogams, have emphasized the influence of environmental factors on the expression of sexual reproduction; the remaining account deals with the angiosperms. Because the gametophytic phase of angiosperms is abbreviated and because it is parasitic on the sporophyte, the maturation of the sporophyte, as manifested by flowering, has received more intensive study in angiosperms than has that of the gametophyte.

Angiosperms that complete their life cycles within one growing season (in the temperate zone) are known as annuals. Perhaps the shortest angiospermous life cycle known is that of *Plantago insularis*, a southern California species, that can grow from seed to the production of its own seed in four to six weeks under domestication; the cycle of most annuals, however, is longer. A number of angiosperms are biennial in the temperate zone: they grow vegetatively for one season, but their flowering and seed production are delayed until a second growing season, after which the plants die (e.g., beets, carrots). Still other angiosperms are perennial: they continue growing, flowering, and producing seeds for a number of growing seasons (e.g., irises, roses, oaks).

It has been demonstrated that duration and wavelength

of light are of paramount importance in controlling the flowering of angiosperms. Based on extensive experimental studies, flowering plants have been classified as "long-day," "short-day," or "day-neutral" with respect to their requirements of light for flowering.

Temperature also plays an important role in flowering. Thus, members of the cabbage family can be grown without flowering when high enough temperatures are maintained. A number of perennial and biennial plants (bulbous plants, beets) require a prior period of low temperature before they flower. In addition to internal (i.e., genetic factors), therefore, temperature and light are of paramount importance for many plants in evoking maturation.

Several other physiological aspects of reproduction in angiosperms are noteworthy. Once transported to the stigma, the germination of the pollen grains is markedly affected by the chemical composition of the stigmatic exudate; e.g., pollen of an unrelated species will not germinate on the stigma. There is evidence also that the directional growth of the pollen tubes through the style toward the ovular micropyle is stimulated by a chemical substance produced by the style, ovules, and probably other tissues of the pistil.

It is also clear that both pollination and fertilization have physiological effects on fruit production. In a number of cases pollination alone (not followed by fertilization) is sufficient stimulus to evoke enlargement of the pistil to form a seedless (parthenocarpic) fruit. This phenomenon occurs in the banana and in certain varieties of citrus fruits, grapes, and cucumbers. Parthenocarpic can also be induced by exposure of the stigma to indoleacetic acid, naphthoxyacetic acid, indole butyric acid, naphthaleneacetic acid, or other synthetic hormones. The hormone gibberellin is effective in producing seedless grapes and is the active component in preparations used to prevent premature dropping of fruit.

Also significant in the reproduction of flowering plants are the phenomena of self-sterility and self-incompatibility, which prevail in certain plants with perfect flowers (having both stamens and pistils). Pollen from one flower or from another flower of the same plant or from a plant with identical genetic constitution, when applied to the stigma, fails to germinate or grows so slowly that fertilization does not occur. For example, sweet cherries are self-incompatible: a number of groups of genetically intrasterile types are known, but cross-pollination of trees of different genetic groups results in fruit production. Self-incompatibility occurs also in certain strains of garden plants and in plum, apple, pear, and tobacco.

Self-sterility, usually associated with differences in chromosome number, often occurs in hybrids from widely divergent parents. This is true of cultivated varieties of blackberry and raspberry. Such chromosomal imbalance creates irregularities in meiosis during formation of the pollen, which results in infertility. (H.C.B.)

Pollination

Pollination is the transference of pollen grains from the stamens, the flower parts that produce them, to the ovule-bearing organs or to the ovules (seed precursors) themselves. In conifers and cycads, in which the ovules are exposed, the pollen is simply caught in a drop of fluid secreted by the ovule. In flowering plants, however, the ovules are contained within a hollow organ called the pistil, and the pollen is deposited on the pistil's receptive surface, the stigma. There the pollen germinates and gives rise to a pollen tube, which grows down through the pistil toward one of the ovules in its base. In an act of double fertilization, one of the two sperm cells within the pollen tube fuses with the egg cell of the ovule, making possible the development of an embryo, and the other cell combines with the two subsidiary sexual nuclei of the ovule, which initiates formation of a reserve food tissue, the endosperm. The growing ovule then transforms itself into a seed. As a prerequisite for fertilization, pollination is essential to the production of fruit and seed crops and plays an important part in programs designed to improve

of life
cycles

Importance
to agri-
culture

plants by breeding. Furthermore, studies of pollination are invaluable for understanding the evolution of flowering plants and their distribution in the world today. As sedentary organisms, plants usually must enlist the services of external agents for pollen transport. In flowering plants, these are (roughly in order of diminishing importance): insects, wind, birds, mammals, and water.

Pollination by insects probably occurred in primitive seed plants, reliance on other means being a relatively recent evolutionary development. Reasonable evidence indicates that flowering plants first appeared in tropical rain forests during the Mesozoic Era (about 65,000,000 to 225,000,000 years ago). The most prevalent insect forms of the period were primitive beetles; no bees and butterflies were present. Some Mesozoic beetles, already adapted to a diet of spores from primitive plants, apparently became pollen eaters, capable of effecting chance pollination with grains accidentally spared. The visits of such beetles to primitive flowering plants may have been encouraged by insect attractants, such as odours of carrion, dung, or fruit, or by sex attractants. In addition, visits of the insects to the plants could be made to last longer and thus potentially be more valuable to the plant as far as fertilization was concerned, if the flower had a functional, traplike structure. Nowadays, such flowers are found predominantly, although not exclusively, in tropical families regarded as ancient; e.g., the water lily (Nymphaeaceae) and the arum lily (Araceae) families. At the same time, other plants apparently began to exploit the fact that primitive gall-forming insects visited the flowers to deposit eggs. In the ancient genus *Ficus* (figs and banyan trees), pollination still depends on gall wasps. In general, Mesozoic flowering plants could not fully rely on their pollinators, whose presence also depended on the existence of a complete, well-functioning ecological web with dung, cadavers, and food plants always available. More advanced flowers escaped from such dependence on chance by no longer relying on deceit, trapping, and tasty pollen alone; nectar became increasingly important as a reward for the pollinators. Essentially a concentrated, aqueous sugar solution, nectar existed in certain ancestors of the flowering plants. In bracken fern even nowadays, nectar glands (nectaries) are found at the base of young leaves. In the course of evolutionary change, certain nectaries were incorporated into the modern flower (floral nectaries), although extrafloral nectaries also persist. Flower colours thus seem to have been introduced as "advertisements" of the presence of nectar, and more specific nectar guides (such as patterns of dots or lines, contrasting colour patches, or special odour patterns) were introduced near the entrance to the flower, pointing the way to the nectar hidden within. At the same time, in a complex pattern of parallel evolution, groups of insects appeared with sucking mouthparts capable of feeding on nectar. In extreme cases, there arose a complete mutual dependence. For example, a Madagascar orchid, *Angraecum sesquipedale*, with a nectar receptacle 20 to 35 centimetres (eight to 14 inches) long, depends for its pollination exclusively on the local race of a hawkmoth, *Xanthopan morgani*, which has a proboscis of 22½ centimetres (nine inches). Interestingly enough, the existence of the hawkmoth was predicted by Charles Darwin and Alfred Russel Wallace, codiscoverers of evolution, about 40 years before its actual discovery.

TYPES: SELF-POLLINATION AND CROSS-POLLINATION

An egg cell in an ovule of a flower may be fertilized by a sperm cell derived from a pollen grain produced by that same flower or by another flower on the same plant, in either of which two cases fertilization is said to be due to self-pollination (autogamy); or, the sperm may be derived from pollen originating on a different plant individual, in which case the process is called cross-pollination (heterogamy). Both processes are common, but cross-pollination clearly has certain evolutionary advantages for the species: the seeds formed may combine the hereditary traits of both parents, and the resulting offspring generally are more varied than would be the case after self-pollination. In a changing environment, some of the individuals resulting from cross-pollination still may be found capable

Figure 11: Types of pollination.

Drawing by M. Moran based on B.J.D. Meeuse, *The Story of Pollination*

of coping with their new situation, ensuring survival of the species, whereas the individuals resulting from self-pollination might all be unable to adjust. Self-pollination, or selfing, although foolproof in a stable environment, thus is an evolutionary cul-de-sac. There also is a more direct, visible difference between selfing and outbreeding (cross-pollination): in those species where both methods work, cross-pollination usually produces more, and better quality, seeds. A dramatic demonstration of this effect is found with hybrid corn (maize), a superior product that results from cross-breeding of several especially bred lines.

Mechanisms that prevent self-pollination. Structural. Not surprisingly, many species of plants have developed mechanisms that prevent self-pollination. Some—e.g., date palms (*Phoenix dactylifera*) and willows (*Salix* species)—have become dioecious; that is, some plants produce only “male” (staminate) flowers, with the rest producing only “female” (pistillate or ovule-producing) ones. In species in which staminate and pistillate flowers are found on the same individual (monoecious plants) and in those with hermaphroditic flowers (flowers possessing both stamens and pistils), a common way of preventing self-fertilization is to have the pollen shed either before or after the period during which the stigmas on the same plant are receptive, a situation known as dichogamy. The more usual form of dichogamy, which is found especially in such insect-pollinated flowers as fireweed (*Epilobium angustifolium*) and salvias (*Salvia* species), is protandry, in which the stamens ripen before the pistils. Protogyny, the situation in which the pistils mature first, occurs in arum lilies and many wind-pollinated plants, such as grasses—although several grasses are self-pollinated, including common varieties of wheat, barley, and oats. Avocado has both protogynous and protandrous varieties, and these often are grown together to encourage cross-fertilization. A structural feature of flowers that discourages selfing is heterostyly, or variation in the length of the style (neck of the pistil). This occurs in the common primrose (*Primula vulgaris*) and species of wood sorrel (*Oxalis*) and flax. In most British primrose populations, for example, approximately half the individuals have so-called “pin” flowers, which possess short stamens and a long style, giving the stigma a position at the flower’s mouth, whereas the other half have “thrum” flowers, in which the style is short and the stamens are long, forming a “thrumhead” at the opening of the flower. Bees can hardly fail to deposit the pollen they receive from one type of flower onto the stigmas of the other type. The genetic system that regulates flower structure in these primroses is so constituted that cross-pollination automatically maintains a 50:50 ratio between pins and thrums. In the flowers of purple loosestrife (*Lythrum salicaria*), the stamens and styles are of three different lengths to limit self-fertilization.

Chemical. Chemical self-incompatibility is another device for preventing self-fertilization. In this phenomenon, which depends on chemical substances within the plant,

Develop-
ment of
nectar

Self-
pollination
and cross-
pollination

the pollen may fail to grow on a stigma of the same flower that produced it or, after germination, the pollen tube may not grow normally down the style to effect fertilization. The process is controlled genetically; it need not be absolute and can change in degree during the flowering season. Not surprisingly, chemical incompatibility usually is not found in those plants that have strong structural or temporal barriers against self-pollination. Formation of one such mechanism during evolution apparently was enough for most plant species.

Mechanisms that permit self-pollination. In many instances, successful self-pollination takes place at the end of a flower's life-span if cross-pollination has not occurred. Such self-pollination may be achieved by curving of stamens or style as occurs, for example, in fireweed. It can be an evolutionary advantage when animal pollinators are temporarily scarce or when the plants in a population are widely scattered. Under such circumstances, selfing may tide the species over until better circumstances for outbreeding arrive. For this reason, selfing is common among annual plants; these often must produce an abundance of seed for the rapid and massive colonization of any bare ground that becomes available. If, in a given year, an annual plant were to produce no seed at all, survival of the species might be endangered. A persistent habit of self-pollination apparently has been adopted successfully by some plant species whose natural pollinators have died out. Continued selfing also is practiced by many food-crop plants. Some of these plants are cleistogamous, meaning that the flowers fail to open, an extreme way of ensuring self-pollination. A similar process is apomixis, the development of an ovule into a seed without fertilization. Apomixis is easily demonstrated in lawn dandelions, which produce seeds even when stamens and styles are cut off just before the flowers open. Consistent apomixis has the same pros and cons as continued selfing. The offspring show very little genetic variability, but there is good survival if the species is well adapted to its habitat and if the environment does not change.

AGENTS OF POLLEN DISPERSAL

Insects. *Beetles and flies.* The ancient principle of trapping insects as a means of ensuring pollination was readopted by some advanced families (e.g., orchids and milkweeds), and further elaboration perfected the flower traps of primitive families. The cuckoopint (*Arum maculatum*), for example, attracts minute flies, which normally breed in cow dung, by means of a fetid smell. This smell is generated in early evening, along with considerable heat, which helps to volatilize the odour ingredients. The flies visiting the plant, many of which carry *Arum* pollen, enter the floral trap through a zone of bristles and then fall into a smooth-walled floral chamber from which escape is impossible. Gorging themselves on a nutritious stigmatic secretion produced by the female flowers at the base of the chamber, the flies effect cross-pollination. Late at night, when the stigmas no longer function, the male flowers, situated much higher on the floral column, proceed to bombard the flies with a rain of pollen. The next day, when smell, heat, and food are gone, the prisoners, "tarred" with stigmatic secretion and "feathered" with pollen, are allowed to escape by a wilting of the inflorescence (flower cluster). Usually the escaped flies are soon recaptured by another inflorescence, which is still in the smelly, receptive stage, and cross-pollination again ensues. Superb timing mechanisms underlie these events. The heat-generating metabolic process in the inflorescence is triggered by a hormone, calorigen, originating in the male flower buds only under the right conditions. The giant inflorescences of the tropical plant *Amorphophallus titanum* similarly trap large carrion beetles.

In general, trap flowers victimize beetles or flies of a primitive type. Although beetles most likely were involved as pollinators when flowering plants as a group were born, their later performance in pollination has been disappointing. Some modern beetles do visit smelly flowers of an open type, such as elderberry and hawthorn, but with few exceptions they are still mainly pollen eaters. Flies as a group have become much more diversified in their habits

than beetles have. Female short-tongued flies may be deceived by open-type flowers with carrion smells; e.g., the flowers of *Stapelia* and *Rafflesia*. Mosquitoes with their long tongues are effective pollinators of certain orchids (*Habenaria* species) in North American swamps. In Europe, the bee fly (*Bombylius*) is an important long-tongued pollinator. Extremely specialized as nectar drinkers are certain South African flies; for example, *Megistorhynchus longirostris*, which has a tongue that is 60 to 70 millimetres (2.3 to 2.7 inches) long.

The voraciousness of flower beetles demonstrates the futility of enticing insect pollinators solely with such an indispensable material as pollen. As a defensive strategy, certain nectar-free flowers that cater to beetles and bees—such as wild roses, peonies, and poppies—produce a superabundance of pollen. Other plants—e.g., *Cassia*—have two types of stamens, one producing a special sterile pollen used by insects as food, the other yielding normal pollen for fertilizing the ovules. Other flowers contain hairs or food bodies that are attractive to insects.

Bees. In the modern world, bees are probably the most important insect pollinators. Living almost exclusively on

flowers

nectar, they feed their larvae pollen and honey (a modified nectar). To obtain their foods, they possess striking physical and behavioral adaptations, such as tongues as long as 2½ centimetres (one inch), hairy bodies, and (in honeybees and bumblebees) special pollen baskets. The Austrian naturalist Karl von Frisch has demonstrated that honeybees, although blind to red light, distinguish at least four different colour regions, namely, yellow (including orange and yellow green), blue green, blue (including purple and violet), and ultraviolet. Their sensitivity to ultraviolet enables bees to follow nectar-guide patterns not apparent to the human eye. They are able to taste several different sugars and also can be trained to differentiate between aromatic, sweet, or minty odours but not foul smells. Fragrance may be the decisive factor in establishing the honeybee's habit of staying with one species of flower as long as it is abundantly available. Also important is that honeybee workers can communicate to one another both the distance and the direction of an abundant food source by means of special dances.

Bee
flowers

Bee flowers, open in the daytime, attract their insect visitors primarily by bright colours; at close range, special patterns and fragrances come into play. Many bee flowers provide their visitors with a landing platform in the form of a broad lower lip on which the bee sits down before pushing its way into the flower's interior, which usually contains both stamens and pistils. The hermaphroditism of most bee flowers makes for efficiency, because the flower both delivers and receives a load of pollen during a single visit of the pollinator, and the pollinator never travels from one flower to another without a full load of pollen. Indeed, the floral mechanism of many bee flowers permits only one pollination visit. The pollen grains of most bee flowers are sticky, spiny, or highly sculptured, ensuring their adherence to the bodies of the bees. Since one load of pollen contains enough pollen grains to initiate fertilization of many ovules, most individual bee flowers produce many seeds.

Examples of flowers that depend heavily on bees are larkspur, monkshood, bleeding heart, and Scotch broom. Alkali bees (*Nomia*) and leaf-cutter bees (*Megachile*) are both efficient pollinators of alfalfa; unlike honeybees, they are not afraid to trigger the explosive mechanism that liberates a cloud of pollen in alfalfa flowers. Certain Ecuadorian orchids (*Oncidium*) are pollinated by male bees of the genus *Centris*; vibrating in the breeze, the beelike flowers are attacked headlong by the strongly territorial males, who mistake them for competitors. Other South American orchids, nectarless but very fragrant, are visited by male bees (*Euglossa* species) who, for reasons not yet understood, collect from the surface of the flowers an odour substance, which they store in the inflated parts of their hindlegs.

Wasp
flowers

Wasps. Few wasps feed their young pollen or nectar. Yellow jackets, however, occurring occasionally in large numbers and visiting flowers for nectar for their own consumption, may assume local importance as pollinators. These insects prefer brownish-purple flowers with easily accessible nectar, such as those of figwort. The flowers of some Mediterranean and Australian orchids mimic the females of certain wasps (of the families Scoliidae and Ichneumonidae) so successfully that the males of these species attempt copulation and receive the pollen masses on their bodies. In figs, it is not the pollinator's sexual drive that is harnessed by the plant but the instinct to take care of the young; tiny gall wasps (*Blastophaga*) use the diminutive flowers (within their fleshy receptacles) as incubators.

Butterflies and moths. The evolution of moths and butterflies (Lepidoptera) was made possible only by the development of the modern flower, which provides their food. Nearly all species of Lepidoptera have a tongue, or proboscis, especially adapted for sucking. The proboscis is coiled at rest and extended in feeding. Hawkmoths hover while they feed, whereas butterflies alight on the flower. Significantly, some butterflies can taste sugar solutions with their feet. Although moths, in general, are nocturnal and butterflies are diurnal, a colour sense has been demonstrated in representatives of both. Generally, the colour sense in Lepidoptera is similar to that of bees, but

swallowtails and certain other butterflies also respond to red colours. Typically, colour and fragrance cooperate in guiding Lepidoptera to flowers, but in some cases there is a strong emphasis on just one attractant; for example, certain hawkmoths can find fragrant honeysuckles hidden from sight.

Typical moth flowers—e.g., jimsonweed, stephanotis, and honeysuckle—are light-coloured, often long and narrow, without landing platforms. The petals are sometimes fringed; the copious nectar is often in a spur. They are open and overwhelmingly fragrant at night. Butterfly flowers—e.g., those of butterfly bush, milkweed, and verbenas—are conspicuously coloured, often red, generally smaller than moth flowers, but grouped together in erect, flat-topped inflorescences that provide landing space for the butterflies.

Moth
flowers
and butter-
fly flowers

Important pollinating moths are the various species of the genus *Plusia*, sometimes occurring in enormous numbers, and the hummingbird hawkmoth (*Macroglossa*), which is active in daylight. A small moth, *Tegeticula maculata*, presents an interesting case. It is totally dependent on yucca flowers, in whose ovules its larvae develop. Before depositing their eggs, the females pollinate the flowers, following an almost unbelievable pattern of specialized behaviour, which includes preparing a ball of pollen grains and carrying it to the stigma of the plant they are about to use for egg laying.

Wind. Although prevalent in the primitive cycads and in conifers, such as pine and fir, wind pollination (anemophily) in the flowering plants must be considered as a secondary development. It most likely arose when such plants left the tropical rain forest where they originated and faced a more hostile environment, in which the wind weakened the effectiveness of smell as an insect attractant and the lack of pollinating flies and beetles also made itself felt. Lacking in precision, wind pollination is a wasteful process. For example, one male plant of *Mercurialis annua*, a common weed, produces 1,250,000,000 grains of pollen to be dispersed by the wind; a male sorrel plant produces 400,000,000. Although, in general, the concentration of such pollen becomes very low about one-fourth mile (0.4 kilometre) from its source, nonetheless in windy areas it can cover considerable distances. Pine pollen, for example, which is naturally equipped with air sacs, can travel up to 500 miles (800 kilometres) although the grains may lose their viability in the process. Statistically, this still gives only a slim chance that an individual stigma will be hit by more than one or two pollen grains. Also relevant to the number of pollen grains per stigma is the fact that the dry, glueless, and smooth-surfaced grains are shed singly. Since the number of fertilizing pollen grains is low, the number of ovules in a single flower is low and, as a consequence, so is the number of seeds in each fruit. In hazel, walnut, beech, and oak, for example, there are only two ovules per flower, and, in stinging nettle, elm, birch, sweet gale, and grasses, there is only one. Wind-pollinated flowers are inconspicuous, being devoid of insect attractants and rewards, such as fragrance, showy petals, and nectar. To facilitate exposure of the flowers to the wind, blooming often takes place before the leaves are out in spring, or the flowers may be placed very high on the plant. Inflorescences, flowers, or the stamens themselves move easily in the breeze, shaking out the pollen, or the pollen containers (anthers) burst open in an explosive fashion when the sun hits them, scattering the pollen widely into the air. The stigmas often are long and divided into arms or lobes, so that a large area is available for catching pollen grains. Moreover, in open areas wind-pollinated plants of one species often grow together in dense populations. The chance of self-pollination, high by the very nature of wind pollination, is minimized by the fact that many species are dioecious or (like hazel) have separate male and female flowers on each plant. Familiar flowering plants relying on wind pollination are grasses, rushes, sedges, cattail, sorrel, lamb's-quarters, hemp, nettle, plantain, alder, hazel, birch, poplar, and oak. (Tropical oaks, however, may be insect-pollinated.)

Wind
flowers

Birds. Because the study of mechanisms of pollination began in Europe, where pollinating birds are rare, their

importance is often underestimated. In fact, in the tropics and the southern temperate zones, birds are at least as important as pollinators as insects are, perhaps more so. About a third of the 300 families of flowering plants have at least some members with ornithophilous flowers; i.e., flowers attractive to birds. Conversely, about 2,000 species of birds, belonging to 50 families, visit flowers more or less regularly to feed on nectar, pollen, and flower-inhabiting insects or spiders. Special adaptations to this way of life, in the form of slender, sometimes curved, beaks and tongues provided with brushes or shaped into tubes, are found in 1,615 species of eight families: hummingbirds, sunbirds, honey eaters, brush-tongued parrots, white-eyes, flower-peckers, honeycreepers (or sugarbirds), and Hawaiian honeycreepers. Generally, the sense of smell in birds is poorly developed and not used in their quest for food; instead, they rely on their powerful vision and their colour sense, which resembles that of man (ultraviolet not being seen as a colour, whereas red is). Furthermore, the sensitivity of the bird's eye is greatest in the middle and red part of the spectrum. This is sometimes ascribed to the presence in the retina of orange-red drops of oil, which together may act as a light filter.

Bird
flowers

Although other explanations have been forwarded, the special red sensitivity of the bird eye is usually thought to be the reason why so many bird-pollinated flowers are of a uniform, pure red colour. Combinations of complementary colors, such as orange and blue, or green and red, also are found, as are white flowers. As might be expected, bird flowers generally lack smell and are open in the daytime; they are bigger than most insect flowers and have a wider floral tube. Bird flowers also are sturdily constructed as a protection against the probing bill of the visitors, with the ovules kept out of harm's way in an inferior ovary beneath the floral chamber or placed at the end of a special stalk or behind a screen formed by the fused bases of the stamens. The latter, often so strong as to resemble metal wire, are usually numerous, brightly coloured, and protruding, so that they touch a visiting bird on the breast or head as it feeds. The pollen grains often stick together in clumps or chains, with the result that a single visit may result in the fertilization of hundreds of ovules. In America, where hummingbirds usually suck the nectar of flowers on the wing, ornithophilous flowers (e.g., fuchsias) are often pendant and radially symmetrical, lacking the landing platform of the typical bee flower. In Africa and Asia, bird flowers often are erect and do offer their visitors, which do not hover, either a landing platform or special perches in the form of small twigs near the flower. Pollinating birds are bigger than insects and have a very high rate of metabolism. Although some hummingbirds go into a state resembling hibernation every night, curtailing their metabolism drastically, others keep late hours. Thus, in general, birds need much more nectar per individual than insects do. Accordingly, bird flowers produce nectar copiously—a thimbleful in each flower of the coral tree, for example, and as much as a liqueur glassful in flowers of the spear lily (*Doryanthus*). Plants bearing typical bird flowers are: cardinal flower, fuchsia, red columbine, trumpet vine, hibiscus, strelitzia, and eucalyptus, and many members of the pea, orchid, cactus, and pineapple families.

Mammals. In Madagascar, the mouse lemurs (*Microcebus*), which are only ten centimetres (four inches) long, obtain food from flowers, and in Australia the diminutive marsupial honey possums and pygmy possums also are flower specialists. Certain highly specialized tropical bats, particularly *Macroglossus* and *Glossophaga*, also obtain most or all of their food from flowers. The *Macroglossus* (big-tongued) species of southern Asia and the Pacific are small bats with sharp snouts and long, extensible tongues, which carry special projections (papillae) and sometimes a brushlike tip for picking up a sticky mixture of nectar and pollen. Significantly, they are almost toothless. Colour sense and that sonar sense so prominent in other bats, seem to be lacking. Their eyesight is keen but, since they feed at night, they are probably guided to the flowers principally by their highly developed sense of smell. The bats hook themselves into the petals with their thumb claws

and stick their slender heads into the flowers, extracting viscid nectar and protein-rich pollen with their tongues. The plants involved have, in the process of evolution, responded to the bats by producing large (sometimes huge) amounts of these foods. One balsa-tree flower, for example, may contain a full 10 grams (0.3 ounce) of nectar, and one flower from a baobab tree has about 2,000 pollen-producing stamens. Some bat flowers also provide succulent petals or special food bodies to their visitors. Another striking adaptation is that the flowers are often placed on the main trunk or the big limbs of a tree (cauliflory); or, borne on thin, ropelike branches, they dangle beneath the crown (flagelliflory). The pagoda shape of the kapok tree serves the same purpose: facilitation of the bat's approach. Characteristics of the flowers themselves include drab colour, large size, sturdiness, bell-shape with wide mouth and, frequently, a powerful rancid or urinelike smell. The giant saguaro cactus and the century plant (*Agave*) are pollinated by bats, although not exclusively, and cup-and-saucer vine (*Cobaea scandens*) is the direct descendant of a bat-pollinated American plant. Calabash, candle tree, and areca palm also have bat-pollinated flowers.

Bat
flowers

Water. Although pollen grains can be made to germinate in aqueous sugar solutions, water alone in most cases has a disastrous effect on them. Accordingly, only a very few terrestrial plants, such as the bog asphodel of the Faroes, use rainwater as a means of pollen transport. Even in aquatic plants, water is seldom the true medium of pollen dispersal. Thus, the famous Podostemonaceae, plants that grow only on rocks in rushing water, flower in the dry season when the plants are exposed; pollination occurs with the aid of wind or insects or by selfing. Another aquatic plant, ribbon weed, sends its male and female flowers to the surface separately. There, the former transform themselves into minute sailboats, which are driven by the wind until they collide with the female flowers. In the Canadian waterweed, and also in pondweed (*Potamogeton*) and ditch grass (*Ruppia*), the pollen itself is dispersed on the water's surface; it is, however, still water-repellent. True water dispersal (hydrophily), in which the pollen grains are wet by water, is found only in the hornworts and eelgrasses.

(B.J.D.M.)

Seed and fruit

A seed is the characteristic reproductive body of both angiosperms (flowering plants) and gymnosperms (conifers, cycads, and ginkgos). Essentially, it consists of a miniature, undeveloped plant (the embryo), which, alone or in the company of stored food for its early development after germination, is surrounded by a protective coat (the testa). Frequently small in size and making negligible demands upon their environment, seeds are eminently suited to perform a wide variety of functions the relationships of which are not always obvious: multiplication, perennation (surviving seasons of stress such as winter), dormancy (a state of arrested development), and dispersal. Pollination and the "seed habit" are considered the most important factors responsible for the overwhelming evolutionary success of the flowering plants, which number more than 300,000 species.

The superiority of dispersal by means of seeds over the more primitive method involving single-celled spores, lies mainly in two factors: the stored reserve of nutrient material that gives the new generation an excellent growing start and the seed's multicellular structure, which provides ample opportunity for the development of adaptations for dispersal, such as plumes for wind dispersal, barbs, and others.

Economically, seeds (and the fruits that contain them) are important primarily because they are sources of a variety of foods; for example, the cereal grains, such as wheat, rice, and maize; the seeds of beans, peas, peanuts, soybeans, almonds, sunflowers, hazelnuts, walnuts, pecans, and Brazil nuts; the fruits of date palm, olive, banana, avocado, apple, and orange. Many fruits, especially those in the citrus family—limes, lemons, oranges, grapefruits—are rich in vitamin C (ascorbic acid); unpolished cereal grains in vitamin B₁ (thiamine); and wheat germ in vita-

Wind pollination: pollen of the lodgepole pine (*Pinus contorta*) and mountain hemlock (*Tsuga mertensiana*) on the surface of Crater Lake, Oregon.

Beetle pollination: pollen-eating longhorn beetle (family Cerambycidae) in a thimbleberry (*Rubus parviflorus*).

Butterfly pollination: great spangled fritillary (*Speyeria cybele*), proboscis extended, feeding on red clover (*Trifolium pratense*).

Bee pollination: pollen-laden honeybee (*Apis mellifera*) on a wall flower (*Erysimum*).

Wind pollination in grasses: yellow free-hanging anthers (pollen producers) and white feathery stigmas (pollen collectors) of meadow fescue (*Festuca pratensis*) provide maximum wind exposure.

Bird pollination: Anna's hummingbird (*Calypte anna*) feeding on nectar of a fuchsia.

Hawkmoth pollination: hawkmoth (Sphingidae) hovering near a honeysuckle (*Lonicera caprifolium*).

Agents of pollen dispersal

Trap flower: pollinating psychodid flies trapped in the floral chamber of cuckoo-pint (*Arum maculatum*; vertical section with spathe cut away).

Deception flower: carrion flower (*Stapelia*) has the appearance and odour of decayed meat. Flies laying eggs crawl over flower's surface and come into contact with stigmas and stamens.

Trap flower: when certain bees land on the hairy, upright petal of the flower of grass-pink orchid (*Calopogon pulchellus*), the petal topples forward, and a visiting bee falls on its back onto the sticky surface of the column.

Nectar guides: spots in throat of foxglove (*Digitalis purpurea* variety *gloxiniaeflora*) provide insects with a visual pathway to nectar glands.

Explosive flower: (top) flower of Scotch broom (*Cytisus scoparius*). (Bottom left) The bumblebee (*Bombus vosnesenskii*) triggers release of the stamens (bottom right) which forcibly strike underside of bee and dust it with pollen.

Flower adaptations related to pollination

Water dispersal: red mangrove seedling (*Rhizophora mangle*) ready to drop into the water after germinating on tree.

Wind dispersal: woolly seeds produced by the seed pods of the kapok tree (*Ceiba pentandra*).

Wind dispersal: winged fruits of the silver maple (*Acer saccharinum*).

Wind dispersal: magnified view of seeds of lady's slipper (*Cypripedium*), an example of the tiny seeds produced by orchids.

Water dispersal: a coconut (*Cocos nucifera*), transported by the sea from a distant tropical island, germinating on a mainland beach.

Self-dispersal: plumes on the fruits of mountain mahogany (*Cercocarpus*), which coil and uncoil to drive seeds into the soil.

Wind, water, and self-dispersal of seeds and fruits

Naras melons (*Acanthosicyos horrida*) growing in the Namib Desert, South West Africa. Seeds are dispersed by the gemsbok oryx (*Oryx gazella*), which feeds on the melons.

Seeds of rosary pea (*Abrus precatorius*), which mimic fleshy red arils (accessory seed coverings) attractive to seed-eaters.

Acorns stored in the trunk of a digger pine (*Pinus sabiniana*) by the acorn woodpecker (*Melanerpes formicivorus*).

Fleshy red appendages of fruits of the yew (*Taxus*), which attract birds.

Seeds and fruit dispersed by animals

Epauletted fruit bat (*Epomophorus wahlbergi*) feeding on wild figs (*Ficus*).

Curve-bill thrasher (*Toxostoma curvirostre*) with a berry in its beak.

min E. Other useful products provided by seeds and fruits are abundant. Oils for cooking, margarine production, painting, and lubrication are available from the seeds of flax, rape, cotton, soybean, poppy, castor bean, coconut, sesame, safflower, sunflower, the cereal grains of maize, and the fruits of olive and oil palm. Essential oils are obtained from such sources as juniper "berries," used in gin manufacture. Waxes such as those from bayberries (wax myrtles) and vegetable ivory from the hard fruits of a South American palm species (*Phytelphas macrocarpa*) are important products. Stimulants are obtained from such sources as the seeds of coffee, kola, guarana, and cocoa; and drugs, such as morphine, come from opium-poppy fruits. Spices—from mustard and nutmeg seeds; from the aril ("mace") covering the nutmeg seed; from fruits of anise, cumins, caraway, dill, vanilla, black pepper, red or chili pepper, allspice, and others—form a large group of economic products. Dyes (Persian berries, butternut brown, sap green) and ornaments (Job's tears from the grass *Coix*, used for curtains; *Abrus*, *Adenantha*, and *Rhynchosia* seeds for necklaces; others for rosaries) are also provided by seeds and fruits.

THE NATURE OF SEEDS AND FRUITS

Seeds. *Angiosperm seeds.* In the typical flowering plant, or angiosperm, seeds are formed from bodies called ovules contained in the ovary, or basal part of the female plant structure, the pistil. The mature ovule contains in its central part a region called the nucellus that in turn contains an embryo sac with eight nuclei, each with one set of chromosomes (i.e., they are haploid nuclei). The two nuclei near the centre are referred to as polar nuclei; the egg cell, or oosphere, is situated near the micropylar ("open") end of the ovule. (These reproductive structures are described above; see *Plant reproductive systems*.)

With very few exceptions (e.g., the dandelion), development of the ovule into a seed is dependent upon fertilization, which in turn follows pollination. Pollen grains that land on the receptive upper surface (stigma) of the pistil will germinate, if they are of the same species, and produce pollen tubes, each of which grows down within the style (the upper part of the pistil) toward an ovule. The pollen tube has three haploid nuclei, one of them, the so-called vegetative, or tube, nucleus seems to direct the operations of the growing structure. The other two, the generative nuclei, can be thought of as nonmotile sperm cells. After reaching an ovule and breaking out of the pollen tube tip, one generative nucleus unites with the egg cell to form a diploid zygote (i.e., a fertilized egg with two complete sets of chromosomes, one from each parent), which, through a limited number of divisions gives rise to an embryo. The other generative nucleus fuses with the two polar nuclei to produce a triploid (three sets of chromosomes) nucleus, which divides repeatedly before cell-wall formation occurs, producing the triploid endosperm, a nutrient tissue that contains a variety of storage materials—such as starch, sugars, fats, proteins, hemicelluloses, and phytic acid (a phosphate reserve).

The events just described constitute what is called the double-fertilization process, one of the characteristic features of all flowering plants. In the orchids and in some other plants with minute seeds that contain no reserve materials, endosperm formation is completely suppressed. In other cases it is greatly reduced, but the reserve materials are present elsewhere—e.g., in the cotyledons, or seed leaves, of the embryo, as in beans, lettuce, and peanuts, or in a tissue derived from the nucellus, the perisperm, as in coffee. Other seeds, such as those of beets, contain both perisperm and endosperm. The seed coat, or testa, is derived from the one or two protective integuments of the ovule. The ovary, in the simplest case, develops into a fruit. In many plants, such as the grasses and lettuce, the outer integument and ovary wall are completely fused, so that seed and fruit form one entity; thus seeds and fruits can logically be described together as "dispersal units," or diaspores. More often, however, the seeds are discrete units attached to the placenta on the inside of the fruit wall through a stalk, or funiculus.

The hilum of a liberated seed is a small scar marking its

former place of attachment. The short ridge (raphe) that sometimes leads away from the hilum is formed by the fusion of seed stalk and testa. In many seeds, the micropyle of the ovule also persists as a small opening in the seed coat. The embryo, variously located in the seed, may be very small (as in buttercups) or may fill the seed almost completely (as in roses and plants of the mustard family). It consists of a root part, or radicle, a prospective shoot (plumule or epicotyl), one or more cotyledons (one or two in flowering plants, several in *Pinus*), and a hypocotyl, which is a region that connects radicle and plumule (see Figure 13). A classification of seeds can be based on size

Figure 13: Longitudinal sections of mature seeds.

(Left) *Zea mays*, maize or Indian corn, a monocotyledonous caryopsis, or grain, which is actually both seed and fruit through the fusion of the seed coat with the ovary wall. (Centre and right) *Ricinus Communis*, castor bean, a dicotyledonous seed, edge and face views.

and position of the embryo and on the proportion of embryo to storage tissue; the possession of either one or two cotyledons is considered crucial in recognizing two main groups of flowering plants, the Monocotyledones and Dicotyledones.

Seedlings, arising from embryos in the process of germination, are classified as epigeal (cotyledons above ground, usually green and capable of photosynthesis) and hypogeal (cotyledons below ground; see Figure 14). Particularly in the monocots, special absorbing organs may develop that mobilize the reserve materials and withdraw them from the endosperm; e.g., in the grasses, the cotyledon has been modified into an enzyme-secreting scutellum ("shield") between embryo and endosperm.

Gymnosperm seeds. In gymnosperms (plants with "naked seeds"—conifers, cycads, ginkgos) the ovules are not enclosed in an ovary but lie exposed on leaflike structures, the megasporophylls. A long time span separates pollination and fertilization, and the ovules begin to develop into seeds long before fertilization has been accom-

Delayed fertilization in gymnosperms

Figure 14: Seedling morphology and germination modes. (Left) Epigeal germination. (Right) Hypogeal germination.

Double fertilization in angiosperms

plished; in some cases, in fact, fertilization does not occur until the ovules ("seeds") have been shed from the tree. In the European pine *Pinus sylvestris*, for example, the female cones (essentially collections of megasporophylls) begin to develop in winter and are ready to receive pollen from the male cones in spring. During the first growing season, the pollen tube grows slowly through the nucellus, while within the ovule the megaspore nucleus, through a series of divisions, gives rise to a collection of some 2,000 nuclei, which are then individually enclosed by walls to form a structure called the female gametophyte or prothallus. At the micropylar end of the ovule, several archegonia (bottle-shaped female organs) develop, each containing an oosphere ("egg"). The pollen tube ultimately penetrates the neck of one of the archegonia. Not until the second growing season, however, does the nucleus of one of the male cells in the tube unite with the oosphere nucleus. Although more than one archegonium may be fertilized, only one gives rise to a viable embryo. During the latter's development, part of the prothallus is broken down and used. The remainder, referred to as "endosperm," surrounds the embryo; it is mobilized later, during germination of the seed, a process that occurs without delay when the seeds are liberated from the female cone during the third year after their initiation.

Fruits. The concept "fruit" is based on such an odd mixture of practical and theoretical considerations that it accommodates cases in which one flower gives rise to several fruits (larkspur) as well as cases in which several flowers cooperate in producing one fruit (mulberry). Pea and bean plants, exemplifying the simplest situation, show in each flower a single pistil, traditionally thought of as a megasporophyll or carpel. The carpel is believed to be the evolutionary product of an originally leaflike organ bearing ovules along its margin, but somehow folded along the median line, with a meeting and coalescing of the margins of each half, the result being a miniature, closed but hollow pod with one row of ovules along the suture. In many members of the rose and buttercup families each flower contains a number of similar single-carpelled pistils, separate and distinct, which together represent what is known as an apocarpous gynoecium. In still other cases, two to several carpels (still thought of as megasporophylls, although perhaps not always justifiably) are assumed to have fused to produce a single compound gynoecium (pistil), whose basal part or ovary may be uniloculate (one cavity) or pluriloculate (with several compartments), depending on the method of carpel fusion. Most fruits develop from a single pistil. A fruit resulting from the apocarpous gynoecium (several pistils) of a single flower may be referred to as an aggregate fruit; a multiple fruit represents the gynoecia of several flowers. When additional flower parts, such as the stem axis or floral tube, are retained or participate in fruit formation, as in the apple, an accessory fruit results.

Certain plants, mostly cultivated varieties, spontaneously produce fruits in the absence of pollination and fertilization; such natural parthenocarpy leads to seedless fruits such as bananas, oranges, grapes, grapefruits, and cucumbers. Since 1934 seedless fruits of tomato, cucumber, peppers, holly, and others have also been obtained for commercial use by administering growth hormones, such as indoleacetic acid, indolebutyric acid, naphthalene acetic acid, and beta-naphthoxyacetic acid to ovaries in flowers (induced parthenocarpy).

Classification systems for mature fruits take into account the number of carpels constituting the original ovary; dehiscence (opening) versus nondehiscence; and dryness versus fleshiness. The properties of the ripened ovary wall, or pericarp, which may develop entirely or in part into fleshy, fibrous, or stony tissue, are important. Often, three distinct pericarp layers can be distinguished: the outer (exocarp), the middle (mesocarp), and the inner layer (endocarp). All purely morphological systems (*i.e.*, classification schemes based on structural features), including the one given in the Table and in Figure 15, are artificial. They ignore the fact that fruits can only be understood functionally and dynamically.

As strikingly exemplified by the word nut, popular terms

Figure 15: Types of fruit.

From H.J. Fuller and O. Tippo, *College Botany*, revised edition, copyright 1954 by Holt, Rinehart & Winston, Inc.; reprinted by permission.

often do not properly describe the botanical nature of certain fruits. A Brazil "nut," for example, is a thick-walled seed enclosed in a likewise thick-walled capsule along with several sister seeds. A coconut is a drupe (a stony-seeded fruit; see the Table) with a fibrous outer part. A walnut is a drupe in which the pericarp has differentiated into a fleshy outer husk and an inner hard "shell"; the "meat" represents the seed—two large, convoluted cotyledons, a minute epicotyl and hypocotyl, and a thin, papery seed coat. A peanut is an indehiscent legume fruit. An almond "nut" is the "stone"—*i.e.*, the hardened endocarp of a drupe usually containing a single seed. Botanically speaking, blackberries and raspberries are not "berries" but aggregates of tiny drupes. A juniper "berry" is comparable to a complete pine cone. A mulberry is a multiple fruit (see the Table) composed of small nutlets surrounded by fleshy sepals; a strawberry represents a much swollen receptacle (the tip of the flower stalk bearing the flower parts) bearing on its convex surface an aggregation of tiny achenes (small, single-seeded fruits; see the Table).

FORM AND FUNCTION

Seed size. In the Late Carboniferous Period (about 280,000,000 to 325,000,000 years ago) some seed ferns produced large seeds (12×6 centimetres [5×2 inches]) in *Pachytesta incrassata*. This primitive, ancestral condition of large seeds is reflected in certain gymnosperms (*Cycas circinalis*, 5.5×4 centimetres; *Araucaria bidwillii*, 4.5×3.5 centimetres) and also in some tropical rain-forest trees with nondormant, water-rich seeds (*Mora excelsa*, 12×7 centimetres). The "double coconut" palm *Lodoicea maldivica* represents the extreme, with seeds weighing up to 27 kilograms (about 60 pounds). Herbaceous, nontropical flowering plants usually have seeds weighing in the range of about 0.0001 to 0.01 grams. Within a given

Table 1: Classification of Fruits

major types	structure	
	one carpel	two or more carpels
Dry dehiscent	Follicle —at maturity, the carpel splits down one side, usually the ventral suture; milkweed, columbine, peony, larkspur, marsh marigold	Capsule —from compound ovary, seeds shed in various ways—e.g., through holes (<i>Papaver</i> —poppies) or longitudinal slits (California poppy) or by means of a lid (pimpernel); flower axis participates in <i>Iris</i> ; snapdragons, violets, lilies, and many plant families
	Legume —dehiscence along both dorsal and ventral sutures, forming two valves; most members of the pea family	Silique —from bicarpellate, compound, superior ovary; pericarp separates as two halves, leaving persistent central septum with seed or seeds attached; dollar plant, mustard, cabbage, rock cress, wall flower Silicle —a short silique; shepherd's purse, pepper grass
Dry indehiscent	Peanut fruit —(nontypical legume) Lomentum —a legume fragmenting transversely into single-seeded "mericarps"; sensitive plant (<i>Mimosa</i>)	Nut —like the achene (see below); derived from 2 or more carpels, pericarp hard or stony; hazelnut, acorn, chestnut, basswood Schizocarp —collectively, the product of a compound ovary fragmenting at maturity into a number of one-seeded "mericarps"; maple, mallows, members of the mint family (Lamiaceae or Labiatae), geraniums, carrots, dills, fennels
	Achene —small, single-seeded fruit, pericarp relatively thin; seed free in cavity except for its funicular attachment; buttercup, anemones, buckwheat, crowfoot, water plantain Cypsela —achene-like, but from inferior, compound ovary; members of the aster family (Asteraceae or Compositae), sunflowers Samara —a winged achene; elm, ash, tree-of-heaven, wafer ash Caryopsis —achene-like; from compound ovary; seed coat fused with pericarp; grass family (Poaceae or Graminae)	
Fleshy (pericarp partly or wholly fleshy or fibrous)	Drupe —mesocarp fleshy, endocarp hard and stony; usually single-seeded; plum, peach, almond, cherry, olive, coconut Berry —both mesocarp and endocarp fleshy; one-seeded: nutmeg, date; one carpel, several seeds: baneberry, may apple, barberry, Oregon grape; more carpels, several seeds: grape, tomato, potato, asparagus Pepo —berry with hard rind; squash, cucumber, pumpkin, watermelon Hesperidium —berry with leathery rind; orange, grapefruit, lemon	
	two or more carpels of the same flower plus stem axis or floral tube	carpels from several flowers plus stem axis or floral tube plus accessory parts
Fleshy (pericarp partly or wholly fleshy or fibrous)	Pome —accessory fruit from compound, inferior ovary; only central part of fruit represents pericarp, with fleshy exocarp and mesocarp and cartilaginous or stony endocarp ("core"); apple, pear, quince, hawthorn, mountain ash Inferior berry —blueberry Aggregate fleshy fruits —strawberry (achenes borne on fleshy receptacle); blackberry, raspberry (collection of drupelets); magnolia	Multiple fruits —fig (a "syconium"), mulberry, osage orange, pineapple, flowering dogwood

lies) and "microsporous" ones (e.g., the milkweed, daisy, heather, nettle, and willow families). The smallest known seeds, devoid of food reserves, are found in orchids, saprophytes (nongreen plants that absorb nutrients from dead organic matter—e.g., Indian pipe, *Monotropa*; coral root, *Corallorhiza*), carnivorous plants (sundews, pitcher plants), and total parasites (members of the families Rafflesiaceae and Orobanchaceae, or broomrapes, which latter have seeds weighing about 0.001 milligrams—about 3.5 hundred-millionths of an ounce). Clearly, seed size is related to life-style—total parasites obtain food from their host, even in their early growth stages, and young orchids are saprophytes that receive assistance in absorbing nutrients from fungi that associate closely with their roots. In both cases only very small seeds that lack endosperm are produced. Dodders (*Cuscuta*) and mistletoes (*Viscum*, *Phoradendron*) live independently when very young and accordingly have relatively large seeds. Many plant species possess seeds of remarkably uniform size, useful as beads (e.g., *Abrus precatorius*) or units of weight—one carat of weight once corresponded with one seed of the carob tree, *Ceratonia siliqua*. In wheat and many other plants, average seed size does not depend on planting density, showing that seed size is under rather strict genetic control. This does not necessarily preclude significant variations among individual seeds; in peas, for example, the seeds occupying the central region of the pod are the largest, probably as the result of competition for nutrients between developing ovules on the placenta. Striking evolutionary changes in seed size, inadvertently created by man, have occurred in the weed *Camelina sativa* subspecies *linicola*, which grows in flax fields. The customary winnowing of flax seeds selects forms of *Camelina* whose seeds are blown over the same distance as flax seeds in the operation, thus staying with their "models." Consequently, *Camelina* seeds in the south of Russia now mimic the relatively thick, heavy seeds of the oil flax that is grown there, whereas in the northwest they resemble the flat, thin seeds of the predominant fibre flax.

Seed size and predation. Seeds form the main source of food for many birds, rodents, ants, and beetles. Harvester ants of the genus *Veromessor*, for example, exact a toll of about 15,000,000 seeds per acre per year from the Sonoran Desert of the southwestern United States. In view of the enormous size range of the predators, which include minute weevil and bruchid-beetle larvae that attack the seeds internally, evolutionary "manipulation" of seed size by a plant species cannot in itself be effective in completely avoiding seed attack. With predation inescapable, however, it must be advantageous for a plant species to invest the total reproductive effort in a large number of very small units (seeds) rather than in a few big ones. The mean seed weight of those 13 species of Central American woody legumes vulnerable to bruchid attack is 0.26 gram; for the 23 species invulnerable by virtue of toxic seed constituents it is three grams.

Seed size and germination. Ecologically, seed size is also important in the breaking of dormancy. Being small, a seed can only "sample" that part of the environment immediately adjacent to it, which is not necessarily representative of the generally prevailing conditions. For successful seedling establishment, there is clearly a risk in "venturing out" too soon. The development in seeds of mechanisms acting as "integrating rain gauges" (see below) should be considered in that light.

The shape of dispersal units. Apart from the importance of shape as a factor in determining the mode of dispersal (e.g., wind dispersal of winged seeds, animal dispersal of spiny fruits), shape also counts when the seed or diaspore is seen as a landing device. The flatness of the enormous tropical *Mora* seeds prevents rolling and effectively restricts germination to the spot where they land. In contrast, *Eusideroxylon zwageri* does not grow on steep slopes because its heavy fruits roll downhill. The grains of the grass *Panicum turgidum*, which have a flat and a round side, germinate much better when the flat rather than the convex side lies in contact with wet soil. In very small seeds, the importance of shape can be judged only by taking into account soil clod size and microtopography

The
smallest
seeds

Functional
aspects of
seed shape

family (e.g., the pea family, Fabaceae or Leguminosae) seed size may vary greatly; in others it is consistently large or small, justifying the recognition of "megasprous" families (e.g., the beech, nutmeg, palm, and soursop fami-

of the soils onto which they are dropped. The rounded seeds of cabbage species, for example, tend to roll into crevices, whereas the reticulate ones of lamb's quarters often stay in the positions in which they first fall. Several seeds have appendages (awns, bristles) that promote germination by aiding in orientation and self-burial. In one study, for example, during a six-month period, awned grains of *Danthonia penicillata* gave rise to 12 times as many established seedlings as de-awned ones.

Polymorphism of seeds and fruits. Some plant species produce two or more sharply defined types of seeds that differ in appearance (colour), shape, size, internal structure, or dormancy. In common spurry (*Spergula arvensis*), for example, the seed coat (part of the mother plant) may be either smooth or papillate (covered with tiny nipple-like projections). Here, the phenomenon is genetically controlled by a single factor, so that all the seeds of a given plant are either papillate or smooth. More common is somatic polymorphism, the production by individual plants of different seed types, or "morphs." Somatic polymorphism occurs regularly in *Atriplex* and *Chenopodium*, in which a single plant may produce both large brown seeds capable of immediate germination and small black ones with some innate dormancy. Somatic polymorphism may be controlled by the position of the two (or more) seed types within one inflorescence (flower cluster) or fruit, as in cocklebur, or it may result from environmental effects, as in *Halogeton*, in which imposition of long or short days leads to production of brown and black seeds, respectively. Since the different morphs in seed (and fruit) polymorphism usually have different dispersal mecha-

nisms and dormancies, so that germination is spread out both in space and in time, the phenomenon can be seen as an insurance against catastrophe. The most spectacular example of heterocarpy (*i.e.*, production of differing fruit) is found in the Mediterranean *Fedia cornucopiae* (family Valerianaceae), which has three astonishingly different kinds of fruits that show adaptations to dispersal by wind and water, ants, and larger animals, respectively.

AGENTS OF DISPERSAL

The dispersing agents for seeds and fruits are indicated in such terms as anemochory, hydrochory, and zoochory, which mean dispersal by wind, water, and animals, respectively. Within the zoochorous group further differentiation according to the carriers can be made: saurochory, dispersal by reptiles; ornithochory, by birds; myrmecochory, by ants. Or the manner in which the diaspores are carried can be emphasized, distinguishing endozoochory, diaspores carried within the animal; epizoochory, diaspores accidentally carried on the outside; and synzoochory, diaspores intentionally carried, mostly in the mouth as in birds and ants. See Figure 16 for examples of fruits and seeds that are adapted for dispersal by various means.

Dispersal by animals. Snails disperse the small seeds of a very few plant species (*e.g.*, *Adoxa*). Earthworms are more important as seed dispersers. Many intact fruits and seeds can serve as fish bait, those of *Sonneratia*, for example, for the catfish *Arius maculatus*. Certain Amazon River fishes react positively to the audible "explosions" of the ripe fruits of *Eperua rubiginosa*. Fossil evidence indicates that saurochory is very ancient. The giant Galapagos

tortoise is important for the dispersal of local cacti and tomatoes. The name alligator apple for *Annona palustris* refers to its method of dispersal, an example of saurochory. Many mammals, ranging in size from mice and kangaroo rats to elephants, eat and disperse seeds and fruits. In the tropics, chiropterochory (dispersal by large bats such as flying foxes, *Pteropus*) is particularly important. Fruits adapted to these animals are relatively large and drab in colour, with large seeds and a striking (often rank) odour; they are accessible to bats because of the pagoda-like structure of the tree canopy, fruit placement on the main trunk, or suspension from long stalks that hang free of the foliage. Examples include mangoes, guavas, breadfruit, carob, and several fig species. In South Africa, a desert melon (*Cucumis humifructus*) participates in a symbiotic relationship with aardvarks—the animals eat the fruit for its water content and bury their own dung, which contains the seeds, near their burrows. Furry terrestrial mammals are the agents most frequently involved in epizoochory, the inadvertent carrying by animals of dispersal units. Burrlike seeds and fruits, or those diaspores provided with spines, hooks, claws, bristles, barbs, grapples, and prickles, are genuine hitchhikers, clinging tenaciously to their carriers. Their functional shape is achieved in various ways—in cleavers, or goose grass (*Galium aparine*), and enchanter's nightshade (*Circaea lutetiana*) the hooks are part of the fruit itself; in common agrimony (*Agrimonia eupatoria*) the fruit is covered by a persistent calyx (the sepals, parts of the flower, which remain attached beyond the usual period) equipped with hooks; in wood avens (*Geum urbanum*) the persistent styles have hooked tips. Other examples are bur marigolds, or beggar's-ticks (*Bidens* species); buffalo burr (*Solanum rostratum*); burdock (*Arctium*); *Acaena*; and many *Medicago* species. The last-named, with dispersal units highly resistant to damage from hot water and certain chemicals (dyes), have achieved wide global distribution through the wool trade. A somewhat different principle is employed by the so-called trample burrs, said to lodge themselves between the hooves of large grazing mammals. Examples are mule grab (*Proboscidea*) and the African grapple plant (*Harpagophytum*). In water burrs, such as those of the water nut *Trapa*, the spines should probably be considered as anchoring devices.

Dispersal by birds. Birds, being preening animals, rarely carry burrlike diaspores on their bodies. They do, however, transport the very sticky (viscid) fruits of *Pisonia*, a tropical tree of the four-o'clock family, to distant Pacific islands in this way. Small diaspores, such as those of sedges and certain grasses, may also be carried in the mud sticking to waterfowl and terrestrial birds.

Synzoochory, deliberate carrying of diaspores by animals, is practiced when birds carry diaspores in their beaks. The European mistle thrush, *Turdus viscivorus*, deposits the viscid seeds of mistletoe (*Viscum album*) on potential host plants when, after a meal of the berries, it whets its bill on branches or simply regurgitates the seeds. The North American mistletoes (*Phoradendron*) are dispersed by various birds, and the comparable tropical species of the plant family Loranthaceae by flowerpeckers (of the bird family Dicaeidae), which have a highly specialized gizzard that allows seeds to pass through but retains insects. Plants may also profit from the forgetfulness and sloppy habits of certain nut-eating birds that cache part of their food but neglect to recover everything, or drop units on their way to the hiding place. Best known in this respect are the nutcrackers (*Nucifraga*), which feed largely on the "nuts" of beech, oak, walnut, chestnut, and hazel; the jays (*Garulus*), which hide hazelnuts and acorns; the nuthatches; and the California woodpecker (*Balanosphyra*), which may embed literally thousands of acorns, almonds, and pecan nuts in bark fissures or holes of trees. Secondarily, rodents may aid in dispersal by stealing the embedded diaspores and burying them. In Germany an average jay may transport about 4,600 acorns per season, over distances of up to four kilometres (2.5 miles). Woodpeckers, nutcrackers, and squirrels are responsible for a similar dispersal of *Pinus cembra* in the Alps near the tree line.

Most ornithochores (plants with bird-dispersed seeds)

have conspicuous diaspores attractive to such fruit-eating birds as thrushes, pigeons, barbets (members of the bird family Capitonidae), toucans, and hornbills (family Bucerotidae), all of which either excrete or regurgitate the hard part undamaged. Such diaspores have a fleshy, sweet, or oil-containing edible part; a striking colour (often red or orange); no pronounced smell; a protection against being eaten prematurely in the form of acids and tannic compounds that are present only in the green fruit; a protection of the seed against digestion—bitterness, hardness, or the presence of poisonous compounds; permanent attachment; and, finally, absence of a hard outer cover. In contrast to bat-dispersed diaspores, they occupy no special position on the plant. Examples are rose hips, plums, dogwood fruits, barberry, red currant, mulberry, nutmeg fruits, figs, blackberries, and others. The natural and abundant occurrence of *Evonymus* (cardinal's hat), essentially a tropical genus, in temperate Europe and Asia, can be understood only in connection with the activities of birds. Birds also contributed substantially to the repopulation with plants of the island Krakatoa after the catastrophic eruption of 1883. Birds have made *Lantana* (originally American) a pest in Indonesia; the same is true of wild plums (*Prunus serotina*) in parts of Europe and *Rubus* species in Brazil and New Zealand.

Mimicry—the protection-affording imitation of a dangerous or toxic species by an edible, harmless one—is shown in reverse by certain bird-dispersed "coral seeds" such as those of many species in the genera *Abrus*, *Ormosia*, *Rhynchosia*, *Adenanthera*, and *Erythrina*. Hard and often shiny red or black and red, many such seeds deceptively suggest the presence of a fleshy red aril and thus invite the attention of hungry birds.

Dispersal by ants. Mediterranean and North American harvester ants (*Messor*, *Atta*, *Tetramorium*, and *Pheidole*) are essentially destructive, storing and fermenting many seeds and eating them completely. Other ants (*Lasius*, *Myrmica*, and *Formica* species) eat the fleshy, edible appendage (the fat body or elaiosome) of certain specialized seeds, which they disperse (see Figure 17). Most myrmecochorous plants (species of violet, primrose, hepatica, cyclamen, anemone, corydalis, *Trillium*, and bloodroot) belong to the herbaceous spring flora of northern forests. Tree poppy (*Dendromecon*), however, is found in the dry California chaparral; *Melica* and *Centaurea* species in arid

Plant
and ant
interrela-
tionships

Mediterranean regions. The so-called ant epiphytes of the tropics (*i.e.*, species of *Hoya*, *Dischidia*, *Aeschynanthus*, and *Myrmecodia*—plants that live in “ant gardens” on trees or offer the ants shelter in their own body cavities) constitute a special group of myrmecochores, providing oil in seed hairs, which in ancestral forms must have served in wind dispersal. The primary ant attractant of myrmecochorous seeds is not necessarily oil; instead, an unsaturated, somewhat volatile fatty acid is suspected in some cases. The myrmecochorous plant as a whole may also have specific adaptations; for example, *Cyclamen* brings fruits and seeds within reach of ants by conspicuous coiling (shortening) of the flower stalk as soon as flowering is over.

Dispersal by wind. In the modern world, wind dispersal (although numerically important) reflects the climatic and biotic poverty of certain regions; it is essentially a feature of pioneer vegetations. The flora of the Alps is 60 percent anemochorous, that of the Mediterranean garigue 50 percent. By making certain assumptions (*e.g.*, for average wind velocity and turbulence) the “average limits of dispersal”—that is, the distance that 1 percent of the diaspores can reach—can be calculated for dispersal units of various construction and weight. This calculation yields values of 10 kilometres (six miles) for dandelion (*Taraxacum officinale*) and 0.5 kilometre (0.3 mile) for European pine (*Pinus sylvestris*). Storms result in higher values—30 kilometres (20 miles) for poplar and 200 kilometres (125 miles) for *Senecio congestus*.

Too much success in dispersal may be ecologically futile, as exemplified by certain Florida orchids that arise from windblown West Indian seeds but do not multiply because of the lack of specific pollinators; usually certain bees or wasps. Anemochorous diaspores can be subdivided into flyers, dust diaspores, balloons, and plumed or winged diaspores; rollers, chamaechores or tumbleweeds; and throwers, ballistic anemochores. Dispersal by means of minute dust diaspores produced in huge quantities is comparable to spore dispersal in lower plants—a “saturation bombing” is required to find the very limited number of targets, or favourable growth habitats, that exist. Not surprisingly, it is practiced mostly by total parasites, such as broomrapes (in which the finding of the specific host is a problem), and saprophytes. The inflated, indehiscent pods of *Colutea arborea*, a steppe plant, represent balloons capable of limited air travel before they hit the ground and become windblown tumbleweeds. Winged fruits are most common in trees and shrubs, such as maple, ash, elm, birch, alder, and dipterocarps (a family of about 600 species of Old World tropical trees). The one-winged propeller type, as found in maple, is called a samara. When fruits have several wings on their sides, rotation may result, as in rhubarb and dock species. Sometimes accessory parts form the wings—for example, the bracts (small green leaflike structures that grow just below flowers) in *Tilia* (linden). Seeds with a thin wing formed by the testa are likewise most common in trees and shrubs, particularly in climbers—jacaranda, trumpet vine, catalpa, yams, butter-and-eggs. Most famous of these is the seed with a giant, membranaceous wing (15 centimetres, or six inches) of *Macrozamia macrocarpa*, a tropical climber of the cucumber family.

Many fruits form plumes, some derived from persisting and ultimately hairy styles, as in clematis, avens, and anemones; some from the perianth, as in the sedge family (Cyperaceae); and some from the pappus, a calyx structure, as in dandelion and Jack-go-to-bed-at-noon (*Tragopogon*). Plumed seeds usually have tufts of light, silky hairs at one end (rarely both ends) of the seeds—*e.g.*, fireweed, milkweeds, dogbane. In woolly fruits and seeds, the pericarp or the seed coat is covered with cotton-like hairs—*e.g.*, willow, poplar or cottonwood, kapok, cotton, balsa, silk-cotton tree, and some anemones. In some cases, the hairs may serve double duty, in that they function in water dispersal as well as wind dispersal. In tumbleweeds, the whole plant or its fruiting portion breaks off and is blown across open country, scattering seeds as it goes; examples include Russian thistle, pigweed, tumbling mustard, perhaps rose of Jericho, and “windballs” of the grass *Spinifex*

of Indonesian shores and Australian steppes. Poppies have a mechanism in which the wind has to swing the slender fruitstalk back and forth before the seeds are thrown out through pores near the top of the capsule.

Dispersal by water. Many beach, pond, and swamp plants have waterborne seeds, which are buoyant by being enclosed in corky fruits or air-containing fruits or both; examples of these plants include water plantain, yellow flag, sea kale, sea rocket, sea beet, and all species of Rhizophoraceae, a family of mangrove plants. Sea dispersal of the coconut palm has been well proved; the fibrous mesocarp of the fruit, a giant drupe, provides buoyancy. Once the nuts are ashore, the mesocarp also aids in the aboveground germination process by collecting rainwater; in addition, the endosperm has in its “milk” a provision for seedling establishment on beaches without much freshwater. A sea rocket species with seeds highly resistant to seawater is gaining a foothold on volcanic Surtsey Island south of Iceland. Purple loosestrife, monkey flower, *Aster tripolium*, and *Juncus* species (rushes) are often transported by water in the seedling stage. Rainwash down mountain slopes may be important in tropical forests. A “splashcup mechanism,” common in fungi for spore dispersal, is suggested by the open fruit capsule with exposed small seeds in the pearlwort (*Sagina*) and mitrewort (*Mitella*). Hygrochasy, the opening of fruits in moist weather, is displayed by species of *Mesembryanthemum*, *Sedum*, and other plants of dry environments.

Self-dispersal. Best known in this category are the active ballists, which forcibly eject their seeds by means of various mechanisms. In the fruit of the dwarf mistletoe (*Arceuthobium*) of the western United States, a very high osmotic pressure (pressure accumulated by movement of water across cell membranes principally in only one direction) builds up that ultimately leads to a lateral blasting out of the seeds over distances of up to 15 metres (49 feet) with an initial velocity of about 95 kilometres (60 miles) per hour. Squirting cucumber (*Ecballium elaterium*) also employs an osmotic mechanism. In Scotch broom and gorse, however, drying out of the already dead tissues in the two valves of the seed pod causes a tendency to warp, which, on hot summer days, culminates in an explosive and audible separation of these valves, with violent seed release. Such methods may be coupled with secondary dispersal mechanisms, effected by ants in the case of Scotch broom and gorse or by birds and mammals, to which sticky seeds may adhere, in the case of *Arceuthobium* and squirting cucumber. Other active ballists are species of geranium, violet, wood sorrel, witch-hazel, touch-me-not (*Impatiens*), and acanthus; probable champions are *Bauhinia purpurea*, with a distance of 15 metres and the sandbox tree (*Hura crepitans*) with 14 metres. Barochory, the dispersal of seeds and fruits by gravity alone, is demonstrated by the heavy fruits of horse chestnut.

Creeping diaspores are found in grasses such as *Avena sterilis* and *Aegilops ovata*, the grains of which are provided with bristles capable of hygroscopic movements (coiling and flexing, in response to changes in moisture). The mericarps (a fruit fragment—see the Table: *Schizocarp*) or stork’s bill (an *Erodium* species), when moistened, bury themselves with a corkscrew motion by unwinding a multiple-barbed, beak-shaped appendage, which, in the dry state, was coiled.

Atelechory, the dispersal over a very limited distance only, represents a waste-avoiding, defensive “strategy” that functions in further exploitation of an already occupied, favourable site. This aim is often achieved by synaptospermy, the sticking together of several diaspores, which makes them less mobile, as in beet and spinach; also, by geocarp, which is either the production of fruits underground, as in the arum lilies *Stylochiton* and *Biarum*, in which the flowers are already subterranean, or the active burying of fruits by the mother plant, as in the peanut, *Arachis hypogaea*. In the American hog peanut (*Amphicarpa bracteata*), pods of a special type are buried by the plant and are cached by squirrels later on. Kenilworth ivy (*Cymbalaria*), which normally grows on stone or brick walls, stashes its fruits away in crevices after strikingly extending the flower stalks. Not surprisingly, geocarp, like

Explosive
fruits

Winged
fruits

synaptospermy, is most often encountered in desert plants; however, it also occurs in violet species, in subterranean clover (*Trifolium subterraneum*)—even when it grows in France and England—and in *Begonia hypogaea* of the African rain forest.

GERMINATION

Dormancy and life-span of seeds. Diaspore dormancy has at least three functions: (1) immediate germination must be prevented even when circumstances are optimal so as to avoid exposure of the seedling to an unfavourable period (e.g., winter), which is sure to follow; (2) the unfavourable period has to be survived; and (3) the various dispersing agents must be given time to act. Accordingly, the wide variation in diaspore longevity can be appreciated only by linking it with the various dispersal mechanisms employed, as well as with the climate and its seasonal changes. Thus, the downy seeds of willows, blown up and down rivers in early summer with a chance of quick establishment on newly exposed sandbars, have a life-span of only one week. Tropical rain forest trees frequently have seeds of low life expectancy also. Intermediate are seeds of sugarcane, tea, and coco palm, among others, with life-spans of up to a year. *Mimosa glomerata* seeds in the herbarium of the Muséum National d'Histoire Naturelle in Paris were found viable after 221 years. In general, viability is better retained in air of low moisture content. Some seeds, however, remain viable under water—those of certain rush (*Juncus*) species and *Sium cicutaefolium* for at least seven years. Salt water can be tolerated for years by the pebble-like but floating seeds of *Caesalpinia* (*Guilandina*) *bonduc* and *C. bonducella*, species that, in consequence, possess an almost pantropical distribution. Seeds of the sacred lotus (*Nelumbo nucifera*) found in a peat deposit in Manchuria and estimated by radioactive-carbon dating to be 1,400 (± 400) years old, rapidly germinated (and subsequently produced flowering plants) when the seeds were filed to permit water entry. In 1967 seeds of the arctic tundra lupine (*Lupinus arcticus*), found in a frozen lemming burrow with animal remains established to be at least 10,000 years old, germinated within 48 hours when returned to favourable conditions. The problem of differential seed viability has been approached experimentally by various workers, one of whom buried 20 species of common Michigan weed seeds, mixed with sand, in inverted open-mouthed bottles for periodic inspection. After 80 years, three species still had viable seeds.

Lack of dormancy. In some plants, the seeds are able to germinate as soon as they have matured on the plant, as demonstrated by wheat, sweet corn, peas, and beans in a very rainy season. Certain mangrove species normally form foot-long embryos on the trees; these later drop down into the mud or seawater. Such cases, however, are exceptional. The lack of dormancy in cultivated species, contrasting with the situation in most wild plants, is undoubtedly the result of conscious selection by man.

Immature embryos. In plants whose seeds ripen and are shed from the mother plant before the embryo has undergone much development beyond the fertilized egg stage (orchids, broomrapes, ginkgo, dogtooth violet, ash, winter aconite, and buttercups), there is an understandable delay of several weeks or months, even under optimal conditions, before the seedling emerges.

Role of the seed coat. There are at least three ways in which a hard testa may be responsible for seed dormancy: it may (1) prevent expansion of the embryo mechanically (pigweed); or (2) block the entrance of water; or (3) impede gas exchange so that the embryos lack oxygen. Resistance of the testa to water uptake is most widespread in the bean family, the seed coats of which, usually hard, smooth, or even glassy, may, in addition, possess a waxy covering. In some cases water entry is controlled by a small opening, the strophliar cleft, which is provided with a corklike plug; only removal or loosening of the plug will permit water entry. Similar seeds not possessing a strophliar cleft must depend on abrasion, which in nature may be brought about by microbial attack, passage through an animal, freezing and thawing, or mechanical means. In horticulture and agriculture, the coats of such seeds are

deliberately damaged or weakened by man (scarification). In chemical scarification, seeds are dipped into strong sulfuric acid, organic solvents such as acetone or alcohol, or even boiling water. In mechanical scarification, they may be shaken with some abrasive material such as sand or be scratched with a knife.

Frequently seed coats are permeable to water yet block entrance of oxygen; this applies, for example, to the upper of the two seeds normally found in each burr of the cocklebur plant. The lower seeds germinate readily under a favourable moisture and temperature regime, but the upper ones fail to do so unless the seed coat is punctured or removed or the intact seed is placed under very high oxygen concentrations.

Afterripening, stratification, and temperature effects. The most difficult cases of dormancy to overcome are those in which the embryos, although not underdeveloped, remain dormant even when the seed coats are removed and conditions are favourable for growth. Germination in these takes place only after a series of little-understood changes, usually called afterripening, have taken place in the embryo. In this group are many forest trees and shrubs such as pines, hemlocks, and other conifers; some flowering woody plants such as dogwood, hawthorn, ash, linden, tulip poplar, holly, and viburnum; fruit trees such as apples, pears, peaches, plums, and cherries; and flowering herbaceous plants such as iris, Solomon's seal, and lily-of-the-valley. In some species, one winter suffices for afterripening. In others, the process is drawn out over several years, with some germination occurring each year. This can be viewed as an insurance of the species against flash catastrophes that might completely wipe out certain year classes.

Many species require moisture and low temperatures; for example, in apples, when the cold requirement is insufficiently met, abnormal seedlings result. Others (cereals, dogwood) afterripen during dry storage. The seeds of certain legumes—for example, the seeds of the tree lupin, the coats of which are extremely hard and impermeable—possess a hilum with an ingenious valve mechanism that allows water loss in dry air but prevents re-uptake of moisture in humid air. Of great practical importance is stratification, a procedure aimed at promoting a more uniform and faster germination of cold-requiring, afterripening seeds. In this procedure, seeds are placed for one to six months, depending on the species, between layers of sand, sawdust, sphagnum, or peat and kept moist as well as reasonably cold (usually 0° to 10° C [32° to 50° F]). A remarkable “double dormancy” has thus been uncovered in lily-of-the-valley and false Solomon's seal. Here, two successive cold treatments separated by a warm period are needed for complete seedling development. The first cold treatment eliminates the dormancy of the root; the warm period permits its outgrowth; and the second cold period eliminates epicotyl or leaf dormancy. Thus, almost two years may be required to obtain the complete plant. The optimal temperature for germination, ranging from 1° C (34° F) for bitterroot to 42° C (108° F) for pigweed, may also shift slightly as a result of stratification.

Many dry seeds are remarkably resistant to extreme temperatures, some even to that of liquid air (−140° C or −220° F). Seeds of Scotch broom and some *Medicago* species can be boiled briefly without losing viability. Ecologically, such heat resistance is important in vegetation types periodically ravaged by fire, such as in the California chaparral, where the germination of *Ceanothus* seeds may even be stimulated. Also important ecologically is a germination requirement calling for a modest daily alternation between a higher and a lower temperature. Especially in the desert, extreme temperature fluctuations are an unavoidable feature of the surface, whereas with increasing depth these fluctuations are gradually damped out. A requirement for a modest fluctuation—e.g., from 20° C (68° F) at night to 30° C (86° F) in the daytime (as displayed by the grass *Oryzopsis miliacea*)—practically ensures germination at fair depths; and this is advantageous because a seed germinating in soil has to strike a balance between two conflicting demands, both depending on depth—on the one hand, germination in deeper layers

Significance of afterripening requirement

Plants
stimulated
by light to
germinate

is advantageous because a dependable moisture supply simply is not available near the surface; but, on the other hand, closeness to the surface is desirable because it allows the seedling to reach air and light rapidly and become self-supporting.

Light and seed germination. Many seeds are insensitive to light, but in a number of species germination is stimulated or inhibited by exposure to continuous or short periods of illumination. So stimulated are many grasses, lettuce, fireweed, peppergrass (*Lepidium*), mullein, evening primrose, yellow dock, loosestrife, and Chinese lantern plant. Corn (maize), the smaller cereals, and many legumes, such as beans and clover, germinate as well in light as in darkness. Inhibition by light is found in chive, garlic, and several other species of the lily family, jimson weed, fennel flower (*Nigella*), *Phacelia*, *Nemophila*, and pigweed (*Amaranthus*). Sometimes, imbibed (wet) seeds that do not germinate at all in darkness may be fully promoted by only a few seconds or minutes of white light. The best studied case of this type, and one that is a milestone in plant physiology, concerns seeds of the Grand Rapids variety of lettuce, which is stimulated to germination by red light (wavelength about 660 nanometres) but inhibited by "far red" light (wavelength about 730 nanometres). Alternations of the two treatments to almost any extent indicate that the last treatment received is the decisive one in determining whether the seeds will germinate.

Ecological role of light. Laboratory experiments and field observations indicate that light is a main controller of seed dormancy in a wide array of species. The absence of light, for example, was found in one study to be responsible for the nongermination of seeds of 20 out of 23 weed species commonly found in arable soil. In regions of shifting sands, seeds of Russian thistle germinate only when the fruits are uncovered, often after a burial period of several years. Conversely, the seeds of *Calligonum comosum* and the melon *Citrullus colocynthis*, inhabiting coarse sandy soils in the Negev Desert, are strongly inhibited by light. The survival value of this response, which restricts germination to buried seeds, lies in the fact that at the surface fluctuating environmental conditions may rapidly create a very hostile micro-environment. The seeds of *Artemisia monosperma* have an absolute light requirement but respond to extremely low intensities, such as is transmitted by a two-millimetre- (0.08-inch-) thick sand filter. In seeds

buried too deeply, germination is prevented. The responsiveness to light, however, increases with the duration of water imbibition. Even when full responsiveness to light has been reached, maximal germination occurs only after several light-exposures are given at intervals. In the field, this combined response mechanism acts as an integrating (cumulative) rain gauge because the seeds (as indicated) become increasingly responsive to light, and thus increasingly germinable, the longer the sand remains moistened. Certain *Juncus* seeds have an absolute light requirement over a wide range of temperatures; consequently, they do not germinate under dense vegetation or in overly deep water. In combination with temperature, light (in the sense of day length) may also restrict germination to the most suitable time of year. In birch, for example, seeds that have not gone through a cold period after imbibing water remain dormant after release from the mother plant in the fall and will germinate only when the days begin to lengthen the next spring.

Stimulators and inhibitors of germination. A number of chemicals (potassium nitrate, thiourea, and ethylene chlorhydrin) and plant hormones (gibberellins and kinetin) have been used experimentally to break seed dormancy. Their mode of action is obscure, but it is known that in some instances thiourea, gibberellin, and kinetin can substitute for light.

Natural inhibitors, which completely suppress germination (coumarin, parasorbic acid, ferulic acid, phenols, protoanemonin, transcinamic acid, alkaloids, essential oils, and the hormone dormin) may be present in the pulp or juice of fruits or in various parts of the seed. The effect of seed coat phenols, for example, may be indirect—being highly oxidizable, they may screen out much-needed oxygen. Ecologically, such inhibitors are important in at least three ways. Their slow disappearance with time may spread germination out over several years (a protection against catastrophes). Furthermore, when leached out by rainwater, they often serve as agents inhibiting the germination of other competitive plants nearby. Finally, the gradual leaching out of water-soluble inhibitors serves as an excellent integrating rain gauge. Indeed, it has been shown that the germination of certain desert plants is not related to moisture as such but to soil water movement—i.e., to the amount and duration of rain received.

Significance of
seed light
requirements

ANIMAL REPRODUCTION

The role of reproduction is to provide for the continued existence of a species; it is the process by which living organisms duplicate themselves. Animals compete with other individuals in the environment to maintain themselves for a period of time sufficient to enable them to produce tissue nonessential to their own survival, but indispensable to the maintenance of the species. The additional tissue, reproductive tissue, usually becomes separated from the individual to form a new, independent organism.

This section describes the reproductive systems in metazoans (multicelled animals) from sponges to mammals, exclusive of man. It focusses on the gonads (sex organs), associated ducts and glands, and adaptations that aid in the union of gametes—i.e., reproductive cells, male or female, that are capable of producing a new individual by union with a gamete of the opposite sex. Brief mention is made of how the organism provides for the development of embryos and of the regulatory role of gonads in vertebrate cycles. (Human reproduction is treated separately below.)

Unlike most other organ systems, the reproductive systems of higher animals have not generally become more complex than those of lower forms. Asexual reproduction (i.e., reproduction not involving the union of gametes), however, occurs only in the invertebrates, in which it is common, occurring in animals as highly evolved as the sea squirts, which are closely related to the vertebrates. Temporary gonads are common among lower animals; in higher animals, however, gonads are permanent organs. Hermaphroditism, in which one individual contains

functional reproductive organs of both sexes, is common among lower invertebrates; yet separate sexes occur in such primitive animals as sponges, and hermaphroditism occurs in animals more highly evolved—e.g., the lower fishes. Gonads located on or near the animal surface are common in the lowest invertebrates, but in higher animals they tend to be more deeply situated and often involve intricate duct systems. In echinoderms, which are among the highest invertebrates, the gonads hang directly into the sea and spill their gametes into the water. In protochordates, gametes are released into a stream of respiratory water that passes directly into the sea. Duct systems of the invertebrate flatworms (Platyhelminthes) are relatively complex, and those of specialized arthropods (e.g., insects, spiders, crabs) are more complex than those of any vertebrate. Copulatory organs occur in flatworms, but copulatory organs are not ubiquitous among vertebrates other than reptiles and mammals. The trend toward fewer eggs and increased parental care in higher animals may account for the relative lack of complexity in the reproductive systems of some advanced forms. Whereas trends toward increasing structural complexity have often been reversed during evolution, reproductive behaviour patterns in many phylogenetic (i.e., evolutionary) lines have become more complicated in order to enhance the opportunity for fertilization of eggs and maximum survival of offspring (see SEX AND SEXUALITY).

A direct relationship exists between behaviour and the functional state of gonads. Reproductive behaviour in-

Synchroni- zation of behaviour and gonadal activity

duced principally but not exclusively by organic substances called hormones promotes the union of sperm (spermatozoa) and eggs, as well as any parental care accorded the young. There are a number of reasons why behaviour must be synchronized with gonadal activity. Chief among these are the following:

Individuals of a species must congregate at the time the gonads contain mature gametes. This often entails migration, and some members of all major vertebrate groups migrate long distances to gather at spawning grounds or rookeries.

Individuals with gametes ready to be shed must recognize members of the opposite sex. Recognition is sometimes by external appearance or by chemical substances (pheromones), but sex-linked behaviour is often the only signal.

Geographical territories frequently must be established and aggressively defended.

The building of nests, however simple, is essential reproductive behaviour in many species.

When fertilization of aquatic forms is external, sperm and eggs must be discharged at approximately the same time into the water, since gametes may be quickly dispersed by currents. Courtship, often involving highly intricate behaviour patterns, serves to release the gametes of both mating individuals simultaneously.

When fertilization is internal, willingness of the female to mate is often essential. Female mammals not in a state of willingness to mate not only will not mate but may injure or even kill an aggressive male. The unwillingness of a female mammal to mate when mature eggs are not present prevents loss of sperm needed to preserve the species.

Parental care of fertilized eggs by one parent or the other has evolved in many species. Parental behaviour includes fanning the water or air around the eggs, thereby maintaining appropriate temperature and oxygen levels; secretion of oxygen from a parent's gills; transport of eggs on or in the parental body (including the mouth of some male parents); and brooding, or incubation, of eggs.

Some species extend parental care into the postnatal period, feeding and protecting the offspring. Such behaviour patterns are adaptations for survival and thus are essential; all are induced by the nervous and endocrine systems and are typically cyclical, because gonadal activity is cyclical (see also BEHAVIOUR, ANIMAL: *Reproductive behaviour*.)

Reproductive systems of invertebrates

GONADS, ASSOCIATED STRUCTURES, AND PRODUCTS

Although asexual reproduction occurs in many invertebrate species, most reproduce sexually. The basic unit of sexual reproduction is a gamete (sperm or egg), produced by specialized tissues or organs called gonads. Sexual reproduction does not necessarily imply copulation or even a union of gametes. As might be expected of such a large and diverse group as the invertebrates, many variations have evolved to ensure survival of species. In many lower invertebrates, gonads are temporary organs; in higher forms, however, they are permanent. Some invertebrates have coexistent female and male gonads; in others the same gonad produces both sperm and eggs. Animals in which both sperm and eggs are produced by the same individual (hermaphroditism) are termed monoecious. In dioecious species, the sexes are separate. Generally, the male gonads ripen first in hermaphroditic animals (protandry); this tends to ensure cross-fertilization. Self-fertilization is normal, however, in many species, and some species undergo sex reversal.

Sponges, coelenterates, flatworms, and aschelminths. Sponges are at a cellular level of organization and thus do not have organs or even well-developed tissues; nevertheless, they produce sperm and eggs and also reproduce asexually. Some species of sponge are monoecious, others are dioecious. Sperm and eggs are formed by aggregations of cells called amoebocytes in the body wall; these are not considered gonads because of their origin and transitory nature.

In hydrozoan coelenterates, temporary gonads are formed by groups of cells in either the epidermis (outer cell layer) or gastrodermis (gut lining), depending on the species;

scyphozoan and anthozoan coelenterates generally have gonads in the gastrodermis. The origin and development of gonads in coelenterates, particularly freshwater species, are often associated with the seasons. Freshwater hydrozoans, for example, reproduce asexually until the onset of cold weather, which stimulates them to form testes and ovaries. Colonial hydrozoans asexually produce individuals known as polyps. Polyps, in turn, give rise to free swimming stages (medusae), in which gonads develop (Figure 18). The body organization of sponges and coe-

Polyps

Figure 18: Life cycle of the colonial hydrozoan *Obelia*.

lenterates is such that most of their cells are in intimate contact with the environment; consequently, gametes are shed into the water, and no ducts are necessary to convey them to the outside.

In contrast to sponges and coelenterates, platyhelminths generally have well-developed organ systems of a permanent nature and, in addition, have evolved secondary reproductive structures to convey sex products. One exception is the acoels, a group of primitive turbellarians; they lack permanent gonads, and germinal cells develop from amoebocytes in much the same manner as in sponges. The majority of flatworms, however, are monoecious, the primary sex organs consisting of one or more ovaries and testes (Figure 19). The tube from the ovary to the outside is called the oviduct; it often has an outpocketing (seminal receptacle) for the storage of sperm received during copulation. In many species the oviduct receives a duct from yolk (vitelline) glands, whose cells nourish the fertilized egg. Beyond the entrance of the duct from the yolk glands the oviduct may be modified to secrete a protective capsule around the egg before it is discharged to the outside. The male organs consist of testes, from which extend numerous tubules (vasa efferentia) that unite to form a sperm duct (vas deferens); the latter becomes an ejaculatory duct through which sperm are released to the outside. The sperm duct may exhibit expanded areas that store sperm (seminal vesicles), and it may be surrounded by prostatic cells that contribute to the seminal fluid. The sperm duct eventually passes through a copulatory organ. The same basic structural pattern, somewhat modified, is found in most higher invertebrates.

Aschelminthes (roundworms) are mostly dioecious; frequently there are external differences between males and females (sexual dimorphism). The males are generally smaller and often have copulatory spicules. Nematodes have relatively simple reproductive organs, a tubular testis or ovary being located at the end of a twisted tube. The portion of the female tract nearest the ovary forms a uterus for temporary storage of fertilized eggs. Some species lay eggs, but others retain the egg in the uterus until the larva hatches. The sperm are released into a cav-

ity called the cloaca. A number of free-living nematodes are capable of sex reversal—if the sex ratio in a given population is not optimal or if environmental conditions are not ideal, the ratio of males to females can be altered. This sometimes results in intersexes; *i.e.*, females with some male characteristics. Hermaphroditism occurs in nematodes, and self-fertilization in such species is common. Unisexual reproduction among rotifers is described below (see *Parthenogenesis*).

Annelids and mollusks. Annelids have a well-developed body cavity (coelom), a part of the lining of which gives rise to gonads. In some annelids, gonads occur in several successive body segments. This is true, for example, in polychaetes, most of which are dioecious. Testes and ovaries usually develop, though not invariably, in many body segments; and the sperm and eggs, often in enormous numbers, are stored in the coelom. Fertilization is external. In oligochaetes (all of which are monoecious) on the other hand, the gonads develop in a few specific segments. Sperm are stored in a seminal vesicle and eggs in an egg sac, rather than in the coelom. A portion of the peritoneum, the membrane lining the coelom, becomes a saclike seminal receptacle that stores sperm received from the mate. The earthworm, *Lumbricus terrestris*, is an example of a specialized annelid reproductive system. Female organs consist of a pair of ovaries in segment 13; a pair of oviducts that open via a ciliated funnel (*i.e.*, with hairlike structures) into segment 13 but open to the exterior in segment 14; an egg sac near each funnel; and a pair of seminal receptacles in segment 9 and another in segment 10. Male organs consist of two pairs of minute testes in segments 10 and 11, each associated with a ciliated sperm funnel leading to a tiny duct, the vas efferens. The two ducts on each side lead to a vas deferens that opens in segment 15. Testes and funnels are contained within two of three pairs of large seminal vesicles that occupy six body segments. Leeches (Hirudinea), also monoecious,

have one pair of ovaries and a segmentally arranged series of testes with duct systems basically similar to those of earthworms.

Although mollusks have a close evolutionary kinship to annelids, they have reduced or lost many structures characteristic of segmented worms. The coelom persists only as three regional cavities: gonadal, nephridial (kidney), and pericardial (heart). In ancestral forms these were interconnected so that gametes from the gonad passed through the pericardial cavity, the nephridial cavity, then to the outside through a nephridial pore. The various groups of mollusks have tended to modify this arrangement, with the result that gonads have their own pore; among amphineurans, for example, the sexes are usually separate, and there is one gonad with an associated pore. Gastropods show considerable variability, but generally one gonad (ovary, testis, or ovotestis—a structure combining the functional gonads of both sexes) is located in the visceral hump and connected to the outside by a remnant of the right kidney. In hermaphroditic forms, one duct carries sperm as well as eggs. The gonadal ducts of gastropod females often secrete a protective capsule around the fertilized eggs; in males, the terminal portion of the duct is sometimes contained in a copulatory organ. Pelecypods may be either monoecious or dioecious, but the gonads are usually paired. In mussels and oysters, the gonads open through the nephridial pore, but in clams the reproductive system opens independently. The cephalopods are all dioecious. The single testis or ovary releases its products into the pericardial cavity and this, in turn, leads to a gonopore, the external opening. The oviduct of the squid is terminally modified to form a shell gland. The male system is more complex—the gonoduct leads into a seminal vesicle where a complicated torpedo-shaped sperm case (spermatophore) is secreted and contains the sperm. Spermatophores are then stored in a special structure (Needham's sac) until copulation occurs.

A remarkable characteristic of some mollusks is the ability to alter their sex. Some species are clearly dioecious; however, among the monoecious species there is considerable variability in their hermaphroditic condition. In some species, male and female gonads, although in the same individual, are independent functionally and structurally. In others, an ovotestis produces both sperm and eggs. Oysters display a third condition; young oysters have a tendency toward maleness, but, if water temperature or food availability is altered, some individuals develop into females. Later, a reversal to the male condition may occur. The sexual makeup of an entire oyster population also has a seasonal aspect; in harmony with the group, an individual may undergo several alterations in the course of a year. A similar phenomenon, called consecutive sexuality, occurs in limpets. These gastropods stack themselves in piles, with the younger animals on top. The animals on top are males with well-developed testes and copulatory organs; those in the middle are hermaphroditic; those on the bottom are females, having lost the testes and copulatory organ (penis) by degeneration. A decrease in the number of females in a stack induces males to assume female characteristics, but the transition is retarded when an excess of females is present. The degree of maleness or femaleness is probably controlled in part by environmental and internal factors.

Arthropods. The phylum Arthropoda includes a vast number of organisms of great diversity. Most arthropods are dioecious, but many are hermaphroditic, and some reproduce parthenogenetically (*i.e.*, without fertilization). The primary reproductive organs are much the same as in other higher invertebrates, but the secondary structures are often greatly modified. Such modifications depend on whether fertilization is internal or external, whether the egg or zygote (*i.e.*, the fertilized egg) is retained or immediately released, and whether eggs are provided some means of protection after they have left the body of the female. The mandibulate arthropods (*e.g.*, crustaceans, insects) include more species than any other group and have invaded most habitats, a fact reflected in their reproductive processes.

Crustaceans (*e.g.*, crabs, crayfish, barnacles) are for the most part dioecious. The primary reproductive organs generally consist of paired gonads that open through paired

Differences between mollusk and annelid systems

Reproductive variation among arthropod groups

ventral (bottom side) gonopores. Females often have a seminal receptacle (spermatheca) in the form of an outpocketing of the lower part of the female tract or as an invagination (inpocketing) of the body near the gonopore. Males have appendages modified for clasping the female during copulation or for guiding sperm. A number of groups have members that reproduce parthenogenetically. Branchiopods (e.g., water fleas, fairy shrimp) have simple paired gonads. The female gonopore often opens dorsally (on the back side) into a brood chamber; the male gonopore opens near the anus. Males have appendages for clasping females during copulation. Ostracods, or seed shrimp, have paired, tubular gonads. The eggs may be brooded by the female, or they may be released into the water via a gonoduct and gonopore. The terminal portion of the male gonoduct is enclosed in a single or paired penis. Many species reproduce parthenogenetically. Some experts contend that this is the only method employed, even though functional males may be present in the population. Copepods (e.g., *Cyclops*) have paired ovaries and an unpaired testis. The terminal portion of the oviduct constitutes an ovisac for storage of eggs. The male deposits sperm in a spermatophore that is transferred to the female. Sexual dimorphism is particularly evident among parasitic copepods. Frequently, parasitic females can hardly be recognized as copepods except for the distinctive ovisacs. Males, on the other hand, are free-living and are recognizable as copepods.

The hermaphroditic Cirripedia (e.g., barnacles) are among the exceptions to the generalization that crustaceans are dioecious. It has been suggested that hermaphroditism in barnacles is an adaptation to their sessile, or stationary, existence, but cross-fertilization is more common than self-fertilization. The ovaries lie either in the base or in the stalk of the animal, and the female gonopore is near the base of the first pair of middle appendages (cirri). The testes empty into a seminal vesicle through a series of ducts; from the vesicle extends a long sperm duct within a penis that may be extended to deposit sperm in the mantle cavity of an adjacent barnacle. The terminal portion of the oviduct secretes a substance that forms a kind of ovisac within the mantle cavity, where fertilized eggs undergo early development. Although most barnacles are hermaphrodites, some display a peculiar adaptation in that they contain parasitic dwarf or accessory males. Dwarf males are much smaller than the host barnacle in which they live and are degenerate, except for the testes. In some species they live in the mantle cavity of hermaphroditic forms and produce accessory sperm; in other species only the female organs persist in the host animal, and the accessory male is a necessity.

Amphipods and isopods (e.g., pill bugs, sow bugs), like most crustaceans, are dioecious and have paired gonads. Females of both groups have a ventral brood chamber (marsupium) formed by a series of medially directed (i.e., toward the body midline) plates (oostegites) in the region of the thorax, the region between head and abdomen. Many isopods are parasitic and have developed unusual sex-related activities. Certain species are parasitic on other crustaceans. After a series of molts (i.e., shedding of the body covering) a parasitic larval (immature) isopod attaches to the shell of a crab. If it is the only larva to do so, it increases in size and develops into an adult female. If another larva subsequently attaches, the new arrival becomes a male. It has been demonstrated that the testes of the functioning male larva will change to ovaries if the larva is removed to a new, uninfected host. Thus, the larvae of these species apparently are intersexual and can develop into either sex. This phenomenon, reminiscent of that in mollusks, demonstrates the way in which similar adaptations have evolved in diverse groups of organisms.

The gonads of crabs and lobsters are paired, as are the gonopores. The females of many species have external seminal receptacles on the ventral part of the thorax; those of other species have internal receptacles in the same region. In some species, seminal receptacles are absent, and the male simply attaches a spermatophore to the female. Thus, males either have appendages (gonopods) by which sperm are inserted in the body of the female or

produce spermatophores for sperm transfer. The sexual dimorphism of many decapods can be altered by parasitism. An example of this is the crab that is parasitized by a barnacle. A barnacle infection in male crabs induces the secondary sex characters of the crab to resemble those of a female; however, masculinization does not occur in parasitized females. At each molt a parasitized male crab increasingly resembles a female even though the testes may be completely unaffected. Feminization results from a hormonal alteration of the parasitized crab.

Insects are rarely hermaphroditic, but many species reproduce parthenogenetically (without fertilization). The insect ovary is composed of clusters of tubules (ovarioles) with no lumen, or cavity (Figure 20). The upper portion of each ovariole gives rise to oocytes (immature eggs) that mature and are nourished by yolk from the lower portion. The oviduct leads to a genital chamber (copu-

Parthenogenesis in insects

latory bursa, or vagina), with which are often associated accessory glands and a seminal receptacle. Some accessory glands form secretions by which eggs become attached to a hard surface; others secrete a protective envelope around the egg. The eighth and ninth body segments are often modified for egg-laying. The paired testes consist of a series of seminal tubules that form primary spermatogonia (immature spermatozoa) at their upper ends. As the spermatogonia mature a covering is secreted around them. Eventually they enter a storage area (seminal vesicle). The terminal portion of the male system is an ejaculatory duct that passes through a copulatory organ. A pair of accessory glands, often associated with the ejaculatory duct, contributes to the semen (fluid containing sperm) or participates in spermatophore formation. The ninth body segment and sometimes the tenth bear appendages for sperm transfer. Scorpions and spiders have tubular or saclike gonads; the female system is equipped to receive and store sperm, and, in some species, the female retains the eggs long after fertilization has occurred. Male spiders may have a cluster of accessory glands associated with the terminal portion of the reproductive system for the manufacture of spermatophores, or they may have expanded seminal vesicles for the retention of sperm until copulation takes place. Often specific appendages are adapted for sperm transfer.

Echinoderms and protochordates. Echinoderms (e.g., sea urchins), hemichordates (including acornworms), urochordates (e.g., sea squirts), and cephalochordates (amphioxus) are restricted to a marine habitat. As with many other marine animals, their gametes are shed into the water. In echinoderms, the gonads are generally suspended from the arms directly into the sea; with few exceptions, the sexes are separate. Female starfishes have been known to release as many as 2,500,000 eggs in two hours; 200,000,000 may be shed in a season. Males produce many times that number of sperm. Acornworms reproduce only sexually, and the sexes are generally separate. The gonads lie on each side of the gut as a paired series of simple or lobed sacs. Each opens to the exterior, either directly or via a short duct. The eggs, when shed, are in coiled mucous masses, each of which contains 2,500 to 3,000 eggs.

Gonads in urochordates and cephalochordates

In urochordates and cephalochordates the gonads develop in the wall of a cavity (atrium) that receives respiratory water after it passes over the gills. Gametes are released into the cavity, then carried into the sea by the water flowing from the cavity. Most urochordates are hermaphroditic. One ovary and one testis may lie side by side, each with its own duct to the atrium; some species have many pairs of ovaries and testes. The eggs develop in so-called ovarian follicles consisting of two layers of cells, as in many vertebrates. The inner layer remains with the ovulated, or shed, egg, and the cells become filled with air spaces, which apparently help the eggs to float. Amphioxus, the highest animals lacking vertebral columns, are dioecious. They have 24 or more pairs of ovaries or testes lacking ducts. When ripe, the gonads rupture, spilling their gametes directly into the atrium.

MECHANISMS THAT AID IN THE UNION OF GAMETES

Sponges, coelenterates, flatworms, and aschelminthes. The processes of sperm transfer and fertilization have been documented for only a few species of sponges. Flagellated (*i.e.*, bearing a whiplike strand) sperm are released from the male gonad and swept out of the body and into the water by way of an elaborate system of canals. A sperm that enters another sponge, or the one from which it was released, is captured by a flagellated collar cell (choanocyte). The choanocyte completely engulfs the sperm, loses its collar and flagellum (or "whip"), and migrates to deeper tissue where the egg has matured. The choanocyte containing the sperm cell fuses with the egg, thus achieving fertilization. In freshwater coelenterates, sperm are also released into the water and carried by currents to another individual. Unlike the mechanism in sponges, however, coelenterate eggs arise in the epidermis, or surface tissue, and are exposed to sperm that may be nearby in the water; thus, no intermediate transport cell is needed. Many species of marine coelenterates expel both sperm and eggs into the water, and fertilization takes place there. Some medusoid coelenterates (jellyfish), however, offer some protection to the egg. After leaving the gonad, the egg becomes temporarily lodged in the epidermis on the underside of the organism, where fertilization and early development occur.

In all flatworms, fertilization is internal. Among species with no female duct, sperm are injected, and fertilization occurs in the inner layer of tissue. Most flatworms, however, have an elaborate system of male and female ducts. Generally, the male gonoduct passes through a penis-like organ, and sperm are transferred during copulation. In parasitic species, which often cannot find a mate, self-fertilization serves as the means for reproduction. Sperm and ova unite in the oviduct, which then secretes yolk around the zygote.

Male nematodes (roundworms) are usually equipped with a pair of copulatory structures (spicules) that guide the sperm during copulation. The posterior end of some males also exhibits a lateral (sideward) expansion (copulatory bursa) that clasps the female during copulation. Other males loop their tail around the female in the region of her gonopore. Unlike many other aschelminthes, nematodes have sperm cells that are amoeboid; *i.e.*, their cell contents seem to flow. Some male rotifers have a copulatory organ.

Annelids and mollusks. In some species of annelid polychaetes (marine worms) reproductive activity is synchronized with lunar cycles. At breeding time the body of both sexes differentiates into two regions, an anterior atoke and a posterior epitoke, in which gonads develop. When the moon is in a specific phase, the epitoke separates from the rest of the body and swims to the surface. The female epitoke apparently stimulates the male epitoke to release sperm, and sperm release, in turn, evokes expulsion of eggs. Fertilization is external. So well coordinated is this phenomenon that tremendous numbers of epitokes appear on the surface at about the same time.

Sexually mature oligochaetes have a clitellum, which is a modification of a section of the body wall consisting of a glandular, saddlelike thickening near the gonopores. During copulation, the clitellum secretes a mucus that keeps the worms paired while sperm are being exchanged.

Following copulation, the clitellum secretes substance for a cocoon, which encircles the worm and into which eggs and sperm are deposited. The worm then manipulates the cocoon until it slips off over the head. Thereupon, the ends of the cocoon become sealed, and fertilization and development take place inside. Many leeches also form a cocoon; but the males of some species have a penis that can be inserted into the female gonopore. In other leeches, a spermatophore is thrust into the body of the mate during copulation.

Union of gametes among mollusks is effected in a number of ways. Marine pelecypods synchronously discharge sperm and eggs into the sea; some freshwater clams are apparently self-fertilizing. One of the more unusual types of reproductive diversity occurs in marine gastropods of the family Scalidae that produce two kinds of sperm cells. A large sperm with a degenerate nucleus acts as a transport cell for carrying numerous small fertilizing sperm through the water and into the oviduct of another individual. Cephalopod males have modified arms for the transfer of spermatophores. The right or left fourth arm of the squid, for example, is so modified. Following an often elaborate courtship, the male squid uses the modified appendage to remove spermatophores from their storage place in his body and place them in the mantle cavity of the female. A cementing substance, which is released from the spermatophore, firmly attaches the spermatophore to the female's body near the oviduct. In some species, the male loses the arm. Manipulation of the eggs by the female's arms may also occur.

Some unusual behaviour patterns have evolved in conjunction with sperm transfer in mollusks. Prior to copulation of certain land snails, a dart composed of calcium carbonate is propelled forcefully from the gonopore of each of the mating individuals and lodges in the viscera of the mate. Even though the snails have assumed a mating posture, sperm transfer cannot occur until each snail has been stimulated by a dart.

Arthropods. Arthropods are as varied as mollusks in their methods of effecting union of sperm and eggs. They have relatively few devices for sperm transfer, but many display a high degree of behavioral complexity.

The male and female scorpion participate in a courtship ritual involving complicated manoeuvres. In some species the male produces spermatophores that are anchored to the ground. In the course of the ritual dance the female is positioned over the spermatophore. The male then presses her down until the sperm packet is forced into her genital chamber, where it becomes attached by means of small hooks. Thus, ultimately, fertilization takes place internally.

Among some spiders the male's pedipalp, a grasping or crushing appendage, contains a bulb and an extensible, coiled structure (embolus). As mating begins, the male dips the pedipalp into semen from his gonopore. The embolus is then placed in the female gonopore, and the sperm are transferred to her seminal receptacle. The female deposits the sperm along with her eggs into a silken cocoon, which she attaches to her body or to an object such as a rock or a leaf.

Sperm transfer in copepods, isopods, and many decapods, often preceded by courtship, is effected by modified appendages, gonopods, or spermatophores. Copepods clasp the female with their antennae while placing a spermatophore at the opening of the seminal receptacle. In some decapods fertilization occurs as eggs are being released into the water.

Fertilization among insects is always internal; there is much variation in the manner in which sperm are transferred to the female. Males of some species form spermatophores that are deposited in a copulatory bursa (vagina) of the female; the wall of the spermatophore breaks down, and the sperm swim to the seminal receptacle. In other species, sperm are introduced directly into the seminal receptacle by an intromittent organ. In still others, sperm, but no spermatophores, are deposited in the copulatory bursa and migrate to the seminal receptacle. In all instances, sperm are retained in the seminal receptacle until after fertilization. An exception to the usual route of sperm transfer occurs in insects that inject sperm into

Sexual behaviour among mollusks

the female's hemocoel (*i.e.*, the space between the body organs). The sperm then migrate to the ovary and oviduct and unite with eggs before the eggshell is formed.

PARTHENOGENESIS

Most frequently, parthenogenesis is the development of a new individual from an unfertilized gamete. Often referred to as unisexual reproduction, it has been observed in almost every major invertebrate group, with the exception of protochordates (including hemichordates), and frequently occurs alternately with bisexual reproduction (reproduction by union of gametes). Some species, in which males are completely unknown, apparently reproduce only by parthenogenesis. Species that alternate between parthenogenesis and bisexual reproduction (heterogenetic species) often do so in response to changes in population density, food availability, or other environmental conditions.

Examples
of
partheno-
genetic
reproduc-
tion

The best known examples of parthenogenetic reproduction are found among rotifers. Males are completely unknown in some genera; in others, they appear in the population only for brief periods and more or less seasonally. Females are the dominant form or are the only sex present in a population throughout most of the year. Because no reductional division (meiosis) occurs in the course of egg maturation, the eggs are diploid—that is, they have the full number of chromosomes; they give rise to new diploid individuals with no chromosomal contribution from a male gamete (diploid parthenogenesis). Even if males were present, sperm could not fertilize the eggs because the latter are already diploid. Under conditions of environmental stress such as seasonal changes, some females form eggs that undergo reductional division, resulting in eggs with the haploid number of chromosomes; such eggs must be fertilized by a male gamete to produce a new female. When the new individual matures, it will probably reproduce parthenogenetically. If, however, there are no males in the population, the haploid eggs can develop into haploid males (haploid parthenogenesis), which then participate in bisexual reproduction. Bisexually produced eggs are often referred to as winter eggs since they have a thick covering that protects the embryo during adverse environmental conditions. Summer eggs, produced parthenogenetically, are thin shelled. Bisexual reproduction occurs, therefore, only often enough to ensure survival of the species.

Nematodes, especially free-living species such as some dioecious soil nematodes, exhibit a type of parthenogenesis known as gynogenesis. In this type of reproduction, the sperm produced by males do not unite with the haploid female egg but merely activate it to begin development. The result is haploid females.

Parthenogenesis, which apparently occurs only rarely in the annelids and mollusks, is found more frequently among the arthropods. The cladocerans (*e.g.*, water fleas), for example, have a reproductive cycle much like that of rotifers—so long as environmental conditions are optimal and food is plentiful, females produce other females by diploid parthenogenesis. When conditions become adverse, males begin to appear in the population, and bisexual reproduction follows. The precise trigger for the appearance of males is not yet known. Fertilized eggs, covered with a highly resistant case, enter a resting stage (ephippium) and can withstand severe temperatures and drying out. The return of favourable conditions leads to the emergence of females that reproduce parthenogenetically. The ability to form a resting stage regulates population density. Whenever the food supply becomes short because of overpopulation by parthenogenetic females, bisexual reproduction is induced, and a dormant stage ensues. During periods of food shortage, the excess females die from lack of food, but the ephippia remain to restore the population.

Insects provide numerous examples of parthenogenesis of varying degrees of complexity. One of the most notable is that of the honeybee. Unfertilized eggs develop into drones, which are males. Fertilized eggs become worker females, which are kept in a nonreproductive state by secretions from the reproductive female, the queen bee.

Life cycles involving alternation between parthenogenesis and bisexual reproduction can be found in many species

of Homoptera and Diptera (flies). Aphids (Homoptera) have a seasonal cycle consisting of a bisexual winter phase and a parthenogenetic summer phase; some species spend each phase on a different host plant. Temperature change, length of day, and food availability play major roles in initiating the phases. In the midge, a type of fly, the bisexual phase occurs in adults, and parthenogenesis takes place among the larvae (paedogenesis). Adult female midges deposit fertilized eggs, from which hatch larvae whose ovaries develop while the rest of the body retains a larval form. The ovaries of the larvae release eggs that enter the larval hemocoel (the space between body organs), where they undergo development while feeding on larval tissue. When sufficiently developed, the parthenogenetically produced young emerge either as larvae that continue parthenogenetic reproduction, forming larvae like themselves, or as male or female larvae that mature to become bisexually reproducing adults.

PROVISIONS FOR THE DEVELOPING EMBRYO

Invertebrates have developed a great many methods for protecting the fertilized egg and young embryo and for providing nutrients for the developing young. This is especially true of freshwater and terrestrial forms. Sponges and freshwater coelenterates, exposed to seasonal drying out, provide a tough covering for the eggs that prevents water loss. Many turbellarians envelop the eggs with a capsule and attach it to a hard surface, where it remains until the young emerge. Other turbellarians retain encapsulated eggs in the body until development is complete and the young emerge. All parasitic flatworms enclose their eggs in a protective capsule within which development occurs after it has left the parent's body. Most nematodes and rotifers do likewise, but a few species are ovoviviparous; *i.e.*, the egg hatches in the mother's body. In many forms the amount of yolk provided in the egg and the nature of the egg capsule are correlated with annual seasons—summer eggs generally have less yolk and thinner capsules than do winter eggs. This is true also in a number of crustaceans. Freshwater and terrestrial annelids provide a cocoon for their young and often deposit it in a moist place. One group of leeches, however, does not form a cocoon; instead, the egg, surrounded by a protective membrane, is attached to the underside of the parent. As the young develop, the adult leech undulates its body so that water currents flow over the young. Presumably this serves as a means of aeration. Mollusks that live in freshwater may provide a protective covering for the eggs, or the eggs may be brooded by the female. Some pelecypods (bivalves) release mature eggs into their gill chambers; here the eggs are fertilized, and embryonic development is completed in a protected location. Cephalopods (*e.g.*, squid, octopus) attach the eggs to a surface, then continuously force jets of water over the egg masses, thereby keeping them free of debris and perhaps aerating them. Some echinoderms also brood the eggs until the young emerge.

Arthropods have a particularly wide range of methods for ensuring offspring survival. Brood pouches, common in branchiopods, isopods, and amphipods, are sometimes part of the carapace, or back plate. In other instances, expanded plates on the lower side (sternum) form the pouches. Crayfish cement the fertilized eggs to their swimmerets (modified appendages) and carry them about as they are brooded by the female. The most elaborate provisions for the embryo are found among terrestrial arthropods, especially insects. Although some species simply deposit their eggs and abandon them, many retain the encapsulated egg within the body during early development. Some are viviparous; that is, they bear living young. The eggs of certain species of scorpions have little or no yolk; the embryo is nourished by the parent in a manner similar to that in mammals—part of the scorpion oviduct becomes modified as a uterus for the embryo; another part lies close to the female's gut and absorbs nutritive substances that are conveyed to the developing young. A similar arrangement has evolved in some insects. Other viviparous insects nourish the larvae by glandular secretions from the uterine lining.

in amount
of yolk

Reproductive systems of vertebrates

GONADS, ASSOCIATED STRUCTURES, AND PRODUCTS

The reproductive organs of vertebrates consist of gonads and associated ducts and glands. In addition, some vertebrates, including some of the more primitive fishes, have organs for sperm transfer or ovipository (egg-laying) organs. Gonads produce the gametes and hormones essential for reproduction. Associated ducts and glands store and transport the gametes and secrete necessary substances. In addition to these structures, most male and female vertebrates have a cloaca, a cavity that serves as a common terminal chamber for the digestive, urinary, and reproductive tracts and empties to the outside. In lampreys and most ray-finned fishes in which the cloaca is small or absent, the alimentary canal has a separate external opening, the anus. In some teleosts the alimentary, genital, and urinary tracts open independently. Hagfishes, which are closely related to the lampreys, have a short cloaca. In many vertebrates other than mammals, especially reptiles and birds, the cephalic, or head, end of the cloaca is partitioned by folds into a urinogenital chamber (urodeum) and an alimentary chamber (coprodeum) that open into a common terminal chamber (proctodeum). Above monotremes (e.g., platypus, echidna) the embryonic cloaca becomes completely partitioned into a urinogenital sinus conveying urine and the products of the gonads, and an alimentary pathway; the two open independently to the exterior.

Embryonic development of gonads Gonads arise as a pair of longitudinal thickenings of the coelomic epithelium and underlying mesenchyme (unspecialized tissue) on either side of the attachment of a supporting membrane, the dorsal mesentery, to the body wall. At first, gonadal ridges bulge into the coelom and are continuous with the embryonic kidney. The germinal epithelium covering the gonadal ridges gives rise to primary sex cords (medullary cords) that invade the underlying mesenchyme. These cords establish within the gonadal blastema (a tissue mass that gives rise to an organ) a potentially male component, the medulla. Secondary sex cords grow inward, spreading just beneath the germinal epithelium to form a cortex. If the gonad is to become a testis, only the medullary component differentiates. If the gonad is to become an ovary, only the cortex differentiates.

The length of an adult gonad depends, in part, upon the extent of gonadal-ridge differentiation. In cyclostomes (lampreys and hagfish), elasmobranchs (sharks, skates, and rays), and teleosts most of it differentiates, and the gonads extend nearly the length of the body trunk. In tetrapods (amphibians, reptiles, birds, and mammals), the cranial portion, at the anterior end, generally does not differentiate; in toads only the more caudal, or posterior, portion does so. The middle segment in toads of both sexes gives rise to a Bidder's organ containing immature eggs. In anurans (frogs and toads) and some lizards of both sexes, one segment of the gonadal ridge gives rise to yellow fat bodies that, especially in anurans, diminish in size just prior to the breeding season. In mammals, only the middle portion of the gonadal ridge differentiates.

Some vertebrate species have only one gonad, which may lie in the midline or on one side; the condition is more common among females. Adult cyclostomes of both sexes have one gonad. In lampreys it is in the middle of the body; in hagfishes it is on the right side. Birds are the only other major group of vertebrates in which most females have one gonad, the right ovary being typically absent. Male birds have a pair of testes, however. Exceptions to the condition of single ovaries among birds include members of the falcon family, in which more than 50 percent of mature hawks have two well-developed ovaries. In all bird species a small percentage of females probably have two ovaries; reported instances include owls, parrots, sparrows, and doves, with estimates for doves ranging from 5 percent to 25 percent. A few teleosts and viviparous elasmobranchs have only one ovary; in sharks the right one is usually present, in rays, the left. In amniotes (i.e., reptiles, birds, and mammals) unpaired gonads are unusual. Some lizards have one testis, and some female crocodiles have one ovary. Among mammals, the platypus usually has

only a left ovary, and some bat species (family Vespertilionidae) have only the right.

One of two explanations may account for unpaired gonads: the paired embryonic gonadal ridges may fuse to form a median gonad—as in lampreys and the perch—or only one gonadal ridge may receive immigrating primordial germ cells (immature sperm or eggs), with the result that the opposite gonad does not develop—as in chickens and ducks. Both gonadal ridges have been reported to exhibit an equal number of primordial germ cells in embryonic hawks, and these typically have two ovaries.

Among lower vertebrates, mature gonads sometimes produce both sperm and eggs. Hermaphroditism is more general in cyclostomes and teleosts than in other fishes. A teleost may function as a male during the early part of its sexual life and as a female later. In some teleost families sperm and eggs mature simultaneously but in different regions of the gonad. These fish normally function as males during one season and as females the next. Cyclostomes generally are ambisexual during juvenile life—i.e., immature male and female sex cells exist side by side, or, as in *Myxine*, the anterior part of the immature gonad may be ovary and the caudal part, the testis. It is thought that cyclostomes normally become unisexual at maturity. Hermaphroditism is uncommon among amphibians, although it frequently occurs as an anomaly. In vertebrates above amphibians, true hermaphroditism probably does not exist.

Both male and female duct systems are occasionally absent. In cyclostomes, a few elasmobranchs, and some teleosts, such as salmon, trout, and eels, the gametes are propelled toward the posterior within the coelom, often by cilia (minute hairlike structures), and exit via a pair of funnel-like genital pores near the base of the tail. In cyclostomes, the pores lead to a sinus, or cavity, within a median papilla (i.e., a fingerlike structure) and are open only during breeding seasons.

Male systems. Testes. In anurans, amniotes (reptiles, birds, and mammals), and even some teleosts, testes are composed largely of seminiferous tubules—coiled tubes, the walls of which contain cells that produce sperm—and are surrounded by a capsule, the tunica albuginea. Seminiferous tubules may constitute up to 90 percent of the testis. The tubule walls consist of a multilayered germinal epithelium containing spermatogenic cells and Sertoli cells, nutritive cells that have the heads of maturing sperm embedded in them. Seminiferous tubules may begin blindly at the tunic, or outermost tissue layer, and pass toward the centre, becoming tortuous before emptying into a system of collecting tubules, the rete testis. Such an arrangement is characteristic of frogs. In certain amniotes—the rat, for example—the tubules may be open ended, running a zigzag course from the rete to the periphery and back again. The average length of such tubules is 30 centimetres (12 inches), and they seldom communicate with each other. In many mammals the tubules are grouped into lobules separated by connective-tissue septa, or walls. The arrangement permits the packing of an extensive amount of germinal epithelium into a small space. In immature males and in adult males between breeding seasons, the tubules are inconspicuous and the epithelium is inactive; in some species, however, spermatogenesis, or production of sperm, proceeds at a variable pace throughout the year. An active epithelium may exhibit all stages of developing sperm. The lumen, or tubule cavity, contains the tails of many sperm (the heads of which are embedded in Sertoli cells), free sperm, and fluid that is probably resorbed. In mammals, in any single zone along a tubule, all sperm are at the same stage of maturation; adjacent zones contain different generations of sperm, and a period of sperm formation and discharge is followed by an interval of inactivity.

In cyclostomes, most fishes, and tailed amphibians the germinal epithelium is arranged differently. Instead of seminiferous tubules there are large numbers of spermatogenic cysts (also called spermatocysts, sperm follicles, ampullae, crypts, sacs, acini, and capsules) in which sperm develop, but in which the epithelium is not germinal. Spermatogenic cells migrate into the cysts from a per-

Theories about unpaired gonads

Seminiferous tubules

manent germinal layer, which, depending on the species, may lie among cysts at the periphery of the testes or in a ridge along one margin of the testis. After invading the thin nongerminal epithelium of a cyst, spermatogenic cells multiply, producing enormous numbers of sperm. The cysts become greatly swollen and whitish in colour; the entire testis also swells and has a granular appearance. As sperm mature, they separate from the epithelium and move freely in the cystic fluid. Finally, the cysts burst, and the sperm are shed into ducts. In the case of cyclostomes and a few teleosts the sperm are shed into the coelom. The cysts, totally emptied, collapse. Then either they are replaced by new ones, or they become repopulated by additional spermatogenic cells. It is not yet known which of these processes occurs.

Testicular stroma, which fills the spaces between seminiferous tubules or spermatogenic cysts, consists chiefly of connective tissue, blood and lymphatic vessels, and nerves; it is more abundant in some vertebrates than in others. Glandular Leydig (interstitial) cells are also present in most, if not all, vertebrates. Thought to be a primary source of androgens, or male hormones, Leydig cells are not always readily distinguishable, and, in some bird species, they may be seen only with the electron microscope. The capillary system of the rat testis, and probably that of many other vertebrates, is such that blood that has bathed the Leydig cells flows to the tubules; it is thus probable that Leydig cell hormones have an immediate effect on the germinal epithelium.

Location of testes in mammalian orders

Testes in vertebrates below mammals lie within the body. This is also true of many, sometimes all, members of the mammalian orders Monotremata, Insectivora, Hyracoidea, Edentata, Sirenia, Cetacea, and Proboscidea. Some male mammals—most marsupials, ungulates, carnivores, and primates after infancy—have a special pouch (scrotum) that the testes occupy permanently. A few mammals have a pouch into which the testes descend and from which they can be retracted by muscular action. These include a few rodents such as ground squirrels; most, if not all, bats; and some primitive primates (loris, potto). The scrotum consists of two scrotal sacs, each connected to the abdominal cavity by an inguinal canal lined with the peritoneal membrane. The canals are the path of descent (and retraction) of the testes to the sacs. In descending, the testes carry along a spermatic duct, blood and lymphatic vessels, and a nerve supply wrapped in peritoneum and constituting, collectively, the spermatic cord. Rabbits, most rodents, and some insectivores, which lack scrotal sacs, have instead a wide inguinal canal into which the testes may be drawn and from which they are retracted when in danger of injury. In these mammals, descended testes cause a temporary bulge in the perineal region (*i.e.*, between the anus and the urinogenital opening). In a small number of mammals, the testes permanently occupy the perineal location.

The scrotum is a temperature-regulating device. Warm blood approaching the testis comes close to the vessels carrying cool blood leaving the testis, so that the blood approaching the testis is cooled; the vessels form an intricate vascular network (pampiniform plexus) within the spermatic cord. Failure of both testes to enter the scrotal sacs (cryptorchidism) results in permanent sterility. In cold weather two sets of muscles, the dartos and cremasteric, pull the testes close to the body. The dartos lies between the two scrotal sacs and is attached to the scrotal skin. The cremaster, wrapped around the spermatic cord, is an extension of the abdominal wall musculature. It retracts the testis. Birds, like mammals, are homoiothermic (warm-blooded), and their testes are near air sacs (extensions of incumbent respiratory tubes). Air in the sacs may help regulate the temperature of the testes.

Ducts. The male duct system begins as the rete testis, a network within the testis of thin-walled ductules, or minute ducts, that collects sperm from the seminiferous tubules. The rete is drained by a number of small ducts—usually fewer than ten—called the vasa efferentia, which are modified kidney tubules. In some fishes and amphibians the vasa efferentia connect the testes with the cranial (anterior) end of the kidneys (Figure 21). In anamniotes

Figure 21: Reproductive systems of two male amphibians. (Left) The sexual kidney is composed of one row of modified tubules that are ciliated for sperm transport and drain into the adult (mesonephric) kidney duct. This duct also collects urine from the kidney. (Right) The mesonephric duct collects only sperm.

(Left and right) From George C. Kent, Jr., *Comparative Anatomy of the Vertebrates*, 2nd ed. (1969); The C.V. Mosby Co., St. Louis. (Left) redrawn from C.J. Baker and W.W. Taylor, *Journal of the Tennessee Academy of Science*, vol. 39, no. 1 (1964).

(*e.g.*, fish and amphibians), therefore, except teleosts, the ducts that drain the kidneys usually drain the testes also. In most amphibians these ducts pass caudad, or posteriorly, to empty independently into the cloaca; in some fishes they pass through a median urinogenital papilla.

Although drainage of the testis and the kidney by the same duct is a basic pattern, there has been a tendency in many vertebrates toward separate spermatic and urinary ducts. This tendency is manifested in one of two ways among anamniotes. In many sharks and in some amphibians (Plethodontidae, Salamandridae, Ambystomatidae), the embryonic kidney duct ultimately drains the testis, and one or more new ducts (ureters) drain the adult kidney. On the other hand, in the primitive fish *Polypterus* and in most teleosts, the embryonic kidney duct drains the adult kidney, and a new duct arises to drain the testis. Many degrees of separation of the two ducts occur in anamniotes, from the condition of the sturgeon, in which the spermatic duct unites with the urinary duct far toward the head, to the condition in *Esox* (a pike), in which spermatic and urinary ducts empty independently to the exterior.

In amniotes, the mesonephric kidney is a temporary structure confined to the embryo, but the mesonephric duct persists in the adult male as a sperm duct. A separate ureter drains the adult kidney. The spermatic and urinary ducts empty independently into the cloaca except in mammals above monotremes, in which they are confluent with the urethra. The epididymis of amniotes, a highly tortuous duct draining the vasa efferentia, usually serves as a temporary storage place for sperm; it is small in birds and large in turtles. In mammals, the first part of the epididymis consists of a head, body, and tail that wrap around the testis; it gradually straightens to become the spermatic duct. The epididymis secretes substances that prolong the life of stored sperm and increase their capacity for motility.

In all vertebrates certain regions of the spermatic duct are lined by cilia and a variety of secretory epithelial cells. One end may enlarge to form a sperm reservoir or secrete seminal fluid. In the catfish *Trachycorystes mirabilis* secretions of the spermatic duct form a gelatinous plug in the female similar to the vaginal plug of mammals. A seminal glomulus in birds functions as a sperm reservoir. In some mammals an enlargement of the spermatic duct called the ampulla contributes to the seminal fluid and stores sperm. Small mucous glands (of Littre) and other glandular structures open into the urethra along its length. Cloacal glands in basking sharks and many salamanders form a jelly that encloses sperm in a spermatophore. Cloacal glands of some lizards produce secretions called pheromones. The siphon sac of elasmobranchs is one of

Sperm storage

the few accessory sex glands that is a separate organ in animals below mammals. It extends as an elongated pocket into the pelvic fin and secretes a nutritive mucus that enters the female reproductive tract with sperm.

Accessory glands. Accessory sex glands that are conspicuous outgrowths of the genital tract are almost uniquely mammalian. The major mammalian sex glands include the prostate, the bulbourethral, and the ampullary glands, and the seminal vesicles. All are outgrowths of the spermatic duct or of the urethra (Figure 22) and all four

From George C. Kent, Jr., *Comparative Anatomy of the Vertebrates*, 2nd ed. (1969); The C.V. Mosby Co., St. Louis

Figure 22: Accessory sex organs of a male golden hamster. Bulbourethral glands arise more toward the tail end and are not shown. The bladder and urethra have been opened to show entrances of ducts.

occur in elephants and horses and in most moles, bats, rodents, rabbits, cattle, and primates. A few members of these groups lack ampullary glands, or ampullary glands and seminal vesicles. Cetaceans (whales, porpoises) have only the prostate, as do some carnivores, including dogs, weasels, ferrets, and bears.

The prostate, the most widely distributed mammalian accessory sex gland, is absent only in *Echidna* (a marsupial) and a few carnivores. It empties into the urethra by multiple ducts. Many rodents, insectivores, and lagomorphs have three separate prostatic lobes; in a few mammals (some primates and carnivores) the prostate is a single mass with lobules and encircles the urethra at the base of the bladder. In a few mammals (e.g., opossum), the prostate is not a compact mass but a partly diffuse gland. In many rodents (e.g., rat, guinea pig, mouse, hamster) and some other mammals, the semen coagulates quickly after ejaculation as a result of a secretion from a male coagulating gland, which is usually considered part of the prostatic mass. Coagulated semen forms a vaginal plug that temporarily prevents copulation.

Bulbourethral (Cowper's) glands arise from the urethra near the penis and are surrounded by the muscle of the urethra or penis. Typically, there is one pair, but as many as three (marsupials) may be found. The glands, small in man, large in rodents, elephants, and some ungulates including pigs, camels, and horses, are absent in cetaceans, mustelids (e.g., mink, weasel), sirenians (manatees, dugongs), pholidotans (pangolins), some edentates, and carnivores such as walrus, sea lion, bear, and dog.

Although many mammals have an ampullary swelling on the spermatic duct near the urethra, only a small number form a separate ampullary gland as an outgrowth of the duct. It is very large in some bats, absent in many mammalian orders, and variable in the rest. Although common in rodents, it is absent in guinea pigs and some strains of mice.

Seminal vesicles are paired, typically elongated and coiled fibromuscular sacs that empty into either the spermatic duct or the urethra. Absent in monotremes, marsupials, carnivores, cetaceans, and in some insectivores, chiropterans, and primates, seminal vesicles are exceptionally large in rhesus monkeys and small in man. They are absent in domesticated rabbits, small or rudimentary in cottontails, large in armadillos, and variable in sloths. They contribute the sugar fructose and citric acid to the semen but do not serve as sperm reservoirs.

Female systems. *Ovaries.* Ovaries lie within the body cavity and are suspended by a dorsal mesentery (mesovar-

ium), through which pass blood and lymph vessels and nerves. Primitive vertebrate ovaries occur in the hagfish, in which a mesentery-like fold of gonadal tissue stretches nearly the length of the body cavity. Unique in the hagfish is the fact that functional ovarian tissue occupies only the forward half of the gonadal mass, the rear part containing rudimentary testicular tissue. In most fishes except very primitive forms, the ovaries are similarly elongated. In tetrapods other than mammals, the ovaries are usually confined to the middle third or half of the body cavity, particularly during nonbreeding seasons. The ovaries of mammals undergo moderate caudal displacement, finally coming to lie between the kidney and the pelvis.

The appearance of an ovary depends on many factors—e.g., whether one egg or thousands are discharged (ovulated); whether the eggs are immature or ripe; whether mature eggs are small or large; or whether pigments occur in the egg cytoplasm, such as those responsible for yellow yolk. Other factors also affect the appearance of the ovary: the season of the year in seasonal breeders (the ovary enlarges during breeding seasons, diminishes in size between seasons); the age of the animal (whether juvenile, reproductively active, or senile, particularly in birds and mammals); and the fate of ovulated, or discharged, egg follicles, or sacs.

The ovaries are covered with a germinal epithelium that is continuous with the peritoneum lining the body cavity. The term germinal epithelium is inappropriate because in most adults it contains no germ cells, these having moved deeper into the ovary. In hagfishes and amphibians, cells that give rise to eggs are known to occur in the germinal epithelium, and it may be that the germinal epithelium in a few other vertebrates contains similar cells. The germinal epithelium undergoes cell division, however. This is particularly true of species in which enormous expansion of the ovary occurs each breeding season. Beneath the epithelium is a layer of connective tissue, the tunica albuginea, which is much thinner than that surrounding the testes.

A typical vertebrate ovary consists of cortex and medulla. The cortex, immediately internal to the tunica albuginea, contains future eggs and, at one time or another, eggs in ovarian follicles (i.e., developing eggs); it undergoes fluctuations in size and appearance that correlate with stages of the reproductive cycle. The cortex also contains remnants of ovulated follicles and, in mammals, clusters of interstitial cells that, in some species, are glandular. The cortical components are embedded in a supportive framework of connective, vascular, and neural tissue constituting the stroma. Internal to the cortex is the medulla, consisting of blood and lymph vessels, nerves, and connective tissue. The medulla, which contains no germinal elements, exhibits no significant cyclical activity, is usually inconspicuous, is continuous with the dorsal mesentery, and, in cyclostomes, is hardly distinguishable from the latter. The mammalian medulla, on the contrary, is almost completely surrounded by cortex and converges on the mesovarium (i.e., the part of the peritoneum that supports the ovary) at a narrow hilus, at which nerves and vessels enter the ovary. In the medulla of the mammalian ovary near the hilus are small masses of blind tubules or solid cords—the rete ovarii—which are homologous (i.e., of the same embryonic origin) with the rete testis in the male. The microscopic right ovary of birds usually consists only of medullary tissue.

Ovaries are characterized as saccular, hollow, lacunate (i.e., compartmented), or compact. The ovary of many teleosts, especially viviparous ones, contains a permanent cavity, which is formed during ovarian development when an invagination of the ovarian surface traps a portion of the coelom. The cavity is therefore unique in that it is lined by germinal epithelium. The lining develops numerous ovigerous folds that project into the lumen and greatly increase the surface area for proliferation of eggs. In most other teleosts, a temporary ovarian cavity develops after each ovulation, when the shrinking cortex withdraws from the outside ovarian wall along one side of the ovary. The resulting cavity is obliterated as eggs of the next generation enlarge. The permanent and temporary cavities of teleost ovaries and a similar cavity in garfish ovaries are

Characteristics of the ovary

The prostate gland

continuous with the lumen of the oviduct, and eggs are shed into them. The ovaries of other fishes lack cavities and are characterized as compact. The amphibian ovary, which contains six or more central, hollow sacs that give it a lobed appearance, is characterized as saccular. The sacs are formed when the embryonic medullary and rete cords become hollow and coalesce. Maturing eggs bulge into the sacs but are not shed into them. The ovaries of reptiles, birds, and monotremes have cavities homologous to those in amphibians; the number of medullary spaces in the adults is considerably larger, however, so that the ovaries contain an extensive network of fluid-filled cavities (lacunae). Such ovaries are characterized as lacunate. The ovaries of mammals above monotremes are compact, having no medullary cavities.

Formation
and fate
of ovarian
follicles

An ovarian follicle consists of an oocyte, or immature egg, surrounded by an epithelium, the cells of which are referred to variously as follicular, nurse, or granulosa cells. In cyclostomes, teleosts, and amphibians, the epithelium is one layer thick. In the hagfish and those vertebrates in which the oocyte receives heavy deposits of yolk (elasmobranchs, reptiles, birds, and monotremes), the epithelium appears to be two cells thick, apparently the result of layering of nuclei in a simple columnar epithelium (*i.e.*, epithelium consisting of relatively "tall" cells). Above monotremes the follicular epithelium appears to be many cells thick; in at least one species, however, this is considered an artifact, and all granulosa cells are said to extend between the outer boundary of the epithelium and the oocyte.

The follicular epithelium originates as a few flattened cells derived from the germinal epithelium. Primary follicles are usually situated just under the tunica albuginea; secondary follicles lie deeper in the cortex. The primitive role of the follicular cells appears to be the secretion of the yolk-forming material onto or into the oocyte. Evidence from mammals indicates that the follicular cells may also have a role in converting substances produced elsewhere into female hormones, or estrogens. In some hibernating bats the granulosa cells are filled with glycogen, or animal starch, which may be a source of energy. Mammalian follicles above monotremes are unique in that they develop a fluid-filled cavity (antrum) within the granulosa layer. During antrum formation cell division of the granulosa cells increases, and fluid-filled spaces develop among the cells. The spaces coalesce to form the antrum. Under the influence of pituitary gonadotropic hormones, many antral follicles thereafter continue to grow, forming large so-called Graafian follicles—less than 400 microns, or 0.4 millimetre (0.16 inch), in diameter in large mammals, 150–200 microns, or 0.15–0.2 millimetre (0.006–0.008 inch), in small ones. Graafian follicles contain mature eggs and appear as large blisters on the ovary. At this stage the ovum, suspended within the fluid of the antrum (liquor folliculi) by a slender stalk of granulosa cells, is surrounded by a cluster of these cells, the cumulus oophorus, or discus proligerus. The remaining follicular cells form a thin wall surrounding the antrum. Antra are lacking in a few insectivores (*Hemicentetes*, *Euriculus*) because the granulosa cells swell and multiply to form corpora lutea, masses of yellow tissue. In the bat *Myotis* the antrum is likewise compressed and disappears just before discharge of the egg, or ovulation.

In all vertebrates, oocytes that have begun to grow and mature may, at any time until just before ovulation, cease development and undergo atresia, or degeneration. This is a normal process that reduces the number of eggs ovulated. In small laboratory rodents, atresia takes place in 50 percent of the Graafian follicles in each ovary one or two days before ovulation, thus reducing the number of ovulatable eggs by 50 percent. A similar reduction takes place in hagfish prior to ovulation. Atretic follicles eventually become lost in the stroma of the cortex of the ovary. In mammals especially, follicles lacking oocytes and antra, called anovular follicles, as well as polyovular follicles (*i.e.*, containing more than one oocyte), occasionally occur.

The theca

The ovarian follicle of vertebrates, commencing with hagfish, is surrounded by a theca, or sheath, composed of two concentric layers of stromal cells. The outer layer

(theca externa) is chiefly connective tissue but may contain smooth muscle fibres. The inner layer (theca interna) has more blood vessels and, in vertebrates that produce heavily yolked eggs, the largest vessels carry venous blood. In these species the cell membranes of the oocyte and granulosa cells have many microvilli (*i.e.*, fingerlike projections), which probably facilitate transport of substances important in yolk formation from the blood vessels to the egg. Mature follicles in the marsupial *Dasyatus* are said to lack theca, and in some bats only one thecal layer has been described.

During the growth phase, eggs in species with massive amounts of yolk may increase in size 10^6 (1,000,000) or more times as a result of vitellogenesis (deposit of yolk). In goldfish, on the other hand, when vitellogenesis commences, the egg has a diameter of 150 microns (0.15 millimetre [0.006 inch]); that of the mature egg is only 500 microns (0.5 millimetre [0.02 inch]). Mammalian eggs contain little yolk and vary little in size. Oogonia (*i.e.*, cells that form oocytes) of the golden hamster average 15 microns (0.015 millimetre [0.0006 inch]) in diameter, and eggs in Graafian follicles average 70 microns (0.07 millimetre [0.003 inch]). The mature eggs of horses and humans are approximately the same size—somewhat less than 150 microns. In seasonally breeding oviparous fishes and amphibians, all eggs are usually in the same stage of development, and the ovary grows to a mature state quite rapidly as a result of growth of the eggs, which frequently number more than 1,000,000. Such ovaries distend the body wall when mature; following spawning, the ovaries shrink rapidly to inconspicuous bodies consisting mainly of oogonia, immature oocytes, and a few stromal cells. In reptiles and birds, ovarian weight also is high in proportion to body weight during egg-laying seasons. The weight of the ovary of the starling, for example, may increase from eight milligrams in early winter to 1,400 milligrams immediately before ovulation. The mature eggs of reptiles and birds are unique in that they are suspended from the ovary by a short stalk (pedicle). The stalk contains a cortex with additional oocytes in various stages of development and extensions of vessels and nerves. Full growth of the follicle in reptiles and birds requires only a few days or weeks (nine days in the domestic hen). In mammals, the ratio of ovarian weight to body weight varies insignificantly throughout the reproductive life of the female, and follicles in many stages of development are constantly present.

Vertebrate eggs are almost universally shed into the coelom or into a subdivision thereof, from which they enter the female reproductive tract. Even in those teleosts in which the eggs are shed into an ovarian cavity, the latter is often of coelomic origin. In many mammals a membranous sac of peritoneum, the ovarian bursa, traps part of the coelom in a chamber along with the ovary. The bursal cavity (periovarian space) may be broadly open to the main coelom, completely closed off from the coelom, or in communication with the coelom by a narrow, slitlike passage. The bursa, moderately developed in lower primates and catarrhines (Old World monkeys), is poorly developed in man. In horses, one edge of the ovary contains a long groove (ovulation fossa) into which all eggs are shed; the groove is found in a cleftlike ovarian bursa. The ovarian bursa increases the probability that all ovulated eggs will enter the oviduct.

The process of ovulation has been described for all vertebrate classes. Elasmobranchs, reptiles, and birds have massively yolked eggs. As ovulation approaches, the fimbria (*i.e.*, frills, or fringes) of the membranous and muscular funnel surrounding the entrance to the oviduct wave in a gentle, undulating motion. An egg that is nearly free of the ovary is grasped and partially encompassed by the fimbria; when the egg is freed, the fimbria draw the egg into the funnel. At this time, the egg has little shape and is partly squirted and partly flows into the oviduct; never completely free in the coelom, its chances of not entering the oviduct are small. In the case of moderately or poorly yolked eggs cilia help to sweep the eggs into the ostium, or opening, of the oviduct. During ovulation in Japanese rice fish, *Oryzias latipes*, a tiny papilla, or fingerlike process, develops on the surface of a bulging mature follicle

Ovulation

in the centre (stigma) of the follicle. The follicle becomes thin at the stigma, an aperture appears, and the egg rolls out. In rabbits this process differs only in detail. During the final 20 minutes before ovulation in rabbits, some of the tiny blood vessels surrounding the stigma rupture, and a small pool of blood forms under the apex of the cone-shaped papilla. The follicular wall shortly gives way at the apex, and follicular fluid oozes from the opening, followed soon after by the egg. The ovulated mammalian egg typically is surrounded by a layer of columnar follicular cells, the corona radiata; but it is naked in some insectivores and some marsupials. Following ovulation in all vertebrates, the ovary may become smaller, become modified for maintenance of pregnancy, or proceed to form additional eggs.

The process of ovulation in vertebrates has been documented, but the immediate causes remain to be clarified. It is almost certain that an ovulatory hormone is secreted by the pituitary gland (*i.e.*, the so-called master endocrine gland) of all vertebrates. It is highly probable that breakdown of very small fibres that bind the follicular cells together may occur at the stigma, weakening the follicular wall at that location. Hormones from the ovary and other sources may play a role, as may neurohormones, which are hormones released at nerve endings. Rhythmic contractions of the entire ovary occur at ovulation in many vertebrates and have been described in rabbits. The role of mechanical pressure within the follicle, however, is not understood. Ovulation in most mammals (spontaneous ovulators) occurs cyclically as a result of the spontaneous release of the ovulatory hormone. In a few mammals (reflex ovulators) the stimulus of copulation is essential for release of the ovulatory hormone.

Striking postovulatory changes take place in the follicles of mammals and, to lesser degrees, of lower vertebrates. Blood vessels from the theca interna invade the ovulated follicles; the granulosa cells divide, enlarge, accumulate fats, and obliterate any remnants of the collapsed antra. Thereafter, they are known as lutein cells. Theca interna cells undergo changes identical to those of the granulosa cells. The result in mammals is the formation of solid masses called corpora lutea, recognizable as prominent reddish-yellow bulges on the ovary. Corpora lutea produce the hormone progesterone, which is essential for the maintenance of pregnancy. The conversion of postovulatory follicles into structures more or less resembling mammalian corpora lutea has been demonstrated in numerous viviparous reptiles, amphibians, and elasmobranchs; in certain other fishes, including cyclostomes; and in some oviparous amphibians and reptiles. In birds, the postovulatory follicle shrinks, and identifiable corpora lutea do not develop, although some granulosa cells accumulate lipids of unknown significance.

Tracts. The female reproductive tract consists of a pair of tubes (gonoducts) extending from anterior, funnel-like openings (ostia) to the cloaca (Figure 23), except as noted

From George C. Kent, Jr., *Comparative Anatomy of the Vertebrates*, 2nd ed. (1969); The C.V. Mosby Co., St. Louis

Figure 23: Reproductive tract of female turtle, *Trionyx euphraticus*. One ovary has been removed.

below. The gonoducts are specialized along their length for secretion of substances added to the eggs; for transport, storage, nutrition, and expulsion of eggs or the products of conception; and, in species with internal fertilization, for receipt, transport, storage, and nutrition of inseminated sperm. The predominately muscular tracts are lined by a secretory epithelium and ciliated over at least part of their length. Fusion of the caudal (tail) ends of the paired ducts may occur. Gonoducts are absent in cyclostomes and a few gnathostome fishes that have abdominal pores. A few vertebrates have only one functional gonoduct.

Gonoducts in lungfishes and amphibians are coiled muscular tubes that are ciliated over most of their length. Only occasionally do they unite caudally in a genital papilla before opening into the cloaca. During breeding seasons their diameter increases severalfold because of the highly active secretory epithelium. Between breeding seasons they are small. In some anurans (frogs, toads), such as *Rana*, the lower end of each gonoduct is expanded to form an ovisac, in which ovulated eggs are stored until spawning; the tube between the ostium (funnel-like opening) and ovisac is the oviduct. In viviparous amphibians the young develop in the ovisac. In amphibians, numerous multicellular glands extend deep into the lining of the female tract. Six successive glandular zones have been described in some urodeles, and these secrete six different gelatinous substances upon the egg. Female urodeles often have convoluted tubular outpocketings of the cloaca called spermatheca; they temporarily store sperm liberated from the male spermatophore.

The two gonoducts of elasmobranchs share a single ostium, a trait found only in Chondrichthyes. The ostium is a wide caudally directed funnel supported in the falciform ligament, which is attached to the liver. The role of the fimbria of the ostium at ovulation has been described (see above *Ovaries*). Two oviducts pass forward from the ostium to the septum transversum (*i.e.*, between the heart and abdominal cavities), curve around one end of the liver, then pass posteriorly on each side. Approximately midway between ostium and uterus each oviduct has a shell (nidamental) gland. Fertilization takes place above the shell gland, which may be immense or almost undifferentiated. Half of the shell gland secretes a substance high in protein content (albumen), and the other half secretes the shell—delicate in viviparous forms, thick and horny in most oviparous species. Horny shells may have spiral ridges and many long tendrils, which entwine about an appropriate surface after the egg is deposited. In the viviparous shark *Squalus acanthias* several eggs pass one after the other through the shell gland, where they are enclosed in one long delicate membranous shell that soon disintegrates. Beyond the shell gland the oviducts terminate in an enlargement, which, in viviparous species, serves as a uterus. An oviducal valve may be found at the junction of oviduct and uterus. Although the two uteri usually open independently into the cloaca, they occasionally unite to form a bicornuate (two-horned) structure. In immature females, the uterus may be separated from the cloaca by a hymen, or membrane. The tract enlarges enormously during the first pregnancy and does not thereafter fully regress to its original size.

The gonoducts of most lower ray-finned fishes resemble those of lungfish, but those of gars and teleosts are exceptional in that the oviducts are usually continuous with the ovarian cavities. A median genital papilla receives the oviducts in teleosts, and the papilla is sometimes elongated to form an ovipositor. European bitterlings deposit their eggs in a mussel by means of the ovipositor, and female pipefish and sea horses deposit them in the brood pouch of a male.

With certain modifications, the gonoducts of reptiles and birds are comparable to those of lower vertebrates. Crocodilians, some lizards, and nearly all birds have one gonoduct; the other is not well developed. Even in birds of prey having two functional ovaries, the right oviduct is sometimes undeveloped. The tracts of reptiles generally show less regional differentiation than do those of birds. The oviduct funnel (ostium) in birds forms the chalazae—two coiled, springlike cords extending from the yolk to the

Gonoducts of fishes and amphibians

Gonoducts of reptiles, birds, and mammals

ends of the egg. In both reptiles and birds, much of the length of the female tract is oviduct. This region, called the magnum in birds, secretes albumen; lizards and snakes do not form albumen. Behind the albumen-secreting region is a shell gland. In lizards, the gland is midway along the tract. In birds, the shell gland is at the posterior end, has thick muscular walls, and is often inappropriately called a uterus. It is preceded by a narrow region, or isthmus, which secretes the noncalcareous, or soft, membranes of the shell. The shell gland leads to a narrow muscular vagina that empties into the cloaca. The vagina secretes mucus that seals the pores of the shell before the egg is expelled. Special vaginal tubules (spermatheca) store sperm over winter in some snakes and lizards; seminal receptacles have been described in the oviduct funnel in some snakes. In birds, sperm storage glands (sperm nests) often occur in the funnel and at the uterovaginal junction. In lizards and birds, ovulation does not usually occur into a tract already containing an egg. Some lizards shed very few eggs per season; the gecko, for example, sheds only two.

The female reproductive tracts of monotremes, the egg-laying mammals, consist of two oviducts, the lower ends of which are shell glands. These open into a urinogenital sinus, which, in turn, empties into a cloaca. Marsupials have two oviducts, two uteri (duplex uterus), and two vaginas. The upper parts of the vaginas unite to form a median vagina that may or may not be paired internally. Beyond the median vagina, the vaginas are again paired (lateral vaginas) and lead to a urinogenital sinus. The posterior end of the pouchlike median vagina is separated from the forward end of the urinogenital sinus by a partition. When the female is delivering young, the fetuses are usually forced through the partition and into the urinogenital sinus, bypassing the lateral vaginas. The ruptured partition may remain open thereafter, resulting in a pseudovagina. It closes in opossums, and in kangaroos both the median and lateral routes may serve as birth canals. The lateral vaginas in marsupials receive the forked tips of the male penis. Fertilization in all mammals takes place in the oviducts (Fallopian tubes).

In eutherian mammals (*i.e.*, all mammals except monotremes and marsupials), with exceptions noted below, female reproductive tracts beyond the ostia (oviduct funnels) consist of two narrow and somewhat tortuous Fallopian tubes, two large uterine horns (each of which receives a Fallopian tube), a uterine body, and one vagina. Fallopian tubes often have a short dilated ampulla, or saclike swelling, just beyond the ostium. Implantation of the egg occurs only in the uterine horns; the embryos become spaced equidistant from one another in both horns even if only one ovary has ovulated. In some species one horn is rudimentary—the left in the impala (an African antelope)—and the embryos become implanted in the other horn, even though both ovaries ovulate. The body of the uterus in some mammals (*e.g.*, rabbits, elephants, aardvarks; some rodents, bats, insectivores) contains two separate canals (bipartite uterus). In other mammals (ungulates, many cetaceans, most carnivores and bats) the body of the uterus has one chamber into which the two horns empty (bicornuate uterus). There are numerous intermediate conditions between the bipartite and bicornuate condition. Apes, monkeys, and man have no horns, and the Fallopian tubes empty directly into the body of the uterus (simplex uterus). In all mammals, the uterine body tapers to a narrow neck (cervix). The opening (os uteri) into the vagina is guarded by fleshy folds (lips of the cervix). The vagina in eutherian mammals other than rodents and primates terminates in a urinogenital sinus that opens to the exterior by a urinogenital aperture. In some rodents and in higher primates the vagina opens directly to the exterior. In the young of many species a membrane, the hymen, closes the vaginal opening. In guinea pigs the hymen reseals the opening after each reproductive period. Sperm are stored over winter in the uterus of some bats and in vaginal pouches in others.

Accessory glands. Female mammals have fewer accessory sex glands than males, the most prominent being Bartholin's glands and prostates. Bartholin's (bulbourethral) glands are homologues of the bulbourethral glands of

males. One pair usually opens into the urinogenital sinus or, in primates, into a shallow vestibule at the opening of the vagina. Prostates develop as buds from the urethra in many female embryos but often remain partially developed. They become well developed, however, in some insectivores, chiropterans, rodents, and lagomorphs, although their function is obscure. A variety of glands (labial, preputial, urethral) are found in the mucosa, or mucous membrane. Glands in the uterine mucosa provide nourishment for embryos before implantation. Cervical uterine glands secrete mucus that lubricates the vagina, which has no glands.

ADAPTATIONS FOR INTERNAL FERTILIZATION

Fertilization among vertebrates may be external or internal, but internal fertilization is not always correlated with viviparity or the presence of intromittent (copulatory) organs. The latter, uncommon among fishes, amphibians, and birds, are present in all reptiles (except *Sphenodon*) and mammals.

A considerable number of fishes are viviparous; in them, fertilization is internal, and the males have intromittent organs. The claspers of most male elasmobranchs are usually paired extensions of pelvic fins that are inserted into the female's uterus for transfer of sperm. The clasper, supported by modified fin cartilages, contains a groove along which sperm are conveyed into the uterus and is raised, or erected, by muscles at its base. Gonopodia of male teleosts are fleshy, often elongated modifications of pelvic or anal fins that are directed posteriorly, have a genital pore at the end, and often serve as intromittent organs. In some teleosts, a large penis-like papilla located under the throat is supported by bones. The spermatid duct opens on one side of the papilla. In a few teleosts, hemal spines (ventral projections of vertebrae) form the skeleton of an intromittent organ. Occasionally, the intromittent organ is an asymmetrical tube that matches the asymmetrical genital opening of the female. Still other teleosts have uncomplicated fleshy genital papillae that can be erected. In at least one teleost species, the female has a copulatory organ that she inserts into the genital pore of the male for receiving sperm.

Certain amphibians have internal fertilization but no intromittent organs. The muscular cloaca of the male caecilian, however, can be everted (turned outward) to protrude into that of the female. The male urodele deposits a spermatophore that the female picks up with the lips of her cloaca. Among anurans, *Nectophrynoides* (a viviparous frog) and *Ascaphus* (a toad) have internal fertilization, but only *Ascaphus* has an intromittent organ. It is a permanent tubular extension of the cloaca and resembles a tail. Other anurans have external fertilization and no intromittent organs.

The provision of an eggshell in reptiles requires that fertilization be internal, and all reptiles have intromittent organs except *Sphenodon*. Reptilian intromittent organs are of two types. Crocodilians and chelonians (turtles) have a penis (phallus), a median thickening in the floor of the cloaca consisting of two cylinders of spongy vascular erectile tissue, the corpora spongiosa. The caudal tip of the penis protrudes into the cloaca as a genital tubercle, or glans penis. The penis is held in the cloacal floor by retractor muscles. When the blood vessels within the spongy bodies are filled with blood, the penis swells, the retractor muscle relaxes, and the genital tubercle protrudes from the vent to serve as an intromittent organ. A longitudinal groove on the surface of the penis directs the flow of sperm. When the spongy bodies are no longer filled with blood, the retractor muscle returns the penis to the cloacal floor. Snakes and lizards have hemipenes, paired elongated outpocketings of the caudal wall of the cloaca that extend under the skin at the base of the tail. Each hemipenis is held in place by a retractor muscle. During copulation the muscle relaxes, the pocket turns inside out and protrudes through the vent in an erect condition. Semen passes along grooves on its surface. Except in pythons, erectile tissue is lacking in hemipenes. Hemipenes protrude independently of each other and are often covered with spines. Very small hemipenes of unknown function are usually present in females.

Copulatory organs in fishes and amphibians

Copulatory organs in reptiles, birds, and mammals

All birds have internal fertilization, although they are not viviparous; most lack intromittent organs. Male swans, ducks, geese, tinamous, ostriches, and some other ratites (flightless birds), however, have an erectile median penis like that of crocodiles and turtles. Chickens have an organ consisting of a small amount of erectile tissue, but lymph vessels, rather than blood vessels, become engorged. Some birds have a vestigial penis.

All mammals have internal fertilization and an erectile penis. That of monotremes is of the reptilian type, nonprotrusible and in the cloacal floor. In higher mammals the penis has been modified. The groove on the surface of the embryonic penis becomes enclosed in a tube along with the corpus spongiosum and two additional erectile masses, the corpora cavernosa. The proximal ends (crura) of the corpora cavernosa are anchored laterally to the pubic and ischial bones by various muscles and constitute the root of the penis. The crura converge in the midline to enter the body of the penis, which also contains the urethra, surrounded by the corpus spongiosum. The latter begins on the pelvic floor as the bulb of the penis and contains a dilation of the urethra (urethral bulb). The body of the penis extends a variable distance beyond the body of the mammal, in contrast to the short genital tubercle of reptiles. Except in ruminants (*i.e.*, cud-chewing animals, such as cattle and deer), cetaceans, and some rodents, the penis terminates in a glans penis, a swelling of the corpus spongiosum that caps the ends of the corpora cavernosa and contains the urinogenital aperture. The glans is supplied with nerve endings and is partly or wholly sheathed, except during erection, by a circular fold of skin, the prepuce. The inner surface of the prepuce is moistened by preputial glands, and the external surface is sometimes covered with spines or hard scales, as in the cat, guinea pig, and wombat. The glans penis of the male Virginia opossum (*Didelphis virginiana*), the bandicoot, and some other species is bifid (*i.e.*, with two equal tips), correlated with the paired vaginas of females. In boars, the glans penis is corkscrew-shaped, and in goats, rams, and many antelopes a urethral (vermiform) process of much smaller diameter extends three or four centimetres (about an inch to an inch and a half) beyond the glans. In some cattle, a sigmoid, or S-shaped, flexure bends the penis, which otherwise would be too long to fit into the preputial sac. The penis of marsupials is directed backward, and that of cats and rodents is directed backward, except during copulation. In some mammals (*e.g.*, bats) it is pendulous; and in armadillos it may extend one third the length of the body during copulation.

Erection of the mammalian penis is initiated typically by an increase in the volume of blood reaching the cavernous and spongy bodies, engorgement of the vessels, and consequent compression of the veins leaving the organ. When a retractor muscle is present (wolf, fox, dog), it relaxes as erection occurs. The amount of erectile tissue in bovines (cattle) is small, and the penis has much fibroelastic tissue. Erection in such species results primarily from relaxation of the retractor muscle, and vascular engorgement provides only rigidity. Among mechanisms that reverse the erectile state are disgorgement of blood from the cavernous spaces, elasticity of the walls of the spaces, and action of a retractor muscle. A penis bone (baculum, os priapi) is present in various degrees of development in many mammals.

Female mammals have an erectile penile organ known as the clitoris in the floor of the urinogenital sinus or vagina. In the young spider monkey *Ateles*, the clitoris is six or seven centimetres (2.4 to 2.8 inches) long. In a few mammals (some rodents, insectivores, lemurs, and hyenas) the urethral canal becomes enclosed within the clitoris, as in males. In hyenas, the clitoris is large and often mistaken for a penis, and female scrotal pouches, lacking gonads, are present. So much do the male and female external genitalia resemble each other that the ancients regarded the hyena as a hermaphrodite. The clitoris of female mammals often contains cartilage or bone. A specialized clitoris is present in female turtles, crocodiles, alligators, and a few species of birds in which the male has a penis.

The spermatic duct of male mammals between the seminal vesicle and the prostatic urethra has a heavy muscular

coat and serves as an ejaculatory duct. In mammals in which the seminal vesicles empty directly into the urethra, the latter is ejaculatory. In birds, the terminal segments of the spermatic ducts are erectile and ejaculatory, and in fish the posterior end of whatever duct transports sperm may be ejaculatory.

ROLE OF GONADS IN HORMONE CYCLES

Neurosecretions formed in the brain in response to environmental stimuli regulate the synthesis and release of hormones known as gonadotropins, which, in turn, stimulate the gonads. Cyclical intervals of illumination (photoperiods) may be the principal environmental factor regulating gonadal activity. Although cyclical temperature changes are experienced by many species, as are fluctuations in food supply, rainfall, and salinity, their precise effects and those of many other stimuli, independently or in combination, have not yet been defined for any species. Photoperiodicity, temperature, and perhaps all other cycles are attributable to the seasons, and to the 24-hour day.

As a result of rhythmic stimulation by gonadotropins secreted by the pituitary gland, the gonads grow, mature, and produce gametes and hormones. Certain of these hormones, known as androgens, are thought to be produced chiefly by interstitial cells and are more abundant in males. Hormones known as estrogens are probably produced chiefly by ovarian follicles and their thecas. Circulating progestins are produced in greatest quantities by corpora lutea. Although the gonadal hormones of different species vary somewhat in structure, their effects are essentially the same. As the quantity of pituitary gonadotropins decreases, the activity of the gonads slows and may temporarily cease.

The effects of gonadal hormones may be summarized as follows:

Gonadal hormones induce growth of and maintain the cyclical function of the reproductive tracts, accessory sex glands, and copulatory or ovipository organs. They thereby provide for the storage, nutrition, and transport of gametes; the secretion of necessary substances onto the surface of gametes; and the ultimate extrusion of sperm, eggs, or the products of conception. In mammals, therefore, they prepare the vagina for copulation and the uterus for implantation of eggs; in addition, gonadal hormones maintain pregnancy until birth or until placental hormones can take over their function. The hormonal basis for the maintenance of viviparity in vertebrates below mammals is almost unknown.

Gonadal hormones participate in the maturation of gametes still in the gonads by augmenting the metabolic effects of other hormones.

Gonadal hormones are essential for the differentiation of many secondary sex characters—the physical differences between the sexes—facilitate amplexus (copulatory embrace) and provide for the protection or nutrition of young. Secondary sex characters include scent glands; sexually linked pigmentation of the skin or its appendages; the nature of any vocal apparatus; hardened areas on the appendages that facilitate amplexus; distribution of hair; body size; mammary gland development; and other features.

Gonadal hormones participate in the induction of behaviour necessary for the union of sperm and eggs; this includes migratory phenomena, heat (estrus) in mammals, courtship, territorial defense, mating, and care of eggs or young.

Gonadal hormones participate in a mechanism that affects the pituitary, thereby imposing certain restraints on the secretion of gonadotropins.

The effects of a cyclical environment on gonads is illustrated in mammals that ovulate spontaneously. Ovulation is induced by ovulatory hormones released rhythmically from the pituitary gland. Newborn mice maintained during the first week of life in regular, natural photoperiods will, on reaching maturity, ovulate regularly. Newborn mice kept in continuous light during this interval will not ovulate regularly. The photoperiods in which these animals live as neonates, or newborn, establish an intrinsic brain rhythm that subsequently results in cyclical

Effects of gonadal hormones

The role of light in establishing periodic reproductive activity

Erectile tissue

reproductive activity. If mature female mice that have been ovulating regularly are subjected to continuous light, ovulation ultimately becomes arrhythmic. This suggests that the rhythmic environment is the ultimate regulator of the gonads. Because of the effects of cyclical photoperiods, spontaneous ovulation occurs about the same time of day or night in all members of species intensively studied thus far. Golden hamsters ovulate shortly after midnight; chickens and Japanese rice fish ovulate in the morning. Not all mammals ovulate spontaneously, however. In those that do not (e.g., reflex ovulators), including some cats, rodents, weasels, shrews, rabbits, the act of mating substitutes for the environmental effects on the pituitary gland in releasing ovulatory hormones (see BIOCHEMICAL COMPONENTS OF ORGANISMS: *Hormones*).

PROVISIONS FOR THE DEVELOPING EMBRYO

Among the requirements of developing embryos are nutrients, oxygen, a site in which to discharge metabolic wastes, and protection from the environment. These needs exist whether the embryo is developing outside the body of the female parent (oviparity), or within, so that she delivers living young (viviparity). Combinations of yolk, albumen, jellies, and shells contributed by the female parent, as well as membranes constructed from the tissues of the embryo meet the embryo's needs.

Oviparous eggs are usually supplied with enough nutrients to last until the new individual is able to obtain food from the environment. The alternative, postnatal parental feeding, is uncommon. Oviparous animals that develop from yolk-laden eggs are not hatched until they resemble adults. Those that develop from eggs with moderate amounts of yolk hatch sooner, usually into free-living larvae; in this case the larvae transform, or undergo metamorphosis, into adults. The eggs of amphioxus, an oviparous protochordate, contain almost no nutrients; the embryos hatch in an extremely undeveloped but self-sustaining state as few as eight hours after fertilization. The yolk mass is large in some animals and becomes surrounded by a membrane called the yolk sac, the vessels of which convey yolk to the embryo. In some species, yolk also passes from the yolk sac directly into the fetal intestine.

Oviparous fishes and amphibians develop in an aquatic environment, and exchange of oxygen and carbon dioxide and elimination of metabolic wastes occur through the egg membranes. Oviparous reptiles, birds, and monotremes develop on land, and gaseous exchange is accomplished by two membranes (allantois, chorion) applied closely to the shell. The allantois also receives some wastes. Drying out or mechanical injury of embryos of reptiles, birds, and mammals is prevented by still another membrane, the amnion, which is a fluid-filled sac immediately surrounding the embryo.

Types of
viviparity

Viviparity has evolved in some members of all vertebrate classes except birds. When eggs heavily laden with yolk and surrounded by a well-formed shell develop within the female, the parent may provide the developing young only with shelter and oxygen (ovoviviparity). At the opposite extreme, if eggs contain only enough nutrients to supply energy for a few cell divisions after fertilization, the female provides shelter, oxygen, and nourishment, and, in addition, excretes all metabolic wastes produced by the developing organism (eu viviparity). Between these extremes are numerous intermediate degrees of dependence on the parent.

Teleosts have evolved many unusual adaptations for viviparity. In some viviparous teleosts the eggs are fertilized in the ovarian follicle, where development occurs. The granulosa cells either form a membrane that secretes nutrients and assists in respiratory and excretory functions or they may be ingested along with follicular fluid, nearby eggs, and other ovarian tissue. A common site for development is the ovarian cavity, which may become distended with as many as nine series of embryos of different ages. Embryos in this location are bathed with nutritive fluids secreted by the epithelium of the cavity. In some species, mortality rates of intraovarian young are high, and surviving individuals ingest those that die. In still other species, extensions of villi in the ovarian lining invade the mouth

and opercular (gill) openings of the embryo, filling the opercular chamber, mouth, and pharynx with surfaces that secrete nutrients. The embryos also develop specialized surfaces for nutrition, respiration, and excretion. An enlarged pericardial (heart) sac or an expansion of the hindgut of the embryo may occur next to the blood-vessel containing (vascular) follicular wall. Vascular extensions may grow out of the anus, urinogenital pore, or gills of the embryo. Other embryonic surfaces—including ventral body wall, fins, and tail—may participate in the support of viviparity. These embryonic surfaces may lie in contact with the follicular or ovarian epithelium, or they may simply be bathed by ovarian fluids. One or more combinations of the maternal and embryonic specializations described above, as well as many others, make viviparity possible among teleost fishes. In a number of teleosts the eggs are incubated, or brooded, in the mouth of the male for periods as long as 80 days. The oral epithelium becomes vascular and highly glandular. In sea horses and pipefish the female deposits her eggs in a ventral brood pouch of the male, and the embryos develop there.

Oral
incubation
in
fish

In viviparous elasmobranchs development takes place in the uterus, the lining of which develops parallel ridges or folds covered with villi or papillae (trophonemata) that constitute a simple placenta (site of fetal-maternal contact). In contact with this region is the yolk sac of the embryo, which serves as a respiratory and nutritive membrane. Trophonemata secrete uterine fluids that supplement the yolk as a source of energy. In one shark (*Pteroplatea micrura*), trophonemata extend into the spiracular chamber (an opening for the passage of respiratory water) of the young and secrete nutrients into the fetal gut. In another (*Mustelus antarcticus*), the uterine folds form fluid-filled compartments for each embryo. The yolk sac may lie in contact with the uterine lining, or projections of the sac may extend into uterine pits. When the stored yolk is used up before birth, the yolk sac may serve for the absorption of nutrients; i.e., as a placenta. In a few species, immature eggs that enter the oviduct are eaten by the developing young.

Very few amphibians bear living young. In the viviparous frog *Nectophrynoides*, all development, including larval stages, occurs in the uteri and the young are born fully metamorphosed; i.e., except for size they resemble adults. *N. occidentalis*, an African species, has a nine-month gestation period. There is almost no yolk in the egg and no placenta, so it is probable that uterine fluids provide nourishment and oxygen. In *N. vivipara* there are as many as 100 larvae in the uteri, each with long vascular tails that may function as respiratory membranes. *Gastrotheca marsupiat*a is an ovoviviparous anuran with a gestation period of three to four months. In certain viviparous salamanders the extent of the nutritional dependence on the mother varies. After depleting their own yolk supply, the larvae of some forms eat other embryos and blood that escapes from the uterine lining. Conventional viviparity is rare among amphibians; however, they have evolved unusual alternatives. In some anurans the young develop in such places as around the legs of the male (*Alytes*), or in pouches in the skin of the back (some females of the genera *Nototrema*, *Protopipa*, and *Pipa*). In *Pipa*, vascular partitions in the skin pouch separate developing young, and the larvae have vascular tails that absorb substances. In *Nototrema* larval gills have vascular extensions with a similar function. The male Chilean toad (*Rhinoderma darwini*) carries developing eggs in the vocal sac until the young frogs emerge.

Some snakes and lizards and all mammals except monotremes exhibit viviparity to some degree. The same extra-embryonic membranes found in oviparous reptiles and mammals (yolk sac, chorioallantoic membrane, amnion) function in viviparous ones. Here, the extra-embryonic membranes lie against the uterine lining instead of against an egg shell. At special sites of fetal-maternal contact (placentas), viviparous young receive oxygen and give up carbon dioxide; metabolic wastes are transferred to maternal fluids and tissues; and, in eu viviparous species, the young receive all their nutrients. Yolk-sac placentas are common in marsupials with short gestation periods (opos-

Placentas

sum, kangaroo) and in lizards. Chorioallantoic placentas (*i.e.*, a large chorion fused with a large allantois) occur in certain lizards, in marsupials with long gestation periods, and in mammals above marsupials. The yolk-sac placenta does not invade maternal tissues, but intimate interlocking folds may occur between the two. The chorioallantoic membranes of reptiles and mammals exhibit many degrees of intimacy with maternal tissues, from simple contact to a deeply rooted condition (deciduate placentas). Chorioal-

lantoic or chorionic placentas represent specializations in a chorionic sac surrounding the embryo. The entire surface of the sac may serve as a placenta (diffuse placenta, as in pigs); numerous separate patches of placental thickenings may develop (cotyledonary placenta, as in sheep); a thickened placental band may develop at the equator of the chorionic sac (zonary placenta, as in cats); or there may be a single oval patch of placental tissue (discoidal placenta, as in higher primates). (G.C.K.)

THE HUMAN REPRODUCTIVE SYSTEM

Man belongs to that group of mammals characterized by the bearing of live offspring that have attained considerable development within the uterus, or womb. Provided all organs are present, normally constructed, and functioning properly, the essential features of human reproduction are (1) liberation of an egg from the ovary at the right time in the reproductive cycle; (2) internal fertilization by spermatozoa (sperm, or male sex cells) of the ovum in the uterine tube; (3) transport of the fertilized ovum along the uterine tube to the uterus; (4) implantation of the blastocyst, the early embryo that develops from the fertilized ovum, in the wall of the uterus; (5) formation of a placenta and maintenance of the intra-uterine existence of the unborn child; (6) birth of the child and expulsion of the placenta; and (7) suckling and care of the child, with an eventual return of the maternal organs virtually to their original state.

For this biological process to be carried out, certain organs and structures are required in both male and female bodies. The source of the ova, the female germ cells, is the female gonad or ovary; that of spermatozoa is the testis. In human beings, the two ovaries are situated in the pelvic cavity, and the two testes are enveloped in a sac of skin, the scrotum, lying below and outside the abdomen. Besides producing the germ cells, or gametes, the ovaries and testes are the source of hormones that cause full development of secondary sexual characteristics and also the proper functioning of the genital (reproductive) tracts. These tracts comprise the uterine tube, the uterus, vagina, and associated structures in females, and, in males, the penis, the sperm channels—epididymis, ductus deferens, and ejaculatory ducts—and other related structures and glands. The function of the uterine tube is to convey an ovum, which is fertilized in the tube, to the uterus, where gestation (development before birth) takes place. The function of the male ducts is to convey spermatozoa from the testis, to store them, and, when ejaculation occurs, to eject them with secretions from the male glands through the penis.

At copulation the erect penis is inserted into the vagina and spermatozoa contained in the seminal fluid are ejaculated into the female genital tract. Spermatozoa then pass from the vagina through the uterus to the uterine tube to fertilize the ovum in the outer part of the tube. Human females exhibit a periodicity in the activity of their ovaries and uterus, which starts at puberty and ends at the menopause. The periodicity is manifested by menstruation at intervals of about 28 days; important changes occur in the ovaries and uterus during each reproductive or menstrual cycle. Periodicity is suppressed during pregnancy and lactation.

The sex of a human child is determined at the time of fertilization of the ovum by the spermatozoon. The differences between a man and a woman are genetically determined by the chromosomes that each possesses in the nuclei of the cells. This stage in the development of the individual is detailed in the article GROWTH AND DEVELOPMENT: *Human embryology*.

Once the genetic sex has been determined there normally follows a succession of changes that will result, finally, in the development of an adult male or female. There is, however, no external indication of the sex of a human embryo during the first eight weeks of its life within the uterus. This is a neutral or indifferent stage during which the sex of an embryo can be ascertained only by examina-

tion of the chromosomes in its cells. The next phase, one of differentiation, begins first in gonads that are to become testes, and a week or so later in those destined to be ovaries. Embryos of the two sexes are initially alike in possessing similar duct systems linking the undifferentiated gonads with the exterior and in having similar external genitalia, represented by three simple protuberances. The embryos each have four ducts, the subsequent fate of which is of great significance in the eventual anatomical differences between men and women. Two ducts closely related to the developing urinary system are called mesonephric, or wolffian, ducts. In males, each mesonephric duct becomes differentiated into four related structures: a duct of the epididymis, a ductus deferens, an ejaculatory duct, and a seminal vesicle (see below). In females, the mesonephric ducts are largely suppressed. The other two ducts, called the paramesonephric or müllerian ducts, persist, in females, to develop into the uterine tubes, the uterus, and part of the vagina; in males they are largely suppressed. Differentiation also occurs in the primitive external genitalia, which in males become the penis and scrotum, and in females the clitoris and labia.

At birth the organs appropriate to each sex have developed and are in their adult positions but are not functioning. Various abnormalities can occur during development of sex organs in human embryos, leading to hermaphroditism, pseudohermaphroditism, and other chromosomally induced conditions. During childhood until puberty there is steady growth in all reproductive organs and a gradual development of activity. Puberty marks the onset of increased activity in the sex glands and the steady development of secondary sexual characteristics.

In males at puberty the testes enlarge and become active, the external genitalia enlarge, and the capacity to ejaculate develops. Marked changes in height and weight occur as hormonal secretion from the testes increases. The larynx, or voice box, enlarges, with resultant deepening of the voice. Certain features in the skeleton, as seen in the pelvic bones and skull, become accentuated. The hair in the armpit and the pubic hair becomes abundant and thicker. A beard, a moustache, and cheek hair develop, as well as hair on the chest, abdomen, and limbs. Hair at the temple recedes. Skin glands become more active, especially apocrine glands (a type of sweat gland that is found in the armpit and groin and around the anus).

These secondary sex characteristics do not develop in individuals castrated before puberty, but the administration of androgens (male sex hormones) to such persons and to males having poorly developed testes can correct, in large measure, some of the poorly developed secondary characteristics. Large amounts of androgen, however, by preventing production of the hormone gonadotrophin by the pituitary, suppress testicular activity, thus depressing formation and release of sperm. Some derivatives of the male sex hormone testosterone can promote general bodily development.

In females at puberty, the external genitalia enlarge and the uterus commences its periodic activity with overt menstruation. The mammary glands develop, and there is a deposition of body fat in accordance with the usual contours of the mature female. Growth of axillary (armpit) and pubic hair is more abundant, and the hair becomes thicker. In a female receiving androgens, the typical male secondary sex characteristics may develop, menstruation may be suppressed, and the mammary glands may atrophy.

Develop-
ment of
sexual
differences
in embryo

The male reproductive system

The male gonads are the testes; they are the source of spermatozoa and also of male sex hormones called androgens. The other genital organs are the epididymides, the ductus or vasa deferentia, the seminal vesicles, the ejaculatory ducts, and the penis, as well as certain accessory structures, the prostate and the bulbourethral (Cowper's) glands. The principal functions of these structures are to transport the spermatozoa from the testes to the exterior, to allow their maturation on the way, and to provide certain secretions that help form the seminal fluid.

EXTERNAL GENITALIA

The penis. The penis, the male organ of copulation, is partly inside and partly outside the body. The inner part, attached to the bony margins of the pubic arch (that part of the pelvis directly in front and at the base of the trunk), is called the root of the penis. The second, or outer, portion is free, pendulous, and enveloped all over in skin; it is termed the body of the penis. The organ is composed chiefly of cavernous or erectile tissue that becomes engorged with blood to produce considerable enlargement and erection. The penis is traversed by a tube, the urethra, which serves as a passage both for urine and for semen.

Adapted from H. Gray, *Anatomy of the Human Body*, 28th ed. by C.M. Goss (1966); Lea & Febiger

Figure 24: Male reproductive organs.

The body of the penis, sometimes referred to as the shaft, is cylindrical in shape when flaccid but when erect is somewhat triangular in cross section, with the angles rounded. This condition arises because the right and left corpora cavernosa penis, the masses of erectile tissue, lie close together in the dorsal part of the penis, while a single body, the corpus spongiosum penis, which contains the urethra, lies in a midline groove on the under surface of the corpora cavernosa. The dorsal surface of the penis is that which faces upward and backward during erection.

The slender corpus spongiosum reaches beyond the extremities of the erectile corpora cavernosa, and at its outer end is enlarged considerably to form a soft, conical, sensitive structure called the glans penis. The base of the glans has a projecting margin, the corona, and the groove where the corona overhangs the corpora cavernosa is referred to as the neck of the penis. The glans is traversed by the urethra, which ends in a vertical, slitlike, external opening. The skin over the penis is thin and loosely adherent and at the neck is folded forward over the glans for a variable distance to form the prepuce or foreskin. A median fold, the frenulum of the prepuce, passes to the under surface of the glans to reach a point just behind the urethral opening. The prepuce can usually be readily drawn back to expose the glans.

The root of the penis comprises two crura, or projections, and the bulb of the penis. The crura and the bulb are attached respectively to the edges of the pubic arch and to the perineal membrane (the fibrous membrane that forms a floor of the trunk). Each crus is an elongated structure covered by the ischiocavernosus muscle, and each extends

Figure 25: Interior view of the penis with corpus spongiosum detached and turned to one side.

Adapted from H. Gray, *Anatomy of the Human Body*, 28th ed. by C.M. Goss (1966); Lea & Febiger

forward, converging toward the other, to become continuous with one of the corpora cavernosa. The oval bulb of the penis lies between the two crura and is covered by the bulbospongiosus muscle. It is continuous with the corpus spongiosum. The urethra enters it on the flattened deep aspect that lies against the perineal membrane, traverses its substances, and continues into the corpus spongiosum.

The two corpora cavernosa are close to one another, separated only by a partition in the fibrous sheath that encloses them. The erectile tissue of the corpora is divided by numerous small fibrous bands into many cavernous spaces, relatively empty when the penis is flaccid but engorged with blood during erection. The structure of the tissue of the corpus spongiosum is similar to that of the corpora cavernosa, but there is more smooth muscle and elastic tissue. A deep fascia, or sheet of connective tissue, surrounding the structures in the body of the penis, is prolonged to form the suspensory ligament, which anchors the penis to the pelvic bones at the mid point of the pubic arch.

The penis has a rich blood supply from the internal pudendal artery, a branch of the internal iliac artery, which supplies blood to the pelvic structures and organs, the buttocks, and the inside of the thighs. Erection is brought about by distension of the cavernous spaces with blood, which is prevented from draining away by compression of the veins in the area.

The penis is amply supplied with sensory and with autonomic (involuntary) nerves. Of the autonomic nerve fibres the sympathetic fibres cause constriction of blood vessels, and the parasympathetic fibres cause their dilation. It is usually stated that ejaculation is brought about by the sympathetic system, which at the same time inhibits the desire to urinate and also prevents the seminal fluid from entering the bladder.

The scrotum. The scrotum is a pouch of skin lying below the pubic symphysis and just in front of the upper parts of the thighs. It contains the testes and lowest parts of the spermatic cord. A scrotal septum or partition divides the pouch into two compartments and arises from a ridge, or raphe, visible on the outside of the scrotum. The raphe turns forward onto the under surface of the penis and is continued back onto the perineum (the area between the legs and as far back as the anus). This arrangement indicates the bilateral origin of the scrotum from two genital swellings that lie one on each side of the base of the phallus, the precursor of the penis or clitoris in the embryo. The swellings are also referred to as the labioscrotal swellings because in females they remain separate to form the labia majora, while in males they unite to form the scrotum.

Septum and raphe

The corpus spongiosum and the corpora cavernosa

The skin of the scrotum is thin, brown, devoid of fatty tissue, and more or less folded and wrinkled. There are some scattered hairs and sebaceous glands on its surface. Below the skin is a layer of involuntary muscle, the dartos, which can alter the appearance of the scrotum. On exposure of the scrotum to cold air or cold water, the dartos contracts and gives the scrotum a shortened, corrugated appearance; warmth causes the scrotum to become smoother, flaccid, and less closely tucked in around the testes. Beneath the dartos muscle are layers of fascia continuous with those forming the coverings of each of the two spermatic cords, which suspend the testes within the scrotum and contain each ductus deferens, the testicular blood and lymph vessels, the artery to the cremaster muscle (which draws the testes upward), the artery to each ductus deferens, the genital branch of the genito-femoral nerve, and the testicular network of nerves.

The scrotum is supplied with blood by the external pudendal branches of the femoral artery, which is the chief artery of the thigh, and by the scrotal branches of the internal pudendal artery. The veins follow the arteries. The lymphatic drainage is to the lymph nodes in the groin.

The testes. The two testes, which usually complete their descent into the scrotum from their point of origin on the back wall of the abdomen in the seventh month after conception, are suspended in the scrotum by the spermatic cords. Each testis is four to five centimetres (about one to one and one-half inches) long and is enclosed in a fibrous sac, the tunica albuginea. This sac is lined internally by the tunica vasculosa, containing a network of blood

Adapted from H. Gray, *Anatomy of the Human Body*, 28th ed. by C.M. Goss (1966); Lea & Febiger

Figure 26: Longitudinal cross section of testis.

vessels, and is covered by the tunica vaginalis, which is a continuation of the membrane that lines the abdomen and pelvis. The tunica albuginea has extensions into each testis that act as partial partitions to divide the testis into approximately 250 compartments, or lobules.

Each lobule contains one or more convoluted tubules, or narrow tubes, where sperm are formed. The tubules, if straightened, would extend about 70 centimetres (about 28 inches). The multistage process of sperm formation, which takes about 60 days, goes on in the lining of the tubules, starting with the spermatogonia, or primitive sperm cells, in the outermost layer of the lining. Spermatozoa (sperm) leaving the tubules are not capable of independent motion, but undergo a further maturation process in the ducts of the male reproductive tract; the process may be continued when, after ejaculation, they pass through the female tract. Maturation of the sperm in the female tract is called capacitation; little is known about it.

Each spermatozoon is a slender elongated structure with a head, a neck, a middle piece, and a tail. The head contains the cell nucleus. When the spermatozoon is fully mature, it is propelled by the lashing movements of the tail.

Production of hormones The male sex hormone testosterone is produced by the cells of Leydig. These cells are located in the connective (interstitial) tissue that holds the tubules together within each lobule. The tissue becomes markedly active at pu-

berty under the influence of the interstitial-cell-stimulating hormone of the anterior lobe of the pituitary gland; this hormone in women is called luteinizing hormone. Testosterone stimulates the male accessory sex glands (prostate, seminal vesicles) and also brings about the development of male secondary sex characteristics at puberty. The hormone may also be necessary to cause maturation of sperm and heighten the sex drive of the male. The testis is also the source of some of the female sex hormone estrogen, which may exert an influence on pituitary activity.

Each testis is supplied with blood by the testicular arteries, which arise from the front of the aorta just below the origin of the renal (kidney) arteries. Each artery crosses the rear abdominal wall, enters the spermatic cord, passes through the inguinal canal, and enters the upper end of each testis at the back. The veins leaving the testis and epididymis form a network, which ascends into the spermatic cord. The lymph vessels, which also pass through the spermatic cord, drain to the lateral and preaortic lymph nodes. Nerve fibres to the testis accompany the vessels; they pass through the renal and aortic nerve plexuses, or networks.

STRUCTURES OF THE SPERM CANAL

The epididymis, ductus deferens, and ejaculatory ducts form the sperm canal. Together they extend from the testis to the urethra, where it lies within the prostate. Spermatozoa are conveyed from the testis along some 20 ductules, or small ducts, which pierce the fibrous capsule to enter the head of the epididymis. The ductules are straight at first but become dilated and then much convoluted to form distinct compartments within the head of the epididymis. They each open into a single duct, the highly convoluted duct of the epididymis, which constitutes the "body" and "tail" of that structure. It is held together by connective tissue but if unravelled would be nearly six metres (20 feet) long. The duct enlarges and becomes thicker walled at the lower end of the tail of the epididymis, where it becomes continuous with the ductus deferens.

The ductules from the testis have a thin muscular coat and a lining that consists of alternating groups of high columnar cells with cilia (hairlike projections) and low cells lacking cilia. The cilia assist in moving spermatozoa toward the epididymis. In the duct of the epididymis the muscle coat is thicker and the lining is thick with tufts of large nonmotile cilia. There is some evidence that the ductules and the first portion of the duct of the epididymis remove excess fluid and extraneous debris from the testicular secretions entering these tubes. The blood supply to the epididymis is by a branch from the testicular artery given off before that vessel reaches the testis.

The ductus deferens is the continuation of the duct of the epididymis. It commences at the lower part of the tail of the epididymis and ascends along the back border of the testis to its upper pole. Then, as part of the spermatic cord, it extends to the deep inguinal ring. Separating from the other elements of the spermatic cord—the blood vessels, nerves, and lymph vessels—at the ring, the ductus deferens makes its way through the pelvis toward the base of the prostate, where it is joined by the seminal vesicle to form the ejaculatory duct. A part of the ductus that is dilated and rather tortuous, near the base of the urinary bladder, is called the ampulla.

The ductus deferens has a thick coat of smooth muscle that gives it a characteristic cordlike feel. The longitudinal muscle fibres are well developed, and peristaltic contractions (contractions in waves) move the spermatozoa toward the ampulla. The mucous membrane lining the interior is in longitudinal folds and is mostly covered with nonciliated columnar cells, although some cells have nonmotile cilia. The ampulla is thinner walled and probably acts as a sperm store.

ACCESSORY ORGANS

The prostate, seminal vesicles, and bulbourethral glands. These structures are the male accessory reproductive organs and provide secretions to form the bulk of the seminal fluid of an ejaculate. The prostate is in the lesser or true

Structure
of prostate

pelvis, centred behind the lower part of the pubic arch. It lies in front of the rectum. The prostate is shaped roughly like an inverted pyramid; its base is directed upward and is immediately continuous with the neck of the urinary bladder. The urethra traverses its substance. The two ejaculatory ducts (see below) enter the prostate near the upper border of its posterior surface. The prostate is of a firm consistency, surrounded by a capsule of fibrous tissue and smooth muscle. It measures about four centimetres across, three centimetres in height, and two centimetres front to back (about 1.6 by 1.2 by 0.8 inch) and consists of glandular tissue contained in a muscular framework. It is imperfectly divided into three lobes. Two lobes at the side form the main mass and are continuous behind the urethra. In front of the urethra they are connected by an isthmus of fibromuscular tissue devoid of glands. The third, or median, lobe is smaller and variable in size and may lack glandular tissue. There are three clinically significant concentric zones of prostatic glandular tissue about the urethra. A group of short glands that are closest to the urethra and discharge mucus into its channel are subject to simple enlargement. Outside these is a ring of submucosal glands (glands from which the mucosal glands develop), and farther out is a large outer zone of long branched glands, composing the bulk of the glandular tissue. Cancer of the prostate is almost exclusively confined to the outer zone. The glands of the outer zone are lined by tall columnar cells that secrete prostatic fluid under the influence of androgens from the testis. The fluid is thin, milky, and slightly acid.

The seminal vesicles are two structures, about five centimetres (two inches) in length, lying between the rectum and the base of the bladder. Their secretions form the bulk of the seminal fluid. Essentially, each vesicle consists of a much-coiled tube with many diverticula or out-pouches that extend from the main tube, the whole being held together by connective tissue. At its lower end the tube is constricted to form a straight duct or tube that joins with the corresponding ductus deferens to form the ejaculatory duct. The vesicles are close together in their lower parts but are separated above where they lie close to the deferent ducts. The seminal vesicles have longitudinal and circular layers of smooth muscle, and their cavities are lined with mucous membrane, which is the source of the secretions of the organs. These secretions are ejected by muscular contraction during ejaculation. The activity of the vesicles is dependent on androgen production by the testes; castration causes atrophy of the seminal vesicles. The secretion is thick, sticky, and yellowish: it contains the sugar fructose and is slightly alkaline.

Reduction
of
Cowper's
glands
in man

The bulbourethral glands, often called Cowper's glands, lie on the underside of the urethra between the prostate and the bulk of the penis. They are hardly larger than a pea. Each has a slender duct that runs forward and toward the centre to open on the floor of the spongy portion of the urethra. These glands are poorly developed in man. Their secretion is liberated during sexual excitement and may help to lubricate and coat the urethra to assist passage of the ejaculate.

Ejaculatory ducts. The two ejaculatory ducts lie on each side of the midline and are formed by the union of the duct of the seminal vesicle, which contributes secretions to the seminal fluid, with the end of the ductus deferens at the base of the prostate. Each duct is about two centimetres (about 0.8 inch) long and passes between a lateral and the median lobe of the prostate to reach the floor of the prostatic urethra. This part of the urethra has on its floor (or posterior wall) a longitudinal ridge called the urethral crest. On each side is a depression, the prostatic sinus, into which open the prostatic ducts. In the middle of the urethral crest is a small elevation, the colliculus seminalis, on which the opening of the prostatic utricle is found. The prostatic utricle is a short diverticulum or pouch lined by mucous membrane; it may correspond to the vagina or uterus in the female. The small openings of the ejaculatory ducts lie on each side of or just within the opening of the prostatic utricle. The ejaculatory ducts are thin walled and lined by columnar cells.

The female reproductive system

The female gonads or sexual glands are the ovaries; they are the source of ova and also of the female sex hormones estrogens and progesterones. The uterine tubes conduct ova to the uterus, which lies within the lesser or true pelvis. The uterus connects through the cervical canal with the vagina. The vagina opens into the vestibule about which lie the external genitalia, collectively known as the vulva.

EXTERNAL GENITALIA

The female external genitalia include the structures placed about the entrance to the vagina and external to the hymen, the membrane across the entrance to the vagina. They are the mons pubis (also called the mons veneris), the labia majora and minora, the clitoris, the vestibule of the vagina, the bulb of the vestibule, and the greater vestibular glands.

Adapted from H. Gray, *Anatomy of the Human Body*, 28th ed. by C.M. Goss (1966), Lea & Febiger

Figure 4: Female reproductive system.

The mons pubis is the rounded eminence, made by fatty tissue beneath the skin, lying in front of the pubic symphysis. A few fine hairs may be present in childhood; later, at puberty, they become coarser and more numerous. The upper limit of the hairy region is horizontal across the lower abdomen.

The labia majora are two marked folds of skin that extend from the mons pubis downward and backward to merge with the skin of the perineum. They form the lateral boundaries of the vulval or pudendal cleft, which receives the openings of the vagina and the urethra. The outer surface of each labium is pigmented and hairy; the inner surface is smooth but possesses sebaceous glands. The labia majora contain fat and loose connective tissue and sweat glands. They correspond to the scrotum in the male and contain tissue resembling the dartos muscle. The round ligament (see below *The uterus*) ends in the tissue of the labium. The labia minora are two small folds of skin, lacking fatty tissue, that extend backward on each side of the opening into the vagina. They lie inside the labia majora and are some four centimetres (about 1.6 inches) in length. In front, an upper portion of each labium minus passes over the clitoris—the structure, in the female, corresponding to the penis (excluding the urethra) in the male—to form a fold, the prepuce of the clitoris, and a lower portion passes beneath the clitoris to form its frenulum. The two labia minora are joined at the back across the midline by a fold that becomes stretched at childbirth. The labia minora lack hairs but possess sebaceous and sweat glands.

The clitoris is a small erectile structure composed of two corpora cavernosa separated by a partition. Partially concealed beneath the forward ends of the labia minora, it possesses a sensitive tip of spongy erectile tissue, the glans clitoridis. The external opening of the urethra is some 2.5 centimetres (about one inch) behind the clitoris and immediately in front of the vaginal opening.

The vestibule of the vagina is the cleft between the labia

Clitoris
and
hymen

minora into which the urethra and vagina open. The hymen vaginae lies at the opening of the vagina: it is a thin fold of mucous membrane that varies in shape. After rupture of the hymen, the small rounded elevations that remain are known as the carunculae hymenales. The bulb of the vestibule, corresponding to the bulb of the penis, is two elongated masses of erectile tissue that lie one on each side of the vaginal opening. At their posterior ends lie the greater vestibular glands, small mucous glands that open by a duct in the groove between the hymen and each labium minus. They correspond to the bulbourethral glands of the male.

The blood supply and nerve supply of the female external genital organs are similar to those supplying corresponding structures in the male.

INTERNAL STRUCTURES

The vagina. The vagina (the word means “a sheath”) is the canal that extends from the cervix (outer end) of the uterus within the lesser pelvis down to the vestibule between the labia minora. The orifice of the vagina is guarded by the hymen. The vagina lies behind the bladder and urethra and in front of the rectum and anal canal. Its walls are collapsed; the anterior wall is some 7.5 centimetres (three inches) in length, whereas the posterior wall is about 1.5 centimetres (0.6 inch) longer. The vagina is directed obliquely upward and backward. The axis of the vagina forms an angle of over 90° with that of the uterus. This angle varies considerably, depending on conditions in the bladder, in the rectum, and during pregnancy. The cervix of the uterus projects for a short distance into the vagina and is normally pressed against its posterior wall. There are, therefore, recesses in the vagina at the back, on each side, and at the front of the cervix. These are known as the posterior fornix (behind the cervix and the largest), the lateral fornices (at the sides), and the anterior fornix (at the front of the cervix). The position of the uterus in relation to the vagina is described further in the section on the uterus.

The upper part of the posterior wall of the vagina is covered by peritoneum or membrane that is folded back onto the rectum to form the recto-uterine pouch. The lower part of the posterior vaginal wall is separated from the anal canal by a mass of tissue known as the perineal body.

Mucous
membrane
and muscle
coat of
vagina

The vagina has a mucous membrane and an outer smooth muscle coat closely attached to it. The mucous membrane has a longitudinal ridge in the midline of both the anterior and posterior walls. The ridges are known as the columns of the vagina; many rugae or folds extend from them to each side. The furrows between the rugae are more marked on the posterior wall and become especially pronounced before birth of a child. The membrane undergoes little change during the menstrual cycle (except in its content of glycogen, a complex starchlike carbohydrate); this is in contradistinction to the situation in many mammals in which marked exfoliation (shedding of the surface cells) can occur. No glands are present in the vaginal lining, and mucus present has been secreted by the glands in the cervical canal of the uterus. The smooth muscle coat consists of an outer longitudinal layer and a less developed inner circular layer. The lower part of the vagina is surrounded by the bulbospongiosus muscle, a striped muscle attached to the perineal body.

The blood supply to the vagina is derived from several adjacent vessels, there being a vaginal artery from the internal iliac artery and also vaginal branches from the uterine, middle rectal, and internal pudendal arteries, all branches of the internal iliac artery. The nerve supply to the lower part of the vagina is from the pudendal nerve and from the inferior hypogastric and uterovaginal plexuses.

The uterus. The uterus, or womb, is shaped like an inverted pear. It is a hollow, muscular organ with thick walls, and it has a glandular lining called the endometrium. The human uterus is normally a single structure, termed a simplex uterus; in the majority of mammals there are two horns or pouches to the uterus (bicornuate). In an adult virgin the uterus is 7.5 centimetres (three inches) long, five centimetres (two inches) in breadth, and 2.5 centimetres (one inch) thick, but it enlarges to four to five

Figure 28: The uterus.

Adapted from H. Gray, *Anatomy of the Human Body*, 28th ed. by C.M. Goss (1966); Lea & Febiger

times this size in pregnancy. The narrower, lower end is called the cervix; this projects into the vagina. The cervix is made of fibrous connective tissue and is of a firmer consistency than the body of the uterus. The two uterine tubes enter the uterus at opposite sides, near its top. The part of the uterus above the entrances of the tubes is called the fundus; that below is termed the body. The body narrows towards the cervix, and a slight external constriction marks the juncture between the body and the cervix.

The uterus does not lie in line with the vagina but is usually turned forward (anteverted) to form approximately a right angle with it. The position of the uterus is affected by the amount of distension in the urinary bladder and in the rectum. Enlargement of the uterus in pregnancy causes it to rise up into the abdominal cavity, so that there is closer alignment with the vagina. The nonpregnant uterus also curves gently forward; it is said to be anteфлекed. The uterus is supported and held in position by the other pelvic organs, by the muscular floor or diaphragm of the pelvis, by certain fibrous ligaments, and by folds of peritoneum. Among the supporting ligaments are two double-layered broad ligaments, each of which contains a uterine tube along its upper free border and a round ligament, corresponding to the gubernaculum testis of the male, between its layers. Two ligaments—sometimes called Mackenrodt's ligaments—at each side of the cervix are also important in maintaining the position of the uterus.

The cavity of the uterus is remarkably small in comparison with the size of the organ. Except during pregnancy, the cavity is flattened, with front and rear walls touching, and is triangular. The triangle is inverted, with its base at the top, between the openings of the two uterine tubes, and with its apex at the internal os, the opening into the cervix. The canal of the cervix is flattened from front to back and is somewhat larger in its middle part. It is traversed by two longitudinal ridges and has oblique folds stretching from each ridge in an arrangement like the branches of a tree. The cervical canal is 2.5 centimetres (about one inch) in length; its opening into the vagina is called the external os of the uterus. In virgins the external os is small, almost circular, and often depressed. After childbirth, the external os becomes bounded by lips in front and in back and is thus more slitlike. The cervical canal is lined by a mucous membrane containing numerous glands that secrete a clear, alkaline mucus. The upper part of this lining, in the region called the isthmus, undergoes cyclical changes resembling, but not as marked as, those occurring in the body of the uterus. Numerous small cysts (Naboth's follicles) are found in the cervical mucous membrane. It is from this region that cervical smears are taken in order to detect early changes indicative of cancer.

The uterus is composed of three layers of tissue. On the outside is a serous coat of peritoneum (a membrane exuding a fluid like blood minus its cells and the clotting factor fibrinogen) which partially covers the organ. In front it covers only the body of the cervix; behind it covers the body and the part of the cervix that is above the vagina and is prolonged onto the posterior vaginal wall; from there it is folded back to the rectum. At the side the peritoneal layers stretch from the margin of the uterus to each side wall of the pelvis, forming the two broad ligaments of the uterus.

The tissue
layers in
the uterus

The middle layer of tissue is muscular (the myometrium) and comprises the greater part of the bulk of the organ. It is very firm and consists of densely packed, unstriped, smooth muscle fibres. Blood vessels, lymphatics, and nerves are also present. The muscle is more or less arranged in three layers of fibres running in different directions. The outermost fibres are arranged longitudinally. Those of the middle layer run in all directions without any orderly arrangement; this layer is the thickest. The innermost fibres are longitudinal and circular in their arrangement.

The innermost layer of tissue in the uterus is the mucous membrane, or endometrium. It lines the uterine cavity as far as the internal os, where it becomes continuous with the lining of the cervical canal. The endometrium contains numerous uterine glands that open into the uterine cavity and that are embedded in the cellular framework or stroma of the endometrium. Numerous blood vessels and lymphatic spaces are also present. The appearances of the endometrium vary considerably at the different stages in reproductive life. It begins to reach full development at puberty and thereafter exhibits dramatic changes during each menstrual cycle. It undergoes further changes before, during, and after pregnancy; during the menopause; and in old age. These changes are for the most part hormonally induced and controlled by the activity of the ovaries.

To understand the nature of the changes in the endometrium during each menstrual cycle it is usual to consider the endometrium to be composed of three layers. They blend imperceptibly but are functionally distinct: the inner two layers are shed at menstruation; the outer or basal layer remains in position against the innermost layer of the myometrium. The three layers are called, respectively, the stratum compactum, the stratum spongiosum, and the stratum basale. The stratum compactum is nearest to the uterine cavity and contains the lining cells and the necks of the uterine glands; its stroma is relatively dense. Superficial blood vessels lie beneath the lining cells. The stratum spongiosum is the large middle layer. It contains the main portions of uterine glands and accompanying blood vessels; the stromal cells are more loosely arranged and larger than in the stratum compactum. The stratum basale lies against the uterine muscle; it contains blood vessels and the bases of the uterine glands. Its stroma remains relatively unaltered during the menstrual cycle.

The menstrual cycle

The menstrual cycle extends over a period of about 28 days (normal range 21–34 days), from the first day of one menstrual flow to the first day of the next. It reflects the cycle of changes occurring in the ovary, which is itself under the control of the anterior lobe of the pituitary. The menstrual cycle is divided into four phases; menstrual, postmenstrual, proliferative, and secretory phases. These states are discussed in more detail below; see *The menstrual cycle*.

The secretory phase reaches its climax about a week after ovulation. Ovulation occurs in midcycle, about 14 days before the onset of the next menstrual flow. The endometrium has been prepared and has been stimulated to a state of active secretion for the reception of a fertilized ovum. The stage has been set for the attachment of the blastocyst, derived from a fertilized ovum, to the endometrium, and for its subsequent embedding. This process is called implantation; its success depends on the satisfactory preparation of the endometrium in both the proliferative and secretory phases. When implantation occurs, a hormone from certain cells of the blastocyst causes prolongation of the corpus luteum and its continued activity. This causes suppression of menstruation and results in the maintenance of the endometrium and its further stimulation by progesterone, with consequent increased thickening. The endometrium of early pregnancy is known as the decidua.

In a cycle in which fertilization of the ovum has not taken place, the secretory phase terminates in menstruation.

The phenomenon of menstruation occurs also in the great apes and in the Old World monkeys, but in New World monkeys, uterine changes are not as dramatic and bleeding is slight. It does not occur in other mammals (except perhaps in modified form in the elephant shrew);

and the slight bleeding that may occur in some mammals at about the time of ovulation, caused by high levels of estrogen, is distinct from menstruation. Menstruation may seem a wasteful process, with its loss of tissue and of blood and the iron contained in the blood. If not excessive or abnormally frequent, this loss can be readily made good by a healthy woman. The endometrium needs to be in a certain state of preparedness before implantation can occur. When this stage has been passed, menstruation occurs. Repair then reestablishes an endometrium capable of being stimulated again to the critical stage when implantation can occur.

The uterus is supplied with blood by the two uterine arteries, which are branches of the internal iliac arteries, and by ovarian arteries, which connect with the ends of the uterine arteries and send branches to supply the uterus. The nerves to the uterus include the sympathetic nerve fibres, which produce contraction of uterine muscle and constriction of vessels, and parasympathetic (sacral) fibres, which inhibit muscle activity and cause dilation of blood vessels.

The uterine tubes. The uterine tubes, often called the fallopian tubes, carry ova from the ovaries to the cavity of the uterus. Each opens into the abdominal cavity near an ovary, at one end, and into the uterus, at the other. Three sections of the tubes are distinguished: the funnel-shaped outer end, or infundibulum; the expanded and thin-walled intermediate portion, or ampulla; and the cordlike portion, the isthmus, that opens into the uterus. The infundibulum is fringed with irregular projections called fimbriae. One fimbria, somewhat larger than the others, is usually attached to the ovary. The opening into the abdomen is at the bottom of the infundibulum and is small. Fertilization of the ovum usually occurs in the ampulla of the tube. Normally the fertilized egg is transported to the uterus, but occasionally it may adhere to the tube and start developing as an ectopic or tubal pregnancy. The tube is unable to support this pregnancy, and the conceptus may either be extruded through the abdominal opening or may cause rupture of the tube, with ensuing hemorrhage.

The uterine tube is covered by peritoneum except on its border next to the broad ligament. There are inner circular and outer longitudinal layers of smooth muscle fibres continuous with those of the uterus. The inner lining has numerous longitudinal folds that are covered with ciliated columnar and secretory cells. Muscular contraction, movement of the hairlike cilia, and the passage of the watery secretions all probably assist in the transport of spermatozoa to the ampulla and of a fertilized ovum toward the uterus.

The ovaries. The female gonads, or primary sex organs, corresponding to the testes in a male, are the two ovaries. Each is suspended by a mesentery, or fold of membrane, from the back layer of the broad ligament of the uterus. In a woman who has not been pregnant, the almond-shaped ovary lies in a vertical position against a depression, the ovarian fossa, on the side wall of the lesser pelvis. This relationship is altered during and after pregnancy. Each ovary is somewhat over 2.5 centimetres (one inch) in length, 1.25 centimetres (0.5 inch) across and slightly less in thickness, but the size varies much with age and with the state of activity.

The mesentery of the ovary helps to keep it in position, and within this membrane lie the ovarian artery and vein, lymphatics, and nerve fibres. The uterine tube arches over the ovary and curves downward on its inner or medial surface.

Except at its hilum, the point where blood vessels and the nerve enter the ovary and where the mesentery is attached, the surface of the ovary is smooth and is covered by cubical cells. Beneath the surface, the substance of the ovary is divided into an outer portion, the cortex, and an inner portion, or medulla. The outermost part of the cortex, immediately beneath the outer covering, forms a thin connective tissue zone, the tunica albuginea. The rest of the cortex consists of stromal or framework cells, contained in a fine network of fibres, and also the follicles and corpora lutea.

The ovarian follicles, sometimes called graafian folli-

Shape, position, structure, of ovaries

Figure 29: Cross section of the ovary.

cles, are rounded enclosures for the developing ova in the cortex near the surface of the ovary. At birth and in childhood they are present as numerous primary or undeveloped ovarian follicles. Each contains a primitive ovum, or oocyte, and each is covered by a single layer of flattened cells. As many as 700,000 primary follicles are contained in the two ovaries of a young child. Most of these degenerate before or after puberty.

During the onset of puberty and thereafter until the menopause (except during pregnancy), there is a cyclic development of one or more follicles each month into a mature follicle. The covering layer of the primary follicle thickens and can be differentiated into an inner membrana granulosa and an outer vascularized theca interna. The cells of these layers (mostly the theca interna) produce estrogenic steroid hormones that exert their effects on the endometrium of the uterus and on other tissues. The maintenance and growth of the follicle to maturity is brought about by a follicle-stimulating hormone (FSH) from the anterior lobe of the pituitary gland. Another hormone, called luteinizing hormone (LH), from the anterior lobe, assists FSH to cause the maturing, now fluid-filled follicle to secrete estrogens. LH also causes a ripe follicle (1.0–1.5 centimetres [0.4–0.6 inch] in diameter) to rupture, causing the liberation of the oocyte into the peritoneal cavity and thence into the uterine tube.

This liberation of the oocyte is called ovulation; it occurs at about the midpoint of the human reproductive cycle, on the 13th–14th day of a 28-day cycle as measured from the first day of the menstrual flow.

After ovulation the ruptured follicle collapses because of loss of its follicular fluid and rapidly becomes transformed into a soft, well-vascularized glandular structure known as the corpus luteum. The human corpus luteum ("yellow body") is not yellow but is a creamy gray on section. It develops rapidly, becomes vascularized after about four days, and is fully established by nine days. The gland produces the steroid hormone progesterone and some estrogens. Its activity is both stimulated and maintained by luteinizing hormone. Progesterone stimulates glandular proliferation and secretion in an endometrium primed by estrogens.

While the ovarian follicle matures, the primary oocyte divides into a secondary oocyte and a small rudimentary ovum called the first polar body. This occurs at about the time when the follicle develops its cavity; the oocyte also gains a translucent, acellular covering or envelope, the zona pellucida. The secondary oocyte is liberated at ovulation: it is 120–140 microns in diameter and is surrounded by the zona pellucida and a few layers of cells known as the corona radiata. The final maturation of the oocyte, with the formation of the rudimentary ovum called the second polar body, occurs at the time of fertilization.

If fertilization does not occur, then the life of the corpus luteum is limited to about 14 days. Degeneration of the gland starts toward the end of this period and menstruation occurs. The corpus luteum shrinks, fibrous tissue is formed, and it is converted into a scarlike structure, called a corpus albicans, which persists for a few months. Should fertilization occur and be followed by implantation of the blastocyst, hormones (particularly chorionic gonadotrophin) are produced by cells of the blastocyst to

prolong the life of the corpus luteum. It persists in an active state for at least the first two months of pregnancy until the placental tissue has taken over its endocrine (hormone-producing) function. The corpus luteum of pregnancy then also retrogresses and is becoming a fibrous scar by the time of parturition.

The ovarian arteries arise from the front of the aorta, in a manner similar to the testicular arteries, but at the brim of the lesser pelvis they turn down into the pelvic cavity. Passing in the suspensory ligament of the ovary, each artery reaches the broad ligament below the uterine tube and then passes into the mesovarium to divide into branches distributed to the ovary. One branch continues in the broad ligament to anastomose with the uterine artery. The ovarian veins emerge from each ovary as a network that eventually becomes a single vein; the terminations are similar to those of the testicular veins. The nerves are derived from the ovarian nerve network on the ovarian artery. (R.J.Ha.)

THE MENSTRUAL CYCLE

Menstruation is the periodic discharge from the vagina of blood, secretions, and disintegrating mucous membrane that had lined the uterus.

The biological significance of the process can best be explained by reference to the reproductive function in other mammals. In a number of species of wild sheep, for example, there is only one breeding season in the year; during this season a cycle of changes takes place in the reproductive organs, characterized by ripening and release of ova from the ovaries, increased blood supply to the genital tract, growth of the uterus, and proliferation of its lining. There is a discharge of blood and mucus from the uterus and vagina, and this is the time when coition may take place. Pregnancy normally follows, but if the ewe is not served by the ram the changes retrogress until the next breeding season. This cycle of changes is termed the estrous cycle.

In many domesticated sheep there is more than one estrous cycle in the breeding season. If the ewe does not become pregnant in the first cycle there is a short resting phase; then ovulation is repeated and another cycle of activity of the reproductive system takes place. After each breeding period, with its succession of estrous cycles, there is a relatively long resting phase.

In most female primates, including women, there is no resting phase; an unbroken series of estrous cycles occurs throughout the year, and pregnancy can occur in any one of them.

In some animals a variety of external stimuli act through the central nervous system on the hypothalamic region of the brain. The hypothalamus controls the release from the pituitary gland of hormones that induce ripening of ovarian follicles—ova and the cellular structures that enclose them. These pituitary hormones, called gonadotropic hormones, are carried to the ovaries by way of the bloodstream. In primates the hypothalamic mechanism normally is independent of external stimuli, and regular discharge of ova into the tubes leading to the uterus occurs even in the absence of coitus. Under the influence of the pituitary gonadotropic hormones, the ovary produces other hormones, which cause growth and increased vascularity of the uterus and vagina. These hormones are estrogens—chiefly 17 beta-estradiol—and progesterone. It is as though the ovary prepares the uterus for the reception of the ovum that is released in the particular cycle.

Phases of the menstrual cycle. The normal human menstrual cycle is 28 days, but no woman is always precisely regular, and cycles as short as 21 days or as long as 35 days are not abnormal. It is customary to call the first day of the menstrual period the first day of the cycle, although menstruation is the end rather than the beginning of a process. On this basis the cycle is described as starting with about five days of menstruation, followed by a proliferative phase that lasts to about the 14th day, and then a secretory phase that lasts until the next menstruation. The external manifestation of menstruation depends upon cyclical change in the lining of the body of the uterus. The lining, called endometrium, consists of tubular glands that

Cyclical development of follicles

Corpus luteum

The estrous cycle

Figure 30: Menstrual cycle.

From Ciba Collection of Medical Illustrations, vol. 4, J. & A. Churchill, Ltd.

open into the uterine cavity. The glands lie in a vascular framework, or stroma, and are separated by it.

The
proliferative
phase

At the end of menstruation, just at the beginning of the proliferative phase, the endometrium is thin, with short, straight glands, and the ovary is quiescent. Under the influence of the gonadotropic hormones from the pituitary gland an ovarian follicle (occasionally more than one) ripens in one of the ovaries. This ovarian follicle contains the ovum, which is a cell about 0.14 millimetre (0.006 inch) in diameter, surrounded by a group of smaller cells, called granulosa cells. The granulosa cells multiply, with the ovum situated in the wall of the rounded structure that they form, and secrete an estrogenic hormone, estradiol (see BIOCHEMICAL COMPONENTS OF ORGANISMS: *Hormones*). This hormone causes proliferative changes in the endometrium, so that the glands become taller and the whole endometrium becomes thicker and more vascular.

The
secretory
phase

At about mid-cycle ovulation occurs: The ovum is discharged out of the follicle and from the surface of the ovary, to be received into the fallopian tube, down which it is carried to the uterus. After ovulation the granulosa cells lining the follicle from which the ovum has been extruded accumulate yellow lipid and are therefore called lutein cells, from the Latin word *luteus*, "saffron-yellow." The altered follicle is called corpus luteum. The corpus luteum continues to secrete estrogens but now also secretes progesterone; this additional hormone induces the secretory phase in the endometrium. The endometrial glands are distended with secretion and become very tortuous, while the stromal cells are swollen. The appearance of the endometrium at the end of the menstrual cycle is indistinguishable from that of early pregnancy, and this endometrial change is a preparation for the reception of the ovum. If it is fertilized, the ovum liberated at mid-cycle reaches the uterine cavity at a time when the endometrium is in the secretory phase, and the ovum embeds itself in the endometrium and starts its growth. If the ovum is not fertilized the endometrium breaks down and menstruation occurs. Menstruation has therefore been described as the outward evidence of the abortive close of one cycle and the hopeful commencement of the next.

When the ovum dies, the corpus luteum degenerates

and ceases to produce hormones. On the withdrawal of estrogens and progesterone there is sudden spasm of the endometrial blood vessels, and all but the basal layer of the endometrium dies. The disintegrating endometrium is shed, together with some blood. The endometrium contains plasmin, an enzyme that dissolves blood clots, so that the menstrual discharge is normally fluid. The total blood loss does not ordinarily exceed 50 millilitres (1.69 U.S. fluid ounces).

After menstruation the endometrium regenerates from the residual basal layer during the proliferative phase of the next cycle.

Hormonal control of menstrual cycle. The ovarian hormones circulate in the blood and are excreted in modified forms in the urine. Estimation of the urinary output by chemical methods gives an indication of the blood levels and of the total production of these substances. There are several natural estrogens, and numerous synthetic modifications of these and of progesterone have been devised; many are active when taken by mouth and are used for treatment of hormonal disorders and as oral contraceptives.

The cyclic events in the ovary that have already been mentioned depend on gonadotropic hormones secreted by the anterior lobe of the pituitary gland; this gland is situated in a small recess at the base of the skull. There are two, and possibly three, gonadotropic hormones: follicle-stimulating hormone (FSH), luteinizing hormone (LH), and, possibly, luteotrophic hormone (LTH).

FSH is secreted in greatest amount in the first half of the menstrual cycle, and LH has its peak of secretion at mid-cycle. It is believed that the sequential action of FSH and LH causes ripening of the follicle and ovulation. In some animals LTH is necessary for maintenance of the corpus luteum, but in women under treatment for infertility ovulation has been successfully induced with FSH and LH alone. Multiple births, as the result of multiple ovulation, have occurred after excessive doses of FSH have been given.

The pituitary gland stimulates the ovary to produce estrogens and progesterone, but there is a "negative feedback" by which the estrogens inhibit the output of FSH from the pituitary gland (and probably stimulate the output of LH). In addition, progesterone is believed to inhibit the further output of LH. In this process, in which the pituitary first stimulates the ovary, and the ovary then inhibits the pituitary, the basic rhythm is under the control of the hypothalamus; nevertheless, ovulation can be inhibited by oral contraceptives, which contain estrogens and progestogens—modifications of progesterone.

The anterior lobe of the pituitary gland is connected by its stalk to the hypothalamic region of the brain. The anterior lobe secretes many important hormones, including those that control the activity of the adrenal and thyroid glands, the growth hormone, and the gonadotropic hormones. From the hypothalamus substances are carried in the veins in the pituitary stalk that cause release of hormones from the pituitary, including FSH and LH, but also a factor that inhibits release of LTH. The higher brain centres no doubt affect the hypothalamic function; this explains the temporary disturbances of menstruation that may follow emotional stress.

Ovulation and the fertile phase. Ovulation occurs at about the midpoint of each normal cycle, and the ovum is probably capable of fertilization for only about two days after this. In the majority of women the time of ovulation is fairly constant. In women with cycles of irregular length the date of ovulation is uncertain; in these women the long menstrual cycles are usually due to prolongation of the proliferative phase; the secretory phase tends to remain normal in length. In some animals, ovulation only follows coitus; this mechanism has been used to explain cases in which human pregnancy has apparently followed coitus early or late in the menstrual cycle, but there is no definite evidence for such a mechanism in women.

The rhythm method of contraception is based on the fact that ovulation normally occurs at mid-cycle, but the date of ovulation may vary unexpectedly even in women whose menstrual cycles were previously regular.

The menarche. The first menstruation, or menarche,

Inhibitory
effect of
estrogens
and
proges-
terone

usually occurs between 11 and 13 years of age, but in a few otherwise normal children menstruation may begin sooner or may be delayed. If the menstrual periods have not started by the age of 16 gynecological investigation is indicated. The menarche is preceded by other signs of estrogenic activity, such as enlargement of the breasts and the uterus and growth of pubic hair. The ovarian response to gonadotropic hormones may be erratic at first, so that irregular or heavy bleeding sometimes occurs, but this irregularity nearly always disappears spontaneously.

Normal menstruation. Each menstrual period lasts for about five days, but the duration and amount of the flow vary considerably even in perfect health.

Discomfort
in normal
menstrua-
tion

In some women there may be premonitory symptoms such as pelvic discomfort, soreness of the breasts (because of the response of these organs to estrogens), and emotional tension. Ovarian hormones cause retention of sodium and water in the tissue fluids; premenstrual tension, sometimes called Premenstrual Syndrome, may be partly due to this and in some cases can be relieved by diuretics, drugs that increase the production of urine. When the menstrual flow starts the uterus contracts to expel the blood and disintegrating endometrium. These contractions may be painful, especially in young women who have never been pregnant. Menstrual discomforts such as those that have been mentioned vary greatly in degree from woman to woman and from time to time but ordinarily do not interfere with normal activities. (Menstrual disorders are discussed in detail below; see *Reproductive system diseases*.)

(S.G.C./Ed.)

MENOPAUSE

"Menopause" (female climacteric) is the final cessation of menstruation and therefore the end of a woman's reproductive life. The popular term "change of life" is neither descriptive nor accurate, for it tends to indicate a physical, mental, and sexual deterioration, whereas deterioration does not occur.

In most women, menopause begins between the ages of 45 and 55 years. Although the average age for onset is about 50 years, menopause may begin as early as age 40 or be delayed to the late 50s. Although the age of onset is probably determined by the hereditary background of the individual, good nutrition and health habits tend to postpone onset.

A premature menopause—i.e., one that takes place spontaneously before the age of 40—occurs in about 8 percent of women. An artificial menopause may be induced by removing the ovaries by surgery or by destroying them with X-rays or radium.

The natural life of the ovaries is about 35 years. The menopause is brought on by a progressive decline in ovarian function. This decline is a normal result of aging and is accelerated as the menopause approaches. During the reproductive years follicles in the ovaries mature and release their ova periodically under hypothalamic-pituitary stimulation. In the years immediately preceding the menopause, however, first some follicles and later all follicles fail to rupture and release their ova. The failure to ovulate results in a disturbed menstrual pattern. A woman may miss a period or two and suspect pregnancy. A medical examination, however, will establish the proper diagnosis. The continued decline in ovarian activity may provoke prolonged intervals between periods or irregular bleeding episodes. The length of the periods may vary, and the flow may become either more scant or profuse. In a fortunate small minority the periods cease abruptly.

As the ovaries decline in function, they produce smaller and smaller amounts of the hormone estrogen; this decline in estrogen initiates subtle rearrangements in the hormonal activity of the glands that control the reproductive function. The decrease in output of estrogen disturbs the neurovascular mechanism of the hypothalamus and probably initiates the vasomotor changes that may provoke the characteristic "hot flashes" of the menopause. The metabolism of the pituitary gland is altered and increasing amounts of follicle stimulating hormone (FSH) appear in the blood and urine. Rearrangements in the hormonal activity of the adrenal and thyroid glands also take place, for

Estrogen
level

the metabolic activities of all these glands are interrelated. These adjustments are usually made without physical or mental disturbances in most women.

Hot flashes are the only characteristic symptoms of the menopause. They often appear before its obvious onset and their duration is usually limited to two or three years. The young woman who has her ovaries removed for disease or other reasons will develop flashes within a week following the operation.

The hot flash usually begins as a sense of warmth over the upper chest. It then spreads to the neck and face and may extend over the entire body, sometimes giving rise to a prickling sensation. The woman is acutely aware of blushing, which usually is disturbing to her, particularly in company. The flashes may recur frequently during the night and may interfere with sleep. She may awaken because of a chilly sensation and may perspire freely.

A variety of other symptoms can and do occur, although many are entirely unrelated to the changes incidental to the menopause. Nervousness, headaches, and dizziness are common complaints. The fear of aging, the altered pattern of life, and changing family relationships also may precipitate many disturbing symptoms.

Many women complain of weight gain during the menopause. Occasionally this is related to decreased thyroid function. In most cases, however, it is brought about by decreased physical activity and by increased food intake. The menopause is not necessarily associated with unusual changes in physical appearance and fitness.

The administration of estrogenic hormones—once a widely approved remedy for relief of menopausal symptoms and also believed to retard the development of atherosclerosis and osteoporosis (bone decalcification)—has been associated with increased incidence of endometrial cancer and is being reevaluated.

(M.E.D./Ed.)

Diseases of the human reproductive system

The human reproductive system may be affected by abnormal hormone production coming from the ovaries or the testes or from other endocrine glands, such as the pituitary, thyroid, and adrenals. Reproductive-system diseases can also be caused by genetic abnormalities, congenital anomalies (abnormalities), infections, tumours, and disorders of unknown cause.

The main divisions of this section are concerned with (1) genetic and congenital abnormalities; (2) functional genital disorders; (3) infections; (4) structural changes of unknown cause; and (5) tumours. Diseases and disorders of pregnancy and delivery are covered below; see *Abnormal changes in pregnancy* and *Accidents during labour*. Endocrine disorders affecting reproductive organs and functions and discussed in the article ENDOCRINE SYSTEMS.

GENETIC AND CONGENITAL ABNORMALITIES

In the male. Congenital anomalies of the prostate and seminal vesicles are rare; they consist of absence, hypoplasia (underdevelopment), or the presence of fluid- or semisolid-filled sacs, called cysts. Cysts of the prostatic utricle (the uterine remnant found in the male) are often found in association with advanced stages of hypospadias (a defect in the urethra, see below) and pseudohermaphroditism (in which sex glands are present but bodily appearance is ambiguous as to sex; i.e., the secondary sexual characteristics are underdeveloped). Cysts may also cause urinary obstructive symptoms through local pressure on the bladder neck.

Severe anomalies of the penis are rare and are generally associated with urinary or other systemic defects that are incompatible with life. Anomalies are those of absence, transposition, torsion (twisting), and reduplication of the penis. An abnormally large penis frequently is present in boys affected by precocious puberty, in congenital imbeciles, in dwarfs, in men with overactive pituitaries, and in persons affected by adrenal tumours. A small penis is seen in infantilism and in underdevelopment of the genitals, or undersecretion of the pituitary or pineal gland, and failure of development of the corpora cavernosa.

The only anomaly of the foreskin of grave concern is

Abnormal-
ities of the
penis

congenital phimosis, characterized by a contracture of the foreskin, or prepuce, sufficient to prevent its retraction over the glans; the preputial opening may be pinhole in size and may impede the flow of urine. The condition is easily remedied by circumcision, a permanent cure.

There is a considerable variety of urethral anomalies. Stenosis (contracture) of the external opening (meatus) is the most common, but congenital stricture of the urethra occasionally occurs at other points. Valves (or flaps) across the anterior or posterior part of the urethra may cause congenital urethral obstruction in boys. Posterior urethral valves are more common than anterior valves and consist of deep folds of mucous membrane, often paper-thin and usually attached at one end to the verumontanum, a small prominence in the back wall of that part of the urethra that is surrounded by the prostate gland. If too tight, the valves may obstruct the urethra and destroy the kidneys.

There are various defects associated with incomplete closure of the urethra. One of the commonest is hypospadias, in which the underside (ventral side) of the urethral canal is open for a distance at its outer end. Frequently the hypospadiac meatus is narrowed, and the penis also has a downward (ventral) curvature beyond the meatus. The posterior part of the urethra is never involved; therefore, the muscle that closes the urethra, the sphincter, functions normally, and urinary control exists. Although the condition occurs in both sexes, it is seen predominantly in the male. There is a high incidence of partial or complete failure of the testes to develop, cryptorchism (failure of the testes to descend into the scrotum), and small external and internal genitalia; variable male-female admixtures may be associated with this deficiency. Epispadias, an opening in the upper (dorsal) side of the penis, is considerably less common than hypospadias. Dorsal curvature may also be present, but the disabling aspect is that the defect usually extends through the urinary sphincter and causes urinary incontinence. Other less common urethral anomalies include complete absence of the urethra, double urethra, urethra fistula (an opening in the urethra), urethrectal fistula (an opening between the urethra and the rectum), and urethral diverticulum (a pouch in the wall of the urethra). Most of the above conditions are correctable by surgery.

Absence or excessive number of testes

Anorchism (absence of one or both testes) is rare; it may be associated with the absence of various other structures of the spermatid tract. Generally, if one testis is absent, the other is found to be within the abdomen rather than in the scrotum. Congenitally small testes may be a primary disorder or may occur because of underactivity of the pituitary. In both disorders, there is a lack of development of secondary sexual characteristics and some deficiency in libido and potency. Supernumerary testicles are extremely rare; when present, one or more of the supernumerary testicles usually shows some disorder such as torsion of the spermatid cord. Synorchism, the fusion of the two testicles into one mass, may occur within the scrotum or in the abdomen. Cryptorchism is the term applied to all forms of imperfectly descended testes, the commonest anomaly of the spermatid tract. The condition is often bilateral, and in the unilateral cases there is no preponderance between the left or right side. Hormonal treatment may be useful in correcting the condition, but usually surgery is necessary for correction.

In the female. The female external genitalia are less complex than those of the male but have anomalies that can at times severely interfere with the functioning of the female urogenital tract. The clitoris, an erectile structure that corresponds to the penis, except that it does not contain the urethra, may be absent but in other cases may be enlarged on either a congenital or a hormonal basis. Fusion of the labia minora (small folds of skin covering the clitoris, the urethral opening, and the opening of the vagina) is a midline "sealing together" of the labia minora; usually a minute unfused area is left just below the clitoris, through which the child urinates and later menstruates. The chief difficulty with this anomaly is concerned with obstruction to the flow of urine and associated urinary-tract infection. An imperforate hymen (the membrane closing off the opening of the vagina) causes distension of

the uterus and vagina with fluid other than blood before puberty and with blood after puberty (the two conditions are called hydrometrocolpos and hematocolpometra, respectively). The distended vagina compresses the urethra enough to interfere with urination and commonly may even cause complete retention of urine in the bladder and distension of the entire upper urinary tract. Fusion of the urethra and the hymen is characterized by a dense hymenal ring and a stenosed urethral opening. The consequent urinary obstruction commonly results in persistent urinary infection. Most of the conditions are readily remedied by surgery.

Anomalies of the vagina and uterus consist of complete absence, incomplete development, and duplication. The female urethra may have a congenitally narrow opening, or meatus; may be distended; may have an abnormal pouch, or diverticulum, in its wall; or may open abnormally into the vagina. Hypospadias may occur in the female but is far less common than in the male. Epispadias is also present in the female. Reconstructive surgery is the only method of treatment. One of the rarest and most severe of the urogenital-tract anomalies, called persistent cloaca, consists in congenital intercommunication between the rectum and the bladder and vagina or between the rectum and the urethra and vagina.

Intersexuality. Intersexuality (having both male and female characteristics) may be noticeable at birth or may become apparent after puberty. Intersexuality noticeable at birth may be classified as female or male pseudohermaphroditism or true hermaphroditism. Female pseudohermaphroditism, or female intersex, may be of adrenal or nonadrenal type. The adrenal type develops because of an inborn error in the metabolism of the adrenal hormone cortisol that leads to an increased secretion of corticotropin (ACTH) and consequent excessive secretion of androgens (male sex hormones). The newborn female with this condition is a chromosomal female and resembles a normal female, but an excess male hormone has a masculinizing effect on the external genitalia; the vagina tends to be connected to the urethra; the clitoris is enlarged, as are the labia (the labia majora are prominent folds of skin, corresponding to the scrotum in the male). Effective treatment can be achieved by administration of adrenal hormones (e.g., cortisone, hydrocortisone), which suppress the pituitary so that its stimulus to adrenal production of androgenic hormones is minimized. The nonadrenal type of intersex is seen in infants whose mothers have been administered synthetic androgens or progestational compounds (substances that stimulate changes in the uterus that further the implantation and growth of the fertilized ovum) during pregnancy. Rarely, the condition is associated with the presence in the mother of a masculinizing tumour of the ovary or the adrenal gland. The newborn infant is a female with varying degrees of ambiguous genitalia; no treatment is necessary, and normal female development occurs at puberty.

Male pseudohermaphrodites are males with varying deficiencies of internal and external virilization. Most commonly, the male intersex has a markedly hypospadiac penis, undescended testes, a cleft scrotum, and an enlarged prostatic utricle; a complete uterus and fallopian tubes may be found, with the vagina opening into the posterior wall of the urethra. (Such persons are pseudohermaphrodites in that they do not have ovaries.)

True hermaphrodites have recognizable ovarian and testicular tissue. A uterus is always present, but the internal genitalia otherwise vary greatly, often including both male and female structures. The external genitalia are usually ambiguous, but in 75 percent of the reported cases the children have been raised as males. At puberty, over 80 percent of them develop enlarged breasts, and approximately half menstruate. Most hermaphrodites are chromatin positive—that is, they have, within and near the periphery of the nuclei of their cells, a substance, chromatin, that is normally found in the cells of females but not in those of males—and over half have a characteristically female set of chromosomes in their peripheral blood cells.

puberty

ther a male or a female configuration of the body is based on the existing physical and psychological findings.

Klinefelter's, Turner's, and testicular feminizing syndromes are intersexuality syndromes that become apparent prior to or after puberty. Klinefelter's syndrome is a genetic disorder of phenotypic males (persons who have a male body configuration) who do not produce sperm, have small testes, and have varying degrees of eunuchoidism. Patients with this syndrome have various associated medical problems, such as chronic disease of the lungs, varicose veins, thrombophlebitis (inflammation of the blood vessels), obesity, diabetes mellitus, hyperlipemia (abnormally high blood levels of fats), and enlarged breasts at the time of puberty. Mental retardation and antisocial behaviour are also associated with this syndrome.

Turner's syndrome is a disorder of phenotypic females—persons who are female in physical configuration. Characteristically, such persons are short, do not menstruate, and show estrogen (a female sex hormone) deficiency; there is a distinctive cluster of congenital anomalies.

The disorder known as the testicular feminizing syndrome is inherited. Affected persons seem to be of normally developed females but have a chromosomal sex that is that of the normal male. The gonads are well-developed testes, and evidence indicates that there is a normal production of testosterone (male hormone), but there is cellular resistance to the action of this hormone, and therefore the affected person becomes female in appearance. Because these gonads are apt to form malignant tumours, they are usually removed surgically. Female sexual characteristics are then maintained by the administration of estrogenic hormones.

FUNCTIONAL GENITAL DISORDERS

Affecting both male and female systems. *Delayed puberty.* The term delayed puberty may be a misnomer, because puberty delayed beyond age 19 is in fact a permanent failure of sexual development because of an abnormally low secretion by the pituitary gland of gonadotropic hormone, the hormone that stimulates growth and activity of the sex glands; this condition is called hypogonadotropic eunuchoidism. The term delayed puberty is usually applied to boys who develop more slowly than the average but who still eventually undergo full sexual development. Only in retrospect—i.e., after the affected person reaches the age of 20—can one clearly differentiate these cases from the classic or incomplete forms of hypogonadotropic eunuchoidism. If there are social and psychological problems related to the sexual underdevelopment, therapy may consist of a course of chorionic gonadotropin, a hormone produced by the placenta and secured from the urine of pregnant women. If puberty is merely delayed, it will usually progress normally after this treatment. If it fails to progress, the patient does not have delayed puberty but rather has hypogonadotropic eunuchoidism.

Precocious puberty. In healthy girls living in a temperate climate, the earliest sign of puberty occurs at a mean age of 10.6 years (standard deviation of 1.2 years), whereas, in boys, testicular growth begins at a mean age of 11.8, with a standard deviation of one year. The average age of menstruation is 13.5 years (range, 9–17 years). What is called true precocious puberty is a condition in which normal pituitary-gonadal function is activated at an abnormally early age. It is always isosexual with the sex gonads (i.e., it is always in keeping with the sex of the gonads) and with development of the secondary sexual characteristics and production of spermatozoa or ova. Pseudoprecocious puberty includes development of secondary sexual characteristics but not production of spermatozoa or ova and may be isosexual or may be heterosexual (i.e., it may involve virilization in the female or feminization in the male).

The causes of true precocious puberty are several—including brain lesions and hypothyroidism (abnormally low secretion by the thyroid glands); the largest proportion of cases are of unknown cause. Precocious pseudopuberty in females may be caused by ovarian tumours, a cyst of the ovary, a tumour of the adrenal cortex (outer substance of the adrenal gland), or congenital overdevelopment of the adrenal gland. In males, the causes include congen-

ital overdevelopment of the adrenal glands, tumour of the adrenal cortex, tumour involving the Leydig cells of the testes, and teratoma (a tumour containing numerous types of tissue; in these circumstances it includes adrenal-cortical tissue).

Infertility. At least 10 percent of marriages are barren, and deficiencies of sperm production in the male are the causal factor in 40 percent of these. The common causes of male infertility are deficiencies in maturation of germ cells (sperm); orchitis (mumps), with destruction of the testes; obstruction of the passageways for sperm; abnormally low thyroid or high adrenal secretion; varicocele (enlargement of the veins of the spermatic cord); or formation of antibodies to sperm by the male or the female. The most important steps in the evaluation of male infertility are examination of the semen and of a specimen of the tissue of the testes. Evaluation also includes chromatin analysis and observation of thyroid, adrenal, and pituitary function. The results of treatment of infertility in the male are usually unsatisfactory, except when a varicocele or obstruction in the sperm passageways is the cause, in which case surgical correction may be beneficial.

Infertility in the female is related to the faulty production of ova or to interferences with their union with spermatozoa. Vaginal causes are usually uncommon, but obstruction may be due to an unruptured hymen or may be functional and arise from enlargement and contraction of the levator ani muscles (these muscles form a supporting sheet under the pelvic cavity, with openings for structures such as the anus and the vagina). Abnormalities of the cervix are among the most important causes obstructing the passage of sperm. (The sperm normally enter the uterus through the cervix and, from the uterus, move into a uterine or fallopian tube, where fertilization of an ovum takes place.) During the few days prior to ovulation—release of an ovum from the ovary—the glands within the cervix normally secrete a thin, watery mucus that is beneficial to sperm survival and migration. Various factors, such as infection or estrogen deficiency, may decrease the quality of the mucus.

Uterine anomalies such as a bicornuate (double) uterus may play a role in infertility. Total or partial blocking of the uterine tubes can result from inflammation due to infection (e.g., gonorrhea) or from endometriosis, a condition involving the presence of tissue resembling that which lines the uterus elsewhere in the pelvic cavity. Thyroid, pituitary, adrenal, or ovarian disease may interfere with ovulation, as may the presence of large numbers of cysts in the ovaries (the condition known as polycystic ovaries).

Finally, emotional factors may play a role in causing infertility. Treatment consists of the use of various hormones, surgical correction of tubal blockage, and psychotherapy. With the advent of new hormone preparations, the results in achieving pregnancy have been vastly improved.

(N.A.Ro./J.K.La.)

Affecting female system. Abnormalities of menstrual function include absence of menstruation, called amenorrhea; excessive blood loss at each period, known as menorrhagia; irregular cycles, or metrorrhagia; and painful menstruation, or dysmenorrhea. In addition, there may be premenstrual tension, and in a few women, pain at the time of ovulation. As a sexual and reproductive function, menstruation has deep emotional significance, but the popular belief that regular menstrual flow is necessary for health is unfounded. The belief arises in part from the fact that in any severe illness, and during emotional disturbances and psychiatric illness, the cycles may be disturbed. This is particularly true of diseases of the endocrine system, not only of the pituitary gland but of other glands, such as the thyroid and the adrenal, as well.

Menstrual abnormality may also be a symptom of local disease of the pelvic organs. Irregular bleeding, bleeding after intercourse, and bleeding at or after the menopause may be early signs of uterine malignant disease.

A few women have transient abdominal discomfort at the time of ovulation because of slight bleeding from the follicle into the peritoneal cavity. Oral administration of estrogens and progestogens will remedy the condition by suppression of ovulation, but the discomfort seldom recurs

in every cycle or is severe enough to merit such treatment.

Premenstrual tension has already been mentioned. When it is due to fluid retention there is increase in weight before menstruation, and diuretics such as chlorothiazide give relief. In most instances emotional tension is the main complaint, and relief is attained by the use of mild sedatives or tranquilizers. Objective studies of women who do fine work show a reduction in accuracy and in concentration at this time, and outbursts of emotion may occur. The claim that relief is obtained by administration of progestogens is not generally accepted.

Painful menstruation in young women who have not borne children is a common complaint; the pain is sometimes so severe as to interfere with daily occupations. There is, as a rule, no endocrine or anatomical abnormality, and fertility is normal. The pain occurs during the active menstrual flow and is due to colicky contractions of the uterus. Minor degrees of pain are adequately controlled with analgesic drugs. In the past severe cases were often treated by surgical dilation of the cervix, and occasionally by severing the nerves that carry the pain impulses from the uterus, but now hormonal treatment is more usual. This type of dysmenorrhea usually does not persist after birth of a child.

Another type of dysmenorrhea results from pelvic disease such as inflammation of the tubes and ovaries, or from endometriosis. In endometriosis, deposits of endometrium, which undergo cyclic response to the ovarian hormones, are found in the ovaries and in other sites outside their normal location; these deposits form blood-filled cysts, and pain and excessive bleeding result. In painful menstruation secondary to pelvic disease there is, before menstruation, pain associated with a feeling of congestion, and the menstrual bleeding is often excessive. Surgical treatment may be required, although the symptoms of endometriosis can be suppressed by use of progestogens.

Excessive or irregular menstrual bleeding; intermenstrual bleeding

Excessive or irregular menstrual bleeding may be due to an imbalance of the pituitary and ovarian hormones, but it may also be the result of local disease of the pelvic organs. This local disease may be inflammation due to infection; it may be a benign tumour such as a fibromyoma, or fibroid; it may be a polyp, or projecting mass of endometrium; or it may be a cancer, especially after age 35. Some types of local pelvic disease may require removal of the uterus or treatment by irradiation but polyps and some fibroids can be removed without loss of the uterus.

Irregular or excessive bleeding often results from emotional disturbance; this type of abnormality tends to disappear spontaneously.

As the menopause approaches, extremely heavy bleeding may occur, causing anemia, tiredness, and ill health. Menorrhagia in this instance is due to overdevelopment of the endometrium as a result of excessive or unbalanced action of estrogens. Younger or childless women can be treated with progestogens; for others removal of the uterus may be necessary.

Bleeding between periods or after intercourse is frequently due to some abnormality of the cervix; in women who have borne children the possibility of cancer must be borne in mind. Such bleeding may also come from a simple polyp on the cervix or a cervical erosion. The latter is a rather common condition in which the glandular lining of the canal of the cervix extends out onto its surface. Treatment is often unnecessary, but erosions are easily dealt with by cauterization. Polyps require removal.

Irregular bleeding also may occur during pregnancy when there is danger of abortion; if any menstrual periods have been missed this possibility must be considered.

Amenorrhea

Amenorrhea, or absence of menstruation, is normal during pregnancy and for a variable time after delivery. If the mother is breast-feeding her baby, as much as six months may pass before return of menstruation; earlier return of menstruation is not abnormal and is to be expected if the mother is not producing milk. Pregnancy is the commonest cause of amenorrhea during the reproductive years.

The term primary amenorrhea refers to the absence of menstruation in a woman who has never previously menstruated. In rare cases, primary amenorrhea is due to gonadal dysgenesis, the failure of the ovaries to develop

normally, and may be associated with chromosomal abnormalities. Instead of the normal female complement of 46 chromosomes in each cell, including two X-chromosomes, a patient may have only one X-chromosome, or even a male pattern of an X- and a Y-chromosome. In such persons the uterus and tubes often are absent, although the general physique may be female.

Even with normal ovaries, absence of the uterus occasionally occurs. A less rare abnormality is vaginal atresia, or closure, an obstruction of the vagina by a membrane just above the level of the hymen; menstruation occurs, but the discharge cannot escape and distends the vagina. This condition, called false amenorrhea or cryptomenorrhea, is easily corrected by an incision in the membrane.

Cessation of periods after menstruation has been established, but before the normal time for the menopause, is usually the result of some general illness, some emotional disturbance, or a psychiatric illness. It may also be due to disease of the endocrine system, not only of the pituitary gland but of other endocrine glands as well. Secondary amenorrhea results if the ovaries are removed or are irradiated but is unlikely to be caused by ovarian disease, as both ovaries would have to be totally destroyed to stop all function. There is a functional disorder of the ovaries in which production of estrogens is disturbed. Symptoms of this disorder include abnormal growth of facial hair because of abnormal androgenic—that is, masculinizing—activity. An ovarian tumour, arrhenoblastoma, that secretes androgenic hormone, is another extremely rare cause of amenorrhea and abnormal growth of hair.

Most cases of secondary amenorrhea are temporary, and spontaneous improvement is to be expected, especially when the cause is some general illness or emotional disturbance. Treatment of amenorrhea serves no purpose unless pregnancy is ultimately desired and is possible. The feasibility of treatment with hormones is determined by a general medical examination and a complete pelvic examination, including various hormonal assays and inspection of a specimen of endometrium.

In some women who complain of infertility but apparently have normal periods, it has been found that the cycles are anovular. Estrogens are produced in each cycle in amounts sufficient to cause endometrial proliferation, but ovulation does not occur and the corpus luteum is not formed, so that there is no secretion of progesterone. The endometrium breaks down and bleeds in each cycle as the estrogens are withdrawn. Cycles of this type occur in women who are using oral contraceptives.

A simple way to determine whether ovulation is occurring is to record the woman's early morning temperature daily. In a normal cycle the temperature is about 0.5° C lower in the first than in the second half of the cycle, and the rise in temperature occurs at the time of ovulation. No rise occurs in anovular cycles. Another test is to remove and inspect a fragment of endometrium in the late part of the cycle; if microscopic examination shows that normal secretory changes are present ovulation must have taken place (see above *Infertility*). (S.G.C./Ed.)

Affecting the male system. *Impotence.* Impotence is inability of the male to have satisfactory sexual intercourse and varies in form from the inability to gain an erection to weak erections, premature ejaculation, or loss of normal sensation with ejaculation. Almost all of these complaints are psychogenic in origin, but impotence may be caused by subnormal functioning of the testes, by arteriosclerosis (hardening of the arteries), diabetes mellitus (a metabolic disease in which there is inadequate secretion or utilization of insulin), or by some disease of the nervous system. Certain medications prescribed for the treatment of such diseases as peptic ulcer, hypertension, or psychiatric illnesses may adversely affect sexual ability. Therapy, usually limited in its success, includes administration of sex hormones and psychotherapy.

Priapism. Priapism is prolonged penile erection that is painful and unassociated with sexual stimulation. The blood in the spaces of the corpora cavernosa becomes sludgelike and may remain for hours or even for days. About 25 percent of the cases are associated with leukemia (a disease of the blood-forming tissues that results in

Menstruation without discharge of an ovum

extremely high numbers of white blood cells), sickle-cell anemia (an inherited disease in which red blood cells are abnormal in shape and function and the hemoglobin is of a particular type), metastatic carcinoma (cancerous development at a distance from the primary site), and diseases of the nervous system, but in the majority of cases the causation is not clear. There have been many forms of therapy, but prompt surgical treatment with evacuation of the blood from the corpora appears to be the best. Regardless of treatment, impotence is common after an episode of priapism and even more common after repeated episodes of priapism.

(N.A.Ro./J.K.La.)

INFECTIOUS DISEASES SPREAD BY SEXUAL CONTACT

Sexually transmitted (or transmissible) diseases, formerly called venereal diseases, are usually contracted during sexual intercourse with an infected partner. The principal disorders commonly transmitted in this manner include syphilis, gonorrhea, genital herpes, nongonococcal urethritis, and chancroid.

In addition, various intestinal disorders, among them amebic dysentery, shigellosis, and giardiasis, and type B hepatitis may be transmitted during sexual intercourse, more frequently in homosexual than in heterosexual relations. An often fatal disease complex designated acquired immune deficiency syndrome (AIDS), first identified by U.S. public authorities in 1980, has also been associated with homosexual contact—as well as with intravenous drug use and blood transfusions. The lowered immunity of AIDS victims renders them particularly susceptible to rare forms of cancer and pneumonia. Cause, cure, and methods of prevention are unknown. Because the above mentioned diseases are also transmitted by other than sexual mechanisms they are not regarded as exclusively sexually transmissible.

Syphilis. Syphilis is caused by the bacterial spirochete *Treponema pallidum*. Although known in Europe since the 15th century, syphilis was not recognized as a venereal disease until some 200 years ago. It first appears as a painless lump on the skin or mucous membranes of the genitals two to four weeks after sexual exposure, although the initial symptoms may appear in other areas in unusual cases. Syphilis is considered a systemic disease from its onset and can have serious consequences in the nervous system and other organs. The initial lump breaks down to form a hard ulcer called a chancre; at this point, diagnosis can be made by observations of spirochetes in material taken from the open sore and viewed under the microscope. The infection induces antibodies against *T. pallidum* that can be identified in the bloodstream by various tests some weeks after the initial infection. If left untreated, the chancre disappears, and the patient develops flat, raised nodules on the genitals (secondary syphilis). Subsurface nodules, called gumma, appear in the tertiary stage of the disease.

The organism invades the nervous system at an early stage, but neurologic symptoms, including behavioral aberrations, often do not occur until the infection has been present for several years. Massive doses of penicillin are used to treat all stages of syphilis but are most effective during the primary stage; penicillin can also prevent transmission of the infection from a pregnant woman to the fetus, which could result in miscarriage or severe congenital defects. Other antibiotics may be effective but generally are used only in patients allergic to penicillin. Syphilis exhibited a marked decline in incidence beginning in 1946, three years after the introduction of penicillin, but has since shown a renewed increase.

Gonorrhea. The most common venereal disease, gonorrhea, was known in ancient times. It is caused by *Neisseria gonorrhoeae*, a bacterium identified in 1879. The organism has an extremely short incubation period, making it difficult to interrupt the chain of transmission. Infection, almost invariably due to sexual intercourse, can be prevented by the use of a condom; some attempts have been made to develop prophylactic vaccines but have not met with much success. The chief symptom of gonorrhea in the male is pain or burning during urination. Some 50

percent of infected females are asymptomatic; in symptomatic cases the signs of infection are similar to those seen in the male. Gonorrhea spreads locally along mucosal surfaces, ascending the urethra in the male and either the vagina or the urethra in the female. The advancing infection causes a purulent discharge into the urine. The bacteria may also be disseminated through the blood to more distant sites; systemic manifestations include headache, and if untreated, arthritis or heart disease.

The usual treatment is penicillin, although *N. gonorrhoeae* has developed resistance requiring a steady increase in the recommended dosage since the drug was introduced. In the 1970s strains of gonorrhea resistant to penicillin at any dosage were identified, chiefly in the Far East; in such resistant infections, more toxic antibiotics may be used. Despite antibiotic therapy, gonorrhea increased steadily in the United States and Britain beginning in the mid-1950s. Testing of an experimental vaccine against gonorrhea began in the early 1980s.

Nongonococcal urethritis. Although recognized only recently by public health officials, nongonococcal, or non-specific, urethritis (NGU) is one of the most common sexually transmitted infections. While caused by a variety of microorganisms, it is most commonly attributed to *Chlamydia* species, which also cause lymphogranuloma venereum (see below). In about half the cases, although no bacteria can be identified, an infectious transmission is strongly implicated. The symptoms are those of low-grade urethritis, chiefly pain and burning on urination, but are generally milder than those of gonorrhea. Treatment varies depending on the causative microorganism.

Herpes. Herpes genitalis became a major problem in the 1970s and '80s. The disease may be caused by the herpes simplex viruses identified as type 1 (HSV-1; the cause of cold sores of the lips and mouth) and type 2 (HSV-2). Another common herpes virus, cytomegalovirus (CMV), present in numerous healthy persons and widespread among male homosexuals, is associated with high mortality in patients taking immunosuppressive drugs. Genital herpes first appears as groups of small blisters on the surface of the penis in men and the vulva in women. The initial infection clears spontaneously within a few days, but herpes commonly recurs with varying frequency thereafter, burning or itching at the infection site containing the lesions. Herpes is generally transmitted only when an active lesion is present; it can be prevented by avoidance of intercourse during the active phase. The risk of transmission is diminished by the use of a condom. At present, there are no satisfactory treatments or effective vaccines against the herpes virus. Active herpes can be fatal to infants during delivery; in a large percentage of cases it causes blindness or brain damage in newborns. In women, genital herpes has also been associated with cancer of the cervix although no causal mechanism is evident.

Chancroid. Chancroid, also called "soft sore," is caused by the microorganism *Haemophilus ducreyi* and occurs chiefly in the tropics and in Asia. The bacteria has a short incubation period, producing small red pustules generally within fewer than five days after exposure but occasionally in as many as 30. The pustules burst to form painful ulcers; chancroid can be diagnosed by culturing bacteria from these ulcers. Unlike syphilis, which it may resemble, chancroid is a purely localized disease of the genitals. Treatment is with sulfonamides, streptomycin, or tetracycline.

Lymphogranuloma venereum. This infection, common in the tropics but very rare in temperate regions, is caused by *Chlamydia*. It is usually transmitted through intercourse but may be contracted in other ways. Typically, a transient genital blister is followed by regional inflammation of the lymph nodes. If untreated, this condition may progress to genital elephantiasis and has in some cases been linked to malignancy. The most effective remedy is sulfonamides, but no treatment is totally reliable. Surgical removal of diseased tissue may be necessary.

Genital warts (condyloma acuminata). Genital warts—caused by the same papilloma virus that produces common skin warts—are almost always transmitted through sexual intercourse. The wart begins as a pinhead-sized

Resistance to penicillin

Acquired immune deficiency syndrome

Genital elephantiasis

swelling that enlarges and becomes pedunculated; the mature wart is often composed of many smaller swellings and may resemble the genital lesions of secondary syphilis.

Granuloma inguinale. Although it may be spread through sexual contact, granuloma inguinale has very low infectivity and has not been shown to be consistently transmitted between sexual partners. Granuloma inguinale is caused by infection with *Donovania granulomatis* and occurs primarily in tropical and subtropical climates, including the southern United States. Initial symptoms are painless papules that become ulcerated, ultimately forming granulomatous masses that tend to bleed easily. These lesions occur on the genitals, thighs, and groin of infected persons and may resemble syphilis lesions, a reason for additional concern. Malignancy has also been associated with granuloma inguinale. Treatment is chiefly with tetracyclines or penicillin.

Genital candidiasis (moniliasis). Local infections with the yeast *Candida albicans* in men almost always are acquired through sexual contacts, but in women, in whom candidiasis is much more common, the infection can be acquired in a variety of ways. In men, candidiasis involves the surface of the glans penis, causing intense burning or itching. In women, candidiasis frequently produces no symptoms but can cause vaginal and vulval irritation (sometimes with production of a thick, white discharge) or pain during urination. The diagnosis is made by culturing yeast from the involved area; treatment is by local antifungal agents.

Trichomoniasis. Infection with the flagellate protozoan *Trichomonas vaginalis* is usually, but not exclusively, spread by sexual contact. The condition is commonly asymptomatic in males. In females trichomoniasis has a variety of manifestations, including vaginal discharge and inflammation of the vulva, perineum, and thighs. Both sexes may experience complications, cystitis and urethritis; males may also contract prostatitis and epididymitis. Treatment with metronidazole, an antibacterial, antiprotozoal agent, is standard.

OTHER INFECTIONS AFFECTING THE REPRODUCTIVE SYSTEM

Puerperal infection. A common cause of death during childbirth, especially before the adoption of modern sanitary practices, puerperal infections occur when bacteria, usually *Streptococcus*, invade wounds in the birth canal. The infection may cause abscess formation and can involve all of the genital organs and adjacent blood vessels, reproductive structures, and other abdominal tissues. Treatment consists of antibiotics, supportive therapy, and occasionally surgical drainage of abscesses.

Tuberculosis. Primary tuberculosis of the reproductive system is rare and is usually brought from elsewhere in the body through the bloodstream. Nodular or pustular lesions on the penis or scrotum of men or the vulva of women, resembling the gumma (nodules) of tertiary syphilis, may appear one week after tubercular infection. The nodules can become ulcerated, resembling the primary chancre of syphilis. Tubercular abscesses can also develop in most of the internal reproductive organs. Treatment consists of administration of antitubercular drugs for up to two years. As the incidence of tuberculosis has declined in the developed countries, tuberculosis of the reproductive system has become exceedingly rare.

Inflammatory conditions. Balanitis, or inflammation of the glans penis, and posthitis, or infection of the prepuce, result from the retention of secretions and bacteria beneath the foreskin and can be prevented with good sexual hygiene. Balanitis can also develop as a complication of certain sexually transmitted diseases. Acute prostatitis, inflammation of the prostate gland, may be caused by any of a variety of microorganisms, including those which cause venereal diseases; chronic prostatitis, the most common reproductive system infection in men older than 50, often follows the acute infection. Epididymitis, inflammation of the epididymis (a duct of the sperm canal), can result in sterility. All of these are nonspecific infections that must be treated with antibiotics appropriate for the causative organisms.

In women, other infections of the reproductive system

include Bartholinitis, an inflammation of Bartholin's duct near the opening of the vagina, and vaginitis, generalized inflammation of the vagina caused by various yeasts and bacteria. The most common symptoms of such ailments are vaginal discomfort or itching and pain during urination or intercourse. Again, treatment of these conditions depends largely on the causative organism. (Ed.)

STRUCTURAL CHANGES OF UNKNOWN CAUSES

In the female: endometriosis. Endometriosis, a disease occurring only during a woman's menstrual life, is the growth of endometrial tissue in an abnormal location. This may occur in the uterus or elsewhere. The most common location of the implants of endometrial tissue are the ovaries; other areas and organs affected (in order of incidence) are uterosacral ligaments (thickened portions of the sheet of connective tissue covering the pelvic organs), the rectovaginal septum (the membrane dividing the rectum from the vagina), the sigmoid colon (that portion of the large intestine that leads into the rectum), the lower genital tract, the round ligaments of the uterus, and the peritoneum (membrane) lining the pelvis. Although endometriosis is a progressive disease in most instances, pain relief following conservative surgery (surgery that preserves ability to bear children) has occurred in an estimated 80 percent of patients, and 40–50 percent were able to become pregnant.

In the male: benign hypertrophy of the prostate. Benign prostatic hypertrophy, an overgrowth of normal glandular and muscular elements of the prostate gland, arises in the immediate vicinity of the urethra and is the most frequent cause of urinary obstruction. The enlarged prostate usually causes symptoms after the age of 50. If undetected, the obstruction may cause bladder and kidney damage. The diagnosis is made by rectal examination, excretory urography (X-raying the urinary tract while an opaque substance is being excreted in the urine), and cystourethroscopy (direct viewing of the bladder and urethra). Treatment is by surgical removal of the excess tissue. The prognosis is good if detection is early and treatment is given before the kidneys are damaged.

TUMOURS

In the male. External genitalia. Tumours of the penis are almost all of epithelial (covering or lining) origin and usually involve the foreskin or glans. Cancer of the penis (epithelioma) is rarely found in men who have been circumcised during infancy. The growth arises on the glans or inner surfaces of the prepuce, and metastases (secondary growths at distant parts) occur through lymph channels that lead to the inguinal (groin) and iliac nodes (nodes along the aorta and iliac arteries). The diagnosis is made by examination of a specimen of the lesion. Treatment for small lesions consists of surgical removal of a part of the penis or by X-ray therapy, while spread to inguinal nodes may be treated by removal of the node. The outlook is good if the cancer is small and there has been no metastasis.

Tumours of the scrotal skin are rare; most are thought to arise from occupational exposure to various carcinogens (cancer-causing substances), such as the soot in chimney sweeps' clothing. Primary tumours of the epididymis are also uncommon, and most are benign.

Testicular tumours. Testicular tumours are usually malignant; the peak incidence is between the ages of 20 and 40 years. This type of cancer accounts for about 0.5 percent of all malignant growths in men and about 4 percent of all tumours affecting the genitourinary tract. The great majority of testis tumours (greater than 95 percent) are of types that do not reproduce cells resembling those of the tissue of origin. The major route of metastases is via the lymphatics. The lymph nodes in the loins and the mediastinum—the region between the lungs—are most commonly involved, but the lungs and liver are also frequent sites of tumour spread. The remaining 5 percent of the testicular tumours, which usually resemble the cells from which they arise, include the hormone-secreting tumours. In general, these tumours have been described in all age groups, have usually been benign in behaviour, and have

Acute
prostatitis

been most frequent in poorly developed or undescended testes.

The most common symptom first observed in all groups is painless enlargement of the testis. If, after careful examination, tumour cannot be ruled out, the testicle is removed for microscopic examination. Further treatment may consist of removal of the retroperitoneal lymph nodes (the lymph nodes in the region behind the peritoneum, the membrane lining the abdomen), X-ray therapy, or chemotherapy.

Carcinoma of the prostate. Carcinoma (cancer) of the prostate is rare before the age of 60 but increases in frequency every decade thereafter. It is the second most common cause of death from cancer in the male, second to cancer of the lung. In men over 60, it is the commonest cause of cancer deaths. Like most tumours, prostatic cancer has no known cause, but it is clear that its growth is strikingly influenced by sex hormones or their withdrawal. Viruses may also play a role. The progress of the cancer is so slow that, by the time it produces symptoms of urinary obstruction, metastasis has occurred in many cases, most frequently to the spine, the pelvic bones, or the upper portions of the thigh bones. The diagnosis is made by finding cancer cells in a specimen of tissue taken from the prostate. Elevated levels of acid phosphatase (an enzyme of the prostate) are found in the blood (in 75 percent of cases) when the cancer has extended outside the prostate capsule and metastases are present.

If the tumour is discovered before it has extended beyond the prostate, the gland is removed. If spread has occurred, various palliative measures offer the affected person much relief.

In the female. **Carcinoma of the vulva.** Primary carcinoma of the vulva (the external female genital organs) usually occurs in women over 50 and usually arises from the labia majora or labia minora. Most patients first notice a lump on the vulva or perineum; the diagnosis is made by examination of a specimen of tissues. Treatment consists of surgical removal of the vulva and of regional lymph nodes.

Cancer of the cervix of the uterus. Cancer of the cervix is the most common malignant tumour of the female genital tract; it is second only to cancer of the breast as a cause of death from cancer in women. The average age of occurrence for cancer of the cervix is the 45th year. The initial diagnosis is made by screening with such tests as those developed by Papanicolaou and Traut. (These con-

sist of staining smears from vaginal and other secretions and examining them for cancer cells.) The final diagnosis rests on examining specimens of tissue from the cervix. Treatment now is usually irradiation instead of surgery because of the uncertainties of total surgical excision and the illness associated with extreme surgery. The prospect of five-year survival is as good as 85 percent if the cancers have not spread beyond the cervix.

Uterine fibromyomas. Uterine fibromyomas (fibroids) are the most frequent cause of enlargement of the uterus. They are most common in Negroes and in persons who have not borne children and are most often identified in women aged 30–45 years. New tumours do not originate after the menopause, and existing ones usually regress at that time but do not disappear. The tumours, which are benign, originate from the smooth muscle cells of the uterus wall and may be single but usually are multiple, pseudoencapsulated nodules. The symptoms are quite variable and depend largely on the location and size of the tumour. Excessive menstrual bleeding is often caused by fibroids. The diagnosis is tentatively made by pelvic examination and confirmed at surgery. Small asymptomatic fibromyomas need not be treated; the larger ones are dealt with by total or partial removal of the uterus or by irradiation.

Carcinoma of the body of the uterus. Cancer of the endometrium (the lining) of the body of the uterus is the second most common malignant tumour of the uterus and the female genital tract. The peak incidence is in the mid-50s, and there is also a strikingly high incidence in women who have not borne children. The chief symptom of the cancer is postmenopausal uterine bleeding. The Papanicolaou smear is not a reliable screening test, and an examination of a specimen of endometrial tissue must be performed. The treatment is primarily surgical but is often supplemented with preoperative intrauterine radium application or preliminary deep X-ray therapy to the pelvis. The survival rate from this disease is relatively good if the tumour is confined to the uterine body.

Ovarian tumours. No other organ in the body develops such a variety of tumours as does the ovary. The symptoms and signs may be due to the hormones secreted or may be only those of an enlarging mass in the pelvis. The final diagnosis is usually made at abdominal exploration. The treatment consists of surgery, X-ray therapy, or chemotherapy. The prognosis is variable and depends on the type of tumour that is present as well as the extent of metastatic spread. HUMAN REPRODUCTION FROM CONCEPTION TO BIRTH

The normal events of pregnancy

INITIATION OF PREGNANCY

A new individual is created when the elements of a potent sperm merge with those of a fertile ovum, or egg. Before this union both the spermatozoon (sperm) and the ovum have migrated for considerable distances in order to achieve their union. A number of actively motile spermatozoa are deposited in the vagina, pass through the uterus, and invade the uterine (fallopian) tube, where they surround the ovum. The ovum has arrived there after extrusion from its follicle, or capsule, in the ovary. After it enters the tube, the ovum loses its outer layer of cells as a result of action by substances in the spermatozoa and from the lining of the tubal wall. Loss of the outer layer of the ovum allows a number of spermatozoa to penetrate the egg's surface. Only one spermatozoon, however, normally becomes the fertilizing organism. Once it has entered the substance of the ovum the nuclear head of this spermatozoon separates from its tail. The tail gradually disappears, but the head with its nucleus survives. As it travels toward the nucleus of the ovum (at this stage called the female pronucleus) the head enlarges and becomes the male pronucleus. The two pronuclei meet in the centre of the ovum, where their threadlike chromatin material organizes into chromosomes.

Originally the female nucleus has 44 autosomes (chromo-

somes other than sex chromosomes) and two (X, X) sex chromosomes. Before fertilization a type of cell division called a reduction division brings the number of chromosomes in the female pronucleus down to 23, including one X-chromosome. The male gamete, or sex cell, also has 44 autosomes and two (X, Y) sex chromosomes. As a result of a reducing division occurring before fertilization, it, too, has 23 chromosomes, including either an X or a Y sex chromosome at the time that it merges with the female pronucleus.

After the chromosomes merge and divide in a process termed mitosis, the fertilized ovum, or zygote, as it is now called, divides into two equal-sized daughter cells. The mitotic division gives each daughter cell 44 autosomes, half of which are of maternal and half of paternal origin. Each daughter cell also has either two X-chromosomes, making the new individual a female, or an X- and a Y-chromosome, making it a male. The sex of the daughter cells is determined, therefore, by the sex chromosome from the male parent.

Fertilization occurs in the uterine tube. How long the zygote remains in the tube is unknown, but it probably reaches the uterine cavity about 72 hours after fertilization. It is nourished during its passage by the secretions from the mucous membrane lining the tube. By the time it reaches the uterus it has become a mulberry-like solid mass called a morula. A morula is composed of 60 or

Union of
the ovum
and the
sperm

The
morula
and the
blastocyst

more cells. As the number of cells in a morula increases, the zygote forms a hollow bubble-like structure, the blastocyst. The blastocyst, nurtured by the uterine secretions, floats free in the uterine cavity for a short time and then is implanted in the uterine lining. Normally, the implantation of the blastocyst occurs in the upper portion of the uterine lining. (The mechanism of implantation is described below.)

DIAGNOSIS OF PREGNANCY

Symptoms and signs; biological tests. Outward early indications of pregnancy are missed menstrual periods, morning nausea, and fullness and tenderness of the breasts; but the positive and certain signs of gestation are the sounds of the fetal heartbeat, which are audible with a stethoscope between the 16th and the 20th week of pregnancy; X-ray views of the fetal skeleton, which can be observed by the 14th or the 16th week; and fetal movements, which usually occur by the 18th to the 20th week of pregnancy. X-ray examinations generally are avoided, however, because of their potential hazard to the fetus.

Persons who note their body temperature upon awakening, as many women do who wish to know when they are ovulating, may observe continued elevation of the temperature curve well beyond the time of the missed period; this is strongly suggestive of pregnancy. During the early months of pregnancy, women may notice that they urinate frequently, because of pressure of the enlarging uterus on the bladder; that they feel tired and drowsy; dislike foods that were previously palatable; have a sense of pelvic heaviness; are subject to vomiting (which can be severe) and to pulling pains in the sides of the abdomen, as the growing uterus stretches the round ligaments that help support it, singly or together. Most of these symptoms subside as pregnancy progresses. The signs and symptoms of pregnancy are so definite by the 12th week that the diagnosis is seldom a problem.

Biological tests for pregnancy

Biological tests for pregnancy depend upon the production by the placenta (the temporary organ that develops in the womb for the nourishing of the embryo and the elimination of its wastes) of chorionic gonadotropin, an ovary-stimulating hormone. In practice, the tests have an accuracy of about 95 percent, although false negative tests may run as high as 20 percent in a series of cases. False negative reports are frequently obtained during late pregnancy when the secretion of chorionic gonadotropin normally decreases. The possibility not only of false negative but also of false positive tests makes the tests, at best, probable rather than absolute evidence of the presence or absence of pregnancy. Chorionic gonadotropin in a woman's blood or urine indicates only that she is harbouring living placental tissue. It does not tell anything about the condition of the fetus. In fact, the greatest production of chorionic gonadotropin occurs in certain placental abnormalities and disorders that can develop in the absence of a fetus.

Tests using immature mice (the Aschheim-Zondek test) and immature rats have been found to be extremely accurate. Tests using rabbits (the Friedman test) have been largely replaced by the more rapid and less expensive frog and toad tests.

The use of the female South African claw-toed tree toad, *Xenopus laevis*, is based on the discovery that this animal will ovulate and extrude visible eggs within a few hours after it has received an injection of a few millilitres of urine from a pregnant woman. The male common frog, *Rana pipiens*, will extrude spermatozoa when treated in the same way. Both of these tests are considered somewhat unsatisfactory because false positive reactions are not uncommon.

Several immunological reaction tests in common use are based upon the inhibition of hemagglutination (clotting of red cells). A positive test is obtained when human chorionic gonadotropin (HCG) in the woman's urine or blood is added to human chorionic gonadotropin antiserum (rabbit blood serum containing antibodies to HCG) in the presence of particles (or red blood cells) coated with human chorionic gonadotropin. The hormone from the woman will inhibit the combination of coated particles

and antibody, and agglutination does not occur. If there is no chorionic gonadotropin in her urine, agglutination will occur and the test is negative.

Several "signs" noted by the physician during an examination will suggest that a patient may be in the early months of pregnancy. Darkening of the areola of the breast (the small, coloured ring around the nipple) and prominence of the sebaceous glands around the nipple (Montgomery's glands); purplish-red discoloration of the vulvar, vaginal, and cervical tissues; softening of the cervix and of the lower part of the uterus and, of course, enlargement and softening of the uterus itself are suggestive, but not necessarily proof of pregnancy.

Conditions that may be mistaken for pregnancy. Other conditions may confuse the diagnosis of pregnancy. Absence of menstruation can be caused by chronic illness, by emotional or endocrine disturbances, by fear of pregnancy or by a desire to be pregnant. Nausea and vomiting may be of gastrointestinal or psychic origin. Tenderness of the breasts can be due to a hormonal disturbance.

Absence of menstruation; false positive tests

Any condition that causes pelvic congestion, such as pelvic tumour, may cause duskeness of the genital tissues. At times a soft tumour of the uterus may simulate a pregnancy. The question of pregnancy may be raised if the woman does not menstruate regularly; the absence of other symptoms and signs of gestation indicates that she is not pregnant. There are rare ovarian and uterine tumours that produce false positive pregnancy tests. It may be difficult for the physician to exclude pregnancy on the basis of his examination if the uterus is tipped back and difficult to feel, or if it is enlarged by a tumour within it. He is helped by the fact that the other signs of pregnancy are absent and that the tests for pregnancy are usually negative.

Childless women who greatly desire a baby sometimes suffer from false or spurious pregnancy (pseudocyesis). They stop menstruating, have morning nausea, "feel life," and have abdominal enlargement caused by fat and intestinal gas. At "term" they may have "labour pains." Signs of pregnancy are absent. Treatment is by psychotherapy.

Menopausal women often fear pregnancy when their periods stop; information that they show no signs of pregnancy usually reassures them. Retained uterine secretions of bloody or watery fluid, caught above a blocked mouth of the uterus (cervix), prevent menstruation, cause softening and enlargement of the uterus, and may cause the patient to wonder whether she is pregnant. There are no other signs of pregnancy, and the hard cervix, closed by scar tissue, explains the problem.

Duration of pregnancy. There are, as a rule, 266–270 days between ovulation and childbirth, with extremes of 250 and 285 days. Physicians usually determine the date of the estimated time for delivery by adding seven days to the first day of the last menstrual period and counting forward nine calendar months; i.e., if the last period began on January 10, the date of delivery is October 17. Courts of law, in determining the legitimacy of a child, may accept much shorter or much longer periods of gestation as being within the periods of possible duration of a pregnancy. One court in the state of New York has accepted a pregnancy of 355 days as legitimate. British courts have recognized 331 and 346 days as legitimate with the approval of medical consultants. Fully developed infants have been born as early as 221 days after the first day of the mother's last menstrual period.

Since the exact date of ovulation is usually not known, it is seldom possible to make an accurate estimate of the date of delivery. There is a 5 percent chance that a baby will be born on the exact date estimated from the above rule. There is a 25 percent chance that it will be born within four days before or after the estimated date. There is a 50 percent chance that delivery will occur on the estimated date plus or minus seven days. There is a 95 percent chance that the baby will be born within plus or minus 14 days of the estimated date of delivery.

ANATOMIC AND PHYSIOLOGIC CHANGES OF NORMAL PREGNANCY

Changes in organs and tissues directly associated with childbearing. *Ovaries.* The ovaries of a nonpregnant

Ovulation and formation of corpus luteum; progesterone and estrogen

young woman who is in good health go through cyclic changes each month. These changes centre about a follicle, or "egg sac." A new follicle develops after each menstrual period, casts off an egg (ovulation), and, after ovulation, forms a new structure (the corpus luteum).

If the egg is fertilized, it is sustained for a short time by the hormones produced by the corpus luteum. Progesterone and estrogen, secreted by the corpus luteum, are essential for the preservation of the pregnancy during its early months. If pregnancy does not occur, the egg disintegrates and the corpus luteum shrinks. As it shrinks, the stimulating effect of its hormones, progesterone and estrogen, is withdrawn from the endometrium (the lining of the uterus), and menstruation occurs. The cycle then begins again.

Pregnancy, if it occurs, maintains the corpus luteum by means of the hormones produced by the young placenta. The corpus luteum is not essential in human pregnancy after the first few weeks because of the takeover of its functions by the placenta. In fact, human pregnancies have gone on undisturbed when the corpus luteum has been removed as early as the 41st day after conception. Gradually the placenta, or afterbirth, begins to elaborate progesterone and estrogen itself. By the 70th day of pregnancy the placenta is unquestionably able to replace the corpus luteum without endangering the pregnancy during the transfer of function. At the end of pregnancy the corpus luteum has usually regressed until it is no longer a prominent feature of the ovary.

During the first few months of pregnancy the ovary that contains the functioning corpus luteum is considerably larger than the other ovary. During pregnancy, both ovaries usually are studded with fluid-filled egg sacs as a result of chorionic gonadotropin stimulation; by the end of pregnancy, most of these follicles have gradually regressed and disappeared.

The blood supply to both ovaries is increased during pregnancy. Both glands frequently reveal plaques of bright red fleshy material on their surfaces, which, if examined microscopically, demonstrate the typical cellular change of pregnancy, called a decidual reaction. In this reaction, cells develop that look like the cells in the lining of the pregnant uterus. They result from the high hormone levels that occur during pregnancy and disappear after the pregnancy terminates.

The uterus and the development of the placenta. The uterus is a thick-walled, pear-shaped organ measuring seven centimetres (about 2.75 inches) in length and weighing 30 grams (about one ounce) in an unpregnant woman in her later teens. It has a buttonlike lower end, the cervix, that merges with the bulbous larger portion, called the corpus. The corpus comprises approximately three-fourths of the uterus. There is a flat, triangular-shaped cavity within the uterus. At term, the uterus is a large, thin-walled, hollow, elastic, fluid-filled cylinder measuring approximately 30 centimetres (about 12 inches) in length, weighing approximately 1,200 grams (2.6 pounds), and having a capacity of 4,000 to 5,000 millilitres (4.2 to 5.3 quarts).

The greater size of the uterus as a result of pregnancy is due to a marked increase in the number of muscle fibres, blood vessels, nerves, and lymphatic vessels in the uterine wall. There is also a five- to tenfold increase in the size of the individual muscle fibre and marked enlargement in the diameters of the blood and lymph vessels.

During the first few weeks of pregnancy, the shape of the uterus is unchanged, but the organ becomes gradually softer. By the 14th week it forms a flattened or oblate spheroid. The fibrous cervix becomes remarkably softer and acquires a protective mucus plug within its cavity, but otherwise it changes little before labour. The lower part of the corpus, the isthmus, first becomes elongated and then, as the uterine contents demand more space, stretches and unfolds to form a bowl-shaped formation called the lower uterine segment. The fibrous nature of the cervix causes it to resist this unfolding action.

The uterine wall is stretched and thinned during pregnancy by the growing conceptus, as the whole product of conception is called, and by the fluid that surrounds it. By term, this process converts the uterus into an elastic, fluid-

filled cylinder. It is only late in pregnancy that the cervix gradually thins out and softens; during labour it dilates for passage of the infant.

As pregnancy progresses, the uterus rises out of the pelvis and fills the abdominal cavity. It is top-heavy near term so that it falls forward and, because of the large bowel on the left side, rotates to the right. It presses on the diaphragm and pushes the other organs aside. The uterus may sink downward in the pelvis several weeks before term in a process that is known as lightening or dropping. This occurs as the fetal head descends into the pelvis. In some women, particularly those who have borne children, lightening does not occur until the onset of labour. Lightening may be impossible in women who have an abnormally small pelvis, an oversized fetus, or a fetus lying in an abnormal position.

For a short time after fertilization, the conceptus, a minute bubblelike structure called a blastocyst, lies unattached in the uterine cavity. The cells that will become the embryo (the embryonic disk) form a thickened layer on one side of the bubble. Elsewhere, the walls of the bubble consist of a single layer of cells; these cells are the trophoblast, which has a special ability to attach to and invade the uterine wall. The trophoblast plays an important role later in the development of the placenta or afterbirth. The conceptus makes contact with the uterine lining about the fifth or sixth day after conception. After contact the blastocyst collapses to form a rounded disk with the embryonic mass on the surface and the trophoblast against the endometrium (uterine lining). The part of the trophoblast

Implan-
tation

The uterus before and during pregnancy

that is in contact with the endometrium grows into and invades the maternal tissue. Concomitant disintegration of the endometrium allows the conceptus to sink into the uterine lining.

The chorionic cavity Soon the entire blastocyst is buried in the endometrium. Proliferation of the trophoblast over the part of the collapsed bubble that is opposite the embryo is part of the implantation procedure that helps to cover the blastocyst. After a few days, a cavity forms that bears the same relation to the embryonic disk that the blastocyst cavity did before; this cavity will become the fluid-filled chorionic cavity containing the embryo. Ultimately it will contain the amniotic fluid that surrounds the fetus, the fetus itself, and the umbilical cord.

The body stalk, which will become the umbilical cord, then begins to separate the embryo from the syncytiotrophoblast, the outer layer of the trophoblast lying against the endometrium; the inner lining of the trophoblast is called cytotrophoblast. As the syncytiotrophoblast advances into the endometrium, it surrounds minute branches of the uterine arteries that contain maternal blood. Erosion of the endometrium about these blood sinuses allows them to open into the small cavities in the trophoblast. The cytotrophoblast, which lines the cavity, forms fingers of

wall is now cytotrophoblast. Fingers of cytotrophoblast in the form of cell masses extend into the syncytial layer. Soon thereafter, a layer of connective tissue, or mesoderm, grows into the villi, which now form branches as they spread out into the blood-filled spaces in the endometrium adjacent to the conceptus.

By the end of the third week, the chorionic villi that form the outer surface of the chorionic sac are covered by a thick layer of cytotrophoblast and have a connective tissue core within which embryonic blood vessels are beginning to develop. The vessels, which arise from the yolk sac, connect with the primitive vascular system in the embryo. As growth progresses the layer of cytotrophoblast begins to regress. It disappears by the fifth month of pregnancy.

The layer of endometrium closest to the encroaching conceptus forms, with remnants of the invading syncytiotrophoblast, a thin plate of cells known as the decidua basalis, the maternal component of the mature placenta; it is cast off when the placenta is expelled. The fetal part of the placenta—the villi and their contained blood vessels—is separated from the decidua basalis by a lakelike body of fluid blood. This pool was created by coalescence of the intervillous spaces. The intervillous spaces in turn were formed from the syncytial lacunae in the young conceptus. Maternal blood enters this blood mass from the branches of the uterine arteries. The pool is drained by the uterine veins. It is so choked by intermingling villi and their branches that its continuity is lost on gross inspection.

The chorionic cavity contains the fluid in which the embryo floats. As its shell or outer surface becomes larger, the decidua capsularis, which is that part of the endometrium that has grown over the side of the conceptus away from the embryo (*i.e.*, the abembryonic side) after implantation, becomes thinner. After 12 weeks or so, the villi on this side, which is the side directed toward the uterine cavity, disappear, leaving the smooth chorion, now called the chorion laeve. The chorion frondosum is that part of the conceptus that forms as the villi grow larger on the side of the chorionic shell next to the uterine wall. The disc-shaped placenta develops from the chorion frondosum and the decidua basalis.

At term, the normal placenta is a disk-shaped structure approximately 16 to 20 centimetres (about six to seven inches) in diameter, three or four centimetres (about 1.2–1.6 inches) in thickness at its thickest part, and weighing between 500 and 1,000 grams (1.1 and 2.2 pounds). It is thinner at its margins, where it is joined to the membrane-like chorion which spreads out over the whole inner surface of the uterus and contains the fetus and the amniotic fluid. The amnion, a thinner membrane, is adherent to and covers the inner surface of the chorion. The inner or fetal surface of the placenta is shiny, smooth, and traversed by a number of branching fetal blood vessels that come together at the point—usually the centre of the placenta—where the umbilical cord attaches. The maternal or uterine side of the placenta, covered by the thin, flaky decidua basalis, a cast-off part of the uterine lining, is rough and purplish-red, and has a raw appearance. When the placenta is cut across, its interior is seen to be made of a soft, crepelike or spongy matrix from which semisolid or clotted blood, caught when it is separated from the uterine wall to which it was attached, can be squeezed. Detailed examination shows that the villi and their branches form an arborescent (treelike) mass within the huge blood lake of the intervillous space. Anchoring villi extend outward from the fetal side and fuse with the decidua basalis to hold the organ's shape. Others, algae-like, float freely in the blood lake. Dividing partitions, formed from the trophoblast shell, project into the intervillous space from the decidual side. They divide the placenta into 15 or 20 compartments, which are called cotyledons.

Maternal blood flows from the uterine vessels into the trophoblast-lined intervillous blood lake. Within each villus is a blood vessel network that is part of the fetal circulatory system. Blood within the villous vessel is circulated by the fetal heart. The blood vessel wall, the connective tissue of the villous core, and the syncytiotrophoblast covering the villus lie between the fetal and the maternal bloodstreams. This is known as the placental

proliferating cells extending into the syncytiotrophoblast. After the placenta is developed, these fingers will be the cores of the root-like placental villi, structures that will draw nutrients and oxygen from the maternal blood that bathes them. This is the first step in uteroplacental circulation, which supplies the fetus with all of the sustenance necessary for life and growth and removes waste products from it. During the third week of pregnancy, the syncytiotrophoblast forms a single layer of cells covering the growing villi and lining the syncytial lacunae or small cavities between the villi. The conceptus is buried in the endometrium, and its whole surface is covered at this time by developing villi. The greater part of the chorionic

Figure 33: Sagittal section of the uterus at the fourth month of pregnancy.

barrier. As pregnancy progresses, the fetal blood vessels become larger, the connective tissue stretches over them, and the syncytiotrophoblastic layer becomes fragmentary. As a result, the placental barrier becomes much thinner. Normally, blood cells and bacteria do not pass through it, but nutrients, water, salt, viruses, hormones, and many other substances, including many drugs, can filter across it.

Uterine tubes. One of the two uterine tubes is the pathway down which the ripe ovum travels on its way to the uterus or womb. The spermatozoa from the male migrate up the tube, and it is there that they meet the ovum and fertilization occurs. During the first few days after fertilization the zygote, or fertilized egg, moves downward in the tube toward the uterus. While it is lying free in the tubal canal the young conceptus is nourished by secretions from the tube. After the fertilized egg (or conceptus) passes into the uterus the tube ceases to play any part in the pregnancy; in fact, the only function the tube has is carried out during those few days before, during, and after conception. As pregnancy goes on the tube gradually enlarges, however, and contains more blood, as do all the pelvic organs; some of its cells may show a reaction, called a decidual reaction, to the hormones of pregnancy. As the uterus increases in size, the tubes stretch upward with it until they become two greatly enlarged elongated strands, one on each side of the uterus.

Vagina. The pinkish-tan colour of the lining of the vagina gradually takes on a bluish cast during the early months of pregnancy as a result of the dilation of the blood vessels in the vaginal wall; later the vaginal wall tends to become a purplish-red colour as the blood vessels become further engorged. The cells of the vaginal mucosa increase

in size. Added numbers of these cells peel off the surface of the mucosa and mix with the increased vaginal fluid. This produces a profuse vaginal secretion. Thickening, softening, and relaxation of the loosely folded, succulent lining of the vagina and the sodden tissues beneath it greatly increase distensibility and capacity of the vaginal cavity; this is a process that partially prepares the birth canal for the passage through it of the large fetal mass.

External genital structures. Changes in the external genitalia are similar to those in the vagina. The tissues become first softened and more succulent and later extremely fragile, as an increasing amount of blood and fluid collects in them. They take on a purplish-red colour because of increased blood supply. Darkening of the vulvar skin, frequently seen during pregnancy, is particularly common among women of Mediterranean ethnic groups.

Other pelvic tissues. The pelvic blood vessels and lymph channels become larger and longer. They develop new branches adequate to transport the greatly increased amounts of blood and tissue fluid that accumulate in the uterus and the other pelvic organs during pregnancy. Congestion and engorgement of blood in the pelvis, both within and without the uterus, are characteristic of pregnancy.

Changes in the muscles, ligaments, and other supporting tissues of the pelvis begin early in pregnancy and become progressively more pronounced as pregnancy continues. These changes are induced by the greatly increased hormonal levels in the mother's blood that characterize pregnancy. Before labour starts, the pelvic supporting tissues must have sufficient elasticity and strength to permit the uterus to grow out of the pelvis and yet support it. The muscles must be soft and elastic enough during delivery so that they can stretch apart and not obstruct the baby's birth. Softening and greater elasticity is brought about not only by the growth of new tissue but also by congestion and retained fluid within the tissues themselves.

The bones forming the mother's pelvis show relatively few changes during pregnancy. Loosening of the joint between the pubic bones in front and of the joints between the sacrum and the pelvis in back occurs as a response to the hormone called relaxin, which is produced by the ovary. Although relaxin, which causes marked separation of the pelvic joints in some animals, usually has too slight an effect in human beings to be noticed, softening of the attachments between the bones may be sufficient to cause a few women considerable distress. The strain on the joint between the sacrum and the spine becomes greater near term when the woman tilts her pelvis forward and bends the upper part of her body backward to compensate for the weight of the heavy uterus. When relaxation is excessive the woman suffers from backache and difficulty in walking. If it is extreme, she may have a waddling gait. Relaxation of the pelvic joints does not disappear quickly after delivery; it accounts for much of the backache complained of by women with new babies.

The mother's bones show no structural change if her calcium reserve and intake are normal. If her reserve and intake are not adequate, the fetus may draw so much calcium from her bones that the bones become soft and deformed. This condition is rarely seen, except in areas of the world where extreme poverty and serious calcium deficiency are major problems.

Breasts. The earliest changes in the breasts in pregnancy are an exaggeration of the frequently experienced premenstrual discomfort and fullness. The sensation is so specific for pregnancy that many women who have been pregnant before are made aware of their condition by the feeling that they have in their breasts. As pregnancy progresses the breasts become larger, the lightly pigmented area (areola) around each nipple becomes first florid or dusky in colour and then appreciably darker; during the later months the areola takes on a hue that is deep bronze or brownish-black, depending on the woman's natural pigmentation. The veins beneath the skin over the breast become enlarged and more prominent. The small oily or sebaceous glands (glands of Montgomery) about the nipple become prominent.

These changes are due to the greatly increased levels of estrogen and progesterone in the woman's blood. These

The blood vessels, muscles, and ligaments

Changes in the breasts before and after delivery

Uterine tube as site of fertilization

ovarian hormones also prepare the breast tissue for the action of the lactogenic (milk-causing) hormone, prolactin, produced by the pituitary gland. During the later part of pregnancy a milky fluid, colostrum, exudes from the ducts or can be expressed from them.

After delivery, the decrease in the estrogen and progesterone levels presumably permits the pituitary gland to release prolactin, which causes the breast to secrete milk. It is thought that the high hormonal levels inhibit the action or secretion of prolactin before delivery. Prolactin continues to be produced, and lactation usually continues, as long as the mother feeds her baby at the breast.

Anatomic and physiologic changes in other organs and tissues. *Cardiovascular and lymphatic systems.* During pregnancy the increasing needs of the growing fetus and of her own tissues throw an added burden on the mother's heart. The work that the heart does is measured by the amount of blood it expels per minute (the cardiac output). Rapid increase in the cardiac output occurs between the ninth and the 14th week of gestation. During the period from the 28th to the 30th week, when the load is heaviest, the heart of a pregnant woman is doing 25 to 30 percent more work than it was doing before pregnancy. As the time of delivery approaches, the heart's work load diminishes to some extent; when the baby is born the load is approximately equal to what it was when the mother was in the nonpregnant state. This decrease in cardiac output and cardiac work, which occurs in spite of the continued needs of the fetus and of the maternal tissues for blood-borne oxygen and nutrients, is explained by the more efficient way that the tissues draw on the mother's blood for oxygen and nourishment during the terminal weeks of pregnancy.

The position of the heart

The position of the heart is changed to a greater or lesser degree during pregnancy. As the uterus enlarges it elevates the diaphragm. This in turn pushes the heart upward, to the left, and somewhat forward, so that it is nearer the chest wall beneath the breast. Near the end of gestation the large uterus may raise the heart until the latter lies almost at a right angle to the long axis of the woman's body. These changes, which also bring some rotation of the heart, vary considerably in different individuals. When present to a marked degree, they may give an examining physician the erroneous impression that a normal heart is considerably enlarged. Actually, in spite of its greater work load, a healthy heart enlarges little or not at all even during the midportion of pregnancy, when the load is greatest.

Changes in the position of the heart, the greater work load, the increased volume of blood that the heart expels per beat, the decreased viscosity of the blood, and the larger amount of blood in the woman's blood vessels (discussed below), will, in many women, cause some distortion of the sounds that the physician hears when he listens to a patient's heart with his stethoscope. Such distorted sounds, called "functional" murmurs (as distinguished from "organic" murmurs, which may be present when the heart is diseased), do not indicate that anything is amiss, although they may be sufficiently atypical to cause the obstetrician to refer the patient to a cardiologist for evaluation. Pregnancy sometimes produces minor changes in the electrocardiogram, but these changes are within normal limits.

Such is the ability of the heart to respond to an increased work load that even the pregnant woman with serious heart disease, given proper care and without an unexpected complication, will usually go through her pregnancy and delivery without a catastrophe. She is likely, however, to encounter disaster when she tries to cope with the stress of caring for her family after the baby is born.

Blood pressure and pulse rate

Normal pregnancy does not increase the mother's blood pressure. Indeed, a slight lowering of the blood pressure is commonly noted during the course of the pregnancy. Any notable rise in a pregnant woman's blood pressure is reason for alertness on the part of her physician, and if it continues to rise, for concern; it usually foretells the onset of toxemia (see below).

The pulse rate is a trifle more rapid during pregnancy, reflecting the more rapid heartbeat that is necessary in order to move the larger volume of blood present. The

rate at which blood flows through the myriads of small blood vessels in the skin (the peripheral circulation) is accelerated during pregnancy, leading to the elevated skin temperature, the tendency to perspire, and, in part, to the redness of the palms and the tiny dilated blood vessels in some women as their pregnancies progress.

The most notable change in the circulatory system during pregnancy, other than those described in the heart, is a slowing of the blood flow in the lower extremities. With this decrease in the rate of flow there is an increase in the pressure within the veins and some stasis—stagnation—of the blood in the legs. These changes, which are believed to be caused primarily by the pressure of the uterus on the large blood vessels in the pelvis, are progressive during pregnancy and disappear after delivery. They also are thought to be caused in part by the marked increase in the amounts of the hormones estrogen and progesterone in the circulating blood. Increased venous pressure, slowing of the rate of venous flow, and partial stasis of the blood in the veins are major factors in causing the swelling of the legs and the varicose (abnormally dilated) veins of the lower legs that are commonly present near the end of pregnancy.

Edema in legs

The lymphatic vessels of the pregnant woman's pelvis become enlarged in response to the increased amount of tissue fluid in the engorged pelvic organs. As the uterus grows in size it presses on these channels, causing impairment of the lymphatic drainage from the woman's legs, with resultant swelling and distention of her feet and legs.

Although some fluid almost invariably collects in the feet, ankles, and legs near the time of delivery, sudden swelling of the feet and legs or a notable increase in swelling may be an early signal of impending toxemia, a serious disorder of pregnancy that is discussed below. Generalized swelling—i.e., swelling of the hands, face, and other parts of the body—is a cause for serious concern.

Respiratory tract. One would expect that, as the uterus grows larger and pushes the diaphragm up, it would interfere with breathing, but the lungs actually work as efficiently as they do in the nonpregnant state. This is due to a change in the shape of the chest cavity during pregnancy; the chest diameter increases as its height decreases, so that there is actually a slight increase in the space that the lungs occupy.

The amount of air drawn in and expelled per minute by the lungs increases progressively during pregnancy. Immediately before delivery the number of breaths per minute is approximately twice what it is after the baby is born. This, like so many of the other changes in the mother's body, is an adaptation of one of her vital functions that is necessary to supply her tissues and those of the growing fetus with increasing amounts of oxygen.

Gastrointestinal tract. A number of alterations, often causing more or less distress, occur in the physical condition and functions of the gastrointestinal tract during pregnancy.

Disturbances of the sensations of taste and smell, relatively common during early months of gestation, are often accompanied by a dislike of odors and a distaste of foods formerly found to be not disagreeable. The inflammation of the mouth and gums that some pregnant women complain of is more often caused by poor oral hygiene, by vitamin deficiencies, or by anemia than by the pregnancy itself.

Taste and smell

Hydrochloric acid and pepsin, adequate amounts of which are necessary for satisfactory digestion, are produced by the stomach in decreased amounts during pregnancy. This decrease in the amount of acid in the stomach may explain some of the otherwise inexplicable anemias that occasionally occur during the course of an otherwise seemingly normal pregnancy.

During pregnancy the stomach muscles lose some of their tone and become more flabby, and the contractility of the stomach is reduced. As a result, the time it takes for the stomach to empty its contents into the intestinal tract is prolonged. As pregnancy progresses, the stomach is pushed upward; near term it lies like a flabby pouch across the top of the uterus instead of hanging downward, as it normally does, in a semivertical position. The loss of tone

of the stomach muscles, the decrease in stomach acidity, and the change in position of the stomach are conducive to the flow of intestinal contents back into the stomach.

These disturbances in gastric function are responsible, in part at least, for the intolerance for fatty foods, the indigestion, the discomfort felt in the upper part of the abdomen, and the heartburn experienced by most pregnant women at some time during their pregnancies.

The musculature not only of the stomach but also of the entire intestinal tract loses much of its tonicity. As a result, peristalsis, the series of wave-like movements of the intestines, is slowed, the length of time it takes food to pass through the intestinal tract is prolonged, and there is more or less stagnation of the intestinal contents.

Intestinal
problems

Constipation and hemorrhoids that cause rectal pain and bleeding are common complaints during pregnancy. The constipation is caused by lack of tone of the intestinal tract and stagnation of the bowel contents. Pregnant women may also lose the urge to defecate because of the pressure of the uterus on the lower bowel and inhibition of a reflex stimulus, known as the gastrocolic reflex, from the stomach to the rectum. The latter mechanism, which depends on normal stomach function, is responsible for the increased activity of the lower bowel that follows increased stomach activity, such as that induced by eating. It is this reflex that causes many persons to feel a desire to defecate within an hour or so after eating a full meal. Hemorrhoids—greatly enlarged or varicose veins in the lower rectum—that appear during pregnancy are due to constipation, to stasis of blood in the pelvic veins, and to pressure by the enlarging uterus on the blood vessels in the pelvis.

Liver. The liver, which plays an essential role in many of the vital processes—processes as diverse as participating in the metabolism of nutrients and vitamins and the elimination of the waste products of metabolism—changes anatomically and functionally during pregnancy to meet the added load placed on it by the maternal organism, the enlarging uterus, and, to a lesser extent, the growing fetus.

The liver's ability to synthesize proteins and to supply minerals and nutrients is augmented in response to the increased requirements of the mother's tissue and the fetus. The liver adjusts to the greatly augmented amounts of hormones circulating in the mother's blood during pregnancy. It helps to dispose of or detoxify the larger amounts of waste material produced by the metabolic processes in the growing fetus, the enlarging uterus, and the mother's tissues. Furthermore, the blood vessels in the liver enlarge to accommodate the larger amount of blood in the mother's blood vessels. At the same time, the liver must compensate for the larger number of circulating red blood cells.

In response to these demands the liver increases in size and weight, and its blood vessels become larger, but otherwise its anatomical structure changes relatively little during pregnancy.

The hormones produced by the placenta and the metabolic changes in the maternal organism, rather than the fetus, are the factors responsible not only for the increased work the liver does but also for many of the physical and functional alterations that appear during gestation.

Urinary tract. Changes that take place in the bladder and the urethra during pregnancy are attributable to relaxation of the muscles supporting these structures, to change in position, and to pressure.

The uterus lies over the bladder and presses upon it during early pregnancy. Later the uterus rises out of the pelvis. As the uterus grows larger and moves upward, the bladder is pushed forward and pulled upward. The urethra, the tube through which urine is discharged from the bladder, is stretched and distorted. As these distortions take place, the wall of the bladder becomes thickened, the blood vessels become enlarged, and fluid collects in the tissues forming the wall of the bladder. The results are swelling, stasis of blood in the blood vessels, and some mechanical inflammation of the bladder wall.

The woman is likely to urinate frequently during the early months of pregnancy when the heavy uterus presses on the bladder. Frequent urination is less common during

midpregnancy, but it recurs after the baby descends into the pelvis near the time of delivery. As the bladder and urethra are pulled upward and distorted by the growing uterus, the stretched muscles that control urination are less efficient, and the woman may lose some urine involuntarily when she coughs, sneezes, or laughs; this is known as stress incontinence.

The swelling, mechanical inflammation, and stasis of blood in the blood vessels of the bladder near the end of pregnancy are conducive to bladder infection, a symptom of which is pain on urination. A microscopic examination of the urine is necessary to differentiate between the effect of pregnancy on bladder function and the symptoms caused by a bladder infection. An untreated bladder infection may lead to serious urinary tract troubles later.

Changes in the structure and function of the ureters, the two rubbery, spaghetti-like tubes that carry urine from the kidneys to the bladder, are present in 80 percent of all pregnancies. As pregnancy progresses each ureter becomes larger, so that it lies in multiple broad curves rather than forming an almost straight line downward from the kidney. In addition, both ureters, but particularly the right one, become greatly dilated, so that the urine flows very slowly or collects in them.

Structure
and
functioning
of ureters

The funnel-like part of the kidney, called the kidney pelvis, also becomes dilated. With this dilation of the kidney pelvis and the ureters there is also a loss of tonicity or contractility in the pelvis of the kidney and the ureters. This loss of tonicity during pregnancy is similar to that mentioned in the description of the changes in the intestinal tract. Since it is the contractility of peristalsis within the ureter that propels urine downward from the kidney into the bladder, stasis of urine in the ureter is accentuated during the pregnancy. In the nonpregnant state the hydrostatic pressure in the kidney is greater than that in the bladder; during pregnancy the situation is reversed. This change of pressure further increases the stasis of urine in the ureter and kidney pelvis. As a result, bladder infections are more serious during pregnancy, because they are more likely to involve the kidney.

After delivery the ureters rapidly return to their normal condition.

The kidney of a healthy person selectively filters and secretes water, sodium, potassium, chlorides, protein, and other substances from the blood. It then reabsorbs water and essential elements in amounts that are needed to maintain the fluid, electrolytic, and other chemical balances in the body. It also filters waste products of metabolism from the blood and excretes them in the urine. During pregnancy the kidney continues to carry on these functions. The work load placed on it, however, is greater because of the increase in the amount of water and blood and in the rate of metabolism during gestation.

Ordinary
functioning
of kidney;
changes in
pregnancy

In early pregnancy, secretion of large amounts of dilute urine of decreased acidity, together with pressure of the uterus on the bladder, causes frequency of urination and nocturnal voiding. Less urine is excreted toward the end of pregnancy. The storage of large amounts of nitrogen, as part of the metabolism of proteins, causes a decrease in the urinary excretion of urea and of total nitrogen during gestation.

Although many healthy pregnant women occasionally show a trace of protein (albumin) in their urine, the detection of even small amounts of protein in the urine is a cause for alertness on the part of a physician, because anything more than an extremely small amount may be the first signal of impending toxemia or kidney disease, both of which are serious complications.

The kidney's ability to reabsorb sugar (glucose) is lower during pregnancy, and for this reason many pregnant women have transient periods during which their urine contains small amounts of glucose; such women have unimpaired ability to metabolize carbohydrates and have normal sugar levels in the blood. Glucose in the urine also may be the first sign that a person has diabetes mellitus, however; consequently, a pregnant woman whose urine contains traces of glucose is tested to make sure that she can metabolize sugar normally.

The preceding discussion of kidney function illustrates

Changes
in bladder
function

the need for a pregnant woman to be under a physician's care, an essential part of which is periodic examination of her urine for protein, sugar, pus, bacteria, and other abnormal constituents.

Increase
in blood
volume

Blood. The total amount of blood in a pregnant woman's body has increased by approximately 25 percent by the time of delivery. The increase is accounted for by the augmented volume of blood plasma (the liquid part of the blood), which is caused by fluid retention, plus an increase in the total number of red blood cells. Additional blood is needed to fill the large vessels of the uterus. Also, more blood is required to carry the oxygen and nutrients needed by the fetus and the maternal tissues and to carry away waste products. Furthermore, it is a protective reserve in case of hemorrhage during delivery.

During pregnancy the blood-forming organs, such as the bone marrow, make more erythrocytes, or red blood cells, which carry iron and oxygen. Despite this, there is usually a decrease in a pregnant woman's blood cell count—the number of red cells per cubic millimetre of blood—because the amount of blood plasma increases approximately 30 percent, while the total number of red blood cells increases by only about 20 percent. This results in apparent anemia. With these changes, the viscosity of the blood decreases and the hematocrit, which measures the relative amounts of liquid and solid constituents in the blood, is lower. Usually there is a moderate increase in the number of white blood cells per cubic millimetre during early pregnancy; this increase disappears during the latter part of pregnancy.

If a pregnant woman is otherwise healthy and receives adequate available iron for the production of hemoglobin, her red blood cell count does not ordinarily fall below 3,750,000 cells per cubic millimetre, her hemoglobin below 13.5 grams per 100 cubic millimetres of blood, and her hematocrit below 35. (Normal values for nonpregnant women are 4,200,000–5,400,000 cells, 13.8–14.2 grams hemoglobin, and 37–47 hematocrit.) Physicians usually make blood counts for their pregnant patients every two months because of the need for repeated evaluation.

Endocrine system. Most of the endocrine glands become larger, and some display alterations in function, during pregnancy; they all revert to a normal state after delivery.

Pituitary,
thyroid,
pancreas,
and
adrenals

The anterior lobe of the pituitary gland increases in size during pregnancy, but the production of pituitary gonadotropins, the gonad-stimulating hormones, ceases soon after the placenta begins to produce chorionic gonadotropins. The pituitary continues to secrete the hormones that stimulate the other endocrine glands. Near term, as the mother's estrogen level drops, a milk-stimulating hormone, prolactin, is produced by the pituitary. The posterior lobe of the pituitary gland does not change in size or weight during pregnancy.

The thyroid gland enlarges moderately, but there is no true increase in thyroid function during gestation. The parathyroid glands also increase in size during pregnancy but presumably are not otherwise affected by it.

The part of the pancreas that secretes insulin, the islets of Langerhans, becomes larger. Whatever increase in function is displayed may be assumed to be a balanced response to the body's demand for the products of carbohydrate metabolism. The level of plasma insulin or of insulin-like substances in the plasma is higher during pregnancy, and the destruction of insulin is also more rapid.

The blood and urinary levels of 17-hydroxycorticosteroids, hormones that affect protein, fat, and carbohydrate metabolism and that are produced by the adrenal glands, rise during pregnancy; but there is no increased effect from the hormones, because their higher level is more than offset by the increased levels of transcortin, a protein that inactivates them.

As gestation progresses, there is an elevation in the secretion of aldosterone, an adrenal hormone that plays a role in the retention of salt and water in the body. It has been suggested that this is a protective mechanism to counterbalance the tendency for progesterone to cause the excretion of sodium ions in the urine.

Skin. Pregnancy usually causes an increase in the secre-

tion of the oil and sweat glands in the skin. Body odours may become more pronounced. Many women notice that their hair becomes thinner and drier and their nails more brittle. Others may develop an increased amount of facial and body hair. The "mask of pregnancy" seen particularly in brunettes is a deposit of brownish pigment in the skin of the forehead, the cheeks, and the nose. Puffiness and thickening of her skin may cause the pregnant woman's face to appear coarse and almost masculine. Increased pigmentation, particularly of the smooth skin about the nipples (the areolas of the breasts) and the vulva, is almost universal.

Bright red discoloration of the palms of the hands and tiny spiderweb-like red blood vessels in the skin of the arms or face are not unusual during pregnancy. Many of these changes are thought to be associated with the greatly increased levels of estrogen in the mother's bloodstream. Most of the changes disappear after delivery.

"Stretch marks," which appear on the breasts and abdomen during pregnancy, are due to the tearing of the elastic tissues in the skin that accompanies enlargement of the breasts, distention of the abdomen, and the deposition of subcutaneous fat. They are pink or purplish-red lines during pregnancy. The lines become permanent grayish-white scarlike marks after delivery. Some women never develop stretch marks despite bearing several children; others lose most of the tone in their skin after one pregnancy. Stretch marks cannot be considered evidence that a woman has borne a child, however, because they sometimes are seen in women who have not been pregnant.

Metabolic changes. Metabolic changes during pregnancy are among the many adjustments that the mother's organs make to meet the requirements created by the increase in her own breast and genital tissues and the growth of the conceptus (the fetus and afterbirth). In addition, reserves must be established to meet the demands that will be put on her body during pregnancy, delivery, and the lying-in period.

The basal metabolic rate. The amount of oxygen consumed is an index of the pregnant woman's metabolism when she is at rest—her basal metabolism. The rate begins to rise during the third month of pregnancy and may double the normal rate (+10 percent) by the time of delivery. The rate rises in specific proportion to the size of the fetus and represents the effects of the mother's activities plus those of the fetus and the uterine structures. An elevation of the basal metabolic rate (BMR) to 20 or 25 percent during pregnancy is not an indication of an overly active thyroid gland.

Weight. The early part of pregnancy usually is accompanied by moderate weight loss caused by the woman's lack of appetite and her nausea and vomiting. Between the third and the ninth month of pregnancy most women gain about nine kilograms (20 pounds) or more. Ideally, during pregnancy body weight is gained at the rate of about one-half kilogram (one pound) per week for a total of not more than nine to 11.5 kilograms (20 to 25 pounds). In an average pregnancy the infant, the afterbirth, and the fluid in the uterus weigh about 4.5 kilograms (10 pounds). The uterus and the breasts together weigh approximately 2.25 kilograms (five pounds). The remaining 2.25 kilograms consist of stored fluids and fat. Weight gain exceeding 11.5 kilograms usually represents fat and fluids that are in excess of the reserve requirements for a normal pregnancy. A woman loses approximately seven kilograms (15 pounds) at delivery, and another 2.25 kilograms of stored fluid are eliminated as the uterus shrinks. She does not lose many additional kilograms during the weeks following the delivery of the baby unless she limits her caloric intake. Fat stored during pregnancy is lost more slowly than stored fluids, proteins, and carbohydrates.

Excessive weight gain during pregnancy is a matter of concern for both the patient and the doctor. Although it may be only the result of overeating, it may be caused by a disturbance in metabolism and by an abnormal retention of fluids and salts. In the latter instance it may be the first sign of toxemia.

Protein. During pregnancy, nitrogen, derived from the metabolism of ingested protein, is needed for growth of

Changes

glands and
skin colour

Changes
in protein,
carbohy-
drate,
and fat
metabolism

the fetus, the placenta, the uterus, and the mother's breasts and other tissues. A considerable amount of nitrogen also is required for the increase in the mother's red cell volume and blood plasma. The fetus's demand for nitrogen is slight at first, but during the last month of pregnancy it acquires almost half of its total protein. In the process of accumulating this store and of building a reserve for the period after delivery, the woman who is on an adequate diet retains between two and three grams of nitrogen daily during her pregnancy; by term she and the fetus will have acquired approximately 500 grams (about 1.1 pounds) of nitrogen.

Carbohydrates. During pregnancy greater quantities of blood are being processed through the kidneys, but the kidneys are incapable of reabsorbing increased amounts of sugar. Consequently, a lower level of sugar in the blood is tolerated, and slight amounts of sugar are excreted in the urine. During pregnancy the level of sugar in the blood after fasting is slightly lower, probably because there is less utilizable insulin in the blood to regulate the sugar metabolism. Oral glucose tolerance tests show a prolonged elevation of blood sugar after ingestion of glucose; this may be an indication that carbohydrate utilization is less rapid or that the absorption of glucose from the gastrointestinal tract is slower. Glucose tolerance tests that depend on injection of the sugar solution into the veins show no difference between nonpregnant and pregnant nondiabetic women. A few women who are potential or mild diabetics demonstrate diabetes for the first time when they are pregnant. This is because pregnancy taxes insulin productivity in women with a marginal pancreatic islet reserve, so that diabetes may first become evident during gestation.

Fat. The total blood lipids average 600 to 700 milligrams per hundred millilitres of blood in the nonpregnant woman. They increase to approximately 900 to 1,000 milligrams per hundred millilitres of blood during the latter part of pregnancy. This increase, which involves all the lipid fractions, has not been explained, but it is worthy of notice that the gain in fat reaches its acme during the period that the fetus acquires most of its adipose (fatty) tissue.

Increases
in body
fluids

Water. Pregnancy is characterized by increases in the amount of body water and in the total volume of body fluid. During pregnancy between 3,500 and 4,000 millilitres of fluid (about 3.2 to 3.6 quarts) will be added to that already present in the tissues of a healthy woman. The uterus, the placenta, the amniotic fluid, and the fetus each account for approximately equal amounts. In addition to the water that makes the increased blood volume, there is also added fluid in the mother's muscles, her pelvic soft tissues, her breasts, and her other tissues.

Toward the end of pregnancy a considerable amount of retained fluid accumulates in the woman's lower extremities. It is this fluid that produces the pitting and swelling of the legs that many normally pregnant women display during the month or two before delivery.

Retention of large amounts of electrolytes, particularly sodium, accompanies the increase in the amount of body fluids. Approximately 12 grams of sodium are retained monthly. In addition to a positive sodium balance, there is a positive chloride and potassium balance during pregnancy. As a result, additional water is required to maintain the balance of the solution of sodium, chloride, and potassium in the blood, in the fluid of the spaces between the tissue cells, and within the cells themselves. Not all of the sodium, however, goes into fluid. Some of it is stored, and some replaces potassium in the cells.

A number of factors contribute to a positive sodium balance, which in turn leads to retention of fluid; these include alterations in the kidneys' excretion of sodium and water; increased retention of water in the pregnant woman's legs; the large amounts of hormones, particularly estrogen, that the placenta secretes; and the secretion of adrenal hormones, especially aldosterone. The latter, in particular, reduces the kidneys' secretion of sodium. Since sodium and water interact with each other, whatever contributes to the retention of one leads to the retention of the other. Generalized swelling appears when the accumulation of sodium and water becomes too great. If the

excess continues the pregnant woman eventually develops toxemia.

Minerals. The pregnant woman's reserves and intake of iron and calcium must be enough not only for her own needs but also for those of the fetus. An increase in serum copper levels occurs during pregnancy. The mother has some phosphorus reserve but must acquire enough from her diet to supply her own tissues and those of the fetus. The utilization of phosphorus and that of calcium are interdependent, so that the utilization of phosphorus depends on the calcium intake.

Abnormal changes in pregnancy

ECTOPIC PREGNANCY

An ectopic pregnancy is one in which the conceptus (the products of conception; *i.e.*, the placenta, the membranes, and the embryo) implants or attaches itself in a place other than the normal location in the lining of the upper uterine cavity. The site of implantation may be either at an abnormal location within the uterus itself or in an area outside the uterus. Ectopic pregnancies outside the uterine cavity occur about once in every 300 pregnancies. They are one of the major causes of maternal deaths.

Normally an ovum or egg passes from the ovary into the tube, is fertilized in the tube, and moves downward into the uterus. It buries itself in the lining of the upper part of the uterine cavity. It may pass farther down and attach itself to the lining of the mouth of the uterus (the cervix), creating a cervical pregnancy. These are rare and cause severe vaginal bleeding; the conceptus is expelled or discovered within a few months after implantation.

If a conceptus attaches itself to the lower part of the uterine cavity it is a low implantation. When a low implantation occurs the placenta grows over the cervical opening, in a formation called a placenta praevia. This causes the woman to bleed, often profusely, through the vagina, because the placenta tears as the cervix begins to open during the latter part of pregnancy.

When the fertilized egg implants in the narrow space or angle of the uterine cavity near the connection of the uterus with the fallopian tube, it is called an angular pregnancy; many angular pregnancies terminate in abortions; others go to term but are complicated because the placenta does not separate properly from the uterine wall after birth of the baby. An angular pregnancy differs from a cornual pregnancy, which develops in the side of a bilobed or bicornate uterus.

Implantation in the narrow part of the fallopian, or uterine, tube, which lies within the uterine wall, produces what is called an interstitial pregnancy. This occurs in approximately 4 percent of ectopic pregnancies. An interstitial pregnancy gradually stretches the wall of the uterus until, usually between the 16th and 20th week of gestation, the wall ruptures in an explosive manner and the woman bleeds profusely into her abdomen.

Most persons associate ectopic pregnancies with tubal pregnancies, because most ectopic pregnancies occur in the uterine tubes. The tube beyond the uterus has three parts: the isthmus, a narrow section near the uterus; the ampulla, which is wider and more dilatable; and the infundibulum, the flaring, trumpet-like portion of the tube nearest the ovary. A tubal ectopic pregnancy is designated by the area of the tube in which it is implanted. An isthmic pregnancy differs from one in the ampulla or infundibulum because the narrow tube cannot expand. Rupture of the affected tube with profuse intra-abdominal hemorrhage occurs early, usually within eight weeks after conception.

Ampullar pregnancies, which are by far the most common, usually terminate either in a tubal abortion, in which the embryo and the developing afterbirth are expelled through the open end of the tube into the abdomen; by a tubal rupture; or, less commonly, by absorption of the conceptus.

Sometimes the tube ruptures into the tissues attaching it to the wall of the pelvis, producing an intraligamentous pregnancy. Rarely, the embryo is expelled into the abdomen and the afterbirth remains attached to the tube; the embryo lives and grows. Such a condition is referred

(J) In the cornu of a double or rudimentary horn of a uterus.

to as a secondary abdominal pregnancy. Primary abdominal pregnancies, in which the fertilized egg attaches to an abdominal organ, and ovarian pregnancies are rarer still.

It is generally believed, but not proved, that most tubal pregnancies are caused by scars, pockets, kinks, or adhesions in the tubal lining resulting from tubal infections. The infection may have been gonorrhea; it may have occurred after an abortion, after the delivery of a baby, or after a pelvic surgical operation; or it may have been caused by appendicitis. Kinking, scarring, and partial adhesions of the outside of the tube may be the result of inflammation following a pelvic operation or of an abdominal inflammation. Tubes, defective from birth, may be too small for the passage of the conceptus or may be pocketed or doubled with one tubal half forming a blind pocket. There may be areas in the tubal lining that behave like the lining of the uterus (they show a decidual reaction that is conducive to implantation) so that they offer a favourable spot for the fertilized egg to implant. Pelvic tumours may distort the tube and obstruct it so that the conceptus cannot move downward. Theoretically, endocrine disturbances may delay tubal motility.

Whatever the cause, when a tubal implantation occurs it may be assumed that either migration of the fertilized egg within the tube was delayed by an extrinsic factor so that the egg grew to the point where it should implant or that the mechanism for implantation within the egg itself was prematurely activated in the tube. One or the other of these causative factors can sometimes be seen when a woman is operated upon for an ectopic pregnancy. There are a great number of cases, however, in which no abnormality of the tube can be found. There is no satisfactory explanation for most abnormal implantations in the uterus, although defective uterine structure has been noted in some cases.

Primary abdominal and ovarian pregnancies can best be explained by a mechanism in which the fertilized ovum is swept out of the tube by a reverse peristalsis of the tube, but it is quite possible that, in rare instances, the ovum and spermatozoa meet and fertilization and implantation take place within the abdomen.

Signs of
ectopic
pregnancy

Ectopic pregnancy is frequently mistaken for other disorders. Typically, but not invariably, the woman who has an ectopic pregnancy in the ampullar part of the tube will have missed one or two menstrual periods. She need not have other symptoms of pregnancy. She has felt enough discomfort in the lower part of her abdomen to lead her to consult a physician. She has had recurrent episodes of rather light, irregular bleeding from the vagina. She has felt weak or faint at times. The signs of pregnancy are not likely to be present, and results of a pregnancy test are more often negative than positive. The physician, on pelvic examination, feels a tender, soft mass in one side

of the pelvis. At this stage he has to differentiate between an ectopic pregnancy and an intrauterine pregnancy with abortion; acute appendicitis; intestinal colic; inflammation of a fallopian tube; and a twisted ovarian tumour. Unless the diagnosis can be made, the patient continues to complain for several more days and then has a sudden severe pain and collapses from brisk bleeding within the abdomen.

Only rarely are sudden acute abdominal pain and collapse due to severe hemorrhage the first signs that something is amiss. If this does happen it is usually because implantation has occurred in the isthmic portion of the tube and hemorrhage and tubal rupture occur simultaneously. More frequently a woman has missed one menstrual period, has a sensation of pelvic pressure, feels that she must urinate and collapses in the bathroom. She may be unconscious and pulseless from loss of blood when she arrives at the hospital.

Interstitial pregnancies are often mistaken for intrauterine ones, but the patient has more pain than she would with a normal pregnancy and may have intermittent vaginal bleeding. After several months she has sudden severe pain, collapses from a massive intra-abdominal hemorrhage, and may die before surgical help can reach her. Most of the women who die from ectopic pregnancies do so from interstitial ones.

Combined pregnancies, in which there is an ectopic pregnancy and a normal one in the uterus, or a fetus in each tube, have occurred and have compounded the difficulty in making a diagnosis. In a number of instances the ectopic conceptus has been removed without complications, and the uterine fetus has progressed to term.

Not all ectopic pregnancies end with a catastrophic hemorrhage and collapse. In a few instances tubal, abdominal, and broad ligament pregnancies have gone on until a living baby was obtained at the time of operation. In other cases the fetus died and, if very young, was resorbed; in others, when the fetus was larger, death was followed by absorption of the fluid in the sac and the fetus was gradually converted into a more or less mummified mass. Some ectopic pregnancies of this type have caused no symptoms and have been carried by women for years. Undoubtedly many ectopic pregnancies that are in an early stage when they are expelled emerge through the open end of the uterine tube, are resorbed, and are never recognized.

Once diagnosed, the treatment of ectopic pregnancies outside the uterine cavity is almost always a matter of prompt surgical intervention with proper attention to replacement of blood and fluid.

ABORTION

Abortion is the termination of a pregnancy before the infant can survive outside the uterus. The age at which a

What
abortion is

fetus is considered viable has not been completely agreed upon. Many obstetricians use either 21 weeks or 400–500 grams (0.9–1.1 pounds) birth weight as the base line between abortion and premature delivery, because few infants have survived when they weighed less than 500 grams at birth or when the pregnancy was of less than 21 weeks' duration. Generally speaking, the fetus has almost no chance of living if it weighs less than 1,000 grams (2.2 pounds) and if the pregnancy is of less than 28 weeks' duration. In one effort to resolve the matter, the American College of Obstetricians and Gynecologists has defined abortion as the expulsion or extraction of all (complete) or any part (incomplete) of the placenta or membranes, with or without an abortus, before the 20th week (before 134 days) of gestation. Early abortion is an abortion that occurs before the 12th completed week of gestation (84 days); late abortion is an abortion that occurs after the 12th completed week but before the beginning of the 20th week of gestation (85–134 days).

In the past the word abortion has usually meant to non-medical persons the criminal interruption of a pregnancy, whereas "miscarriage" indicated that there had been a spontaneous expulsion of the uterine contents. The term miscarriage is seldom used medically.

Spontaneous abortion is the expulsion of the products of conception before the 20th week of gestation without deliberate interference. As a general rule, natural causes are responsible for loss of the pregnancy. An induced abortion is the deliberate interruption of a pregnancy by any means before the 20th week of gestation. In medical terminology an abortion may be therapeutic or nontherapeutic. A therapeutic abortion is the interruption of a pregnancy before the 20th week of gestation because it endangers the mother's life or health or because the baby presumably would not be normal. A nontherapeutic abortion is the interruption of a pregnancy for nonmedical reasons by any means before the 20th week of gestation. The terms criminal abortion and illegal abortion are legal rather than medical terms.

Stages of
spontaneous
abortion

A spontaneous abortion usually passes through several progressive stages. The first stage is a threatened abortion in which a woman, known to be less than 20 weeks pregnant, notices a small amount of bloody discharge from her vagina and, perhaps, a few cramping pains in her uterus. By pelvic examination it is determined that her cervix has not started to open or dilate. Either the symptoms subside or the matter progresses to an inevitable abortion, in which there is increased bleeding, the uterine cramps become more severe, and the cervix, or mouth of the uterus, opens for the expulsion of the uterine contents. An inevitable abortion terminates either as a complete or an incomplete abortion, depending on whether or not all of the products of gestation are expelled. The process may start abruptly with pain and profuse bleeding and be over in a few hours, or it may go on for days with only a modest loss of blood. Spontaneous abortions early in pregnancy tend to be complete. When the pregnancy is further advanced it is more likely to be incomplete. Usually the physician removes the retained tissue in the uterus surgically when there is an incomplete abortion.

If the fetus dies and is retained in the uterus for eight weeks or longer the condition is referred to as a missed abortion. Women who lose three or more consecutive pregnancies of less than 20 weeks' duration are said to suffer from habitual abortion. An infected abortion is an abortion associated with infection of the genital organs.

Approximately 10 percent of all pregnancies terminate in spontaneous abortion. Some are lost so early that the woman and her physician are not sure whether she aborted or had a menstrual period that was slightly delayed, particularly heavy, and more painful than usual. The majority occur between the 6th and the 12th week after conception. The number of nontherapeutic abortions is unknown, but it probably equals the number of spontaneous ones. Modifications in the abortion laws in several countries, including the United States, have greatly increased the number of requested abortions; it is believed that in some areas the number of abortions exceeds that of babies delivered alive.

At least half of all early abortions are caused by defective development of the structures that grow from the fertilized egg; *i.e.*, the baby, the afterbirth, and the membranes that surround the baby and hold the water that it floats in. Some of these abortions are genetic accidents caused by abnormal characteristics carried in the egg or sperm or by the failure of normal development of the chromosomes after the egg and sperm unite. It has been shown in animals that disturbances in the transportation of the fertilized egg to the uterus may cause premature or delayed implantation of the conceptus; too young or too old fertilized eggs tend to abort. Inadequate secretion of the ovarian hormones estrogen and progesterone, needed for the development of the newly fertilized egg, may cause failure of the lining of the uterus and its secretions to sustain the young embryo. Later, failure of the placenta to take over the hormone-producing function of the ovary may adversely affect the growth of the uterus and its contractility. X-rays in large doses, radium, and certain drugs may cause abortion because they damage embryonic tissues. Abnormal development of the mother's uterus may make it impossible for it to retain the pregnancy.

Causes of
abortion

Late abortion is sometimes caused by the weakness of the mouth of the uterus or by fetal death following knotting of the umbilical cord. Uterine tumours may cause abortion because they increase uterine irritability or create an unfavourable environment for embryonic growth. In most instances in which psychic factors allegedly caused an abortion, examination of the baby and of the afterbirth have shown defects in one or both that had occurred before the mother had suffered her emotional disturbance. Physical injury to the mother is a causative factor in only one in a thousand abortions. Abortions thought to be caused by automobile accidents, falls, kicks, and so forth are often the result of deleterious changes in the fetus and sac that occurred before the injury. Systemic diseases may play a role in causing an abortion. This is particularly true of acute infectious diseases with high fever and bacteria in the bloodstream, or of diseases such as pneumonia, in which there is a marked reduction in the supply of oxygen to the fetus. Heart disease, kidney disease, diabetes, high blood pressure, and other chronic diseases may be associated with premature birth and fetal death after the 21st week but do not ordinarily cause abortions.

Perhaps 3 percent of threatened abortions are prevented by rest and hormonal therapy. Most abortions are inevitable because the fertilized egg is abnormal; these cannot be controlled medically. Many women who suffer from habitual abortion respond well to treatment; in some of these cases corrective surgery is necessary. An early spontaneous abortion without infection is rarely followed by ill health when the affected person receives proper medical treatment. Infected abortions, many the result of nontherapeutic interruptions of pregnancy, have caused chronic pelvic distress and, in some cases, sterility.

Avoidance
of abortion;
effects
of abortion

SYSTEMIC DISEASES AND PREGNANCY

Heart disease. Heart disease occurs in approximately 1 percent of pregnant women. It is first as a cause of maternal deaths among the disorders incidental to pregnancy and fourth, after hemorrhage, toxemia, and infection, as a cause of all maternal deaths. Rheumatic heart disease is the most prevalent type. Congenital heart disease accounts for approximately one-fourth of the cases.

A number of factors, including her response to physical activity, a history of heart failure, the type of heart disease that she has, and her age, are used in estimating how a particular woman will fare during pregnancy and labour. A person whose heart disease causes no limitation of normal physical activity will usually go through a normal pregnancy and delivery without notable difficulty, provided that she avoids undue physical activity, has sufficient rest, avoids infections, and is under the care of an obstetrician and a cardiologist who are on the alert for signs of early heart failure. Such a person will not face an appreciably increased risk, and her heart disease will not be affected by the pregnancy.

The woman whose physical activity is limited to some extent because it causes undue fatigue, shortness of breath,

heart palpitation, or heart pain, but who has never experienced heart failure, will seldom suffer heart failure if she follows a strict regimen outlined by her physicians throughout the pregnancy, the labour, and the puerperium (the period immediately after childbirth) and if she does not experience a complication of pregnancy or of her heart disease. A diseased heart, although able to carry the load put on it by pregnancy, may not be able to stand up under an additional burden. This is particularly true if the pregnant woman gains an excessive amount of weight; if she develops toxemia, kidney disease, pulmonary disease, or an infection; or if she overworks physically, is subjected to sudden severe emotional stress, or becomes anemic. The possibility that a woman with serious heart disease will have heart failure is greater if she is over 35 years of age. A number of persons with heart disease who get along well during pregnancy with good care do suffer heart failure when they take on the added labours of caring for their family, home, and the new baby.

Management of pregnancy preceded by heart failure

Over half of the women who have suffered from heart failure before they become pregnant do so again during pregnancy, usually between the fifth and the ninth month, when pregnancy throws the greatest work load on the heart. Because so many women with a history of previous heart failure have difficulties during pregnancy, many obstetricians and cardiologists restrict the physical activity of such women and try to keep them in the hospital and under close medical surveillance. Some women with serious heart disease are kept in bed in the hospital throughout the course of the pregnancy and thus avoid heart failure. Cardiac surgery during the first few months of pregnancy, although a hazardous procedure, has lessened the necessity for prolonged bed rest in some cases and materially improved the prognosis in others.

Women with serious heart disease often deliver prematurely, and their labours are often short and their deliveries easy. There is an increase in fetal mortality because many pregnancies are interrupted and because many of the babies of women with heart disease are born prematurely. Babies who are not born prematurely are not notably different from those of normal mothers.

Endocrine diseases. *Diabetes.* Before insulin was available, most diabetic women were sterile, or, if they became pregnant, aborted. Half of the babies and one-fourth of the mothers died if they went to term. Today, if they are adequately supervised, less than 1 percent of pregnant diabetic women die of diabetes during pregnancy or the puerperium. Diabetic women do suffer from an increased incidence of toxemia, infections, and polyhydramnios (excessive amniotic fluid). Abnormalities of labour are increased because the babies tend to be unusually large, and congenital abnormalities of the fetus are more common, as is polyhydramnios; polyhydramnios is a problem in 25 percent or more of diabetic women.

Complications from diabetes

Untreated diabetes is associated with a high incidence of fetal defects, abortion, stillbirths, premature labour, and excessively large babies. Even with diet and insulin, over 50 percent of the babies delivered by diabetic women weigh over eight pounds at birth. Even though they appear healthy at birth, many of them are not as strong as smaller babies whose mothers are not diabetic. Fetal loss is greater if the mother became diabetic in childhood, if she has been diabetic for a long time, or if she has vascular or kidney disease. Toxemia, which occurs with approximately 30 percent of diabetic pregnancies, would be more common if it were not for the practice of terminating such pregnancies several weeks before term.

Pregnancy frequently has an adverse effect on diabetes, and diabetes may first become evident during pregnancy. There is a tendency for the carbohydrate metabolism of the diabetic patient to be upset. Most diabetics need more insulin during gestation; a few, for reasons not understood, need less. The changing condition from day to day makes some diabetics, who have no problem maintaining a balance when they are not pregnant, difficult to manage. Even so, adequate medical supervision can bring most diabetics and their babies safely through pregnancy.

Thyroid disease. Simple goitres that are not associated with a change in the amount of thyroid hormone in the

mother's blood do not affect pregnancy, nor does pregnancy affect the thyroid in such a case. An inactive or too active thyroid gland, if not adequately treated during pregnancy, may be associated with an increased incidence of abortion. In the few cases in which persons with untreated myxedema, a severe form of hypothyroidism (deficiency of thyroid hormone), have conceived and gone to term there has been an increased incidence of congenital anomalies of the fetus. Pregnancy and hyperthyroidism (overabundance of thyroid hormone) seem to have no adverse effects on each other.

Pituitary disorders. Most persons with pituitary hypofunction fail to ovulate because their pituitary glands do not produce the gonadotropic hormones necessary for stimulation of the ovaries. Most of these persons also suffer from a lack of hormones from their other endocrine glands because these, too, lack stimulation by the pituitary. A few persons with hypopituitarism have, nevertheless, become pregnant. Their condition is better when they are pregnant because their placentas produce many of the hormones that their endocrine glands, lacking pituitary stimulation, do not ordinarily secrete.

Adrenal glands. Women suffering from adrenal gland insufficiency are not likely to become pregnant. If they do so, they have more tendency to suffer from circulatory disturbances and carbohydrate, electrolyte, and fluid imbalance because of the important role the adrenal glands play in the metabolism of water, sodium, potassium, chlorides, and glucose. Such patients and their babies do well if they receive hormonal therapy during gestation.

The increased secretion of adrenal hormones that occurs with hyperplasia of the adrenal cortex (enlargement of the outer layer of the adrenal gland, also called Cushing's disease) usually inhibits ovulation. A number of women with this disorder, after treatment with cortisone, have conceived, gone to term, and delivered normal children. Cushing's disease complicated by pregnancy is rare; the few cases reported have been associated with a high incidence of severe high blood pressure.

The maternal death rate is approximately 50 percent and the death rate of the child immediately before or after birth is approximately 40 percent when pheochromocytoma (a type of adrenal tumour associated with, among other things, a high blood pressure) complicates pregnancy.

Urinary tract diseases. Infections of the urinary tract are more frequent during pregnancy, and women who have acute infections of the bladder and kidneys while pregnant have a higher incidence of premature labour. This is in accord with the known fact that pregnant women with any type of acute infection tend to deliver prematurely. Many women with pyelonephritis (infection of the kidney) in one pregnancy will enter a second pregnancy with bacteria already in the urinary tract but causing no symptoms. These women have a greatly increased chance of developing acute urinary tract infections during their prepartum course and have some risk of eventually developing serious kidney disease. Glomerulonephritis, a kidney disease that affects the clusters of capillaries in the nephrons, the functioning kidney units, usually is preceded by infection with streptococcus organisms. The incidence of abortion and of premature delivery is increased among women in whom the condition develops during pregnancy. If the glomerulonephritis has become chronic the fetus may not survive and the mother's life may be in danger of kidney failure.

Healed tuberculosis of the kidney is not a contraindication to pregnancy if the disease has been quiescent for three years or longer and kidney function is normal. If tuberculosis of the kidneys is present but without symptoms, pregnancy may cause it to become active. If this happens, and if the infection is limited to one kidney, there is an increased danger that the opposite kidney will become infected in some way. The interference with the flow of urine that is characteristic of pregnancy is an important factor in the development of such infections. The accepted treatment when tuberculosis was present in one kidney during pregnancy formerly was therapeutic abortion followed by removal of the tuberculous kidney. This procedure is now avoided in some instances because of the effectiveness of the antituberculous drugs that have been developed.

Goitres; pituitary insufficiency; adrenal hypo- and hyperfunction

Kidney and bladder infections

Pregnancy after removal of a kidney. It is sometimes necessary to remove a person's kidney because of an infection, a stone, a tumour, or tuberculosis. The remaining normal kidney has a reserve that is greatly in excess of the demands that will be made by gestation, provided that it does not become infected. Infections, impaired kidney function, congenital defects, and toxemia, however, are more serious for a woman with a solitary kidney than they are for the patient with a normal urinary tract.

Pulmonary disease. Pulmonary disorders have an adverse effect on pregnancy if they seriously decrease the amount of oxygen supplied to the fetus, if they make the mother desperately sick, or if they create a blood infection that is transmitted to the placenta.

Respiratory
infections

An infection of the upper respiratory tract—the nose and throat—does not ordinarily disturb the course of gestation. It may be serious when it occurs in late pregnancy because of the danger that the mother will transmit disease-causing bacteria to her own genitalia or will carry virulent bacteria from her own nose and throat into the labour room and develop a blood infection after the delivery.

Epidemic influenza is associated with an increased incidence of maternal deaths. Many women who suffer from it abort or deliver prematurely. The infection may pass through the placenta and cause infection in the fetus. Pregnant women who acquire epidemic influenza are more likely to develop pneumonia than are persons who are not pregnant.

Pregnancy may increase or decrease the severity of asthma or may fail to affect it. A severe attack of asthma may be followed by abortion, but otherwise asthma does not affect pregnancy.

Pneumonia occurring during pregnancy is associated with a high rate of maternal and fetal death unless the pulmonary infection is susceptible to antibiotics or chemotherapy. The mother's cardiovascular system, already carrying the load placed on it by pregnancy, cannot sustain the added stress produced by pneumonia. The fetus often dies from oxygen starvation or from intrauterine infection.

Severe bronchitis and bronchiectasis—abnormal dilation of bronchi with some destruction of bronchial walls—may so interfere with the mother's respiration that the extra strain put on her cardiorespiratory system by pregnancy may put her life in jeopardy. If the disorders are severe enough to cause impaired pulmonary ventilation the fetus may suffer from a lack of oxygen and may be either stillborn or delivered prematurely. Pregnancy does not adversely affect the course of these pulmonary diseases.

Pulmonary tuberculosis is not, as a rule, affected by pregnancy. This is particularly true if the patient's infection has been quiescent for several years before she becomes pregnant. Even women with active tuberculosis, if given adequate care, usually go through pregnancy without any deterioration in their pulmonary condition. This is not universally true, however, because there is a small group with active disease whose disease becomes worse during pregnancy. For that reason individual evaluation of each person is necessary.

Although there have been a few cases of infection transmitted to the fetus prenatally, the great majority of babies born of tuberculous mothers are healthy at birth.

Pregnant women who have had portions of their lungs removed for tuberculosis, tumours, or other reasons do well provided that, before becoming pregnant, they are not short of breath with ordinary exertion. The added load of an additional pulmonary infection may not leave such persons with enough pulmonary reserve for the added burden of pregnancy; they may therefore experience difficulties if they contract pneumonia, severe influenza, or acute bronchitis during pregnancy.

Peptic ulcer; colitis; appendicitis

Gastrointestinal diseases. Women may already suffer from a gastrointestinal disease such as gastric or peptic ulcer, gallbladder disease, or ulcerative colitis when they become pregnant; or they may develop some type of gastrointestinal disturbance during the course of the pregnancy. In either event, pregnancy complicates their problems because the gastrointestinal disturbances that often accompany pregnancy may confuse the diagnosis in an individual case.

Gastrointestinal diseases have little or no effect on pregnancy. Pregnancy, on the other hand, tends to aggravate gastrointestinal disorders; the exception is gastric ulcer, which often improves because the concentration of acid in the stomach is decreased with pregnancy. Women with chronic ulcerative colitis are generally advised to avoid pregnancy until their bowel disease has been quiescent for two years; actually, since the woman's psychological reaction to pregnancy is what affects the bowel, the colitis may be made either better or worse by gestation.

Acute appendicitis, occurring during pregnancy, is often confused with other gastrointestinal complaints, and many patients' lives have been jeopardized either because they ignored the symptoms or because the diagnosis was confused by pregnancy. A diagnosis of acute appendicitis calls for an immediate operation regardless of the duration of the pregnancy or the hazard to the fetus.

Nervous system disorders. Neurological disorders and pregnancy most often are coincidental and have no effect on each other, but there are a few neurological diseases that develop during pregnancy, have a deleterious effect on it, or are adversely affected by it.

Epilepsy of unknown cause does not affect the course of pregnancy but may occur for the first time during gestation. An epileptic person may find her condition improved, aggravated, or unchanged by pregnancy; the effect of gestation cannot be foretold. There is some evidence that excessive fluid and salt retention induces epileptic seizures.

Epilepsy;
poliomyelitis; polyneuritis;
neuralgia

Pregnant women are more susceptible to poliomyelitis (infantile paralysis), but pregnancy does not affect the severity or the course of the disease, nor does poliomyelitis affect the course of pregnancy. If the muscles of respiration are paralyzed the patient will have difficulty during the latter part of pregnancy, when the uterus presses upward on the diaphragm. There have been a few instances in which babies have acquired infections from the mother before birth.

Polyneuritis, a disorder of the nerves usually resulting from vitamin B deficiency, may complicate pregnancy; this is particularly likely if the patient has suffered from severe and prolonged vomiting. Polyneuritis does not affect the gestation.

Neuralgia (pain that radiates along the nerve) occurs frequently near term. It affects especially the sciatic nerve, which is compressed between the pelvic wall and the head of the fetus.

Brain injury, including hemorrhage into the substance of the brain, sometimes occurs as part of the clinical picture of severe toxemia. Some types of brain tumours appear to be adversely affected by pregnancy, but, for the most part, brain tumours are not altered by pregnancy and do not disturb gestation.

Brain injury;
psychoses

Latent psychiatric disorders in unstable persons may be aggravated by pregnancy, but major psychiatric problems seldom appear for the first time during the period before delivery. There are a number of mild emotional disturbances, such as increased anxiety, emotional irritability, and fear of labour or for the normality of the fetus, that are likely to be most intense during the early months of gestation. Such disturbances seem to be most prevalent in women who did not anticipate becoming pregnant or who are unduly worried about the baby. Psychiatric disorders rarely influence pregnancy. Emotional disturbances have been said to be a factor in some spontaneous abortions, but satisfactory proof of the relationship is lacking. An intensely unwanted pregnancy may so seriously disturb an emotionally unstable woman that therapeutic abortion may be recommended after psychiatric evaluation.

DISEASES OF PREGNANCY

Acute toxemia. The toxemias are disorders occurring spontaneously only in human females and only during pregnancy or the puerperium. They are characterized by one or more of the following signs: high blood pressure; an accumulation of fluid in the tissues, often with marked swelling (edema); weight gain and proteinuria (albumin in the urine). If the toxemias are severe the affected women may suffer convulsions and loss of consciousness (coma).

In addition there may be eye, brain, kidney, heart, pulmonary, or gastrointestinal disturbances. Severe toxemia may cause death. The factors producing toxemia are unknown, but it has been shown that there is a generalized spasm of the arterioles (minute arteries) with associated severe circulatory effects.

The term toxemia of pregnancy is a misnomer, although it has long been in common use; there is no evidence to link the patient's symptoms and behaviour with the effects of toxic substances. The terms pre-eclampsia and eclampsia, used of subtypes of toxemia, are not particularly descriptive, although they are acceptable. Generally speaking, pre-eclampsia refers to the less severe, nonconvulsive type of toxemia. The term eclampsia is reserved for those instances in which there are convulsions or coma.

Toxemias
classified
by severity

Toxemias of pregnancy are classified according to the severity of their symptoms. The following classification, now in general use in the United States, was adopted by the American Committee on Maternal Welfare:

1. Acute toxemia of pregnancy (onset after 24 weeks)
 - a. Pre-eclampsia
 - (1) Mild
 - (2) Severe
 - b. Eclampsia (convulsions or coma, usually both, when associated with high blood pressure, edema or proteinuria)
2. Chronic hypertensive (vascular) disease with pregnancy
 - a. Without superimposed acute toxemia (no exacerbation of hypertension, no proteinuria)
 - (1) Hypertension known to antedate pregnancy
 - (2) Hypertension appearing during or before the 24th week and persisting after pregnancy
 - b. With superimposed acute toxemia
3. Unclassified toxemias
4. Recurrent toxemias

A woman is said to have mild pre-eclampsia when she is 24 or more weeks pregnant and exhibits one or more of the following signs: a definite trace or more of protein in her urine on two successive days; persistent edema of her face or hands; a systolic blood pressure of 140 millimetres of mercury (mm Hg) or more; a diastolic blood pressure of 90 mm Hg or more; or an elevation of 30 mm Hg or more in the systolic or 15 mm Hg in the diastolic pressures. (The systolic is the highest blood pressure after the heart has contracted; the diastolic, the lowest after the heart has expanded.) Her blood pressure is elevated on two occasions six hours or more apart.

Severe pre-eclampsia is characterized by the presence, after the 24th week of pregnancy, of any of the following: a systolic blood pressure of 160 mm Hg or above, or a diastolic pressure of 110 mm Hg or above, on two or more occasions at least six hours apart, with the woman resting in bed; the excretion of five grams (0.165 ounce) or more of protein in the urine in 24 hours; the excretion of 400 millilitres (about four-fifths of a pint) or less of urine in 24 hours; cerebral or visual disturbances; pulmonary edema or cyanosis (bluish or purplish colour of the skin).

Cerebral and visual disturbances and pulmonary edema and cyanosis are indications of a rapidly deteriorating situation in which the toxemia is seriously affecting, in the first instance, the patient's central nervous system or, in the second instance, her cardiorespiratory apparatus. Cyanosis and pulmonary edema (fluid in the lungs) indicate that the heart is not able to carry out its task and that heart failure is in progress.

The division of pre-eclampsia into mild and severe types by these rigid standards is not truly satisfactory because the physician, when he is attending a patient with toxemia, must evaluate many different things: her age and general appearance, her blood pressure, the amount of swelling, the severity of the proteinuria, her urinary output, and the presence of neurological symptoms. Any condition that has so many facets requires individualization in diagnosis and treatment for each patient.

The woman who develops pre-eclampsia often goes through a characteristic course: she has an inexplicable sudden weight gain of several pounds in a few days, moderate elevation of her blood pressure, and a small amount

of albumin in her urine. She is unaware of the latter two symptoms. She is in serious jeopardy by the time swelling of her face and hands, headaches, blurred vision or even blindness, and reduced urinary output occur.

Eclampsia is the presence of convulsions and coma superimposed on the symptoms of pre-eclampsia; *i.e.*, high blood pressure, protein in the urine, and fluid retention.

During pregnancy essential hypertension (chronic hypertensive vascular disease, which many people identify more commonly as "high blood pressure") may become extremely severe, with the symptoms identical to those of pre-eclampsia/eclampsia. Also, pre-eclampsia/eclampsia may be superimposed on chronic hypertensive vascular disease, leading rapidly to an extremely dangerous situation and often ending in eclampsia. Although the reason is not known, chronic hypertensive vascular disease appears to be more common in nonwhite than in white populations.

Some degree of toxemia occurs in from 5 to 10 percent of pregnant women. It is most common in women having their first baby and is common in women with twins, diabetes, or hydatidiform mole (an abnormality of the conceptus that is discussed below); it is one of the three major causes of maternal deaths, along with infection and hemorrhage. It is thought that at least 30,000 babies in the United States are lost annually through stillbirths or prematurity as a result of the toxemias. Eclampsia occurs in less than 1 in 1,000 pregnant women when they receive adequate antenatal care. It is interesting to note that the toxemias occur more frequently in young women or in those who are having their first babies, and in women who are diabetic or have excessive amounts of amniotic fluid.

An eclamptic convulsion may seize a toxemic patient at any time. It usually occurs near the end of pregnancy. It may happen when the woman is asleep. Characteristically it begins with facial twitching, a fixed stare, and body rigidity. The eyes then protrude, the face becomes a deep purplish-red, and all the muscles of the body go through rapid, strong, and agitated contractions and relaxations so that the woman throws herself about violently. She usually bites her tongue, foams at the mouth, and falls to the floor. The seizure lasts approximately 60 seconds and is followed by a period of unconsciousness, in which the woman breathes again, her face assumes a normal colour, and her breathing gradually becomes more rapid and deeper. There may be only one attack or many. Death may occur during or after the first seizure or may not occur even though the patient is unconscious for many days. A woman may be in labour when a seizure occurs or may go into labour after one. As a rule, delivery is followed by cessation of the convulsions. Eclampsia after delivery is rare.

When eclampsia occurs, it is usually, but not necessarily, in a patient who has toxemia. The pathological changes characteristic of eclampsia have been discovered in women dying with pre-eclampsia without convulsions, and even in a few rare instances in which the pregnant woman did not have hypertension, edema, or proteinuria. Death may be due to clots or hemorrhages into the brain, liver, kidneys, or heart muscles. The changes noted are characteristically in the blood vessels and are essentially due to generalized spasm of small arteries in many of the vital organs.

The cause of toxemia of pregnancy is unknown. A toxemia-like state has been produced experimentally in primates by partially obstructing the blood supply to the uterus. It is generally agreed that there is no evidence that toxic substances are responsible for the toxemias. Whatever the cause, it would seem that it produces an increase in tonicity or contractility of the walls of the finest capillaries throughout the body; this explains the proteinuria and the rise in blood pressure that are part of the clinical picture of toxemia.

The earliest possible recognition of mild pre-eclampsia and its energetic treatment from the first appearance of the symptoms that herald its onset are effective in warding off severe pre-eclampsia and eclampsia. The effect of such care was dramatically demonstrated in Sydney, Australia, in the 1950s; when prevention was based on the earliest possible discovery of excessive weight gain and increased

Characteristics of
eclampsia

Eclamptic
convulsion

Treatment
of
eclampsia

blood pressure, there were only ten cases of eclampsia among 37,850 patients delivered between 1948 and 1957. In order to achieve such a record it was necessary at times for the medical authorities in Sydney to send the constabulary to inform women who did not keep their appointments for prenatal care.

The treatment of mild pre-eclampsia is directed toward avoiding severe pre-eclampsia and eclampsia. Preferably the affected woman is hospitalized; retained salt and water are eliminated; and an adequate protein diet, rest in bed, and close observation are essential.

The treatment of severe pre-eclampsia attempts to overcome central nervous system hyperexcitability, to reduce vasospasm, and to lower the blood pressure through the use of suitable drugs. As a result, cerebral and renal circulation are increased, urinary output is promoted, and retained sodium and water are excreted. A patient with severe pre-eclampsia belongs in the hospital. Usually, but not invariably, it is safest to perform a therapeutic abortion if a woman has severe pre-eclampsia.

The treatment of eclampsia is directed toward prevention of further convulsions; decreasing vasoconstriction; reducing blood pressure; increasing urinary output; and maintaining fluid balance.

Termination of pregnancy by inducing labour or by cesarean section is the only definitive treatment for toxemia. If waiting is safe for the mother, it is desirable not to deliver the fetus until it can survive. Delivery is accomplished, after eclampsia is controlled, by whatever means seem best, induction of labour being preferable to cesarean section.

Diseases of the placenta. *Placenta praevia.* Implantation takes place in the lower half of the uterus in approximately 1 in 500 pregnant patients. The condition is

From J. Huffmann, *Gynecology and Obstetrics* (1962); W.B. Saunders Co.

Figure 35: (A) Normal implantation of the placenta in the top or fundus of the uterus. (B) Low implantation. (C) Partial placenta praevia. (D) Complete placenta praevia.

known as placenta praevia when the placenta lies over all or a portion of the internal opening of the cervix. A total placenta praevia is present when the cervical opening is completely covered. When there is a low implantation of the placenta, the latter lies close to but not over any part of the cervical opening.

Recurrent painless bleeding from the vagina without other symptoms after the sixth month of pregnancy is the typical manifestation of placenta praevia. It is caused by disruption of the placenta as the cervix and lower uterine segment are pulled upward. Each bleeding episode tends to become heavier. Without proper treatment the baby is likely to die and the mother may do so. Unremitting watchfulness of the woman with placenta praevia until the fetus has a chance of survival, with preparation for immediate delivery if hemorrhage becomes brisk, a practice accepted in many clinics, has resulted in a decreased infant mortality without an increase in maternal deaths.

Abruptio placentae. Abruptio placentae is separation, during the latter half of pregnancy, of the normally implanted placenta from its attachment to the uterus before birth of the baby. It also is correctly referred to as "premature separation of the normally implanted placenta" and is called "accidental hemorrhage" in Great Britain. It occurs in approximately 1 in 100 pregnancies. The cause is unknown. It is more common in women who have borne several children.

When a small portion of the placenta separates from

the uterus, a condition called partial abruptio placentae, blood either collects in a pool between the uterus and the placenta (concealed hemorrhage) or seeps out of the uterus into the vagina (external hemorrhage). When the entire placenta separates from the uterus, there is massive hemorrhage into the uterine cavity and sometimes into the wall of the uterus. Massive hemorrhage is associated with uterine tenderness, abdominal pain, shock, and loss of fetal movement and fetal heart tones. The baby usually dies. If hemorrhage is severe the mother's life is in danger. Defective blood clotting occurs in at least 35 percent of patients with abruptio placentae. Kidney failure develops in approximately 1 percent of the cases; it is seen most often in those instances in which treatment has been delayed. Blood replacement, the treatment of shock, the administration of fibrinogen if the patient's clotting mechanism is defective, the administration of oxytocics, and early delivery are the basic essentials of the treatment of abruptio placentae. Delivery is usually by cesarean section.

Placental infarction. Infarction is degeneration and death of a tissue and its replacement with scar tissue. Small areas of infarction, caused by interference with the maternal circulation, occur normally in the placenta as pregnancy progresses. The fetus usually is not affected by infarction of the placenta unless the process is extensive.

Placenta accreta. Placenta accreta is an abnormal adherence of the placenta to the uterine wall. The chorionic villi attach themselves directly to the uterine muscle in areas where the decidua is poorly developed or absent. All or part of the placenta may be affected. As a result of this abnormality of implantation the placenta does not separate normally at the time of delivery. Attempts to remove it manually by the physician are frequently followed by severe hemorrhage. Removal of the uterus may be required to save the mother's life.

Placental cysts and benign tumours. Placental cysts and benign tumours are relatively rare. Chorionic cysts of small size are disk-shaped, grayish-white structures filled with a yellowish fluid and located on the fetal side of the placenta. Decidual cysts are smoothly lined small cavities in the centre of the placenta; they are the result of decidual degeneration and are not true tumours. Angiomas, hemangiomas, fibromas, myxofibromas, and the like are benign growths arising from the placental blood vessels and connective tissue. Solid or semisolid tumours, usually creating small nodular elevations on the fetal side of the placenta, are rarely of clinical significance.

Inflammation of the placenta. Inflammation of the placenta is usually secondary to infection of the membranes. Most often such infections follow the introduction of pus-forming bacteria into the uterus by instrumentation through the vagina; they are the aftermath of prolonged labour or of prolonged rupture of the membranes. If labour is prolonged, bacteria penetrate the fetal side of the placenta, enter the fetal circulation, and often cause death of the infant after delivery.

The placenta may become infected from organisms in the maternal blood. Maternal syphilis, toxoplasmosis, tuberculosis, and malaria may affect the placenta. The viruses of chickenpox and smallpox may cause placental lesions. A number of pathogenic bacteria and viruses cross the placenta and sometimes kill the fetus without causing any specific changes that have been noted in the placenta.

Placental anomalies. Abnormalities in the structure of the placenta are relatively common. It may be partially divided into two or more lobes; there may be extra lobes; or the placenta may be divided into two or more separate structures. Abnormal placentas result from shallow and from deep implantation. The former type, called placenta circumvallata, is associated with several maternal and fetal complications; the latter type, called placenta membranacea, may cause problems at delivery; e.g., bleeding, failure of the membrane to separate.

Anomalies of the umbilical cord. "False knots," which are simply enlarged blood vessels in the cord, are not significant. Actual knots in the cord may become tightened and kill the fetus by cutting off the blood to it. Twisting of the cord also may kill the fetus in the same manner. Spontaneous rupture of the cord interferes with the fetal

Placental cysts and tumours

Characteristics, course, and outcome of abruptio placentae

blood supply and causes fetal death. Extreme shortness of the umbilical cord may interfere with delivery, cause premature separation of the placenta, or tear and cause fetal death from hemorrhage. Another abnormality, called velamentous insertion of the cord, in which multiple blood vessels spread out over the membranes and cervix rather than forming one single cord, is dangerous for the baby because the vessels may tear or be compressed during labour and delivery.

Abnormalities of the amniotic fluid. *Polyhydramnios.* Polyhydramnios is the presence of an excessive amount of amniotic fluid. Normally the uterus contains approximately 1,000 millilitres (slightly more than one quart) of amniotic fluid; anything over 2,000 millilitres is abnormal. Accumulations of more than 3,000 millilitres occur in approximately one pregnancy in a thousand. Lesser degrees of polyhydramnios probably occur in about 1 in 150 deliveries. The appearance of large amounts of fluid within the space of a few days is rare; such a condition is met with in less than 1 in 4,000.

Polyhydramnios occurs most often in association with fetal abnormalities, particularly those of the nervous, digestive, and renal systems; when the fetus has erythroblastosis, a disease resulting from incompatibility between the infant's and the mother's blood; when there is more than one fetus; or when the mother has diabetes or one of the toxemias. Almost all pregnancies in which the fetus suffers from obstruction of the esophagus and half of those in which there are severe brain anomalies are accompanied by excessive amniotic fluid.

Acute polyhydramnios causes rapid overdistention and enlargement of the uterus. The woman experiences abdominal pain, nausea and vomiting, and difficulty in breathing. Her heart and blood vessels are put under severe stress; she may show signs of heart failure. Swelling of the feet and legs develops. These manifestations are all caused by the pressure of the rapidly enlarging uterus upon the other viscera.

Chronic polyhydramnios usually causes enough pressure from the abnormally enlarged uterus to make the affected person uncomfortable.

The cause of polyhydramnios is unknown. The most tenable theory is that there is a reduction in the amount of fluid that passes from the fetus to the mother and an increase in the amount that passes from the fetus to the amniotic sac. This would explain the relationship between fetal anomalies and polyhydramnios.

The baby's prospects are poor when there is polyhydramnios. Many pregnancies complicated by an abnormal amount of amniotic fluid terminate prematurely. The fetus has a greatly increased chance of suffering from congenital anomalies. Roughly half of the babies in this group have been lost in the series of cases that have been reported. The greater the amount of fluid, the higher the fetal mortality. Women with polyhydramnios are also faced with a somewhat higher risk. Premature separation of the placenta and postpartum hemorrhage are the two most significant maternal complications associated with it.

Minor degrees of polyhydramnios require no treatment. Removal of the excess fluid is the only effective management if symptoms from uterine distention become too distressing. This may be done either by perforating the membranes through the cervix or, preferably, by inserting a needle through the abdominal wall and the wall of the uterus; care is taken to avoid injury to the woman's bowel or the placenta. Either procedure is likely to start labour.

Oligohydramnios. True oligohydramnios, a deficiency in amniotic fluid, is a rare condition of unknown cause. If it occurs early in pregnancy there are usually firm adhesions between the membranes and the embryo, with distortion of the fetus. A decrease in the amount of fluid later in pregnancy allows the membranes and uterine wall to press on the baby. The baby's position is distorted, and as a result it may be born with a clubfoot or wryneck. Its skin is dry and thickened. Defective development of the kidneys is common with oligohydramnios. As a rule, the condition causes the mother no distress, but the infant has a greatly increased chance of being born with major anomalies.

Trophoblastic disease. *Hydatidiform mole.* A hydatidiform mole is an abnormality of the conceptus in which changes that began early in embryonic life convert the placental villi into a mass of thin-walled, grapelike, translucent vesicles, or blisters, filled with a gelatinous or watery fluid. In a typical case the uterus is distended by a spongy mass of these vesicles. The primary cause of molar changes is unknown; however, it has been correctly described as a "temporary missed abortion of a blighted ovum." The embryo is either absent or dead. The immediate condition that causes hydatidiform swelling is disappearance of the blood vessels in the villi, with continued growth and often overgrowth of the trophoblast. Distention of the villi by fluid is due to continued activity of the trophoblast in the absence of a functioning villous circulation.

In the ova there are many degrees of hydatidiform change; many of the changes, usually in younger specimens, are not marked enough to warrant being called hydatidiform moles. True moles—characterized by hyperplasia, or overgrowth, of the trophoblast, edema of the villous connective tissue framework, and defective growth of the villous blood vessels—occur perhaps once in 2,000 pregnancies. They are not tumours and are not the aftermath of a former pregnancy. They are themselves an abnormality of a current pregnancy. Occasionally in a twin pregnancy one fetus is normal and the other a mole. Eighty percent of the moles are expelled about the 20th week of pregnancy and bring the patient no more trouble. Approximately 16 percent of hydatidiform moles invade the uterine muscle, causing bleeding. This type of mole, referred to as an invasive mole or chorioadenoma destruens, may in rare instances perforate the uterus and cause death from hemorrhage. Rarely molar villi are carried to the lung or brain. When they are, the patient may suffer from hemorrhage into the lung or die from hemorrhage within the brain.

The woman who develops a hydatidiform mole has the symptoms of pregnancy; her uterus usually enlarges more rapidly than it should, she is more likely to suffer from toxemia, and she begins to bleed vaginally, usually by the 20th week of gestation. The molar pregnancy is expelled vaginally, or, if hemorrhage is severe, the obstetrician may remove it by surgery.

In approximately 2.5 percent of patients, hydatidiform moles change into choriocarcinoma, a highly malignant tumour of the trophoblast. For that reason, patients who have hydatidiform moles are observed carefully. Continued bleeding or a rising quantity of chorionic gonadotropin in her urine or blood after passage of a mole suggests that a patient has either an invasive mole or a choriocarcinoma. Chemotherapy has been effective treatment for many cases of this type. Removal of the uterus may be necessary. The complexities of diagnosis and the differences in situations require that therapy be keyed to the individual.

Choriocarcinoma. Choriocarcinoma is a rare, extremely malignant type of tumour arising from the trophoblast. The reasons that normal chorionic cells undergo cancerous change, with exaggeration of their natural and potent tendency to invade the uterine muscle and break down blood vessels, are unknown. Choriocarcinoma occurs approximately once in 160,000 normal pregnancies. In approximately 50 percent of the cases the tumour develops from a hydatidiform mole, in another 25 percent after an abortion, and in 25 percent after a normal pregnancy. Occasionally it appears after a tubal pregnancy. It has been known to coexist with pregnancy. It is, for some unknown reason, more common in the Orient. Choriocarcinoma developing as a teratoid tumour of the ovary (a tumour made up of a number of different tissues) is a rare entity not related to pregnancy and is not to be confused with the tumour being discussed here.

As a rule, in the development of a choriocarcinoma there has been a normal pregnancy, an abortion, or the delivery of a mole, and the uterus has not returned to its normal size. The woman begins to bleed from the vagina. Blood loss may be modest or excessive in amount. Tissues obtained by a curettage (scraping) may be, but are not always, indicative of choriocarcinoma.

The tumour begins in the uterus, where it forms a spongy,

Too little amniotic fluid

bleeding mass of easily torn tissue or a shaggy ulcer. When examined microscopically, it is found to consist of both cytotrophoblast and syncytiotrophoblast. The cells spread rapidly by way of the bloodstream, producing secondary tumours in the lung, the brain, the liver, or elsewhere.

Choriocarcinoma formerly was almost invariably fatal. Today, an impressive (two out of three in some case series) number of patients have survived for many months after the administration of chemotherapeutic agents. Most workers in this field at this time are using methotrexate. The rapidly growing embryonic cells of the trophoblast need nucleic acids for growth and division; for the synthesis of nucleic acids, folic acid is essential, and methotrexate, by preventing the conversion of folic acid to folinic acid, cuts off the supply of the latter. A number of other cytotoxic drugs (drugs destructive to cells) are also being used in the treatment of choriocarcinoma, and other chemotherapeutic agents are being tested for effect on this type of tumour. Removal of the uterus is frequently, but not always, a part of the treatment of choriocarcinoma.

Parturition: the process of birth

Parturition, or labour, is the process of bringing forth a child from the uterus, or womb. (The prior development of the child in the womb is described in the article GROWTH AND DEVELOPMENT: *Human embryology*.)

THE STAGES OF LABOUR

First stage: dilatation. Early in labour the uterine contractions come on at intervals of 20 to 30 minutes and last about 40 seconds. They are then accompanied by slight pain, which usually is felt in the small of the back. The term labour pains is often used as a synonym for uterine contractions.

As labour progresses these uterine contractions become more intense and also progressively increase in frequency until, at the end of the first stage, when dilatation is complete, they recur about every three minutes and are quite severe. With each contraction a twofold effect is produced to facilitate the opening up of the cervix. Because the uterus, or womb, is a muscular sac containing a bag of waters (the sac containing the amniotic fluid) that more or less surrounds the child, contraction of the musculature of its walls should diminish its cavity and compress its contents. Because its contents are quite incompressible, however, they are forced in the direction of least resistance, which is in the direction of the internal os, or upper opening of the neck of the womb, and are driven, like a wedge, farther and farther into this opening. In addition to forcing the uterine contents in the direction of the cervix, shortening of the muscle fibres that are attached to the neck of the womb tends to pull these tissues upward and away from the opening and, thus, add to its enlargement. By this combined action each contraction of the uterus not only forces the bag of waters and fetus downward against the dilating neck of the womb but also pulls the resisting walls of the latter upward over the advancing bag of waters, presenting (farthest advanced) part of the child.

In spite of this seemingly efficacious mechanism, the duration of the first stage of labour is rather prolonged, especially in women who are in labour for the first time. In them the average time required for the completion of the stage of dilatation is between 13 and 14 hours, while, in women who have previously given birth to children, the average is eight to nine hours. Not only does a previous labour tend to shorten this stage but this tendency often increases with succeeding pregnancies, with the result that a woman who has given birth to three or four children may have a first stage of one hour or less in her next labour.

The first stage of labour is often somewhat prolonged, also, in women who become pregnant for the first time after they have passed the age of 35, because the cervix dilates less readily. A similar delay is to be anticipated in cases where the cervix is extensively scarred as a result of previous labours, amputation, deep cauterization, or any other operation on the cervix. Even a woman who has borne several children and whose cervix, accordingly,

should dilate readily may have a prolonged first stage if the uterine contractions are weak and infrequent or if the child lies in a faulty position and, as a direct consequence, cannot be forced into the mother's pelvis.

On the other hand the early rupturing of the bag of waters often increases the strength and frequency of the labour pains and thereby shortens the stage of dilatation; occasionally, premature loss of the waters leads to molding of the uterus about the child and thereby delays dilatation by preventing the child's normal descent into the pelvis. Just as an abnormal position of the child and molding of the uterus may prevent the normal descent of the child, an abnormally large child or an abnormally small pelvis may interfere with the descent of the child and prolong the first stage of labour.

Second stage: expulsion. About the time that the cervix becomes fully dilated, the bag of waters breaks, and the force of the involuntary uterine contractions is augmented by voluntary bearing-down efforts of the mother. With each labour pain she takes a deep breath and then contracts her abdominal muscles. The increased intra-abdominal pressure thus produced may equal or exceed the force of the uterine contractions. When properly used, accordingly, these bearing-down efforts may double the effectiveness of the labour pains. As the child descends into and passes through the birth passages, the sensation of pain is often increased. This condition is especially true in the terminal phase of the stage of expulsion, when the child's head distends and dilates the maternal soft parts as it is being born.

Transverse position of the head. The manner in which the child passes through the birth canal in the second stage of labour depends upon the position in which it is lying and the type of the mother's pelvis. The sequence of events described in the following numbered paragraphs is that which frequently occurs when the mother's pelvis is of the usual type and the child is lying with the top of its head lowermost and transversely placed and the back of its head (occiput) directed toward the left side of the mother (A in Figure 36). The top of the head, accordingly, is leading and its long axis lies transversely.

1. The force derived from the uterine contractions and the bearing-down efforts exerts pressure on the child's buttocks and is transmitted along the vertebral column to drive the head into and through the pelvis. Because of the eccentric attachment of the spine to the base of the skull, the back of the head is made to advance more rapidly than the brow with the result that the head becomes flexed (*i.e.*, the neck is bent) until the chin comes to lie against the breastbone (B in Figure 36). As a consequence of this flexion mechanism, the top of the head (occiput) becomes the leading pole and the ovoid head circumference that entered the birth canal is succeeded by a smaller, almost circular circumference, the long diameter of which is about two centimetres (three-fourths inch) shorter than that of the earlier circumference.

2. As the head descends more deeply into the birth canal, it meets the resistance of the bony pelvis and of the sling-like pelvic floor, or diaphragm, which slopes downward, forward, and inward. When the back of the head, the leading part of the child, is forced against this sloping wall on the left side, it naturally is shunted forward and to the right as it advances, just as a ferryboat is shunted into its wharf by meeting the sloping resistance of its ways (C in Figure 36). This internal rotation of the head brings its longest diameter into relation with the longest diameter of the pelvic outlet and thus greatly assists in the adaptation of the advancing head to the configuration of the cavity through which it is to pass.

3. Further descent of the head directly downward in the direction in which it has been travelling is opposed by the lower portion of the mother's bony pelvis, behind, and the resisting soft parts that are interposed between it and the opening of the vagina (C in Figure 36). Less resistance, on the other hand, is offered by the soft and dilatable walls of the lower birth canal, which is directed forward and upward. The back of the child's head accordingly advances along the lower birth canal, distending its walls and dilating its cavity while the head progresses. Soon the

Drawing by Ramon Goas after Alfred C. Beck

back of the child's neck becomes impinged against the bones of the pelvis, in front, and the chin is forced farther and farther away from the breastbone. Thus, as extension (bending of the head backward) takes the place of flexion, the occiput, brow, eye sockets, nose, mouth, and chin pass successively through the external opening of the lower birth canal and are born (D in Figure 36).

4. The neck, which was twisted during internal rotation of the head, untwists as soon as the head is born. Almost immediately after its birth, therefore, the occiput is turned toward the left and backward.

As the child's lower shoulder advances, it meets the sloping resistance of the pelvic floor on the right side and is shunted forward and to the left toward the middle of the pelvis in front. This position brings the long diameter of the shoulder circumference into relation with the antero-posterior, or long diameter, of the pelvic cavity. Because of this internal rotation of the shoulders, the occiput undergoes further external rotation backward and to the left so that the child's face comes to look directly at the inner aspect of the mother's right thigh (E in Figure 36).

Birth of the shoulders. Soon after the shoulders rotate, the one in front appears in the vulvovaginal orifice and remains in this position while the other shoulder is swept forward by a lateral bending of the trunk through the same upward and forward curve that was followed by the head as it was being born. After this shoulder is delivered, the shoulder in front and the rest of the child's body are expelled almost immediately and without any special mechanism.

An average of about one hour and 45 minutes is required for the completion of the second stage of labour in women who give birth for the first time. In subsequent labours the average duration of the stage of expulsion is somewhat shorter.

Posterior position of the occiput. The child may lie so that the back of its head is directed backward and toward either the right or left side. The leading pole is then in the right or left posterior quadrant of the mother's pelvis, and the condition is referred to as a posterior position of the occiput. In such cases the back of the child's head usually

rotates to the front of the pelvis and labour proceeds as in transverse positions. Because of the longer rotation required, labour may be somewhat more prolonged than in transverse positions.

Face presentation. When the child's head becomes bent back (extended) so that it enters and passes through the pelvis face first, the condition is known as a face presentation. The chin is then the leading pole and follows the same course that is followed by the back of the head in occipital presentations. If the chin lies to the front as it enters the pelvis, labour often is easy and of short duration. Should it be directed backward, on the other hand, considerable difficulty may be encountered, and the head may have to be flexed or rotated artificially.

Breech presentation. Passage of the lower extremities or the buttocks through the pelvis first, called breech presentation, is encountered about once in every 30 labours. Because the head in such cases is the last part of the child to be delivered and because this part of the delivery is the most difficult, the umbilical cord (navel string) may be compressed while the aftercoming head is being born, with the result that the child may be asphyxiated. Asphyxia or injuries to the child that result from the attendant's effort to hasten the delivery in order to prevent the child's asphyxiation are responsible for the loss of three times as many breech babies as head-on babies.

The infant mortality rate in countries with well-developed systems of medical care varies from 2 to 10 percent according to the size of the child and skill of the attendant. Because very small, premature infants are particularly susceptible to the dangers of breech delivery, the mortality among them is very high when they are born breech first.

Transverse presentation or cross birth. In this relatively rare situation the long axis of the child tends to lie across, or transverse to, the long axis of the mother. Unless the child is very small or has been dead for some time and has become greatly softened, delivery through the natural passages is impossible in such cases. For this reason the child must be turned by the attendant or delivered by the surgical procedure called cesarean section (through the mother's abdominal wall) if it is alive.

That the above-mentioned complications are infrequent and can be cared for easily is shown by the excellent statistics of many maternity services, in which the maternal death rate is less than one per 1,000 and would be still lower if the deaths caused by complicating systemic diseases were excluded. The infant mortality rate is also usually low, ranging between 1.5 and 3 percent. It likewise would be much lower if the premature and poorly developed infants were excluded. In other words, the risk to a healthy mother who carries her child to maturity is less than one per 1,000, and the risk to her mature child is about 0.5 percent.

Third stage: placental stage. With the expulsion of the child, the cavity of the uterus is greatly diminished (F in Figure 36). As a consequence the site of placental attachment becomes markedly reduced in size, with the result that the placenta (afterbirth) is separated in many places from the membrane lining the uterus. Within a few minutes subsequent uterine contractions complete the separation and force the afterbirth into the vagina, from which it is expelled by a bearing-down effort. The third stage of labour, accordingly, is of short duration, seldom lasting longer than 15 minutes. Occasionally, however, the separation may be delayed and accompanied by bleeding, in which case artificial removal of the placenta is necessary. The attendant always remains with the mother until the possibility of hemorrhage has been eliminated by firm retraction of the uterus. (A.C.Bk.)

RELIEF OF PAIN IN LABOUR

Not much was done to relieve the suffering of childbirth before chloroform was first widely used in the 1850s for this purpose. Because of its toxicity, even this drug was employed sparingly and ultimately came into disuse. Early in the 20th century, a combination of the drugs morphine and scopolamine was given, according to the "twilight sleep" technique, to lessen the pain that accompanies the stage of cervical dilatation. While this technique was

Slight risk during pregnancy

found to be less safe than had been hoped, it gave a new and strong impetus to the search for a satisfactory method of pain relief, with the result that the old methods were improved and many new ones were suggested. No completely satisfactory method was found, and it remains impossible to secure total relief from pain in all women without adding to the maternal and fetal risk. On the other hand, the judicious employment of one or more of the drugs described briefly in the following paragraphs eliminates much of the pain of childbirth with safety (see also DRUGS AND DRUG ACTION: *Anesthetics*).

Morphine and scopolamine. By the use of injections of morphine and scopolamine, a condition of seminarcois, twilight sleep, is induced. When the method is successful, the mother awakens after her child is born and has no recollection of having felt any pain during her labour. Such a result is attributable either to the actual relief of pain or to her inability to remember such pain as did occur because of the scopolamine-induced loss of memory. If given too soon, these drugs may stop the labour completely. If given too late, their effect on the child's respiratory centre may cause its death from asphyxia. This lack of safety has led to more or less abandonment of the twilight sleep routine.

Barbiturates. The barbiturate drugs, usually combined with scopolamine, are frequently employed for the relief of pain during labour. As in the case of twilight sleep, their successful use is followed by a loss of memory, and the mother either has no pain or forgets it completely. Unpleasant side effects sometimes are encountered. The commonest of these is excitement of varying degrees. Restraint may be necessary, and the constant presence of a nurse or other attendant is required. The patient's restlessness or inability to use her bearing-down efforts properly often makes it necessary to deliver the child with instruments and with the mother under anesthesia. Although some infants delivered in this way do not breathe so readily as do those born to mothers who have had no medication, the effect of the barbiturates on the child is much less marked than that produced by the twilight sleep routine.

Meperidine. The drug meperidine, combined with scopolamine, has been employed to relieve pain and to induce forgetfulness during labour. Evidence accumulated after the mid-20th century seemed to indicate that this combination would prove to be the safest and best method of pain relief during the first stage of labour. The dilatation of the cervix apparently is hastened by use of meperidine. If the combination of meperidine and scopolamine is supplemented by local anesthesia during the stage of expulsion, the greater part of the pain of childbirth may be eliminated without risk to mother or child.

Nitrous oxide. Nitrous oxide, or laughing gas, is one of the most popular of the analgesic (pain-relieving) agents. It is given during the latter part of the first and throughout the second stage of labour and is administered only for the duration of the uterine contractions. While the child is being delivered, the addition of ether is usually necessary. Unless adequate amounts of oxygen are added to the nitrous oxide mixture that the mother breathes, the child may suffer from lack of oxygen or die from asphyxia.

Chloroform, ether, ethylene, and cyclopropane. Chloroform, ether, ethylene, and cyclopropane are often given while the child is being delivered. Chloroform is rarely used because of its toxicity. Ether is much safer than chloroform but is not pleasant to take and is irritating to the respiratory passages. Ethylene is not widely used in obstetrics, because it is disagreeable to take and is highly explosive. For cyclopropane, an excellent gaseous anesthetic agent well suited to the needs of obstetric practice but highly explosive, a special apparatus is required for administration, and adequate measures must be employed to prevent the occurrence of static sparks. Trichloroethylene, a volatile analgesic agent, is suitable for self-administration during the latter part of labour. The patient inhales it through a special inhaler that she places over her nose and mouth at the onset of each uterine contraction. Loss of consciousness occurs before the contraction ends; the inhaler thus drops away from her nose and the administration of the gas is discontinued. Trichloroethylene analgesia is used extensively in Great Britain. (J.W.Hu.)

NATURAL CHILDBIRTH

In the 1930s Grantly Dick-Read, a British obstetrician, developed a technique of delivery called natural childbirth that minimized the surgical and anesthetic aspects of delivery and concentrated upon the mother's conscious effort to give birth to her child. Although opposed by many physicians who felt that it denied the progress of modern medicine and needlessly primitivized the process of birth, the method was gradually accepted and by the late 1950s was practiced by a sizable percentage of women, especially in the United States and England.

Natural childbirth—sometimes called psychoprophylaxis, prepared childbirth, or the Lamaze method—as formulated by Dick-Read and later advanced by Fernand Lamaze and others, stems from the premise that childbirth need not be accompanied by excessive pain. It is believed that labour pains are the result of unnatural physical tension caused by fear, which can be counteracted by understanding and by developing the ability to relax. The various methods prescribe for the expectant mother and a partner a lengthy course of instruction in the mechanics of labour and birth as well as exercises to strengthen the musculature and to encourage proper breathing. Emphasis is placed on involving other family members, especially the father, in the birth process. During her labour the mother is aided by trained personnel and her partner, or “coach,” and anesthetic is made available to her when needed. No claims are made that natural childbirth is totally painless; rather it enables the mother's physical response to transcend discomfort.

Natural childbirth is not considered advisable for women in poor health or for those who have physical defects or psychological problems. For the healthy, determined young mother, it presents the advantage of allowing her to participate actively, rather than passively, in labour and to experience the actual moment of birth. A disadvantage is the amount of time required for the prenatal instruction course, which is impractical for many mothers. (Ed.)

Arguments
for natural
childbirth

OPERATIVE OBSTETRICS

Most women deliver a baby spontaneously. Complications, however, that were present before labour or that develop during labour may threaten the life of the mother or of the baby and may require intervention by the attending physician.

When a complication develops, the obstetrician's choice of treatment depends upon the problem. He may use the obstetrical forceps, an instrument that is so constructed that it can be applied to the fetal head for the purpose of extracting the fetus by traction or of rotating the fetal head in order to correct an unsatisfactory or undeliverable position. Forceps delivery is indicated when the mother's expulsive forces are unable to effect a spontaneous delivery because of ineffective uterine contractions, abnormalities in the mechanism of labour, or lesser degrees of disproportion between the size of the baby's head and the mother's pelvis. Labour is terminated by forceps when the mother or the fetus is in distress that can be relieved by prompt delivery. It is often used for delivery of the after-coming head. Forceps delivery may save the mother from the stress of the second stage of labour in some cases of heart disease, tuberculosis, and other debilitating diseases. Infection occurring during delivery, certain cases of placenta praevia, and premature separation of the placenta may be indications for forceps delivery. (Placenta praevia, described above in *Abnormal changes in pregnancy*, is development of the placenta so that it covers the internal opening of the cervix and must precede the infant during delivery.) Conditions must be suitable, of course, for forceps delivery before the instrument is employed.

Manual rotation may be used instead of the forceps when the fetal head is in an abnormal position that makes delivery difficult or impossible. In carrying out the procedure, the obstetrician inserts his hand into the birth canal and turns the fetal head to a more favourable position.

Bleeding from the uterus during or after the third stage of labour may be controlled by manual removal of the placenta and packing of the uterus. In the former method the operator inserts his hand into the uterine cavity and

Cesarean
section

separates the adherent placenta from the uterine wall. Modern obstetricians rarely pack the uterus with gauze to control bleeding, because it fails to stop bleeding, and it carries with it an increased risk of infection.

When conditions are such that the delivery of a child through the vagina would be a hazard to the mother or to the fetus, it may be necessary or preferable to resort to cesarean section, a procedure in which the fetus is delivered through a surgical opening in the uterus made after the uterus has been exposed through an opening in the abdominal wall.

Cesarean section is so much better for the mother and the fetus when there is bleeding from a placenta praevia or prematurely separated placenta that it is the preferred method of delivery in many cases of uterine hemorrhage during the later months of pregnancy and labour. Difficult or prolonged labour is a frequent indication for abdominal delivery. Uterine inertia, once one of the most common causes for prolonged labour, makes cesarean section necessary less frequently than it did a decade ago because of the widespread use of very weak solutions of oxytocin to stimulate uterine contractions in such cases. (Oxytocin is a hormone produced by the nerve cells of the hypothalamus, a centre at the top of the brainstem; the hormone is stored in the posterior lobe of the pituitary.)

Prolonged or difficult labour resulting from either a small maternal pelvis, a large fetus, or a malposition or malpresentation of the fetus is one of the most frequent reasons that some women have their first, or primary, cesarean section.

As a general rule after a woman has undergone one abdominal delivery, she is delivered thereafter in the same fashion. The principle of "once a cesarean, always a cesarean" came about because of the danger of rupture of the uterine scar, with loss of the baby's and often the mother's life if she is permitted to deliver vaginally after a previous cesarean section.

The woman who suffers from obstructed labour is delivered abdominally if labour cannot be terminated vaginally without danger to her or the baby. Threatened rupture of the uterus is treated by immediate cesarean section. Ordinarily the patient in labour who has been neglected and for this reason is actually or potentially infected is delivered by some type of cesarean section.

A number of conditions that would not be considered imperative reasons for abdominal delivery may, at times, be factors influencing the choice of cesarean section. Breech presentation by itself is not a reason for cesarean section; a large baby, however, that is presenting by the breech in a woman past her middle 30s who is bearing a child for the first time could quite possibly be considered an indication for cesarean section because of the increased hazard to a large baby in a breech delivery and the possibility that it might be the patient's only opportunity to bear a child. Absolute or relative indications for cesarean section include a number of uncommon conditions, such as multiple pregnancy; prolonged pregnancy; a malignant tumour of one of the pelvic organs; a previous operation, the results of which interfere with normal function of the uterus; an anomaly of the genitalia; a benign pelvic tumour that obstructs the birth canal; a paralytic neuromuscular disorder, such as poliomyelitis, that prevents the mother from exercising her voluntary expulsive forces; or death of fetuses before or during earlier childbirths.

Cesarean
section
in
diabetes
or
toxemia

Cesarean section is often necessary when the mother is diabetic or has toxemia of pregnancy, a complex series of metabolic disorders that involve or may involve excessive vomiting, convulsions, and coma. The procedure is also resorted to in some instances when a woman has her first child late in her child-bearing years. Cesarean section may seem necessary if the mother has not only chronic high blood pressure and disease of the blood vessels but also pre-eclampsia, a condition in which there is a sudden rise in blood pressure, fluid accumulates in the tissues, and protein in the blood reaches abnormal heights. Premature expulsion of the umbilical cord may call for cesarean section if the child is alive and immediate vaginal delivery is not possible. Many sexually transmissible infections, if in an active state at the time of delivery, threaten the life

or health of an infant that passes through the birth canal. Such complications may be avoided by cesarean section.

In rare instances the obstetrician may make incisions in the incompletely dilated uterine cervix. The incisions permit vaginal delivery in those cases in which labour is unduly prolonged and the incomplete dilatation of the cervix is the only thing that is delaying delivery.

ACCIDENTS DURING LABOUR

Lacerations. *Lacerations of the perineum, vulva, and vagina.* Vaginal lacerations usually make themselves known by profuse bleeding after delivery of the baby. Not all extensive lacerations cause bleeding, however, and a large tear in the vaginal wall may not be discovered until the obstetrician inspects the vagina after the placenta is delivered. There is no difficulty in diagnosing lacerations near the external opening of the birth canal, because they are easily seen by the obstetrician. Even minor lacerations are repaired, because, if they are not, granulation tissue may form in the wounds and delay healing. Deep lacerations require anatomical reconstruction of the torn tissues. Extensive tears of the perineum (the tissues between the genital organs and the anus) can often be avoided by performing an episiotomy—an incision in the vulvar orifice, the external genital opening—before delivery of the infant's head. Also, attention on the obstetrician's part to the mechanism of labour, manual assistance in delivery of the head and shoulders, avoidance of too rapid delivery, delivery between pains, and the proper use of the forceps are some of the many measures that help to avoid injuries not only to the perineum but to all of the genital tissues.

Cervical lacerations. The cervix, the lower end of the uterus that projects into the vagina, is usually inspected after the placenta has been delivered. Superficial tears look somewhat like a frayed edge on the cuff-like cervix. Deeper lacerations usually cause serious bleeding immediately before or after delivery of the placenta.

Small cervical lacerations are not repaired; they heal spontaneously. Deeper tears are sutured. The management of extensive tears into the body of the uterus or the broad ligaments that support the uterus depends on the extent of the injury and its location; an abdominal operation is sometimes required to control the bleeding and to repair the uterus. Occasionally hysterectomy—removal of the uterus—is necessary.

Other accidents. *Rupture of the uterus.* Rupture of the uterus may occur spontaneously; it may be caused by trauma, or it may occur when a cesarean-section scar gives way. The classical signs of impending spontaneous rupture are gradually increasing, constant, severe pain in the lower part of the abdomen, restlessness, a rising temperature, an increasing pulse rate, and a tense, tender uterus that does not relax between strong contractions. When rupture occurs, the patient complains, usually, of extreme pain and then a sensation of something tearing or giving way. Uterine contractions stop. There is extensive internal bleeding. The baby's body can be felt in the mother's abdomen beside the contracted uterus.

Signs of
impending
rupture

Prompt delivery, almost always by cesarean section, is the treatment of impending rupture. The patient is anesthetized to stop uterine contractions as soon as the diagnosis is made.

An immediate abdominal operation follows the diagnosis of uterine rupture. Bleeding from the torn uterine walls must be stopped as promptly as possible. The fetus is removed. A hysterectomy is usually performed, because the ragged uterine scar is likely to rupture again if the patient has another term pregnancy, and bleeding from the torn uterus is difficult to control. Such patients often require generous quantities of transfused blood. Antibiotics are given, because infection is or may be present.

Injuries to the pelvic supporting tissues. Injuries to the pelvic supporting tissues may not be evident during labour. Months or years later the diagnosis will be made, because the patient complains of something bulging from the vagina, involuntary loss of urine while coughing or laughing, a sensation of things falling down, dragging pelvic discomfort, and difficulty in emptying the lower bowel. The bulging mass formed by a cystourethrocele or

rectocele, when seen at vaginal examination, confirms it. (A cystourethrocele is a sagging of the urethra and bladder out of position; a rectocele is a protrusion of the rectum into the vagina.) At times the result of the injuries to the pelvic supporting ligaments and muscles may be so severe that the uterus lies completely outside the vagina, and the vagina is turned inside out, forming a huge ball-shaped mass lying between the patient's thighs.

Treatment depends on the severity of the symptoms. Many women live out their lives without much distress from small cystourethroceles and rectoceles. Larger lesions are repaired surgically.

Inversion of the uterus. Another accident that may occur during labour is inversion of the uterus. The uterus turns inside out and upside down so that its inner surface lies outside and against the wall of the vagina. Inversion causes sudden shock. There may be severe bleeding. The diagnosis is made by noting the pear-shaped mass, covered by a shaggy, dark-red, bleeding surface, filling the vagina or hanging outside. The placenta may be still attached to it.

Restoration of a uterus to its normal position is accomplished after the patient's shock and hemorrhage are treated, and she is anesthetized. The obstetrician inserts his hand into the patient's vagina and lifts up the uterus. The tension applied to the uterine ligaments by this procedure usually reinverts the uterus.

Embolisms. Embolisms may occur. (An embolism is a blockage of a blood vessel, as by a blood clot or bubble of air.) Amniotic fluid embolism causes sudden, severe respiratory distress, signs of shock, cyanosis (blueing of the skin), heart collapse, and circulatory failure. If the diagnosis is made promptly, oxygen, blood transfusion, and the injection of fibrinogen, a clotting factor, into a vein may be lifesaving.

Air embolism causes the patient to become suddenly short of breath and cyanotic. She may have heart pain and show signs of shock. The heart beats irregularly, and swishing sounds, caused by the presence of air mixed with blood in the heart, can often be heard. Death follows quickly unless the diagnosis is made at once. Treatment consists of drawing the air from the heart with a needle and syringe.

Fibrinogenopenia. Fibrinogenopenia, a shortage of fibrinogen, which causes defective blood clotting and serious bleeding, may result from a number of circumstances, including premature separation of the placenta and a hard, forceful labour. The diagnosis is confirmed by testing the mother's blood. It lacks fibrinogen if it does not clot firmly in 10 minutes or if the clot that does form dissolves when incubated at 37° C (98.6° F) for one hour. Treatment includes management of the condition responsible for the lack of fibrinogen, replacement of blood lost through bleeding, and the administration of fibrinogen intravenously.

Placenta accreta. Abnormal adherence of the placenta to the uterus, a condition called placenta accreta, is suspected when the placenta cannot be expelled. If the adherence is only partial, there is usually brisk bleeding from the remainder of the placental site. Formerly, placenta accreta was treated by immediate removal of the uterus. In the late 1960s it was suggested that the placenta should be left in place to disintegrate, in which case the patient is protected from infection with antibiotics.

Genital bleeding during labour. Genital bleeding during labour is a symptom of a number of obstetrical complications in addition to those discussed above. The diagnosis of premature separation of the placenta (abruptio placentae) is made when the patient complains of sudden abdominal pain and when there is uterine tenderness and vaginal bleeding. The mother may go into shock, and the fetus may die. There may be signs of hidden bleeding and concealed blood within the uterus. This condition is differentiated from placenta praevia by the fact that the placenta is not in the lower uterine segment.

In cases of suspected placenta praevia, the placenta can be located with considerable accuracy, as by X-ray. The definitive diagnosis of placenta praevia is made, however, when vaginal examination, which is not performed until everything is in readiness for immediate vaginal or

abdominal delivery, reveals part of the placenta in the lower uterus.

In every case of serious blood loss, bleeding must be controlled and lost blood replaced in amounts sufficient to protect the mother. Most patients with placenta praevia and premature detachment of the placenta are treated by cesarean section. Cesarean section is not performed for premature detachment of the placenta (abruptio placentae) until a shortage of fibrinogen is corrected. Removal of the uterus may be necessary in rare cases of abruptio placentae when the uterine wall has been so infiltrated by blood that it cannot contract.

Severe bleeding not related to the pregnancy, such as that resulting from rupture of one of the pelvic veins or rupture of the spleen, may occur during labour. When it occurs, it must be treated regardless of the pregnancy.

Accidents to the umbilical cord. An accident to the umbilical cord is suspected when there is marked irregularity in the fetal heart rate and particularly when the irregularity is accentuated by uterine contractions. A prolapsed cord—that is, a cord lying below the head—can be felt through the membranes on vaginal examination. After the membranes have ruptured, the cord can be felt and seen in the vagina. It may hang out of the vulva. The patient is delivered by cesarean section if the infant is alive and if the head can be prevented from pressing on the cord while preparations are made for the operation. The baby is delivered vaginally if the cervix is completely dilated and if conditions are favourable for prompt vaginal delivery. Attempts to replace the cord in the uterus are seldom successful. Vaginal delivery is allowed to continue if the infant is dead.

True knots in the cord and rupture of the cord with bleeding are seldom diagnosed until after delivery. They are usually associated with sudden and, at the time, inexplicable fetal death.

Puerperium or period of involution

Within six to eight weeks after childbirth, most of the structures of the maternal organism that underwent change during pregnancy return more or less to their prepregnancy state. The enlarged uterus, which at the end of gestation weighed about 1,000 grams (35 ounces), shrinks to a weight of about 60 grams (two ounces). Along with this process of uterine involution, the lining membrane of the uterus is almost completely shed and replaced by a new lining, which is then (six to eight weeks after delivery) ready for the reception of another fertilized ovum (egg). The greatly dilated neck of the womb and lower birth passage likewise undergo marked and rapid involution, but they seldom return exactly to their prepregnancy condition. As a rule examination of a woman who has given birth accordingly reveals evidence of this. The markedly stretched abdominal wall also undergoes considerable involution, particularly if abdominal exercises are carried out. Although the intradermal tears (striae gravidarum) become smaller and silvery white, they do not completely disappear but remain as evidence of the marked and rapid stretching of the skin that took place during pregnancy.

(J.W.Hu.)

LACTATION

The breasts, unlike most of the other organs, continue to increase in size. Although mammary growth begins during pregnancy under the influence of ovarian and placental hormones and some milk is formed, copious milk secretion sets in only after delivery. Since lactation ensues after a premature birth, it would appear that milk production is held back during pregnancy. The mechanism by which this inhibitory effect is brought about, or by which lactation is initiated at delivery, has long been the subject of an argument that revolves around the opposing actions of estrogen, progesterone, and prolactin, as studied in laboratory animals, goats, and cattle. During pregnancy the combination of estrogen and progesterone circulating in the blood appears to inhibit milk secretion by blocking the release of prolactin from the pituitary gland and by making the mammary gland cells unresponsive to this

Effects of

embolism

Abruptio
placentae

pituitary hormone. The blockade is removed at the end of pregnancy by the expulsion of the placenta and the loss of its supply of hormones, as well as by the decline in hormone production by the ovaries, while sufficient estrogen remains in circulation to promote the secretion of prolactin by the pituitary gland and so favour lactation. It is also possible that a relative increase in the blood level of adrenal hormones favours the production of milk.

Milk-producing complex of hormones

For lactation to continue, necessary patterns of hormone secretion must be maintained; and disturbances of the equilibrium by the experimental removal of the pituitary gland, in animals, or by comparable diseased conditions in human beings, quickly arrest milk production. Several pituitary hormones seem to be involved in the formation of milk, so that it is customary to speak of a lactogenic ("milk-producing") complex of hormones. To some degree, the role of the pituitary hormones adrenocorticotropin, thyrotropin, and growth hormone in supporting lactation in women is inferred from the results of studies done on animals and from clinical observations that are in agreement with the results of animal studies. Prolactin, growth hormone, and adrenal hormone seem of greatest value in restoring lactation after removal of the pituitary, although the precise response varies from species to species.

Suckling and the release of oxytocin

The stimulus of nursing or suckling supports continued lactation in two ways: it promotes the secretion of prolactin (and possibly other pituitary hormones of value in milk formation), and it triggers the release of yet another hormone from the pituitary gland—oxytocin, which causes contraction of special muscle cells around the alveoli in the breast and ensures the expulsion of milk. It is in this way that a baby's suckling at one breast may cause an increase in milk flow from both, so that milk may drip from the unsuckled nipple. About 30 seconds elapse between the beginning of active suckling and the initiation of milk flow.

The nerve supply to the mammary glands is not of great significance in lactation, for milk production is normal after the experimental severing of nerves to the normal mammary glands in animals or in an udder transplanted to the neck of a goat. Milk ejection, or "the draught," in women is readily conditioned and can be precipitated by the preparations for nursing. Conversely, embarrassment or fright can inhibit milk ejection by interfering with the release of oxytocin; alcohol, also, is known to block milk ejection in women, again by an action on the brain. Beyond its action on the mammary glands, oxytocin affects uterine muscle, so that suckling can cause contractions of the uterus and may sometimes result in cramp. Since oxytocin release occurs during sexual intercourse, milk ejection in lactating women has been observed on such occasions. Disturbance of oxytocin secretion, or of the milk-ejection reflex, stops lactation just as readily as a lack of the hormones necessary for milk production, for the milk in the breast is then not extractable by the infant. Many instances of nursing failure are due to a lack of milk ejection in stressful circumstances; fortunately, treatment with oxytocin, coupled with the reassurance gained from a successful nursing, is ordinarily successful in overcoming the difficulty.

Suckling can initiate lactation in nonpregnant women. This has been seen most often in women of child-bearing age but also has been observed in older persons. A baby who had lost his mother was suckled by his 60-year-old grandmother, who had borne her last child 18 years before. The grandmother produced milk after a few days and continued to nurse the baby until he was a year old and could walk. Rarely, lactation has been reported to set in after operations on the chest; in such instances it is attributed to injury or irritation of the nerves in this region. Such observations argue against the possibility that lactation continues simply as a consequence of emptying the breasts.

The production of milk during lactation seems to decline with age, regardless of the number of previous pregnancies. Some correlation exists between the size of the breasts and milk secretion, but women with small breasts secrete milk normally, so that output could probably be raised by increasing the frequency of nursing. Drinking water

beyond the demands of thirst impairs lactation and has been advocated as a means of suppressing this process.

WEANING AND THE CESSATION OF LACTATION

Composition and properties of milk. Milk can be regarded as an emulsion of fat globules in a colloidal solution of protein together with other substances in true solution. Two constituents of milk, the protein casein and milk sugar, or lactose, are not found elsewhere in the body. The general assumption that breast milk provides the ideal food for human babies, in that it contains all the elements required in a good diet and in the most appropriate proportions, though entirely reasonable, is extremely difficult to prove, for controlled experiments are hardly possible with human infants. It is also extremely difficult to disprove, for the faster growth that may occur with supplemented diets is not necessarily optimal growth. While supplying an excellent infant diet, breast feeding confers other benefits, for the milk is normally delivered from a sterile container, and the feelings of well-being and the emotional bond generated between mother and child are important in the psychological welfare of both.

The milk released from the breast when lactation starts differs in composition from the mature milk produced when lactation is well established. The early milk, or colostrum, is rich in essential amino acids, the protein building blocks essential for growth; it also contains the proteins that convey immunity to some infections from mother to young, although not in such quantity as among domestic animals. The human infant gains this type of

Colostrum

immunity largely within the uterus by the transfer of these antibody proteins through the placenta; the young baby seldom falls victim to mumps, measles, diphtheria, or scarlet fever. For a short time after birth, proteins can be absorbed from the intestine without digestion, so that the acquisition of further immunity is facilitated. The growth of viruses and bacteria in the intestines is probably inhibited by immune factors in human milk. After childbirth the composition of milk gradually changes; within four or five days the colostrum has become transitional milk; mature milk is secreted some 10 days after delivery.

Some variations between human colostrum, transitional milk, and mature milk and cow's milk are shown in the accompanying table. The greater amount of protein in unmodified cow's milk is largely responsible for its dense, hard curd, which the infant cannot digest; the difficulty can be avoided by heat treatment or dilution of the milk. Ordinarily, when cow's milk is fed to young infants, it is modified so as to match its composition as far as possible to breast milk.

There is no typical age at which human infants are weaned, for this varies from country to country and among the social classes of a nation. In India women in the higher socioeconomic groups tend to use artificial feeding, while the reverse relationship holds in Britain and the United States. Most commonly, weaning is a gradual process, with a gradual increase in the proportion of solid food supplied to the infant together with breast milk. Pe-

Varying customs with respect to weaning

diatricians in general have concluded that, on the basis of present knowledge, no nutritional superiority or psychological benefits result from the introduction of solid foods into the infant diet earlier than $2\frac{1}{2}$ to $3\frac{1}{2}$ months and that normal full-term infants can be expected to thrive for the first three months of life on a diet consisting exclusively of milk, either normal human milk or properly modified milk from other sources.

With the reduced demand of the baby, lactation slowly declines and stops. Estrogen treatment is often used to suppress lactation, and the high doses used may accomplish this; but there is often a rebound effect at the end of treatment. Lactation may be slightly depressed when oral contraceptives are being taken in high dosage.

Nursing as
a contra-
ceptive
technique

Apart from providing nourishment for the infant, nursing may be continued as a means of contraception. In a recent study in which the subjects were women of European stock, menstruation was found to return in a high proportion of the women who had lactated for three months or more, while nearly all women who had discontinued lactation some two months after delivery resumed menstruation within six weeks. Different results emerged from studies on Punjabi women, for whom the mean duration of lactation was 21 months and the median length of time from the date of giving birth to the return of menstruation was 11 months. The lesser effect of lactation in delaying menstruation in women of European descent may have been due to the provision of supplementary food in addition to the breast milk so that the suckling stimulus was reduced in intensity. (B.T.D./Ed.)

BIBLIOGRAPHY

Reproduction: JAMES WATSON, *The Molecular Biology of the Gene*, 2nd ed. (1970), an up-to-date summary of molecular replication by one of the pioneers in the field; HAROLD C. BOLD, *The Plant Kingdom*, 2nd ed. (1964), a brief, general botany textbook that clearly describes the different modes of plant reproduction; ROBERT D. BARNES, *Invertebrate Zoology* (1963), the reproduction of each major invertebrate group is discussed and illustrated; ROBERT T. ORR, *Vertebrate Biology*, 2nd ed. (1966), contains a good general discussion of vertebrate reproduction; J.T. BONNER, *Size and Cycle* (1965), a very general discussion of the evolutionary significance of life cycles in animals and plants.

Fertilization: C.B. METZ and A. MONROY (eds.), *Fertilization*, 2 vol. (1967-69), a major source of information; A. MONROY, "Biochemical Aspects of Fertilization," in R. WEBER (ed.), *The Biochemistry of Animal Development*, vol. 1, pp. 73-135 (1965), *Chemistry and Physiology of Fertilization* (1965), a brief, understandable text; E.B. WILSON, *The Cell in Development and Inheritance* (1906; 3rd rev. ed., *The Cell in Development and Heredity*, 1925), a classic work.

Plant reproductive systems: D.W. BIERHORST, *Morphology of Vascular Plants* (1971), a treatment of the vascular plants at an advanced level, with many photographs and an extensive bibliography; H.C. BOLD, *The Plant Kingdom*, 3rd ed. (1970), a brief account of the structure and reproduction of representative plant types, and *Morphology of Plants* (1967), a profusely illustrated textbook designed for the advanced undergraduate and beginning graduate students; A.S. FOSTER and E.M. GIFFORD, *Comparative Morphology of Vascular Plants* (1959), a textbook account of the structure of vascular plants; R.F. SCAGEL et al., *An Evolutionary Survey of the Plant Kingdom* (1965), a multi-authored treatment of the plant kingdom, with abundant illustrations; K.R. SPORNE, *The Morphology of Gymnosperms* (1965), a brief but recent summary of the structure and reproduction of gymnospermous seed plants, living and fossil, and *The Morphology of Pteridophytes*, 2nd ed. (1966), a short but broadly conceived treatment of vascular cryptogams, living and fossil.

Pollination: K. FAEGRI and L. VAN DER PIJL, *The Principles of Pollination Ecology*, 2nd ed. (1972), a well-balanced work based on extensive experience in both tropic and temperate regions; B.J.D. MEEUSE, *The Story of Pollination* (1961), semipopular, well-illustrated book dealing with the principles and agents of pollination; M. PROCTOR and P. YEO, *The Pollination of Flowers* (1973), an excellent work on the process of pollination; M.S. PERCIVAL, *Floral Biology* (1965), a most useful book, in which practical aspects are not ignored; P. JAEGER, *The Wonderful Life of Flowers* (1961), especially valuable for its superb illustrations; L. VAN DER PIJL and C.H. DODSON, *Orchid Flowers: Their Pollination and Evolution* (1967), a discussion of the diverse and highly complex pollination mechanisms in the orchid family; K.A. and V. GRANT, *Hummingbirds and Their Flowers* (1968), an account of an important group of pollinators, the hummingbirds.

Seed and fruit: L.V. BARTON, *Seed Preservation and Longevity* (1961), an excellent monograph reflecting many years of practical experience; M. BLACK, "Light-Controlled Germination of Seeds," *Symp. Soc. Exp. Biol. No. 23: Dormancy and Survival*, pp. 193-217 (1969), an appraisal of the role of light reactions in germination; J.L. HARPER, P.H. LOVELL, and K.G. MOORE, "The Shapes and Sizes of Seeds," *Ann. Rev. Ecology and Systematics*, 1:327-356 (1970), a team of experts highlights the significance of seed shape and size for agriculture, dispersal, germination, physiology, evolution, etc.; D. KOLLER, "The Survival Value of Germination-Regulating Mechanisms in the Field," *Herb. Abstr.*, 34:1-7 (1964), careful observation, a thorough knowledge of germination physiology, and intelligent speculation combine to result in a fine review; P. MAHESHWARI (ed.), *Recent Advances in the Embryology of Angiosperms* (1963), an account of the progress in this area (embryology), by an old master; A.M. MAYER and A. POLJAKOFF-MAYBER, *The Germination of Seeds* (1963), a very readable, responsible account, presented in a well-organized, fairly concise manner. W.L. MCATEE, "Distribution of Seeds by Birds," *Am. Midl. Nat.*, 38:214-223 (1947), focusses on a group of dispersers well-known and attractive to many humans; S. ODUM, "Germination of Ancient Seeds," *Dansk Bot. Ark.*, vol. 24, no. 2 (1965), fascinating reading for historians and archaeologists; A.E. PORSILD, C.R. HARRINGTON, and G.A. MULLIGAN, "*Lupinus arcticus* Wats. Grown from Seeds of Pleistocene Age," *Science*, 158:113-114 (1967), an account of the almost incredible case in which 10,000-year-old seeds germinated to produce perfect plants; L. VAN DER PIJL, "The Dispersal of Plants by Bats," *Acta Bot. Neerl.*, 6:291-315 (1957), a monograph dealing with the intriguing animals that preceded us in the appreciation of tropical fruit; "Ecological Aspects of Fruit Evolution," *Proc. K. Ned. Akad. Wet.*, Series C, 69:597-640 (1966), a scholarly article covering various theoretical angles; *Principles of Dispersal in Higher Plants* (1969), a highly original and most stimulating little book, displaying a thorough knowledge of both tropical and temperate-region biology; H.N. RIDLEY, *The Dispersal of Plants Throughout the World* (1930), an almost inexhaustible source of information for the student of this field; E.J. SALISBURY, *The Reproductive Capacity of Plants* (1942), a truly thoughtful work that gives much more than the modest title suggests; J.C.T. UPHOF, "Ecological Relations of Plants with Ants and Termites," *Bot. Rev.*, 8:563-598 (1942), one of the very few articles in the English language that gives some information on the role of ants in seed dispersal; UNITED STATES DEPARTMENT OF AGRICULTURE, *Manual for Testing Agricultural and Vegetable Seeds*, Agriculture Handbook no. 30 (1952), of obvious practical importance; *Seeds: Yearbook of Agriculture, 1961* (1961), a treasure-trove of information, many-faceted; P.F. WAREING and I.D.J. PHILLIPS, *The Control of Growth and Differentiation in Plants* (1970), written with a physiologist's appreciation for the experimental approach, covers admirably various aspects of dormancy; F.W. WENT, "A Long-Term Test of Seed Longevity II," *Aliso*, 7:1-12 (1969), the latest results of Went's long-range experiments on differential longevity among seeds.

Animal reproductive systems: E.J.W. BARRINGTON, *The Biology of Hemichordata and Protochordata* (1965), contains much information on reproduction and life histories that can be read profitably by specialist and nonspecialist alike; V.N. BEKLEMISHEV, *Principles of Comparative Anatomy of Invertebrates*, 2 vol. (1969; orig. pub. in Russian, 1964), a concise account of basic structural patterns in major groups; R.P. DALES, *Annelids* (1963), a college-level account; K.G. DAVEY, *Reproduction in the Insects* (1965), a somewhat advanced but excellent review; R.W. HEGNER and J.G. ENGEMANN, *Invertebrate Zoology* (1968), a college-level text covering major groups but in somewhat less detail than the work by Meglitsch cited below; L.H. HYMAN, *The Invertebrates*, 6 vol. (1940-67), the most authoritative and detailed work in existence on Protozoa through Molluscs, with extensive bibliographies; P.A. MEGLITSCH, *Invertebrate Zoology* (1967), a college-level text covering all major groups, highly readable and well illustrated; J.E. MORTON, *Molluscs*, 4th rev. ed. (1967), a readable and interesting account for the nonspecialist; W.D. RUSSELL-HUNTER, *A Biology of Lower Invertebrates* (1968), an introductory work, not extensive but very readable; W.L. SCHMITT, *Crustaceans* (1965), an elementary account; J.H. WILMOTH, *Biology of Invertebrata* (1967), readable, introductory accounts of reproduction; S.A. ASDELL, *Patterns of Mammalian Reproduction*, 2nd ed. (1964), species-by-species data in capsule form on selected reproductive processes of the world's mammals; J.F. DANIEL, *The Elasmobranch Fishes*, 3rd rev. ed. (1934), a definitive work on the anatomy of representative cartilaginous fishes, including reproductive systems; P. ECKSTEIN and S. ZUCKERMAN, "Morphology of the Reproduction Tract," in F.H.A. MARSHALL, *Physiology of Reproduction*, 3rd ed. by A.S. PARKES, vol. 1 (1959). E.S. GOODRICH, *Studies on the Structure and Development of Vertebrates*, 2 vol. (1930, reprinted 1958), out of date with respect to development

and certain theoretical discussions but an excellent reference for morphological details of vertebrates, with extensive bibliography; A.E. HARROP, *Reproduction in the Dog* (1960), a thorough, readable text including basic reproductive anatomy and physiology and veterinary information; A.D. JOHNSON, W.R. GOMES, and N.L. VANDEMARK (eds.), *The Testis*, vol. 1, *Development, Anatomy, and Physiology* (1970), one of the few complete works on the subject, with extensive bibliography; S. SISSON, *Anatomy of the Domestic Animal*, 4th ed. rev. by J.D. GROSSMAN (1953), a basic anatomy for veterinary medical students, but quite readable by the nonspecialist; A. VAN TIENHOVEN, *Reproductive Physiology of Vertebrates* (1968), primarily for the reproductive physiologist, but contains valuable anatomical data relating to all vertebrate classes; W.C. YOUNG (ed.), *Sex and Internal Secretions*, 2 vol. (1961), primarily for endocrinologists, but with a wealth of data on reproductive activities and structures of vertebrates, with extensive bibliographies; S. ZUCKERMAN (ed.), *The Ovary* (1962), a detailed account of the development, structure, and function of vertebrate ovaries, commencing with protochordates; *The Cambridge Natural History*, 10 vol. (1895-1936), phylogenetically arranged detailed discussions of anatomy and natural history of invertebrates and vertebrates, with a section on reproductive organs included for most major taxonomic groups; PETER GRAY (ed.), *The Encyclopedia of the Biological Sciences* (1961), includes very brief but valuable information on reproduction in most animal groups; T.J. PARKER and W.A. HASWELL, *A Text-Book of Zoology*, 7th ed., 2 vol. (1962-63), a thorough college-level study of the basic morphology of the major invertebrate and vertebrate phyla, extensively illustrated.

The human reproductive system: R.J. HARRISON, *Reproduction and Man* (1967), a concise review of the characteristics of human reproduction and reproductive organs, and with W. MONTAGNA, *Man* (1969), a general text comparing reproduction in man with that in primates and other mammals; W. INGIULLA and R.B. GREENBLATT (eds.), *Endocrinologic and Morphologic Correlations of the Ovary* (1969), a review of modern research on hormonal activities in the ovary; A.S. PARKES (ed.), *Marshall's Physiology of Reproduction*, 3rd ed., 3 vol. (1960-66), a comprehensive reference work on comparative aspects of reproduction; R.M. WYNN, *Cellular Biology of the Uterus* (1967), a useful summary of modern research on many aspects of uterine anatomy and physiology; W.C. YOUNG (ed.), *Sex and Internal Secretions*, 3rd ed., 2 vol. (1961), a useful reference work on basic reproductive patterns and on the endocrine control of reproductive organs; S. ZUCKERMAN (ed.), *The Ovary*, 2 vol. (1962), a standard work on structure and function in the ovary.

Menstruation: Additional information may be found in the following textbooks: S.G. CLAYTON, D.B. FRASER, and T.L.T. LEWIS (eds.), *Gynaecology by Ten Teachers*, 12th ed. (1971); E.R. NOVAK, E.S. JONES, and H.W. JONES, *Novak's Textbook of Gynecology*, 7th ed. (1965); S.L. ISRAEL, *Menstrual Disorders and Sterility*, 5th ed. (1967); R.B. GREENBLATT (ed.), *Ovulation* (1966); W. CALDWELL (ed.), *Sex and Internal Secretions*, 2 vol., 3rd ed. (1961); and A. MCLAREN (ed.), *Advances in Reproductive Physiology* (1969).

Human reproductive system diseases: P.B. BEESON and W. McDERMOTT (eds.), *Cecil-Loeb Textbook of Medicine*, 13th ed. (1971); and M.M. WINTROBE et al. (eds.), *Harrison's Principles of Internal Medicine*, 6th ed. (1970), are two excellent general textbooks of medicine that cover many of the subjects in this article in a short concise manner. "The Male Reproductive

System" in *Christopher's Textbook of Surgery*, 9th ed. (1968), is one of the best summaries of the diseases of the male reproductive system. F.H. NETTER, *A Compilation of Paintings on the Normal and Pathological Anatomy of the Reproductive System* (1954), is one of the best books for anatomical illustrations on the reproductive system. M.F. CAMPBELL and J. HARTWELL HARRISON (eds.), *Urology*, 3rd ed., 3 vol. (1970), represents one of the most complete textbooks in the field of urology; D.R. SMITH, *General Urology*, 6th ed. (1969), is well written and quite complete. D.D. FEDERMAN, *Abnormal Sexual Development* (1967), presents in complete detail all aspects of abnormal sexual development. E. STEWART TAYLOR, *Essentials of Gynecology*, 4th ed. (1969); and R.W. KISTNER, *Gynecology* (1964), cover the field of gynecology in detail; W.D. and D.W. BEACHMAN, *Synopsis of Gynecology*, 7th ed. (1967), is a good outline on female reproductive diseases. N.J. EASTMAN and L.M. HELLMAN (eds.), *Williams Obstetrics*, 13th ed. (1966), is a classic in the field of obstetrics. R.H. WILLIAMS (ed.), *Textbook of Endocrinology*, 4th ed. (1968), covers in detail the endocrine aspects of the male and female reproductive systems.

Pregnancy: Additional information on this subject may be found in the following texts, where the contents in most instances are indicated by their titles: L.B. AREY, *Developmental Anatomy*, 7th ed. (1965); W.J. HAMILTON, J.D. BOYD, and H.W. MOSSMAN, *Human Embryology*, 3rd ed. (1962); C.A. VILLEE (ed.), *The Placenta and Fetal Membranes* (1960); A.T. HERTIG, *Human Trophoblast* (1968); J.W. WILLIAMS, *Obstetrics*, 13th ed. by N.J. EASTMAN and L.M. HELLMAN (1966); W.J. DIECKMANN, *The Toxemias of Pregnancy* (1952); S.R.M. REYNOLDS, *Physiology of the Uterus* (1949); E.L. HOLLAND and A.W. BOURNE, *British Obstetric and Gynecological Practice*, 2 vol. (1955); C.S. BURWELL and J. METCALFE, *Heart Disease and Pregnancy* (1958); C.L. MENDELSON, *Cardiac Disease in Pregnancy* (1960); F.J. and J.C. MCCLURE BROWNE, *Antenatal Care and Postnatal Care*, 9th ed. (1960); F.E. HYTTEN and I. LEITCH, *The Physiology of Human Pregnancy* (1964); J.D. BOYD and W.J. HAMILTON, *The Human Placenta* (1970); and J.W. HUFFMAN, *Gynecology and Obstetrics* (1962).

Parturition: Readers wishing to pursue the subject further are directed to the following specialized texts: N.J. EASTMAN and L.M. HELLMAN, *Williams Obstetrics*, 13th ed. (1966); J.P. GREENHILL, *Obstetrics*, 13th ed. (1965); J.W. HUFFMAN, *Gynecology and Obstetrics* (1962).

Mammary glands and lactation: S.J. FOLLEY, *The Physiology and Biochemistry of Lactation* (1956), a compact and readable survey; S.K. KON and A.T. COWIE (eds.), *Milk: The Mammary Gland and Its Secretion*, 2 vol. (1961), a comprehensive work and an excellent starting point for further reading; G.W. HARRIS and B.T. DONOVAN (eds.), *The Pituitary Gland*, 3 vol. (1966), a treatise covering many aspects of the structure and function of the pituitary, with chapters on the control of milk secretion and milk ejection; R.H. WILLIAMS, *Textbook of Endocrinology*, 4th ed. (1968), a summary of the control of mammary growth and lactation in women; B.T. DONOVAN, *Mammalian Neuroendocrinology* (1970), a short text that deals with many of the interactions between the brain and the endocrine system, including the control of lactation. Reptiles

Reptilia is a class of vertebrate animals that includes the snakes, lizards, crocodiles, alligators, turtles, and the tuatara, among the living forms, and a great many extinct types such as dinosaurs, pterosaurs, and ichthyosaurs.

Intermediate between amphibians and the warm-blooded

vertebrates, reptiles may be described as those air-breathing vertebrates with internal fertilization and a scaly body covering instead of hair or feathers.

For coverage of related topics in the *Macropædia* and the *Micropædia*, see the *Propædia*, section 313, and the *Index*. This article is divided into the following sections:

REPTILES: CLASS REPTILIA

General features

Importance. The economic and ecological importance of reptiles to humans is not as great as the other major vertebrate groups—birds, fishes, and mammals. Locally, some species are eaten on occasion, if not regularly. The green turtle (*Chelonia mydas*) is the most widely eaten species of reptile. The giant Galápagos tortoise was especially popular as food among 19th-century seafarers and, for this reason, nearly became extinct. Among the lizards, iguanas are perhaps the most popular as a local food.

Leather goods, including luggage, gloves, belts, handbags, and shoes, are made from the skins of lizards, crocodilians, and snakes. This has led to the virtual extinction of several species of crocodilians and to severe reduction of populations of large lizards, snakes, and turtles. As living subjects for biological research, lizards in particular have been useful to the scientist. Venomous species constitute little hazard to humans except in limited rural areas.

Size range. Although persistent but unsubstantiated reports have been made of 12-metre (40-foot) anacondas, this gigantic South American snake, while it probably is the largest living species, does not usually exceed nine metres (30 feet) in length. The reticulated python of Southeast Asia and the East Indies has been recorded at 8.4 metres (27.6 feet). The rock python (*Python sebae*) of Africa reaches 7.5 metres (24.6 feet). No other group of living snakes approaches the pythons and boas in weight, although the king cobra of Asia and the East Indies comes close in length (5.4 metres, or 17.7 feet) and is the longest venomous snake. The heaviest venomous snake is probably the eastern diamondback rattlesnake (*Crotalus adamanteus*), which, though not exceeding 2.4 metres (7.9 feet), may weigh as much as 15.5 kilograms (34 pounds). The largest of the common nonvenomous snakes of the family Colubridae is probably the Oriental rat snake, *Ptyas carinatus* (3.73 metres; 12.2 feet).

Four living species of crocodilians grow larger than six metres (20 feet): the American crocodile (*Crocodylus acutus*), the Orinoco crocodile (*C. intermedius*), the saltwater crocodile (*C. porosus*), and the gavia (*Gavialis gangeticus*). The last two may approach nine metres (30 feet).

Largest
snakes

The giant among living turtles is the marine leatherback (*Dermochelys*), which reaches a total length of about 2.7 metres (8.9 feet) and a weight of about 680 kilograms (1,500 pounds). The largest of the land turtles is a Galápagos tortoise weighing 255 kilograms (560 pounds).

The largest modern lizard is a monitor, the Komodo dragon of the East Indies; it attains a length of three metres (10 feet). Two or three other species of monitors reach 1.8 metres (5.9 feet). The common iguana comes close to that size, but no other lizard does.

None of the living reptiles, with the possible exception of snakes, is as large as the largest extinct representative of its particular group. The 2.7-metre leatherback turtle is smaller than the extinct 3.6-metre (11.8-foot) marine turtle *Archelon*, and no modern crocodile approaches the estimated 15-metre (49-foot) length of *Phobosuchus*. The Komodo dragon does not compare with the six-metre (20-foot) or more mosasaur *Tylosaurus*. Lengths exceeding 30 metres (100 feet) and weights of 91,000 kilograms (200,000 pounds) or more may have been achieved by some browsing, quadruped dinosaurs.

The smallest reptiles are the geckos, some of which grow no longer than three centimetres (slightly more than one inch). Certain blind snakes (Typhlopidae) are less than 10 centimetres (four inches) in length when fully grown. The smallest turtles weigh less than 450 grams (one pound) and reach a maximum length of 12.5 centimetres (about five inches). The smallest crocodilians are the dwarf crocodile (*Osteolaemus tetraspis*) and the smooth-fronted caiman (*Paleosuchus*), about 1.7 metres (5.6 feet) in length.

Distribution and ecology. *North Temperate Zone.* Although living reptiles, which number some 6,000 species, are primarily tropical animals, many inhabit the temperate zones. The northernmost ranges are those of the lacertid lizard (*Lacerta vivipara*) and the common viper (*Vipera berus*), both of Europe and Asia. These ovoviviparous (live-bearing, but the unborn snakes develop within eggs) species live north of the Arctic Circle, at least in Scandinavia. Two other lizards, the slowworm (*Anguis fragilis*) and the sand lizard (*Lacerta agilis*), and two snakes, the grass snake (*Natrix natrix*) and the smooth snake (*Coronella austriaca*), reach 60° N in Europe. Of the six

northern species, all but the grass snake are ovoviparous. Across Siberia only *Lacerta vivipara* and *Vipera berus* live north of 60°.

In North America no reptile reaches the 60th parallel. Two species of garter snakes live as far north as 55° in western Canada. In North America and Eurasia the northern limit of turtles is about 55° N.

It is only south of 40° N that reptiles become abundant. In the eastern United States and eastern Asia, water snakes (*Natrix*), rat snakes (*Elaphe*), racers (*Coluber*), green snakes (*Ophiodrys*), northern skinks (*Eumeces*), glass "snakes" (lizards of the genus *Ophisaurus*), and soft-shelled turtles (*Trionyx*) are common. One of the two living species of *Alligator* lives in southeastern United States; the other lives in China. Even though both regions are characterized by many species of emydid turtles (family Emydidae), the genera to which the species belong are found in only one region or the other. Many lizards of temperate Eurasia belong to the families Agamidae and Lacertidae, which do not occur at all in the Americas. On the other hand, many lizards of North America are in the families Iguanidae and Teiidae, which do not live in Eurasia.

The fauna of the eastern United States is almost as distinct from that of the western United States and northern Mexico (which is faunistically part of the same region) as it is from that of eastern Asia. The eastern United States has many genera and species of emydid turtles; the western United States (defined by a diagonal line running southeast to northwest through Texas, then northward along the Continental Divide) has only four or five species. Few genera and species of iguanid lizards inhabit the eastern United States, whereas the western United States has many. Although the eastern United States has more species of water snakes, the western United States contains more garter snakes. More species of snakes appear in the eastern United States than in the western areas, while the converse is true of lizard species.

Reptiles of the North Temperate Zone include many ecological types. Aquatic groups are represented in both hemispheres by the water snakes, many emydid turtles, and the two alligators. Terrestrial groups include tortoises, ground-dwelling snakes, and many genera of lizards. Arboreal snakes are few, and arboreal lizards are almost nonexistent. Burrowing snakes are common. Specialized burrowing lizards are few.

Central and South America. In Central America the reptile fauna becomes richer. Besides several turtle families found in the eastern United States, Central America has three genera of turtles (*Dermatemys*, *Claudius*, and *Staurotypus*) not living elsewhere. Crocodilians become more numerous both in species and individuals. Lizards and snakes are particularly more abundant.

Many of the genera of iguanid lizards occurring in the western United States have species in Mexico; one genus of spiny lizards (*Sceloporus*) reaches its peak of numbers of species in Mexico. South of Mexico the North American iguanid genera disappear and are replaced by tropical groups such as the black iguanas (*Ctenosaura*), the helmeted iguanids (*Corytophanes*), the casque-headed iguanids (*Laemancus*), and the basilisks (*Basiliscus*). The lizard family Teiidae, though represented in the United States by the race-runner genus (*Cnemidophorus*), is tropical, and its real development begins in Central America with the large, conspicuous, and active ameivas (*Ameiva*) and several small genera that live in concealment.

Among snakes, the fer-de-lance genus *Bothrops*, the coral snakes (*Micrurus*), the rear-fanged snakes such as the cat-eyed snakes (*Leptodeira*), and nonvenomous genera such as the tropical green snakes (*Leptophis*) either appear for the first time or begin their proliferation of species in Central America.

Reptiles become increasingly numerous in northern South America. Vine snakes (*Oxybelis* and *Imantodes*), false coral snakes (*Erythrolamprus*), slender ground snakes (*Drymobius*), and the burrowing spindle snakes (*Atractus*) are most abundant there. Most of the genera of the lizard family Teiidae occur in this area. Iguanid lizards of the anole genus (*Anolis*) are represented in northern South America by approximately 165 species. Other iguanid genera—e.g., the long-legged *Polychrus*—make their appearance.

Crocodilians, in terms of species, are more numerous in South than in Central America, and turtles are also abundant. Some of the North American groups—for example, the mud turtles (*Kinosternon*) and sliders (*Chrysemys*)—are represented, but the majority of species are members of genera and even families (e.g., the side-necked turtles, families Pelomedusidae and Chelidae) unknown in temperate North America.

Several groups that form important, if not dominant, elements of the fauna of the Eastern Hemisphere are largely or completely absent from the American tropics: the lizard families Scincidae, Lacertidae, Chamaeleontidae, and Agamidae and the snakes of the cobra (*Naja*) and water snake (*Natrix*) genera.

South of the tropics, in the temperate zone of South America, the reptilian fauna diminishes rapidly. Crocodilians and turtles do not occur south of northern Argentina. An ovoviparous pit viper reaches almost 50° S there; two iguanid lizards range almost to 55° S.

Asia. Apart from the genera of reptiles listed above as common to the eastern United States and eastern Asia, the temperate zone of Eurasia is noted for its many lizards of the families Agamidae, Lacertidae, and to lesser degrees Gekkonidae and Scincidae. Most of the lizards are terrestrial; extremely specialized burrowers include desert-dwelling skinks (*Ophiomorphus* and *Scincus*). Most of the snakes characteristic of this vast area are also terrestrial. Arboreal snakes are represented almost exclusively by the rat snakes (*Elaphe*). The leaf-nosed snakes (*Lyterhynchus*) and the sand boas (*Eryx*) are the distinctive burrowing snakes of the region. Except for the Chinese alligator and the Indian gaviel, temperate Eurasia lacks crocodilians. A few species of turtles are found.

A few types characteristic of the Oriental tropics extend into the temperate zone—e.g., several rear-fanged snakes

Ecological types of the North Temperate Zone

(*Boiga trigonata* and *Psammodynastes*), a cobra or two (*Naja*), several species of soft-shelled turtles (*Trionyx*), and some species of true chameleons (*Chamaeleo*).

In the Oriental tropics the reptilian fauna is extremely rich in species and diverse types. Aquatic groups are represented by snakes of various genera (e.g., *Natrix*, *Enhydria*, *Acrochordus*), several groups of lizards (*Tropidophorus* among the skinks and *Hydrosaurus* among the agamids), many emydid and soft-shelled turtles, and five species of crocodiles. The numerous terrestrial reptiles include the small kukri snakes (*Oligodon*), the big Oriental rat snakes (*Ptyas*), cobras, monitor lizards (*Varanus*), many species and genera of skinks, some geckos, and several land turtles (*Cuora*, *Geochelone*). Specialized burrowing snakes (e.g., the family Uropeltidae and the colubrid genus *Calamaria*) and lizards (e.g., the family Dibamidae and the skink genus *Brachymeles*) are also abundant.

The distinctive life-forms of reptiles in tropical Asia are arboreal. They include pythons and Oriental pit vipers (*Trimeresurus*), vine snakes (*Ahaetulla*), slug-eating snakes (*Pareas*), "flying" snakes (*Chrysopelea*), and tree racers (*Gonyosoma*). Some lizards climb only with the aid of claws (e.g., the monitors), a few with the help of prehensile, or grasping, tails (e.g., the deaf agamids, *Cophotis*), and many with the help of clinging pads under the digits (e.g., many geckos). The most striking arboreal reptiles of this area are the flying lizards (*Draco*) and the parachuting gecko (*Ptychozoon*), which has fully webbed digits, a fringed tail, and wide flaps of skin along its sides.

Australia. Because New Guinea, although geographically part of the East Indies, has a reptilian fauna more akin to that of Australia, the two areas are considered here as one. The Australian region is the only area in the world in which venomous species of snakes outnumber harmless ones. The family Colubridae, comprising the majority of the nonvenomous or slightly venomous snakes of the world, is poorly represented in Australia, which has only 12 species. The Australian region has many snakes of the cobra family (family Elapidae), but no vipers. The fauna also include several pythons and minute blind snakes (family Typhlopidae); a variety of geckos, skinks, and agamid lizards; side-necked turtles; and three species of crocodiles.

Africa. The reptilian fauna of Africa forms two main divisions. The first, the fauna of the North African coast, is akin to that of central and southwestern Asia and southern Europe and is therefore mainly a temperate-zone fauna. The racers, the burrowing sand skink (*Scincus*), and the emydid turtle (*Mauremys caspica*) are elements of temperate fauna in North Africa. Some species of the great tropical fauna lying south of the Sahara Desert occur in North Africa and in Southwest Asia. Examples are the sand snakes (*Psammophis*), cobras, and chameleons (family Chamaeleontidae). As is true of the temperate fauna of Eurasia, the North African reptiles, though representing many families, are principally terrestrial and burrowing. Many lacertid and agamid lizards scamper over rocks and sand by day; they are replaced at night by small geckos and are preyed upon by the racers (*Coluber*) and sand snakes (*Psammophis*). In addition to cobras, the venomous snakes of North Africa include the common vipers, the saw-scaled viper (*Echis carinatus*), and the horned vipers (*Cerastes*). The last two are true desert animals. Land tortoises (*Testudo*) are common in the semi-arid land.

The second and much larger division of the African fauna is the great tropical assemblage that ranges from the Sahara southward to the Cape of Good Hope. In common with tropical Asia, this vast area has cobras, many skinks, and many geckos. Its fauna differs from that of Asia in the absence of pit vipers (subfamily Crotalinae), the near absence of emydid turtles, and the poor representation of agamid lizards. These groups are replaced in tropical Africa by the many true vipers (subfamily Viperinae), the side-necked turtles (family Pelomedusidae), and the lacertid and cordylid lizards. Chameleons and land tortoises are abundant. Three species of crocodiles occur in Africa.

In Africa are found all of the diverse reptilian types characteristic of a tropical area: aquatic turtles, crocodiles, and snakes; terrestrial turtles, snakes, and lizards; burrow-

ing snakes of the blunt-headed and auger types; limbless and virtually blind burrowing lizards; and a profusion of arboreal snakes and lizards.

The large island of Madagascar, off the eastern coast of Africa, has a peculiar fauna that appears in part as a collection of castoffs, groups that in Africa have not been able to meet the competition of more advanced forms. With few exceptions the reptiles of Madagascar belong to genera found only there.

Madagascar

Natural history

Reproduction and life cycle. *Courtship.* Courtship in some form is such a widespread prelude to mating among modern reptiles that it must have characterized many extinct groups as well. When courting, the male of some freshwater turtles, such as the red-eared turtle (*Chrysemys scripta elegans*) of the eastern United States, orients himself in the water so that he is directly in front of a female and facing her. With his forefeet close together, the male vibrates his claws against her head. If the female is receptive, she swims forward slowly while the male backs away. Finally the female sinks slowly down. The male then mounts her from behind, clutching her shell with all four feet. His tail is brought under hers and his penis introduced into her cloaca.

The male of some terrestrial turtles of North America (e.g., the gopher tortoises, *Gopherus*) begins courtship by extending his neck and bobbing his head up and down. The courted female may bob her head in return. The male advances, nips at the female, and then circles her as she turns away from him. As soon as she shows signs of response, the male mounts her from the rear and begins a series of pumping movements that bump the rear of his shell against the ground. Finally the female extends her tail, and copulation begins. Males of the smaller box turtles (*Terrapene*) nip and butt at the female.

Male crocodilians bellow during the mating season, and in many cases the females respond with an answering call. The male American alligator, which copulates in water, grasps the female's neck with his jaws and slips the rear part of his body under hers to enable him to insert his penis into her cloaca.

Mating
behaviour
of croco-
dilians

Lizards have rather elaborate courtship patterns usually involving display and posturing by the males, who often have distinctive patches of colour on their throats or low on their sides. The male bobs up and down, thus exposing the patches of colour, which may be blue, orange, red, or black depending on the species. Males of some species, such as the green anole (*Anolis carolinensis*) of the southeastern United States, have brightly coloured folds of skin at the throat (dewlaps) that are expanded during courtship. If the female seems receptive, the male straddles her back, often gripping her back or legs with his jaws. Just before copulation, his tail is bent under hers.

The courtship patterns of snakes are simpler; they usually consist of the male's crawling over the back of the female and adopting every curve her body takes, then vibrating against her body or nudging it with waves of his own. Male boas and pythons stroke or scratch the female's body with their vestigial hind limbs. The male water snake rubs his chin against the female's back. The male rattlesnake (*Crotalus*) frequently nudges the female with his head. The male bull snake (*Pituophis*) grasps the female's neck with his jaws during copulation.

When the male king cobra (*Ophiophagus hannah*) crawls onto the back of a receptive female, he flicks his tongue against her repeatedly. The female raises her head and spreads her hood. The male nudges her neck and head with his snout and lifts the rear of her body with his tail. Copulation between cobras may last more than two hours.

The embryo. The embryo of a reptile develops a thin sac, the amnion, that envelops the embryo and becomes filled with a watery fluid. The entire structure serves to protect the embryo from desiccation and mechanical injury. A parchment-like shell, which also contributes mechanical protection, is produced by the female parent and surrounds the amnion; between the shell and the amnion a second sac, the allantois, becomes inserted. The allan-

tois, which is supplied with many fine blood vessels, serves as a respiratory organ, absorbing the oxygen and emitting the carbon dioxide that pass through the somewhat porous shell.

Egg laying. The typical mode of reptilian reproduction is oviparous (*i.e.*, the female lays eggs in which the young develop). The eggs are laid shortly after fertilization, and development of the embryos takes place largely after the eggs have been laid. This pattern characterizes crocodilians, turtles, the tuatara, most lizards and snakes, and many extinct reptiles. The size of eggs laid by lizards and snakes varies according to the size of the females. The banded rock lizard (*Petrosaurus mearnsi*) of the western United States, which ranges from 7.5 to 10 centimetres (three to four inches) in length, lays eggs that are about one centimetre (0.4 inch) long; those of the 30- to 60-centimetre (12- to 24-inch) ringneck snake (*Diadophis punctatus*) from the eastern United States are 1.25 centimetres (0.5 inch) long. Eggs of the three-metre Komodo dragon lizard (*Varanus komodoensis*) and of the six-metre (20-foot) Indian python (*Python molurus*) are about 11.25 centimetres (4.5 inches) long.

A minority of modern and extinct reptiles are (and were) live-bearing, or viviparous. Strictly speaking, most of this minority are not truly viviparous but ovoviviparous, because the embryos develop with their shells or shell membranes intact and are nourished wholly by the yolk. In a few modern reptiles the embryonic membranes and the tissues lining the oviducts of the females come into close contact and are modified in one of several ways to provide a temporary organ, through which food and respiratory gases are exchanged; *i.e.*, a structure similar to the placenta of mammals. In the simplest reptilian "placenta," the most superficial layer (the lining of the oviduct partially degenerates, thereby bringing the blood vessels of embryo and mother closer together. The approximation of the two bloodstreams facilitates the exchange of oxygen and carbon dioxide, this gas exchange being the only function of the organ at this stage of evolution. Several Australian snakes (*Denisonia superba* and *D. suta*) and a number of lizards—*e.g.*, the common East Indian brown-sided skink (*Mabuya multifasciata*) and the cylindrical skink (*Chalcides ocellatus*) of southern Europe and North Africa—are known to have this type of organ, as presumably do many ovoviviparous reptiles.

The best developed reptilian "placentas" consist of apposed, thickened, folded elliptical areas of the outer embryonic membrane and lining of the oviduct. The ridges of the oviductal areas are filled with blood vessels, and the epithelium between ridges is thickened and glandular. Usually, eggs developing with this type of "placenta" have less yolk; food and oxygen are transmitted from mother to embryo. Several species of Australian lizards, American water snakes, and the common European viper (*Vipera berus*) are known to provide this type of internal environment for their developing young.

The line between oviparity (egg laying) and ovoviviparity (hatching of eggs in the mother's body) is arbitrary. Females of some lizards and snakes retain the fertilized eggs in their bodies for a few days before laying them. Other species retain the eggs for most of the developmental period, hatching occurring shortly after laying. For the grass snake of England (*Natrix natrix*), the lapse of time between copulation and egg laying is usually two months; the young hatch six to ten weeks later. The interval between mating and egg laying is one month in the Texas horned lizard (*Phrynosoma cornutum*). A given species may be ovoviviparous in parts of its range and oviparous elsewhere.

The nest. The eggs of modern reptiles may be deposited in a nest prepared by the female or simply laid under some convenient cover, such as a rock or log. Crocodilians invariably prepare a nest, and the female invariably does the work. Most turtles dig their nests, scooping out a flask-shaped cavity in the ground with their hindfeet. When the hole has reached the proper size, the oval or spherical eggs, 1.5 to 3.75 centimetres (0.6 to 1.5 inches) in diameter depending on the species, are dropped into the nest from the female's cloaca. The female scratches soil over the eggs,

usually obliterating the nest site. Crocodilians either dig a nest along the bank of a river or lake or heap together a mass of dead vegetation in which the eggs are laid; their oval eggs are usually about five centimetres (two inches) long.

Most oviparous lizards merely hide their eggs under some convenient cover such as under a rock or in a hole in a tree. Nest construction among lizards, though appearing in such diverse families as the iguanids, skinks, and true chameleons, is neither so elaborate nor so rigid in pattern as among turtles. The nest consists of a small hole made by either the snout or the limbs. Soil or leaves usually are pushed on top of the eggs to hide the nest, although the entrance to the nest cavity is kept open in a few species. Snakes, like lizards, usually lay their eggs under natural, pre-existing cover. The king cobra, one of the very few nest-building snakes, drags dead vegetation into a low heap by bending its body. The eggs are laid in a cavity at the centre. Other snakes deposit their eggs in holes they have scooped out of sand or soft earth with their snouts.

Number of offspring. The number of eggs in a clutch or offspring in a brood varies from one to 200 among living reptiles; presumably similar variation occurred among the extinct types. Crocodilians lay from 20 to 70 eggs, turtles from one to 200. In turtles, more so than in crocodiles, the number varies with the species and roughly with the size attained by the females. The big marine turtles have the largest clutches (usually more than 100); the smaller land and freshwater turtles have much smaller ones. The number of eggs or young is not so closely related to the size of mature females in species of lizards and snakes. With few exceptions, lizards of the family Gekkonidae lay two eggs at a time, regardless of the size of the female. Lizards of the family Scincidae have broods varying from two to about 30; one of the largest members of this family, the 30-centimetre-long (12-inch) stump-tailed skink (*Tiliqua rugosa*) of Australia, has only two young at a time, whereas the Great Plains skink (*Eumeces obsoletus*) of the United States usually lays between ten and 20 eggs in a clutch.

Clutch size in the 1.5-metre (five-foot) bull snake (*Pituophis catenifer*) of western United States is usually ten or 12; in the grass snake of England and Europe, which measures 60 to 90 centimetres (two to three feet), it is 30 to 40; in the giant reticulated python of Southeast Asia and the East Indies, it may reach 100.

Parental care. Parental care of eggs and newborn young is neither well developed nor elaborated among reptiles. Female crocodilians generally remain in the vicinity of their nests and chase would-be predators from the site. In a few lizards the female returns to the nest between feeding excursions to coil around the eggs and turn them at intervals. The male and female king cobra remain in the vicinity of the nest, and one of the parents usually is coiled above the egg cavity.

Female pythons coil around their eggs and pull them into a heap. Females of some species remain with the eggs for the entire two-month incubation period; others leave the eggs only to drink. In at least one species (*Python molurus*) the female provides heat by muscular contraction to keep the eggs at incubation temperature on cool nights. Turtles and the majority of egg-laying lizards and snakes abandon their eggs after they are laid.

Incubation period. The incubation (or gestation) period of reptilian eggs is affected by many factors and to such an extent that it is difficult to assign a figure characteristic of a given species. One source of complication is the combination of oviparous and ovoviviparous habits by certain species. The developmental period of the embryo, whether it occurs within the female's body or outside it, is referred to as the gestation period.

In general, the gestation period lasts from 60 to 105 days in most American and European reptiles. The eggs of the American alligator hatch about 63 days after they are laid, those of the small Eastern fence lizards (*Sceloporus undulatus*) in about the same time. The gestation period in the common European viper lasts from 60 to 90 days. Eggs of marine turtles hatch between 30 and 75 days after they are laid, depending on the site. The temperatures to which a brood is subjected shorten or lengthen gestation according to whether the temperatures are high or low.

Relationship of brood size to adult size

Oviparity and ovoviviparity in lizards and snakes

Growth and longevity. Giant Galápagos tortoises kept under nearly ideal conditions have been known to increase their weight from 3.2 to six kilograms (seven to 13 pounds) to about 82 kilograms (180 pounds) in nine years. Smaller species also grow rapidly. The box turtle of the United States has a shell about 3.75 centimetres (1.5 inches) long at the end of its first year; at the end of five years, the length has doubled.

Under favourable conditions a one-year-old American alligator is about 60 centimetres (24 inches) long and weighs about 1.8 kilograms (four pounds). At the end of six years, males average about 190 centimetres (about six feet) and about 36 kilograms (80 pounds). The red diamond rattlesnake is about 30 centimetres long at birth, grows to about 65 centimetres in its first year, reaches about 85 centimetres (33 inches) by the end of its second year, and grows more slowly after that. The pattern for lizards is much the same: rapid growth early in life and slow growth afterward. The significant difference between growth in reptiles and that in mammals is that a reptile has the potential of growing throughout its life, whereas a mammal reaches a terminal size and grows no more, even though it may subsequently live many years in ideal conditions.

The length of time needed to attain sexual maturity varies greatly among reptiles and, although roughly related to the size usually attained by the species, is even more closely related to the climate in which the animal lives. The red diamond rattlesnakes in southern California, for example, bear their first young when three years old; on the other hand, the northern Pacific rattlesnake (*Crotalus viridis oreganus*) bears its first litter when four years old. The much smaller common garter snake is sexually mature shortly before the age of two years.

The 12.5- to 15-centimetre (five- to six-inch) northwestern sagebrush lizard (*Sceloporus graciosus gracilis*), living in the Sierra Nevada range of California at an elevation (about 1,800 metres [6,000 feet]) where it has, at most, six months of activity each year, requires two years or more to reach sexual maturity. Another lizard, the green anole (*Anolis carolinensis*), similar in size to the sagebrush lizard but living in the lowlands of the southern United States, may reach maturity in four or five months in Florida.

Turtles mature at a slower rate. Females of the red-eared turtle of the central United States lay their first eggs when they are from three to eight years old, depending upon how long it takes them to reach a shell length of 15 centimetres (six inches). Females of the musk turtle, or stinkpot (*Sternotherus odoratus*), in Michigan require nine to 11 years to mature, at which time their shells are 7.5 to 10 centimetres (three to four inches) long. Presumably, turtles living in the tropics mature more rapidly.

The maximum age, meaning the potential longevity, of modern reptiles varies greatly and can be determined only from records of captive animals. Turtles as a group seem capable of living longer than the others, and about 30 species have been kept in captivity more than 20 years. Several species, said to have lived 150 years or more, may be cases of two individuals whose periods of captivity overlapped. There is no reliable evidence for believing that the giant land tortoises live much longer than some smaller species. Two crocodilians (*Alligator mississippiensis* and *A. sinensis*) have survived in zoos for more than 50 years. Several species of pythons and boas have lived longer than 20 years. Lizards seem to have an upper limit near that of snakes. A slowworm, *Anguis fragilis*, has been kept in captivity for more than 30 years.

Behaviour

Defense. *Avoidance and noise.* Avoidance, the commonest form of defense in the animal kingdom, is also the commonest one in reptiles. At the first recognition of danger, most snakes and lizards crawl or scamper away into the undergrowth; turtles and crocodilians plunge into water and sink out of sight. But should the danger arise so suddenly and so close at hand that flight may be hazardous, other expedients are adopted.

Crocodiles, some lizards, turtles, and some snakes hiss

loudly when confronted by an enemy. Rattlesnakes rapidly vibrate the tip of the tail, which consists of loose, dry, horny rings. A few snakes without rattles (e.g., the fox snake, *Elaphe vulpina*, of the United States) vibrate the ends of their tails rapidly, and if, as often happens, the tail hits dry leaves, it makes a sound deceptively like the rattle of a rattlesnake.

Body form and posturing. Change in body form, which is relatively common in snakes, usually involves spreading the neck, as in cobras (family Elapidae), or the whole body, as in the harmless hognose snakes (*Heterodon*) and DeKay's snake (*Storeria dekayi*) of the United States. Some snakes inflate the forward parts of their bodies; inflation is one of the defensive actions of the large South American tree snake *Spilotes* and of the African boomslang (*Dispholidus*).

Threatening postures may be assumed by snakes as they change their body form. A cobra raises the forepart of its body and spreads its hood when endangered. The typical defensive posture of a viper is with the body coiled and the neck held in an S-curve, the head poised to strike.

Some lizards flatten their bodies, puff out their throats, and turn broadside to the enemy. The helmeted iguanids (*Corytophanes*) of Central America and the chameleons of Africa increase their apparent size in this way when approached by snakes. The Australian bearded lizard (*Amphibolurus barbatus*) spreads its throat downward and outward. The Australian frilled lizard (*Chlamydosaurus kingi*) suddenly raises a wide membrane, or frill, which extends backward from the throat. Many lizards and snakes open their mouths when threatened, but do not strike. A common African lizard, *Agama atricollis*, faces an enemy with head held high and mouth open to show the brilliant orange interior.

Display of colour. Display of colour in *Agama atricollis* may not be part of a threatening mechanism, but it is so in the instances of certain red- or yellow-bellied snakes that turn over or curl up their tails, exposing the brightly coloured undersurface. This behaviour, known in harmless (e.g., the American ring-necked snake, *Diadophis*) as well as venomous snakes (e.g., the coral snake, *Micrurus frontalis*), is displayed only by snakes having red, orange, or yellow undersides. These colours must have some significance, as yet not fully understood, to predacious animals, for they are also the common colours in insects having warning coloration.

The defense mechanism of camouflage involving form and colour is common. Many arboreal snakes and lizards (e.g., chameleons) are green; some of the green snakes (e.g., the vine snakes of South America, *Oxybelis*, and of southern Asia, *Ahaetulla*) are very slender, resembling plants common in the habitat. Lizards of semi-arid and rocky country frequently are pale in colour and blotched in pebble fashion—e.g., the leopard lizard (*Crotaphytus wislizeni*) of the southwestern United States.

Mimicry of dangerous species by harmless snakes is a passive defense. Its validity as an actual mechanism of defense is, however, sometimes challenged. The venomous coral snakes (*Micrurus*) of the Western Hemisphere are ringed with bright red, yellow, and black. A series of relatively harmless snakes, such as *Erythrolamprus* and *Anilius* of South America and the scarlet king snake, *Lampropeltis triangulum doliata*, of southeastern United States, have similar colours and patterns that may confer some protection against predators.

Striking and biting. If a threatening posture does not succeed in driving off an enemy, many reptiles become more aggressive. Some snakes (e.g., DeKay's snake) strike, but with their mouths closed. Others (e.g., the hognose snakes) strike with their mouth open but do not bite. Still others strike and bite viciously. Among the nonvenomous snakes of North America, few are as quick to bite as the water snakes (*Natrix*). The sole danger from the bites of these snakes is infection of the wound.

Most of the dangerously venomous snakes (vipers, pit vipers, and cobras) bite in self-defense. Vipers and pit vipers usually strike from a horizontally coiled posture. From this position the head can be shot forward, stab the enemy, and be as rapidly pulled back in readiness for

Hissing and tail rattling

Achievement of sexual maturity

Mimicry

the next strike. From the typical raised posture a cobra sweeps its head forward and downward to bite. To strike again it raises its head and neck once more; such aggressive, defensive movements of cobras are slower than those of pit vipers.

Many lizards, regardless of family and size, bite in defense. *Gekko gekko* of Southeast Asia bites if sufficiently threatened. Although small lizards have a bite effective against only the smallest predators, a large monitor lizard (*Varanus*) can inflict a painful wound with its large teeth and strong jaws. Some turtles, particularly the soft-shelled turtles (*Trionyx*), bite frequently, vigorously, and effectively.

Spitting. The spitting of venom by certain African cobras, the ringhals (*Hemachatus haemachatus*), and the black-necked cobra (*Naja nigricollis*) is a purely defensive act directed against large enemies. A fine stream of venom is forced out of each fang, which, instead of having a straight canal ending in a long opening near the tip as in most cobras, has a canal that turns sharply forward to a small round opening on the front surface well away from the tip. At the moment of ejection the mouth is opened slightly, and venom is forced out of the fangs by contraction of the muscle enveloping the poison gland. Usually a spitting cobra raises its head and the forepart of its body in the characteristic cobra defensive posture prior to spitting, but venom can be ejected from any position. The effect on skin is negligible; the eyes, however, may be severely damaged, and blindness can result unless the venom is washed out quickly.

Use of the tail. A few lizards, representing different families, have in common thick tails covered by large, hard, spiny scales. Such a tail swung vigorously from side to side is an effective defense against snakes, especially when the head and body of the lizard are in a burrow or wedged between rocks.

Voluntary
tail
shedding

Lizards' tails are useful in defense in another way. When captured, many lizards voluntarily shed their tails, which wriggle violently, temporarily confusing the predator and allowing the lizard to escape. Each vertebra of the tails of lizards with this capacity has a fracture line and can be split on that line when tail muscles contract violently. Simultaneous stimulation of the nerves in the severed portion keeps it twitching for a few seconds after separation. Usually the tail is broken in only one place, but a few lizards, particularly the so-called glass snakes (*Ophisaurus*), break their tails into several pieces. The stump heals quickly, and a new tail grows; often, however, the regenerated tail is not so long as the original and has simpler scales.

Snakes, turtles, and crocodiles may have their tails bitten off by predators, but they cannot break them voluntarily or regenerate them. Some snakes use their tails in diversionary tactics by raising them and moving them slowly. Species with this habit commonly have thick, blunt, brightly coloured tails. The small African python *Calabaria* and the Oriental venomous snake *Maticora* wave their tails in the air as they move slowly away from a threat.

Balling. Many snakes, both harmless and venomous, attempt to hide their heads under coils of their bodies. The body may be coiled loosely, as it is in most species with this habit, or tightly so that it forms a compact ball with the head in the centre. Balling, as the latter habit is called, is a characteristic response of *Calabaria* and another African python, *Python regius*.

The African armadillo lizard (*Cordylus cataphractus*), a species with heavy scales on its head and hard spiny scales covering its body and tail, rolls on its back and grasps its tail in its mouth. It thus presents a ring of hard spines to a predator.

Odours. Some reptiles use musk-secreting glands when other defensive measures fail. The water snakes (*Natrix*), the garter snakes (*Thamnophis*), the alligator lizards (*Gerrhonotus*), and the musk turtles (*Sternotherus*) emit a foul-smelling substance from anal glands.

Feeding habits. With few exceptions, modern reptiles feed on some form of animal life: insects, mollusks, birds, frogs, mammals, fishes, or other reptiles. Land tortoises

are vegetarians, eating leaves, grass, and in some cases even cactus. The big green iguana (*Iguana iguana*) of Central and South America, its relative the chuckwalla (*Sauromalus obesus*) of southwestern United States and northern Mexico, and the spiny-tailed agamids (*Uromastix*) of North Africa and southwestern Asia also are herbivorous. The marine iguana (*Amblyrhynchus cristatus*) of the Galápagos Islands dives into the sea for seaweed.

The majority of carnivorous reptiles have nonspecialized diets, feeding on a variety of animals. In general, the smaller the reptile, the smaller is its prey. Only the very largest of living snakes—the reticulated python (*Python reticulatus*), the Indian python (*P. molurus*), and the anaconda (*Eunectes murinus*)—are capable of eating large mammals such as small pigs and deer. Among crocodiles the largest species—the Nile crocodile (*Crocodylus niloticus*), the East Indian saltwater crocodile (*C. porosus*), and the Orinoco crocodile (*C. intermedius*)—have been known to attack and to eat men. Presumably, even larger prey was devoured by the great carnivorous dinosaurs such as *Allosaurus* and *Tyrannosaurus*, which were almost certainly capable of killing the largest of their herbivorous contemporaries.

Man-eating
reptiles

Locomotion. *Walking and crawling.* The majority of reptilian orders are quadrupedal—i.e., four-legged. Among the land vertebrates, the limbs gradually shifted from a lateral to a ventral position. In most amphibious reptiles the limbs projected out to the side and then bent downward to the ground at the knee and elbow. With few exceptions, the quadrupedal reptiles have the same awkward position. With such an orientation, the centre of gravity of the body is not in the same axis as the hands and feet, resulting in a sideways as well as a forward component of thrust when the animal walks. The typical reptile throws its body into a slight horizontal curve to progress straight forward. In mammals the limbs are directly underneath the body, the centre of gravity is in the axis of the limbs, and all of the thrust of the limbs is directed forward. The latter position and type of motion are more efficient. The lateral orientation of the limbs in amphibians and reptiles also makes it more difficult to raise the body off the ground.

Despite the awkwardness of the orientation of their limbs, some reptiles are (and many extinct forms probably were) capable of moderate speeds. Crocodilians raise their bodies off the ground and make short, fast rushes. Short-bodied lizards also can move fast for short distances; longer-bodied lizards have greater difficulty in raising their bodies. They usually have short legs and proceed in a serpentine fashion, with the body, thrown in horizontal curves, doing much of the work.

A snake moves by pushing backward against rocks, sticks, or any relatively fixed point—a lump of earth or a small depression in uneven ground—with the rear surface of the horizontal curves of its body. Each joint of the body passes through the same curves, pressing against the same object and thrusting the forepart of the body forward. Heavy-bodied snakes such as pythons and certain rattlesnakes can move forward without throwing their bodies into curves. This rectilinear movement depends on the ability of snakes to stretch or contract their bodies in the longitudinal axis. By raising a part of its belly, stretching that part forward, lowering it to the ground, and repeating the process alternately with other parts of the body, a heavy snake moves forward smoothly in a straight line.

Some modern lizards have adopted semi-bipedal locomotion. The collared lizard (*Crotaphytus collaris*) of the United States and the frilled lizard (*Chlamydosaurus kingi*) of Australia show the early stages of bipedalism, a phenomenon widespread among the dinosaurs and therefore important in reptilian history. These lizards run on their long hindlegs with the forward parts of their bodies at an angle of about 60° off the horizontal.

Bipedal
loco-
motion

Presumably, bipedalism among the dinosaurs began as it did among modern lizards, as an occasional means of obtaining bursts of speed. Because the centre of gravity is in front of the hips, modern bipedal lizards must move forward continuously in order to maintain a semi-erect posture; they can stand still in that position only for very short periods.

The awkward sideways orientation of the limbs forces bipedal lizards to swing each leg outward as it is brought forward and to push the body sideways and forward when each leg thrusts backward against the ground. Bipedal dinosaurs eliminated this inefficient rocking motion; for during the course of evolution their hind limbs were rotated forward so that they were directly under their bodies. Thus, they delivered their full force in the forward direction. So successful was this mode of locomotion that dinosaurs utilizing it dominated terrestrial life for millions of years.

Clinging and climbing. Associated with arboreal life are groups of anatomical features mainly concerned with clinging. The commonest clinging structures in vertebrates are claws; they seem to be the only arboreal adaptations of some lizards, such as the common iguana (*Iguana iguana*). Similar structures appear in many lizards of the family Gekkonidae, in the anoles (*Anolis*) of the family Iguanidae, and in some skinks of the family Scincidae.

Pads on the feet consist of wide plates or scale under the fingers and toes. The outer layer of each plate or scale is composed of innumerable tiny hooks formed by the free, bent tips of cells. These minute hooks catch in the slightest irregularities and enable geckos to run up apparently smooth walls and even upside down on plaster ceilings. Because the hooklike cells are bent downward and to the rear, a gecko curls its toes upward to disengage them. Thus, when walking or running up a tree or wall, a gecko must curl and uncurl its toes at every step.

Prehensile
tails

The giant Solomon Islands skink (*Corucia*), true chameleons (Chamaeleontidae), arboreal vipers, boas, and pythons use prehensile tails—that is, tails capable of supporting most of the weight of the animal or used habitually for grasping—for clinging to their aerial supports. For this purpose, however, true chameleons rely mainly on a tonglike arrangement of their digits, which are united into two opposed bundles on each foot—three on the inside and two on the outside of the front foot, and two on the inside and three on the outside of the hindfoot.

Slender vine snakes of several genera of the family Colubridae are capable of extending half the body length in a horizontal plane without support; they do so habitually in bridging the gap between branches. Most snakes can reach across an open space, but all except the vine snakes can extend only a short length of the body, and that portion invariably sags like a cable. The vine snakes bridge an open space like an I-beam. This ability is based partly on reduced body weight and partly on deepened and strengthened vertebrae.

Swimming. In water, of course, neither bipedal nor quadrupedal locomotion is very effective. Aquatic reptiles, with few exceptions, use the same means of propulsion as do fish and whales—that is, powerful beats of the tail. Crocodilians and aquatic lizards such as some monitors (Varanidae) lash their tails from side to side while holding the limbs against the body. The same method was used by the ancient mesosaurs (Mesosauria) and ichthyosaurs (Ichthyosauria). The marine ichthyosaurs, which were the reptilian counterpart of the porpoises, may have used their very short limbs for steering.

A fishlike method of swimming requires a flexible body and at least a moderately long tail. Turtles propel themselves by using their feet as paddles—the hindfeet, which have webbed toes, in the case of freshwater turtles, and the forefeet, which are modified into large paddles, in the case of marine turtles.

The extinct marine plesiosaurs (suborder Plesiosauria), with their short bodies and tails and their large paddlelike limbs, swam the way marine turtles do, although they may have used their hindlimbs for more than just steering. Both pelvic and pectoral (shoulder) girdles were modified in the plesiosaurs into structures having small upper portions and very large lower portions. As the upper element, especially that of the pelvic girdle, has the important function of transferring the weight of the body to the limbs, it is likely that the limbs of plesiosaurs could not support the body weight on land and that the plesiosaurs never came out of water.

Most plesiosaurs had long necks. By moving toward their

prey with the neck curved, they probably could strike suddenly. The heavy trunk would provide the inertia against which the neck could move, thus preventing a significant backward shift of the animal as the head shot forward. The modern sea snakes (Hydrophidae) show the same adaptation. Though they swim with an eel-like undulation of the body, the sea snakes have relatively small heads, slender necks, and very heavy middle and rear sections. With most of the body mass concentrated in the second half of the animal, almost all of the force of the strike is used to drive the head forward.

Loco-
motion
of sea
snakes

Flying. Three groups of reptiles have experimented with flight. Thecodontia, a group of Archosauria (the so-called ruling reptiles, which included dinosaurs and crocodilians), became highly successful at this means of locomotion and evolved into birds.

A second group of archosaurs, the Pterosauria, developed wings that were supported along the front margin by the arm and an extremely elongated finger. The pterosaur wing was made of skin; since it lacked both internal supports and feathers, it probably lacked the flexibility or durability of a bird wing. Flight of the pterosaurs presumably amounted to soaring and gliding. It is not understood how they moved when not flying and how they managed to take off if they happened to land on level ground. Since most remains have been found in marine deposits, it is assumed that they lived along ocean shores, probably roosting on cliffs from which takeoff would have been easy.

The third experiment with flight was made by a group of modern lizards (*Draco*). The “wing” of these small lizards consists of skin supported by five or six elongated ribs between the arm and leg. At rest the ribs and the wings are folded against the sides of the body. In flight the wings form broad semicircles from arm to leg on each side. These flying lizards, which live in the forested country of Southeast Asia and the East Indies, are capable only of gliding. A flying lizard launches itself from a tree into the air and glides toward another tree, turning upward sharply just before lighting on the new perch. Since the arms and legs are not modified, this lizard is capable of scampering about like any strictly arboreal lizard.

“Flying”
lizards

Form and function

External covering. The external covering of reptiles is characteristically dry. It bears few glands or none at all and differs in this respect from the skin of amphibians and mammals. The so-called malpighian layer of the epidermis secretes the outer layer, which is tough and horny. Bony plates develop in the dermis, which lies just below the epidermis. The arrangement of scales is usually characteristic for each species.

Internal features. *Skeletal system and dentition.* The skeleton of reptiles fits the general pattern of vertebrates. They have a bony skull, a long vertebral column that encloses the spinal nerve cord, ribs that form a bony basket around the viscera, and a framework of limbs.

Each group of reptiles developed its own particular variations on this major pattern in accord with the general adaptive trends of the group. Snakes, for example, have lost the limb bones, although a few retain vestiges of the hindlimb. The limbs of several types of marine reptiles became modified into fins or flippers with obvious functional significance. In groups such as the extinct ichthyosaurs and plesiosaurs, the bones of the limbs, no longer supporting the weight of the body against the pull of gravity, became much shortened. At the same time the bones that in other reptiles composed the digits multiplied in number, forming a long flipper.

Groups of reptiles whose modes of life came to depend heavily on passive defense also developed specializations of the skeleton. The bony and horny shell of turtles and rows of bony plates on the back of ankylosaurs (Cretaceous dinosaurs) are cases in point.

The skulls of the several subclasses and orders vary in the ways mentioned below. In addition to differences in openings on the side of the skull and in general shape and size, the most significant variations in reptilian skulls are those affecting movements within the skull.

Reptilian skulls as a group differ from those of early amphibians, the vertebrates from which reptiles arose, in lacking an otic notch (an indentation at the rear of the skull) and several small bones at the rear of the skull roof. The skulls of modern reptiles are sharply set off from those of mammals in many ways, but the clearest differences are in the lower jaw and adjacent regions. Reptiles have a number of bones in the lower jaw, only one of which, the

Figure 2: Diagrammatic reptilian skulls.

Differences between reptile and mammal skulls

dentary, bears teeth. Behind the dentary a small bone, the articular, forms a joint with the quadrate bone near the rear of the skull. In mammals the lower jaw consists of a single bone, the dentary, and the articular and quadrate have become part of the chain of little bones in the middle ear. An almost complete transition between these two very different arrangements is known from fossils of mammal-like reptiles (order Therapsida).

The dentition of most reptiles shows little specialization along the tooth row. A division into distinctive bladelike incisors, tusklike canines, and flat-crowned molars, such as characterize mammals, does not occur in reptiles. Instead, the entire tooth row usually consists of long conical teeth. Venomous snakes have one or several hollow or grooved fangs, but they have the same shape as most snake teeth. The principal differences between species lie in the number, length, and position of the teeth. Crocodilians among the living forms and dinosaurs among the extinct forms have but a single upper and a single lower tooth row. Snakes and many extinct reptilian groups have teeth on the palatal bones (vomer, palatine, pterygoid) and on the bones of the upper jaw (premaxilla, maxilla); only one row of teeth is present on the lower jaw.

Lizards have conical or bladelike bicuspid or tricuspid teeth. Some species have conical teeth at the front of the jaws and cuspid teeth toward the rear, but the latter are not comparable to the molars of mammals in either form (they are not flat-crowned) or function (they do not grind food). Turtles, except for the earliest extinct species, lack teeth, having instead upper and lower horny plates that serve to bite off chunks of food.

The teeth of reptiles are also less specialized in function than are mammalian teeth. The larger carnivorous reptiles are equipped only to tear off or bite off large pieces of their prey and to bolt them without chewing. Insectivorous lizards (the majority of lizards) usually crack the exoskeleton of their insect prey, and then swallow the prey without grinding it up. Snakes simply swallow their prey whole without any mechanical reduction.

Skull and joint structures. Many reptiles developed joints (in addition to the hinge for the lower jaw) within the skull, permitting at least slight movement of one part relative to others. The capacity for such movement within the skull, called kinesis, enables an animal to increase the gape of the mouth and thus is an adaptation for swallowing large objects. Apparently some of the large carnivorous theropod dinosaurs (e.g., *Allosaurus*) had a joint between the frontal and parietal bones in the roof of the skull. All reptiles of the subclass Lepidosauria (lizards, snakes, rhynchocephalians, and the extinct eosuchians) have had kinetic skulls, but they differ from the dinosaurs in having the joint on the floor of the skull at the juncture of basisphenoid and pterygoid bones.

Kinesis

The skulls of the lepidosaurs became increasingly kinetic as new groups evolved. The Rhynchocephalia (which include the living tuatara) and their antecedents, the Eosuchia, had only the basisphenoid-ptyergoid joint. The lizards lost the lower temporal bar, thereby freeing the quadrate bone and allowing greater movement to the lower jaw, which is hinged to the quadrate. Finally, in the snakes, this trend culminates in the most kinetic skull among the vertebrates—a skull having the ancestral basisphenoid-ptyergoid joint, a highly mobile quadrate (which gives even greater mobility to the lower jaw), upper jaws capable of rotating on their longitudinal axes and of moving forward and backward, and often a hinge on the roof of the skull between the nasal and frontal bones that allows the snout to be raised slightly. In short, the only part of a snake's skull incapable of movement is the braincase.

Nervous system. As in all vertebrates, the nervous system of reptiles consists of a brain, a spinal nerve cord, nerves running from the brain or spinal cord, and sense organs. Reptiles have small brains compared with mammals. The most important difference between the brains of these two vertebrate groups lies in the size of the cerebral hemispheres, the principal associative centres of the brain. In mammals these hemispheres make up the bulk of the brain and, when viewed from above, almost hide the rest of the brain. In reptiles the relative and absolute size of the cerebral hemispheres is much smaller. The brain of snakes and alligators forms less than $\frac{1}{1,500}$ of the total body weight, whereas, in mammals such as squirrels and cats, the brain accounts for about $\frac{1}{100}$ of the body weight. A stegosaur (Stegosauria), roughly the size of an elephant, had a braincase no larger than that of a 2.4-metre (8-foot) crocodile, about large enough to contain a brain the size of a large walnut.

Circulatory system. Modern reptiles do not have the capacity for rapid sustained activity found in birds and mammals. It is generally accepted that this lower capacity is related to differences in the circulatory and respiratory systems. Before the origin of lungs, the vertebrate circulatory system had a single circuit: in the fishes, blood flows from heart to gills to body and back to the heart. The heart consists of four chambers arranged in a linear sequence.

With the evolution of lungs in amphibians, a new and apparently more efficient circulatory system evolved. Two chambers of the heart, the atrium (or auricle) and ventricle, became increasingly important, and the beginnings of a double circulation appeared. An early stage in this evolution can be seen in amphibians today, where one of the main arteries from the heart (the pulmonary artery) goes directly to the lungs, whereas the others (the systemic arteries) carry blood to the general body. The blood is aerated in the lungs and carried back to the atrium of the heart. From the left side of the atrium, which is at least partially divided for the first time, the aerated blood is pumped into the ventricle and there mixes with the nonaerated blood from the body that was returned to the heart via the right half of the atrium. Then the cycle begins again. One of the features of the amphibian system is that the blood leaving the heart for the body is only partially aerated; part of it is the deoxygenated blood returned from the body.

All groups of modern reptiles have a completely divided atrium; it is safe to assume, therefore, that this was true of most, if not all, extinct reptiles. In reptiles, the ventricle

Evolution of the reptile heart

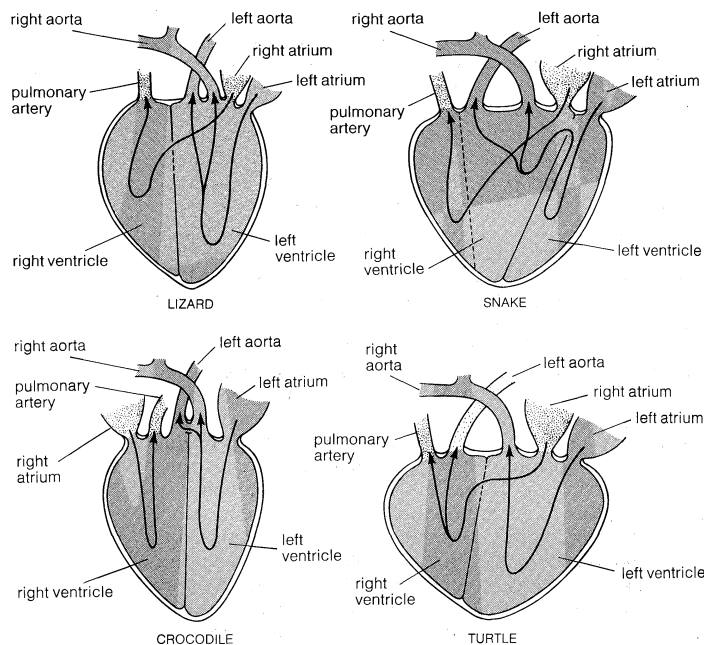

Figure 3: Types of reptilian hearts.

for the first time becomes at least partially divided in the four major living groups.

When the two atria of a lizard's heart contract, the two streams of blood (aerated blood from the lungs in the left atrium and nonaerated blood from the body in the right atrium) flow into the left chamber of the ventricle. As pressure builds up in that chamber, the nonaerated blood is forced through the gap in the partition into the right chamber of the ventricle. Then, when the ventricle contracts, nonaerated blood is pumped into the pulmonary artery and thence to the lungs, while aerated blood is pumped into the systemic arteries (the aortas) and so to the body.

In snakes all three arterial trunks come out of the chamber of the ventricle that receives the nonaerated blood of the right atrium. During ventricular contraction, a muscular ridge forms a partition that guides the nonaerated blood into the pulmonary artery, while the aerated blood received by the other chamber of the ventricle is forced through the opening in the ventricular septum and out through the aortas.

In crocodiles the ventricular septum is complete, but the two aortas come out of different ventricular chambers. A semilunar valve at the entrance to the left aorta prevents nonaerated blood in the right ventricle from flowing into the aorta. Instead, part of the aerated blood from the left ventricular chamber pumped into the right aorta flows into the left by way of an opening.

The ventricle of the turtle is not perfectly divided, and some slight mixing of aerated and nonaerated blood takes place.

Despite the peculiar and complex circulation, a double system has been achieved by lizards, snakes, and crocodilians. Tests of the blood in the various chambers and arteries have shown that the oxygen content in both systemic aortas is as high as that of the blood just received by the left atrium from the lungs and is much higher than that of the blood in the pulmonary artery. Except for the turtles, limitation of activity in reptiles cannot be explained on the basis of imperfect heart circulation.

An explanation may lie in the chemistry of the blood. Apparently, the blood of reptiles has less hemoglobin and thus can carry less oxygen than that of mammals.

Respiratory system. The form of the lungs and the methods of irrigating them may also influence activity by affecting the efficiency of respiration. In snakes the lungs are simple saclike structures having small pockets, or alveoli, in the walls. In the lungs of many lizards and turtles and of all crocodilians the surface area is increased by the development of partitions that, in turn, have alveoli.

Because exchange of respiratory gases takes place across surfaces, an increase of the ratio of surface area to volume leads to an increase in respiratory efficiency. In this regard, the lungs of snakes are not so effective as those of crocodilians. The elaboration of the internal surface of lungs in reptiles is simple, however, compared with that reached by mammalian lungs with their enormous number of very fine alveoli.

Most reptiles breathe by changing the volume of the body cavity. By contractions of the muscles moving the ribs, the volume of the body cavity is increased, creating a negative pressure, which is restored to atmospheric level by air rushing into the lungs. By contraction of body muscles, the volume of the body cavity is reduced, forcing air out of the lungs.

This system applies to all modern reptiles except turtles, which, because of the fusion of the ribs with the rigid shell, are unable to breathe by this means; they do use the same mechanical principle of changing pressure in the body cavity, however. Contraction of two flank muscles enlarges the body cavity, causing inspiration. Contraction of two other muscles, coincident with relaxation of the first two, forces the viscera upward against the lungs, causing exhalation.

The rate of respiration, like so many physiological activities of reptiles, is highly variable, depending in part upon the temperature and in part upon the emotional state of the animal.

Digestive and urogenital systems. The digestive system of modern reptiles is similar in general plan to that of all higher vertebrates. It includes the mouth and its salivary glands, esophagus, stomach, and intestine, ending in a cloaca. Of the few specializations of the reptilian digestive system, the evolution of one pair of salivary glands into poison glands in the venomous snakes is the most remarkable.

During development the embryos of higher vertebrates (reptiles, birds, and mammals) use three separate sets of kidneys consecutively; these are arranged in longitudinal sequence in the body cavity. The first set, the pronephroi, are vestigial organs left over from the evolutionary past that soon degenerate and disappear without having had any function. The second set, the mesonephroi, are the functional kidneys of adult amphibians, but their only contribution to the lives of reptiles is in providing the duct (the wolffian duct) that forms a connection between the testis and the cloaca. The operational kidneys of reptiles, birds, and mammals are the last set, the metanephroi, which have separate ducts to the cloaca. The principal function of the kidney is the removal of nitrogenous wastes resulting from the oxidation of proteins. Vertebrates eliminate three kinds of nitrogenous wastes: ammonia, urea, and uric acid. Ammonia and urea are highly soluble in water; uric acid is not. Ammonia is highly poisonous, urea slightly so, and uric acid not at all. Among reptiles the form taken by the nitrogenous wastes is closely related to the habits and habitat of the animal. Aquatic reptiles tend to excrete a large proportion of these wastes as ammonia in solution. This method, involving a great loss of body water, is no problem for an alligator, which eliminates between 40 and 75 percent of its nitrogenous wastes as ammonia. Terrestrial reptiles, such as most snakes and lizards, which must conserve body water, convert their nitrogenous wastes to insoluble, harmless uric acid, which forms a more or less solid mass in the cloaca. In snakes and lizards these wastes are eliminated from the cloaca together with wastes from the digestive system.

Prior to the evolution of the metanephric kidney, the products of the male gonad, the testis, travelled through the same duct with the nitrogenous wastes from the kidney. But with the appearance of the metanephros, the two systems became separated. The female reproductive system never shared a common tube with the kidney. Oviducts in all female vertebrates arise as separate tubes with openings usually near, but not connected to, the ovaries. The oviducts, like the wolffian ducts of the testes, open to the cloaca. Both ovaries and testes lie in the body cavity near the kidneys.

With the evolution of the reptilian egg, internal fertiliza-

Discharge routes for eggs and sperm

Oxygen capacity of reptile blood

tion became necessary. The males of all modern reptiles, with the exception of the tuatara, have copulatory organs. The structures vary from group to group, but all include erectile tissue as an important element of the operating mechanism, and all are protruded through the male's cloaca into that of the female during copulation. Unlike the penis of turtles and crocodilians, the copulatory organ of lizards and snakes is paired, each unit being called a hemipenis. The hemipenes of lizards and snakes are elongated tubular structures lying in the tail. The penis of a crocodile or turtle is protruded through the cloacal opening wholly by means of a filling of blood space (sinuses) in the penis; protrusion of a lizard's or snake's hemipenis, however, is begun by a pair of propulsor muscles. Completion of the erection is brought about by blood filling the sinuses in the erectile tissue. Only one hemipenis is inserted into a female, but which one is a matter of chance. Unlike the penis of mammals, the copulatory organs of reptiles do not transport sperm through a tube. The ducts from the testes, as already mentioned, empty into the cloaca, and the sperm flow along a groove on the surface of the penis or hemipenis.

Sense organs. *Sight.* In general construction the eyes of reptiles are like those of other vertebrates. Accommodation for near vision in all living reptiles except snakes is accomplished by pressure being exerted on the lens by the surrounding muscular ring (ciliary body), which thus makes the lens more spherical. In snakes the same end is achieved by the lens being brought forward under pressure built up on the vitreous humour by contractions of muscles at the base of the iris. The pupil shape varies remarkably among living reptiles, from the round opening characteristic of all turtles and many diurnal lizards and snakes to the vertical slit of crocodilians and nocturnal snakes and the horizontal slits of a few tree snakes. Undoubtedly the most bizarre pupil shape is that of some geckos, in which the pupil contracts to form a series of pinholes, one above the other. The lower eyelid has the greater range of movement in most reptiles. In crocodilians the upper lid is more mobile. Snakes have no movable eyelids, their eyes being covered by a fixed transparent scale. The tuatara and all crocodilians have a third eyelid, the nictitating membrane, a transparent sheet that moves sideways across the eye from the inner corner, cleansing and moistening the cornea without shutting out the light.

Visual
acuity

Visual acuity varies greatly among living reptiles, being poorest in the burrowing lizards and snakes (which often have very small eyes) and greatest in active diurnal species (which usually have large eyes). Judging by the size of the skull opening in which the eye is situated, similar variation existed among the extinct reptiles. Those that hunted active prey (e.g., the ichthyosaurs) had large eyes and presumably excellent vision; many herbivorous types (e.g., the horned dinosaur *Triceratops*) had relatively small eyes and weak vision. Colour vision has been demonstrated in few living reptiles.

Hearing. The power of hearing is variously developed among living reptiles. Crocodilians and most lizards hear reasonably well. Snakes and turtles are sensitive to low-frequency vibrations, thus they "hear" mostly earth-borne, rather than aerial, sound waves. The auditory apparatus in reptiles typically consists of a tympanum, a thin membrane located at the rear of the head; a small bone, the stapes, running between the tympanum and the skull in the tympanic cavity (the middle ear); the inner ear; and a eustachian tube connecting the middle ear with the mouth cavity. In reptiles that can hear, the tympanum vibrates in response to sound waves and transmits the vibrations to the stapes. The inner end of the stapes abuts against a small opening (the foramen ovale) to the cavity in the skull containing the inner ear. The inner ear consists of a series of hollow interconnected parts: the semicircular canals; the ovoidal or spheroidal chambers called the utricle and sacculus; and the lagena, a small outgrowth of the sacculus. The tubes of the inner ear, suspended in a fluid called perilymph, contain another fluid, the endolymph. When the stapes is set in motion by the tympanum, it develops vibrations in the fluid of the inner ear; these vibrations activate cells in the lagena, the seat of the sense

of hearing. The semicircular canals are concerned with equilibrium.

Most lizards can hear; details of the acuity of hearing, however, are largely unknown. The majority have a tympanum, tympanic cavity, and eustachian tube. The tympanum, usually exposed at the surface of the head or at the end of a short open tube, may be covered by scales or may be absent. In general the last two conditions are characteristic of lizards that lead a more or less completely subterranean life and presumably do not hear airborne sounds. The middle ear of these burrowers is usually degenerate as well, often lacking the tympanic cavity and eustachian tube.

Snakes have neither tympanum nor eustachian tube, and the stapes is attached to the quadrate bone on which the lower jaw swings. Snakes are obviously more sensitive to vibrations in the ground than to airborne sounds. A loud sound above a snake does not elicit any response provided the object making the sound does not move or, if it does, the movements are not seen by the snake. On the other hand, the same snake will raise its head slightly and flick its tongue in and out rapidly if the ground behind it is tapped or scratched. Snakes undoubtedly "hear" these vibrations by means of bone conduction. Sound waves travel more rapidly and strongly in solids than in the air and are probably transmitted first to the inner ear of snakes through the lower jaw, which is normally touching the ground, thence to the quadrate bone, and finally to the stapes. Burrowing lizards presumably hear ground vibrations in the same way.

Crocodilians, all of which have an external ear consisting of a short tube closed by a strong valvular flap and ending at the tympanum, have rather keen hearing. The American alligator (*Alligator mississippiensis*) can hear sounds within a range of 50 to 4,000 cycles per second. The hearing of crocodilians is involved not only in detection of prey and enemies but also in their social behaviour, for males roar or bellow either to threaten other males or to attract females.

Although turtles have well-developed middle ears and usually large tympana, their ability to hear airborne sounds is still an open question. Measurements of the impulses of the auditory nerve between the inner ear and the auditory centre of the brain show that the inner ear in several species of turtles is sensitive to airborne sounds in the range of 50 to 2,000 cycles per second, but this does not prove that the animals are aware of the sounds.

Chemoreception. Chemical-sensitive organs, used by many reptiles to find their prey, are located in the nose and in the roof of the mouth. Part of the lining of the nose consists of cells subserving the function of smell and corresponding to similar cells in other vertebrates. The second chemoreceptor is Jacobson's organ, originally an outpocketing of the nasal sac in amphibians and remaining so in the tuatara and crocodilians. It has been lost by turtles. Jacobson's organ is best developed in lizards and snakes, in which its connection with the nasal cavity has been closed and is replaced by an opening into the mouth. The nerve connecting Jacobson's organ to the brain is a branch of the olfactory nerve.

Jacobson's
organ

The use of Jacobson's organ is most obvious in snakes. If a strong odour or vibration stimulates a snake, its tongue is flicked in and out rapidly. With each retraction the forked tip touches the opening of Jacobson's organ in the roof of the mouth, transmitting any chemical fragments adhering to the tongue. In effect, Jacobson's organ is a supplement to taste and is a short-range chemical receptor, as contrasted with the long-range testing of the true sense of smell located in the nasal tube.

Some snakes (notably the large vipers) and lizards (especially skinks and burrowing species of other families) rely upon the olfactory tissue and Jacobson's organ to locate food, almost to the exclusion of other senses. Other reptiles, such as certain diurnal lizards and crocodilians, appear not to use scent in searching for prey, though they may use their sense of smell for locating a mate.

Some snakes, notably pit vipers, boas, and pythons, have special heat-sensitive organs on their heads as part of their food-detecting apparatus. Just below and behind the nos-

tril of a pit viper is the pit that gives the group its common name. The lip scales of many pythons and boas have depressions (labial pits) that are analogous to the viper's pit. The labial pits of pythons and boas are lined with skin thinner than that covering the rest of the head and are supplied with dense networks of blood capillaries and nerve fibres. The facial pit of the viper is relatively deeper than the boa's labial pits and consists of two chambers separated by a thin membrane bearing a rich supply of fine blood vessels and nerves. In experiments using warm and cold covered electric light bulbs, pit vipers and pitted boas have been shown to detect temperature differences of less than 0.6° C (1.1° F).

Since many pit vipers, pythons, and boas are nocturnal and feed largely on mammals and birds, the facial sense organs enable them to direct their strikes accurately in the dark, once their warm-blooded prey arrives within range. The approach of the prey to that point is probably detected by the chemical receptors—either the nose, Jacobson's organ, or both.

Thermal relationships. Reptiles are often described as being cold-blooded, which is not always true. Their body temperatures are not always low, but they have no internal mechanism for regulating body temperature and thus approximate closely the temperature of their surroundings. This condition is termed poikilothermy. Mammals and birds maintain their relatively high body temperatures at a fairly constant level by physiological means that are independent of the external environment, a condition called homoiothermy. When the body temperature of a dog or a man falls below the normal range, he begins to shiver, blood vessels in the skin contract, muscular activity generates heat, and the contraction of the superficial blood vessels, by reducing the volume of blood flow at the surface, reduces heat loss by radiation. By contrast, a reptile, when its body temperature falls below the optimum, must move to some portion of the environment having a higher temperature; in less than optimal temperatures, its activity drops, its movements become sluggish, its heartbeat slows, and its rate of breathing drops. In short, it becomes incapable of the normal activities required for growth, reproduction, and survival.

Mammals and birds have some physiological means of cooling their bodies (e.g., panting and sweating, expansion of superficial blood vessels), but a reptile must ordinarily move away from a spot in which the temperature is too high or it will perish very quickly. Some reptiles also pant, but most of their temperature accommodations are behavioral (e.g., orienting to sun or wind, raising body from the ground).

Each group of reptiles has its own characteristic thermal range. One genus of lizards, for example, may require temperatures of 29°–32° C (84°–90° F) for maximum efficiency, and another may require 24°–27° C (75°–81° F). As a result of such physiological differences, lizards of the two groups will be active at different times of the day or occupy slightly different habitats.

In general the normal activity temperatures of reptiles are lower than those of most mammals; however, a few sun-loving (heliothermic) lizards (e.g., the greater earless lizard, *Holbrookia texana*, of southwestern United States) have average activity temperatures above 38° C (100° F), several degrees higher than the average human body temperature. Such high temperatures are exceptional, and the majority of lizards have normal activity temperatures in the 27°–35° C (81°–95° F) range.

Evolution and paleontology

Historical development. Reptiles occupy an evolutionary position between amphibians, on the one hand, and the birds and mammals on the other, the last two classes having evolved from reptilian ancestors. Reptiles first appear in the fossil record of the Carboniferous Period, more than 280,000,000 years ago. By the Triassic, about 50,000,000 years later, they began to dominate the terrestrial life of the world and continued that dominance through the Mesozoic Era (65,000,000–225,000,000 years ago). Reptiles succeeded in adapting to deserts, swamps,

Range of body temperatures

Figure 4: Family tree of the reptiles.

forests, grasslands, rivers, lakes, and even the air and the seas. Coincident with the rise of mammals at the end of the Mesozoic, most reptilian groups became extinct.

The big evolutionary step made by reptiles was the final emancipation from life in water, for, until that step was taken, vertebrates could not exploit all of the Earth's surface. That breakthrough required two basic changes, the first of which took place in the skin. Modern amphibians have naked skins that lack horny scales, hair, and other protective devices. One small amphibian group, the caecilians, has small fishlike scales embedded in the skin; similar scales occurred in certain extinct amphibians. Because of their thinness and position, such amphibian scales are no protection against desiccation, one of the principal hazards of life for all animals, vertebrate and invertebrate. This susceptibility to drying out forces amphibians to remain in water or in very humid places, thus limiting their exploitation of the terrestrial environment. Reptiles evolved a different type of scale consisting of keratin (or horn) deposited in the outermost layer of the skin. This type of scale was in a position and of a thickness to prevent desiccation.

The second basic change made by the reptiles was the development of the amniote egg. This development expanded the possibilities of exploiting terrestrial environments. The egg could be laid under rocks or logs, in holes in the ground, in deserts or forests—in fact, almost anywhere except in water.

The development of the reptilian egg had several other consequences. An egg that is enclosed by a shell must be fertilized before that shell is deposited, thus necessitating internal fertilization. The evolution of a land egg also increased the efficiency of the life cycle of terrestrial vertebrates. An amphibian, hatching from an aquatic egg, must develop and grow in water in a larval form, the tadpole. The history of a reptile, on the other hand, is one of development and growth of adult structures adapted for a terrestrial life. It need not develop gills or a lateral line system (series of sense organs), which are needed by the aquatic tadpole and which must be resorbed and reworked into other structures. This important change in the type of development was made possible by a great increase in the amount of yolk in the reptilian egg.

The large amount of yolk also permitted the lengthening

Consequences of amniote egg

Figure 5: Body plans of extinct reptiles.

of the embryonic period, which in turn allowed the development of all structures that are necessary for successful existence on land. When a reptile hatches, it is ready to carry out all of the activities of the adult (with the exception of reproduction), and in the same environment and manner.

After reptiles acquired scaly protection for their skin and an egg that did not have to be laid in water, they were free to move over most of the Earth's surface. That freedom set the stage for the evolution of the many varied types of reptiles and, ultimately, for the evolution of birds and mammals.

Fossil distribution. What is known of the fossil record of reptiles shows that most of the major groups, or orders, were worldwide or nearly so at some time in their individual histories. Few orders are known from South America and Australia; the absence of most major groups from these areas more likely is explained on the basis of lack of preservation or lack of discovery of fossil beds than on the basis of a genuine absence of the animals throughout such a long interval as the Mesozoic. In the following discussion the names of present-day continents are used, though it should be understood that continental outlines in the past did not always coincide with those of today.

Few orders of reptiles are known from Paleozoic times—i.e., Carboniferous (280,000,000–345,000,000 years ago) and Permian (225,000,000–280,000,000 years ago). The stem reptiles, the *Cotylosauria*, have been found in Carboniferous deposits of eastern and western North America and western Europe and in Permian beds of the Soviet Union and Africa. Presumably they also lived in Asia during this interval of more than 100,000,000 years, but their remains have yet to be found there. In the same period the *Pelycosauria* lived in North America and Europe, where their fossils are well known, and possibly in Africa and

Asia. The related mammal-like *Therapsida* and perhaps other forms were fossilized in Africa and Europe. The probable ancestors of turtles appeared in Africa, and the first diapsids (reptiles having two-arched temporal structures) appeared in Africa and Europe in the Permian.

By the Triassic (190,000,000–225,000,000 years ago), the earliest portion of the Mesozoic, the mammal-like reptiles had spread to all of the continents except Australia. Turtles were still in Africa and had spread at least as far as Europe. The *Ichthyosauria* were living in seas covering what is now western North America and western Europe and may have been much more widely distributed, considering their oceanic habitat. North America at that time was also the home of primitive diapsids (*Thecodontia*), *phytosaur*s (suborder *Phytosauria*), and the earliest dinosaurs (*Saurischia*) and crocodiles. Besides the mammal-like therapsids, Eurasia and Africa in the Triassic had *phytosaur*s, the first *Rhynchocephalia*, and the early dinosaurs. The major groups of reptiles, therefore, were essentially worldwide in distribution by the Triassic.

The giant dinosaurs began their efflorescence in the Jurassic (136,000,000–190,000,000 years ago). The big carnivorous types, such as *Allosaurus*, roamed the landscapes of the major continents, presumably preying on even larger herbivorous dinosaurs (*Apatosaurus*, *Diplodocus*, etc.), whose remains have been found in North America, Europe, Africa, and Australia. Marine *ichthyosaur*s and

Figure 6: Body plans of extinct reptiles.

plesiosaurs (order Sauropterygia) still swam in the shallow seas of both hemispheres. The ornithischian dinosaurs (Ornithischia), the ancestors of the duckbilled and horned dinosaurs, became widely distributed in the Jurassic. One group, the armoured stegosaurians (suborder Stegosauria), left fossils in North America, Europe, and Africa. The flying reptiles (Pterosauria) also made their appearance at least in Africa and Europe during the Jurassic.

The culmination of dinosaur evolution occurred in the Cretaceous 65,000,000–136,000,000 years ago, when every part of the world had herbivorous ornithischian dinosaurs: the ankylosaurs (suborder Ankylosauria), medium-sized dinosaurs armoured with heavy plates and large spines, ranging from South America to Africa; the duck-billed dinosaurs (suborder Ornithomimidae), ranging from North America to Africa; and the horned dinosaurs (suborder Ceratopsia) in North America and Asia. Everywhere they were preyed upon by the big carnivorous types, which culminated in North America in the gigantic carnivore *Tyrannosaurus*. The skies over North America, Africa, and Europe (and probably Asia and South America as well) were the province of the flying reptiles (Pterosauria). There were also inconspicuous groups that later inherited the reptilian world. Lizards (suborder Sauria) appeared in most continents, and snakes (suborder Serpentes) appeared in some places. Birds, having splintered off from reptilian ancestors in the Jurassic, became more numerous in the Cretaceous; mammals, which ultimately replaced most of the reptiles, were represented on most continents by small creatures.

Through all this evolutionary activity, the conservative turtles continued their plodding evolutionary pace, changing but little, yet lasting through all. (Ed.)

Classification

Distinguishing taxonomic features. The major reptile groups are distinguished on the basis of vertebral and skull features, particularly the number and positions of the temporal fenestrae (*i.e.*, large openings in the temporal bone). Beyond these, the pelvic structure and that of the teeth and

From *The Procession of Life* by Alfred S. Romer (1968); Universe Books, New York, and Weidenfeld & Nicolson Ltd.

Figure 7: The types of dinosaur pelvis.

limbs are important. Any extraordinary structural development (*e.g.*, the wings of pterosaurs, the shell of turtles) is also a major factor in the system of classification. In recent reptiles (four out of some 17 orders), the structure of the heart, the male secondary sex organs, the extent and kind of dermal armour, and the structure of other soft organs are used. Discoveries in serology (the study of blood serum) and karyology (the study of chromosomes) have little effect, as yet, on the systems of classification.

Annotated classification. The following classification of the reptiles is based on that of A.S. Romer (1956, 1966), the American vertebrate paleontologist, as later modified by himself (1968) and in minor respects by E.H. Colbert (1965), B.W. Halstead (1969), and H.G. Dowling (1971). No single system of reptile classification is acceptable to all herpetologists, and widely differing views are held by various authorities. Considerable change in the recogni-

tion and content of both major and minor categories is to be expected. Groups marked with a dagger (†) are extinct and known only from fossils.

CLASS REPTILIA

Air-breathing, vertebrate animals without hair or feathers, the body usually covered with infolded epidermal scales. The occipital condyle (a protuberance where the skull attaches to the 1st vertebra) is single (except in transitional forms such as Therapsida), and representatives with well-developed limbs have 2 or more sacral vertebrae. The single auditory bone, the columella, is equivalent to the mammalian stapes. The lower jaw is made up of several bones and connects to the braincase by way of the quadrate bone and often by way of the supratemporal, the squamosal, or both. The systemic arch (part of the aorta) is paired; the respiratory and systemic portions of the circulatory system are incompletely separated. The red blood cells contain nuclei. Reproduction typically is by leathery-shelled or calcareous-shelled eggs with specialized membranes (chorion and amnion) that help to protect the embryo. In some lizards and snakes and in some extinct reptiles (*e.g.*, ichthyosaurs) the eggs are retained in the oviducts of the mother, sometimes with a placental connection, and the young are born alive. There are about 6,000 living species.

Subclass Anapsida

Pennsylvanian to present. Skull typically without temporal openings.

†Order Cotylosauria (cotylosaurs)

Lower Pennsylvanian (300,000,000–325,000,000 years ago) to Upper Triassic (190,000,000–210,000,000 years ago). Vertebrae amphicoelous (*i.e.*, concave at both ends) with small intercentra (crescentic elements between vertebrae); neural arches (the portion of the vertebra that encloses the nerve cord from above) convex. Skull with large toothed flange on pterygoid (a bone of the palate); a lateral temporal fenestra (between jugal and squamosal) in some advanced forms. Mostly small and lizard-like.

†Order Mesosauria (mesosaurs)

Upper Pennsylvanian (280,000,000–300,000,000 years ago) or Lower Permian (250,000,000–280,000,000 years ago) of South Africa and South America. A small fish-eating aquatic reptile with cotylosaur-like vertebrae. The temporal region of the skull is poorly known, but there may have been a lateral fenestra. Slender, long-jawed reptiles 40–90 cm (16–35 in.) long.

Order Chelonina (or Testudines; turtles)

Upper (possibly Middle) Triassic to present. Skull without pineal (on the midline of the “forehead”) or temporal fenestrae, though the temporal region may be emarginated, or indented. Jaws toothless (though there were palatine teeth in some extinct forms), with a horny beak. A shell (dorsal carapace and ventral plastron) covers the body and encloses the pectoral and pelvic girdles. Most modern turtles have shells less than 60 cm (24 in.) long, but oceanic forms have larger ones (2.7 m; 8.9 ft), and those of some extinct turtles exceeded 3.6 m (11.8 ft) in length.

Subclass Lepidosauria (lepidosaurians)

Upper Permian (225,000,000–250,000,000 years ago) to present. Primitive forms had 2 openings in the temporal region of the skull; most of the descendants have lost the lower (jugal-quadratojugal) temporal arch. The earliest known forms already had a jaw that was shortened. Usually a pineal eye (degenerate, median eyelike structure), no trend toward bipedalism. Ribs single-headed in advanced forms.

†Order Eosuchia (eosuchians)

Upper Permian to Eocene (38,000,000–54,000,000 years ago). Primitive lizard-like reptiles with 2 temporal arches and without a beaked snout.

Order Rhynchocephalia (beaked reptiles)

Lower Triassic to present. Scaled reptiles with 2 temporal arches. The premaxillary overhangs the lower jaw as a beak; the teeth are acrodont (*i.e.*, attached to the edge of the jaw rather than inserted in sockets). The vertebrae are amphicoelous, and the ribs are single-headed. Mostly lizard-like forms 30–90 cm (12–35 in.) long; one group (rhynchosaurs) attained lengths of up to 180 cm (71 in.). One living species.

Order Squamata (scaly reptiles)

Lizards, snakes, and amphisbaenians. Upper Triassic to present. The quadrate is freed by loss of the lower (jugal-quadratojugal) arch and reduction of the squamosal to allow some movement at both ends. Vertebrae procoelous (*i.e.*, with the centre part concave on the anterior side, convex on the posterior side) except in a few geckos (Sauria), in which they are amphicoelous. Living species possess unique paired copulatory structure (hemipenes).

Suborder Sauria (lizards). Upper Triassic to present. Most

generalized suborder; most species with well-developed limbs, an external ear opening, movable eyelids, or some combination of these structures. The skull typically has a pineal opening, and epipterygoid, lacrimal, and jugal bones. About 3,000 living species.

Suborder Amphisbaenia (amphisbaenians). Eocene to present. Highly specialized, limbless, burrowing reptiles with the eyes hidden under the skin, no pineal opening, and the body scales fused into annuli, or rings. The skull is solidly constructed as a burrowing wedge. About 140 living species.

Suborder Serpentes (snakes). Upper Cretaceous (65,000,000–100,000,000 years ago) to present. A highly specialized group, without pectoral limbs or girdle, pelvic limbs rudimentary when present. Without external ear or movable eyelids. Upper temporal arch (postorbital–squamosal) absent, leaving quadrate movable at both ends. No pineal opening; no epipterygoid, lacrimal, or jugal bones. About 2,500 living species.

Subclass Archosauria (ruling reptiles)

Upper Permian to present. Reptiles with 2 temporal openings (diapsid) and a tendency toward bipedalism. Most have long hindlegs and short forelimbs. Typically without a pineal opening in the skull, but with an antorbital fenestra and one on the outer surface of the lower jaw. Ribs typically 2-headed, at least anteriorly. Ischium and pubis (bones of pelvis) elongated. Teeth in deep sockets (thecodont). Most with some armour.

†*Order Thecodontia* (primitive archosaurs)

Upper Permian to Upper Triassic. Lightly built bipedal or more heavily armoured reptiles, some (phytosaur) crocodile-like and presumably amphibious, but with nostrils far back on the snout. Most had at least 2 rows of bony plates along the spine.

Order Crocodylia (crocodilians)

Upper Triassic to present. Aquatic or amphibious reptiles, rather generalized in body form, but with a flattened skull, the nostrils on the tip of the snout, and a well-developed secondary palate. Typically, the pubis is excluded from the acetabulum, or hip socket, and the 5th toe is reduced to a stump; 21 living species.

†*Order Saurischia* (carnivorous dinosaurs and giant herbivorous dinosaurs)

Middle Triassic (200,000,000 years ago) to Upper Cretaceous. Pelvis triradiate (*i.e.*, 3-branched). Some reduction in digits. Forelimbs usually distinctly shorter than hind. Three to 7 sacral vertebrae. Some herbivorous forms were more than 24 m (78 ft) long.

†*Order Ornithischia* (herbivorous dinosaurs)

Upper Triassic to Upper Cretaceous. Pelvis tetradriate (*i.e.*, 4-branched). Typically with a beaklike structure in the front part of the mouth and grinding teeth in the rear. Toes often with hooflike structures. Many with heavy armour and horns. Largest about 9 m (30 ft) long.

†*Order Pterosauria* (pterydactyls)

Lower Jurassic (150,000,000–190,000,000 years ago) to Upper Cretaceous. Highly specialized flying reptiles with hollow bones; 4th digit of the forelimb greatly elongated to support the flying membrane of the wing. Early forms toothed and with long tails; later forms tended to be larger and to have lost both teeth and tail.

†**Subclass Euryapsida** (plesiosaurs and relatives)

Lower Permian to Upper Cretaceous. Mainly aquatic reptiles with an upper temporal opening (between postorbital, squamosal, and parietal bones), and a broad plate of bone below.

†*Order Araeoscelidia* (primitive euryapsids)

Lower Permian to Upper Triassic. Primitive terrestrial reptiles with lizard-like proportions, some with a specialized cervical region.

†*Order Sauropterygia* (nothosaurs and plesiosaurs)

Middle Triassic to Upper Cretaceous. Aquatic reptiles with strongly developed ventral ribs, dorsally placed nostrils, and a highly modified palate (pterygoids and often palatines are joined in the midline). Limbs paddle-like in advanced forms.

†*Order Placodontia* (placodonts)

Lower to Upper Triassic. A side branch of euryapsids, apparently mollusk eaters. In some the body was armoured and turtle-like in form.

†*Order Ichthyosauria* (ichthyosaurs)

Middle Triassic to Upper Cretaceous. Highly aquatic reptiles with porpoise-like bodies, a dorsal fin, and a reversed-heterocercal tail (*i.e.*, with the lower lobe longer than the upper). Limbs paddle-like; snout often elongated and beaklike.

†**Subclass Synapsida** (mammal-like reptiles)

Lower Pennsylvanian to Middle Jurassic (160,000,000 years ago). A single lateral temporal opening with the postorbital and squamosal bones joining above it in primitive forms; the opening extends upward to the parietal in later forms. Pineal present. Teeth differentiated. Two coracoids in pectoral girdle.

†*Order Pelycosauria* (primitive synapsids, pelycosaurs)

Lower Pennsylvanian to Middle Permian (250,000,000 years ago), especially in Europe and North America. Neural arches higher and less swollen than in the contemporary cotylosaurs. Abdominal ribs present in most.

†*Order Therapsida* (advanced synapsids, therapsids)

Middle Permian to Middle Jurassic, mainly in South Africa. Temporal opening expanded in advanced forms, a secondary palate formed. Occipital condyle double and dentary bone much enlarged.

Critical appraisal. A natural classification of reptiles is more difficult than that of many animals because the main evolution of the group was during Mesozoic time; 13 of 17 recognized orders are extinct. The consequent reliance on osteological (bone) characters may have obscured some important evolutionary trends, and there is little agreement among herpetologists and paleontologists on reptile taxonomy. Even the major categories of reptile classification are still in dispute. Although the ideas of Watson, Colbert, and Romer have dominated the field, some authorities question most of the basic elements—from subclass to suborder—on which the framework of their classification depends. Halstead, for example, would discard the entire system of reptile subclasses and recognize a “superclass Reptilia” with seven reshuffled “classes.”

On the other hand, there is general agreement that the base reptilian stock is the Cotylosauria, which evolved from an amphibian labyrinthodont stock (the captorhinomorphs) at about the Mississippian–Pennsylvanian transition. It is also quite clear that the cotylosaurs early divided into two lines, one of which (the pelycosaurs) represented the stock that gave rise to the mammals. Another branch led to all of the other reptiles, and, later, to the birds as well. Thus, most of the questions of reptilian evolution and classification deal with inter-reptilian relations, rather than with their relationships with other animals. (H.G.Do.)

MAJOR REPTILIAN GROUPS

The remainder of this article consists of a review of the major living orders and suborders of the class Reptilia, arranged in accordance with the *Annotated classification* above. Extinct groups (designated in the *Annotated classification* by a dagger [†]) are treated in the following sections under the headings *Evolution* or *Paleontology*; additional information about the origin and evolution of the reptiles is contained in the *Macropædia* article GEOCHRONOLOGY: *Fossil record*.

Chelonia (turtles)

Turtles are members of the Chelonia, an ancient order of reptiles chiefly characterized by a shell that encloses the

vital organs of the body and more or less protects the head and limbs. Although there has been much confusion over the scientific as well as the common name of the group, most scientists now accept the term Chelonia rather than Testudines or Testudinata. Two common names are in wide use: “tortoise” and “turtle.” “Tortoise” is applied in the British Isles to all members of the group except the few marine species, all of which have paddle-shaped limbs. “Turtle” has long been much more broadly applied in the United States, with the addition of “terrapin” for some edible species. Usage both in the British Isles and in the United States has left the group without a general name comparable to “bird” or “mammal.” The American Society of Ichthyologists and Herpetologists standardized

the common names of the reptiles found in the United States, assigning "turtle" to all of those with a shell. The name "tortoise" is employed secondarily for the slow-moving terrestrial species, primarily those of the genera *Testudo* and *Gopherus*.

NATURAL HISTORY

Most turtles prefer a varied diet. Fibrous parts of plants are avoided because the jaws are not sharp enough to cut well and are entirely incapable of grinding. Small invertebrates, such as worms, snails, slugs, insects, thin-shelled bivalves and crayfishes and other crustaceans make up the bulk of the animal food in the turtle diet. Large aquatic turtles are able to catch fish and occasionally a few birds and small mammals.

Turtles have been toothless for more than 150,000,000 years, but in some modern types the moderately sharp

and jagged edges of the horny jaws function as teeth. Food is chewed, the claws of the forelimbs often assisting in manipulation, until it is reduced to fragments that can be swallowed.

A few turtles have special ways of securing prey. The gigantic alligator snapping turtle (*Macrochelys temminckii*) of the southern United States has a wormlike lure on the floor of the mouth with which it entices prey into its open jaws. The grotesque matamata, or fringed turtle (*Chelys fimbriata*), of South America has, on the neck and chin, soft projections with which, apparently, it detects the presence of prey by water movements. The floor of the large throat is quickly lowered as the head thrusts forward, the mouth agape. Water rushing into the mouth takes the unwary prey with it.

Turtles, like other reptiles, can survive long fasts, being able to live on weekly or even monthly feedings; however,

Food
habits

Drawing by M. Moran based on (all except *Sternotherus* and *Malaclemys*) J.Z. Young, *The Life of Vertebrates*, 2nd ed. (1962), The Clarendon Press, Oxford

Figure 8: Representative chelonians.

when food is readily available, they may eat frequently and grow very fat. The rate of digestion varies with the temperature. In the wild, they probably maintain a relatively constant temperature by seeking suitable surroundings, which may require constant activity. Turtles drink readily, and some store water in cloacal bladders, an ability that allows them to survive long droughts.

Copulation is usually preceded by a courtship that is highly characteristic for a given species or related group of species. The male's part in the mating display may include various types of head-waving, antics such as lunging at the female while roaring, or, in some aquatic species, gracefully swimming backward in front of her while stroking her lores (cheeks) with the excessively long nails of his forelimbs. The penis, paired in snakes and lizards, is single in turtles.

The most unusual aspect of turtle reproduction is the ability of females to lay fertile eggs for years after a single mating; among higher animals the rule that copulation must precede each pregnancy has few exceptions. In the diamondback terrapin (*Malaclemys*), fertile eggs may be laid for as many as four years after copulation. In a controlled experiment, ten old females were penned without the males they had been living with. During the first season after penning, they laid 124 eggs, all but one of which hatched; during the fourth season they deposited 108 eggs, only four of which hatched, however.

Egg-laying behaviour

Both terrestrial and aquatic turtles lay their eggs on land. The female usually selects a sunny place for the nest. She then digs a hole about as deep as her hindlimbs are long, into which she deposits round or elliptical, whitish eggs, the shells of which may be either flexible or brittle, but never pigmented like bird eggs. Several clutches may be laid in a season, though this is by no means the rule. A clutch may have more than 200 eggs (as in some sea turtles) or as few as one. The sea turtles and the largest tortoises lay eggs about five centimetres (two inches) in diameter, whereas nearly all of the other turtles lay much smaller ones.

Many nests are carefully constructed and hidden; a few are crudely made. The most spectacular laying is that of the sea turtles. The female green turtle (*Chelonia mydas*), for instance, crawls up the beach to a point above high tide and excavates a shallow depression, using all four flippers, then digs an egg pit in the bottom of the depression. The sand is removed by hind flippers, used alternately. During this delicate procedure the flipper must be curled and gently lowered to get its load, a feat often accomplished without loss of sand. A final flip sends the sand directly backward and clear of the hole. She then deposits the eggs, usually two at a time, and carefully covers them. Before leaving she obliterates the exact site by flinging sand about with the front flippers. The entire process consumes a few hours.

The period of incubation depends to an appreciable extent on the temperature. After the nest is completed, the mother appears to take no further interest in it, or, for that matter, in the hatchlings. As a result, the nest is often robbed of eggs, and freshly hatched turtles, whose shells are still soft, are frequently preyed on by large birds and small mammals. Again, in the case of the sea turtles, favoured beaches may become the centre of aggregation of countless animals, devouring the hatchlings as they scurry down the beach. Even in the water they are not safe, since predacious fishes lurk there.

Longevity

These shelled reptiles outlive all other vertebrates, including man, the longest-lived mammal. A marked eastern box turtle (*Terrapene carolina*) of the U.S. survived 138 years in the wild. There is good evidence of a turtle of another species having lived more than a century and a half. Turtles do not grow very slowly; maturity is reached in less than ten years, and growth in a large species may be more rapid than in man himself.

Age estimates are sometimes made by counting the growth rings on the horny shields of the shells, but this method is of little practical value, because the rings become indistinct with maturity. Size is sometimes untrustworthy as an indication of age.

Although scientific evidence is lacking, turtles appear to

depend heavily on their sense of smell. Their sight is good. They easily distinguish differences in intensity of light and it is known that they recognize at least four colours: blue, green, yellow, and red, especially the last, which often figures in the adornment of the turtles themselves. In experimental situations they learn to choose among these colours and among various complex black-and-white patterns to receive reward or avoid punishment. The receptors of the eye are all cones, which are responsible for the ability of colour recognition. Many semi-aquatic species can make alterations in curvature of the lens for vision under water, but only the eyes of sea turtles are fully adapted for such vision.

Turtles respond readily to vibrations of the substratum, but those of the air are another matter. Casual observations do not suffice to evaluate turtle sensitivity and response to aerial sounds, and even scientific workers have disagreed. Experiments reported in 1915 by an American indicated that turtles do hear, but this was contradicted in 1925 by a Japanese. A few years later a Soviet investigator concluded that turtles do hear, but his paper was published only in the U.S.S.R. and largely ignored elsewhere. It was not until 1966 that two Americans demonstrated that at least some turtles hear low-frequency airborne waves, ranging from about 20 to about 1,000 cycles per second. The corresponding figures for man are 20 to 20,000, a fact that may help to explain the difficulty of arriving at a suitable conclusion for the turtle.

Turtles seldom emit sounds, except when courting or mating; even then they do little more than grunt or roar. Exceptions are a few sea turtles that can give a loud cry under extreme provocation.

Experiments on the intelligence of turtles indicate that they learn readily; in some ways they are comparable to the laboratory rat. Persons with extensive experience with pets sometimes elicit from turtles a degree of intelligence usually credited only to mammals. To the casual observer, however, a turtle often appears to be very stupid, especially when it repeatedly climbs over a large object it could easily go around.

The turtle is proverbially one of the slowest animals, and there is some justification for this reputation, at least for certain land forms. It is odd that, in general, aquatic species move faster, even on land. The tortoises of the genus *Gopherus* have been clocked at rates of 0.21 to 0.48 kilometres (0.13 to 0.30 miles) per hour, whereas the rate on land of a normally aquatic cooter (*Pseudemys floridana*) has been recorded at 1.7 kph (1.07 mph) in spite of, or possibly because of, the fact that it was out of its element.

The marine green turtle (*Chelonia mydas*) has been known to swim 480 kilometres (300 miles) in 10 days; it must have travelled at an appreciable rate, since it scarcely could have swum steadily ahead without taking time to eat, sleep, or rest. Soft-shell turtles (Trionychidae) are able to move their limbs at a rate comparable to that in birds and mammals.

The sense of location is well developed; turtles released in an enclosure will usually pick out a resting place and spend much time in it. Many species have a "home area" to which they will return if they are taken a short distance away. The sea turtles (Cheloniidae) are exceptions to the general rule of living in a restricted area; some make long migratory journeys and mass migrations from breeding beach to feeding ground and back.

When a sea turtle hatches out high on a beach, it is faced with something of a problem; from its low eye-level the ocean probably is not visible. Considerable attention has been paid to its problem and the conclusion drawn that scanning of the horizon and landscape enables the turtle to pick out the proper direction, by moving away from the darker areas or by going toward the lighter ones. This method works both day and night.

ECONOMIC VALUE

Man has always relished turtles, and it is likely that almost every species has at one time or another satisfied the broad human appetite. The green turtle (*Chelonia mydas*), with its distribution extending around the world, no doubt has

Senses

Locomotion

supplemented the diet of peoples of more different cultures than has any other wild vertebrate. Tortoise populations of many oceanic islands have been decimated; it has been estimated that 10,000,000 land giants were taken from the Galápagos Islands as food supply for the early whaling ships. Turtle eggs are also prized as food. These are deposited in such abundance on certain beaches that harvesting them has become a national industry in Malaysia.

Just as turtle meat has long satisfied man's appetite, so has "tortoise shell" gratified his sense of beauty. Plastics have come to the rescue of the hawksbill turtle (*Eretmochelys*), chief source of the horny shields from which tortoise-shell ornaments are made.

FORM AND FUNCTION

The protective shell, to which the evolutionary success of turtles is largely attributed, is a casing of bone covered by horny shields. Plates of bone are fused with ribs, vertebrae, and elements of shoulder and hip girdles. There are many shell variations and modifications from family to family, some of them extreme. At its highest development, the shell is not only surprisingly strong but also completely protective. A box turtle (*Terrapene*) of North America, for example, can readily support a weight 200 times greater than its own; a man with a proportionate supporting power could bear up two large African elephants. The lower shell (plastron) can be closed so snugly against the upper (carapace) that a thin knife blade cannot be inserted between them. This, of course, means that the plastron of the box turtles has a hinge allowing it to move upward to fit into the carapace. Such a movable joint occurs here and there among turtles and is not as simple as it might at first seem. Since the horny shields of the surface do not ordinarily coincide with the bony plates below, the presence of a hinge calls for adjustment to bring about coincidence of the borders of certain shields and plates. Although the hinge is usually in the plastron, the carapace of the African genus *Kinixys* has the hinge, permitting it to move up and down to a limited extent.

The protection of the turtle shell was acquired by the development of structural peculiarities, two of which are especially worthy of mention. As a rule, the limb girdles of vertebrates lie outside the rib box; in turtles, however, they are partly within it, due to a fusion of the developing ribs with the growing shell, which carries the ribs to a position partially surrounding the limbs.

In man the ribs play an important part in the chest expansion, enabling him to breathe. The turtle's ribs are immovable, so the task of chest expansion has been transferred to abdominal muscles; two muscles enlarge the chest cavity for inspiration, and the others press the organs against the lungs to force the air out. Some aquatic species

have additional methods of breathing: the vascularized mucous membrane of the cloacal region or of the throat can function like the gill of a fish. Such accessories to ordinary respiration enable turtles to lie quietly submerged for hours or even days.

The vertebral column, with very little to support, underwent drastic modification. The trend in turtles, in contrast to that in most other reptiles, has been to reduce the number of vertebrae. The ability to retract the head into the shell is related to the retention of eight specialized vertebrae. The result is that the neck has almost as many vertebrae as does the central part of the column (between neck and tail). The manner in which the neck bends is of importance in classification (see below).

Turtles run the gamut in size. The Atlantic leatherback (*Dermochelys coriacea*), largest of living kinds, may weigh more than 680 kilograms (1,500 pounds) and measure 3.7 metres (12 feet) from the tip of one front flipper to that of the other. An extinct marine giant, *Archelon*, of the family Protostegidae, was probably much larger, and an extinct land turtle of Asia (*Colossochelys atlas*) had a shell 2.1 metres (seven feet) long. The largest living tortoises may weigh more than 225 kilograms (500 pounds).

At the opposite extreme, the adults of some species weigh less than a pound and have a shell less than five inches long. The shell length of most adult turtles falls between five and 15 inches.

ORIGIN AND EVOLUTION

The evolution of the turtle is one of the most remarkable in the history of vertebrates. Unfortunately, the origin of this highly successful order is obscured by the lack of early fossils, although turtles leave more and better fossil remains than do other vertebrates. By the middle of the Triassic Period (about 200,000,000 years ago) turtles were numerous and in possession of basic turtle characteristics. Teeth are lacking in all living turtles, but were present in a few fossils. The teeth of even the Triassic turtles were oddly placed, apparently having been confined to the palate. Intermediates between turtles and cotylosaurs, the primitive reptiles from which turtles probably sprang, are entirely lacking. The most likely link is a small, toothed reptile (*Eunotosaurus*) of the Permian Period of southern Africa. The skull roof of *Eunotosaurus* is not known, but the shoulder and pelvic girdles were overlapped by the ribs, possibly a beginning of the condition found in turtles.

Many turtles today live in marshes and swamps and it is likely that this way of life has been a common one throughout their history. A fairly large group has become terrestrial, but a stronger tendency has been in the opposite direction, toward aquatic life. The extreme development of aquatic types has been large marine species with limbs

turned into paddles. The shell may become modified and reduced as seen in the gigantic leatherback (*Dermochelys*), in which the horny shields are gone and the shell has become leathery.

While some reptiles flourished and vanished (as the dinosaurs), others persisted, some as once-successful groups and a few as initiators of expanding groups (snakes and lizards). The turtles, however, have plodded a stolid and steady course through evolutionary time, changing very little in basic structure.

CLASSIFICATION

Distinguishing taxonomic features. The suborders and superfamilies of the Chelonia are defined primarily on the basis of the completeness of the skull and degree of posterior emargination. The most obvious diagnostic feature separating the two modern suborders is the manner of folding the neck (vertical or horizontal) when the head is withdrawn. Family distinctions are based primarily on characters of the skull and shell.

Annotated classification. The classification presented here is adapted from A.S. Romer, 1956 and 1966. Three unimportant fossil families have been omitted from the first two suborders.

ORDER CHELONIA

Reptiles with temporal region of skull complete or emarginate, but without true fenestrae. 18 presacral vertebrae, typically 8 cervicals and 10 dorsals; 2nd to 8th dorsals fused to neural elements of carapace (when present). Shoulder girdle internal to ribs and shell. Clavicles and interclavicle incorporated in shell.

†Suborder Proganochelydia

Fossil only.

†Superfamily Proganochelyoidea

†*Family Proganochelyidae*. Skull solidly roofed, sculptured. 7 cervicals. Teeth present. Oldest and most primitive of true turtles. Found only in the Late Triassic of Europe. Presumably amphibious.

†Suborder Amphichelydia

Fossil only. Skull roof complete, rarely emarginate from behind. Little or no retraction of neck. Teeth absent. Suborder includes the more primitive turtles, which were almost entirely Mesozoic and lacked the distinctive features of the cryptodires and pleurodires.

†Superfamily Pleurosternoidea

Skull generally elongate, sculptured, or tuberculate; roof at times moderately emarginate. 8 cervicals. Chiefly amphibious but some marine.

†*Family Pleurosternidae*. Temporal region well roofed. Common aquatic chelonians of the Jurassic and Lower Cretaceous. Europe and North America. About 10 genera.

†*Family Plesiochelyidae*. Temporal roof completed by enlarged postorbital. Jurassic and Cretaceous. Europe and Asia. Ancestral to the following family. 2 genera.

†*Family Thalassemyidae*. Temporal region usually less roofed

than in foregoing families. Initial development, in the Upper Jurassic, of an important marine group; also Cretaceous. Europe and Asia.

†Superfamily Baenoidea

Skull short. Neck possibly a little retractile. Includes forms leading to cryptodires.

†*Family Baenidae*. Skull roof complete. Upper Cretaceous to Eocene. North America.

†*Family Meiolaniidae*. Skull roof complete and with protuberances. Upper Cretaceous to Pleistocene. South America and Australian region.

†*Family Eubaenidae*. Skull roof emarginate. Transitional to cryptodires. Upper Cretaceous. North America.

Suborder Cryptodira

Temporal region of skull frequently emarginate from behind; if completely roofed, probably secondarily so. Neck retracted in a vertical plane. Shell primitively complete, but elements lost or reduced in aquatic, especially marine, species. These are the dominant turtles of today.

Superfamily Testudinoidea

Temporal region usually reduced. Bony shell usually complete and always covered by horny shields.

Family Dermatemnydidae. Central American river turtle. Temporal region emarginate from behind. 1 Recent species in Central America and Mexico; others from Late Cretaceous and Early Tertiary of North America. Size medium; adult length to 25 cm (10 in.).

Family Chelydridae. Common and alligator snapping turtles. Head proportionately large, shell, especially plastron, reduced. Temporal region emarginate. Inhabit swamps, rivers, and shallow lakes of North and a little of South America. Aggressive but not dangerous to man. Miocene to Recent. Adult size: Common snapper 20–46 cm (8–18 in.), 5–30 kg (11–66 lb); alligator snapper 42–70 cm (16.5–27.5 in.), 18–100 kg (40–220 lb).

Family Kinosternidae. Mud and musk turtles. Plastron often reduced and in some, singly or doubly hinged. Some exude a disagreeable odour when handled. Pliocene to Recent. Aquatic. Widespread in New World temperate and tropical regions. 21 living species, adult length 7–20 cm (3–8 in.).

Family Testudinidae. Terrestrial turtles, or tortoises. Shell usually with high dome; hinged plastron in 1 species. Temperate and tropical regions of all continents except Australia; also on islands of eastern Africa and Galápagos Islands. Eocene to Recent. About 40 living species. Moderate to large size; adult length 20–100 cm (8–40 in.), weight 1–200 kg (2–440 lb).

Family Platysternidae. Big-headed turtle. Broad, flat plastron; large head. Inhabits moving streams in southeastern Asia. 1 species; adult length about 15 cm (6 in.).

Family Emydidae. This family contains most of the familiar turtles. Temporal region primitively and usually emarginate from behind; bony carapace and horny covering complete. Abundant in Northern Hemisphere; a few species in South America and Africa. Eocene to Recent. About 76 living species; adult length 7–22 cm (3–8.7 in.).

Superfamily Chelonoidea

Marine turtles. Temporal region well roofed. Limbs generally paddle-like.

†*Family Toxochelyidae*. Nasal bones small or absent (except in one genus). Upper Cretaceous to Eocene. North America and Europe.

†*Family Protostegidae*. Powerful beak, jaws with large crushing surfaces. Upper Cretaceous to Oligocene of North America and Europe. Some species very large, length up to 4 m (13 ft; *Archelon*).

Family Cheloniidae. Modern sea turtles. Secondary palate, formed by vomer and palatine bones. Distribution worldwide in warmer oceans. Fossils from Cretaceous of Europe, North America, Africa and Asia. 5 to 6 living species; adult length 60–210 cm (24–83 in.); weight 20–500 kg (44–1,100 lb). Most are economically important, for eggs and meat.

Superfamily Dermochelyoidea

Family Dermochelyidae. Leatherback turtle and fossil species. Shell of leatherback without horny plates but with prominent ridges of cornified skin down the back. Worldwide in warm seas. Eocene to Recent. Adult leatherback very large, length to 225 cm (88 in.), weight to 600 kg (1,320 lb).

Superfamily Carettochelyoidea

Family Carettochelyidae. New Guinea plateless turtle and fossil species. Upper Cretaceous to Recent; fossils from North America, Europe, and Asia.

Superfamily Trionychoidea

Family Trionychidae. Soft-shell turtles. Horny shields absent; considerable bony carapace supporting flexible leathery covering of the back. Temporal region widely open. Flat, round body; webs between toes. Nostrils in a projecting snout. Fossils from Cretaceous. Freshwater habitats on temperate and tropical parts of continents except South America and Australia. Adult length 5–60 cm (2–24 in.).

Suborder Pleurodira

Temporal roof may be emarginate from behind, and is invariably emarginate from below. Neck retracted in a horizontal plane.

Family Pelomedusidae. Side-necked turtles. Skull moderately emarginate behind, variably so below. Aquatic habitats in Africa, Madagascar, and South America. Fossils from Cretaceous onward, all continents except Australia. Adult shell length 20–75 cm (8–30 in.).

Family Chelydidae. Snake-necked turtles. Skull slightly emarginate behind, greatly from below. Head and neck may be half of total length. Fossils few, Pliocene to Recent. Present distribution: Australia and South America. Family includes all living land and freshwater turtles of Australia. Adult shell length 12–40 cm (5–16 in.).

†Suborder Eunotosauria

Known from a single partial specimen from Middle Permian of South Africa. 10 dorsal vertebrae known, 8 with expanded ribs. Incomplete carapace with dermal ossifications (in rows). Shoulder and pelvic girdles overlapped by ribs. Upper skull unknown; palate with marginal and palatal teeth.

†**Family Eunotosauridae.** Characters are as for the suborder.

Critical appraisal. This classification now has wide acceptance. The chief difference of opinion has been in regard to the modern soft-shell types such as the aquatic trionychid group and especially the marine leatherback (*Dermochelys*) with its highly atypical leathery shell. The leatherback has, in fact, been considered very primitive and consequently assigned to subordinal rank, rather than being placed among the cryptodires. There is no certainty that *Eunotosaurus* is ancestral to turtles, but the adaptations of its vertebrae and ribs suggest that it is on an evolutionary line leading toward the turtles. (C.H.P.)

Rhynchocephalia (tuatara)

The Rhynchocephalia constitute one of the four orders of living reptiles; the only surviving representative of the group is the tuatara, or sphenodon (*Sphenodon punctatus*). Structurally, the tuatara is not much different from related forms, also assigned to the order Rhynchocephalia, that may have appeared as early as the Lower Triassic Period (more than 200,000,000 years ago).

Until recently the tuatara lived on the two main islands of New Zealand. Today, it is found only on certain islets in Cook Strait between the main islands and on islets between East Cape and North Cape of the North Island of New Zealand.

NATURAL HISTORY

Male tuataras may attain a length of 60 centimetres (about 24 inches) and a weight of 1,000 grams (about 2.2 pounds). Females grow to about 50 centimetres (20 inches) and sometimes weigh as much as 500 grams (1.1 pounds). Eight to 15 eggs are laid in a nesting burrow covered by several centimetres of soil. The young emerge about 13 months later, in early summer to midsummer. Adult size is not reached for 50 to 60 years, and the animal may live to the age of 100. Sexual maturity is believed to occur after about 20 years.

During mating, the more prominent crest of the male becomes turgid and erect as he stalks the female, approaching her in a slow, jerky fashion. He then grips her over the shoulders with his forelimbs. Unlike the lizards, the tuatara does not use the jaw for grasping the female. The length of time between mating and egg laying is not known.

The mode of locomotion is primitive. The animal moves in a sprawling fashion, the belly leaving the ground only momentarily. The pattern of limb movement is unusual in that the forelimb contacts and leaves the ground before the hindlimb on the opposite side. As it moves, the body is thrown into marked lateral, or sideward, bends.

Male tuatara with white spines erected, a behaviour characteristic of the tuatara when excited or hunting.

W.H. Dawbin

Tuataras are essentially solitary, nocturnal, burrowing animals, seldom travelling more than a few metres from their burrows during the day. Feeding takes place mainly at night. The principal diet of the young is insects; adults eat, in addition to insects, snails, lizards, young seabird chicks, and eggs. They will drink water if it is available but can survive for months on water obtained from dew and solid food.

The islands inhabited by the tuatara have large numbers of ground insects, which are an important source of food. Bird burrows often serve as ready-made homes for the tuatara, but the animal is capable, from the time it hatches, of making its own burrow if none is already available. The burrow may be shared by a bird and a tuatara, as well as by the bird's chick or egg. (Occasionally the tuatara preys on the chick or adult sharing the burrow.) The largely nocturnal habits of the animal conceal it from many potential predators, but occasionally it is preyed upon by hawks, gulls, or kingfishers. Rats, introduced by man, are serious enemies of eggs and the young. The animal may be regarded as seriously threatened with extinction on islands where rats occur.

Natural
enemies

FORM AND FUNCTION

The tuatara has two pairs of well-developed limbs, a strong tail, and a scaly crest down the neck and back. The scales, which cover the entire animal, vary in size. The tuatara also has a bony arch, low on the skull behind the eye, that is not found in lizards. This arch is formed by the presence of two large openings (temporal fossae) in the region of the temple. It has been used as evidence that the tuatara is a survivor of the otherwise extinct order Rhynchocephalia and is not a lizard. The teeth of the tuatara are acrodont—i.e., attached to the rim of the jaw rather than inserted in sockets. The tuatara is also unique among reptiles in not possessing a male copulatory organ. As in birds, sperm transfer is effected during contact between the male and female cloacae.

The heartbeat and respiratory rate of the tuatara are relatively slow; oxygen consumption, accordingly, is low. Tuataras actively forage in temperatures as low as 6° C (43° F) and can briefly tolerate temperatures above 37° C (99° F). Tests indicate that the preferred temperature is about 22° C (72° F)—rather low for a reptile. The excretion of nitrogenous wastes, a by-product of the animal's metabolism, are in the form of uric-acid masses, or concretions. About 10 to 30 percent of this waste may occur as the substance urea in the urine; the urea concentration rises as the amount of protein increases in the food consumed.

EVOLUTION AND CLASSIFICATION

The tuatara has changed remarkably little in skeletal features since the Jurassic Period (136,000,000–190,000,000 years ago), when the closely related *Homoosaurus* occurred in Europe. There is some evidence that the line of rhynchocephalians began as early as the Lower Triassic Period. Most forms of that time were of moderate size and, except for one specialized family (Rhynchosauridae), they

Distribution

were never abundant. Fossils are unknown in any region during Tertiary times (2,500,000–65,000,000 years ago). Remains from the Pleistocene Epoch (10,000–2,500,000 years ago) in New Zealand are structurally identical with the living tuatara.

The order Rhynchocephalia belongs to the subclass Lepidosauria of the class Reptilia. Three families (Sphenodontidae, Rhynchosauridae, and Sappeosauridae) are assigned to the order; two families (Claraziidae and Pleurosauridae) are tentatively assigned.

In addition to the living species, *Sphenodon punctatus*, the family Sphenodontidae is represented by European fossils of three genera from the Upper Triassic (200,000–000 years ago); by Asian, European, and North American fossils of genera from the Upper Jurassic Period; and by a southern African fossil of a genus from the Lower Triassic.

The family Rhynchosauridae is represented by fossils of eight genera, some tentatively assigned. All are from the Triassic Period and occurred in Europe, South America, south Asia, southern Africa, and East Africa.

The family Sappeosauridae is represented by one genus from the Upper Jurassic Period in Europe. (W.H.D.)

Sauria (lizards)

Lizards (suborder Sauria) are familiar scaly-skinned reptiles, closely allied to snakes but usually distinguished by the possession of legs, movable eyelids, and external ear openings. Most of the 3,000 living species of lizards inhabit warm regions of the Earth, but some species of lizards are found nearly to the Arctic Circle in Eurasia and others to the southern tip of South America. The lizards are usually considered part of the reptilian order Squamata. The “worm lizards,” or amphisbaenians, which are included in this section for convenience of comparison with lizards, are placed in their own suborder, Amphisbaenia, by many modern taxonomists. (For a further discussion of this problem, see the *Annotated classification* in the first section of this article.)

Distribution

GENERAL FEATURES

Lizards are by far the most diverse group of modern reptiles in body shape and size. They range in total length from geckos of three centimetres (1.2 inches) to monitor lizards of three metres (10 feet), and in adult weight from less than a gram (0.04 ounce) to more than 150 kilograms

Figure 10: Variation in body form among lizards.

(A) Old World chameleon (*Chamaeleo*). (B) Flying lizard (*Draco*). (C) Wall lizard (*Lacerta*). (D) Basilisk (*Basiliscus*). (E) Horned lizard (*Phrynosoma*). (F) Gecko (*Gekko*). (G) Glass snake (*Ophisaurus*). (H) Worm lizard (*Amphisbaena*). (I) Gila monster (*Heloderma*). (J) Cylindrical skink (*Chalcides*).

(330 pounds). The popular conception of a lizard as a scampering reptile with head and body about 15 centimetres (six inches) long and a slender tail of about equal length may be applied accurately to only a small number of species. Representatives of several families are limbless, resembling snakes; others have elongate hind legs and can run bipedally. A variety of ornaments is found, including extensible throat fans, tail crests, horns or casques on the head, and spines and frills around the throat.

Lizards occupy diverse habitats: underground, on the surface, and in elevated vegetation. Some are slow-moving, relying on cryptic coloration for protection; others can run swiftly across desert sands. The mosasaurs, an extinct family, were strictly marine. Some were giants, attaining lengths of 10 metres (33 feet), with an elongate head, short neck, and long thin body and tail. One living lizard, the marine iguana of the Galápagos Islands, feeds on algae in the sea. No other extant species is marine, but several are partially aquatic, feeding on freshwater organisms.

Modern lizards do not play a major role in human ecology. Some large species (iguanas) are eaten, and others are used for leather goods. Predators, such as the tegu, can be pests around chicken farms, but the vast majority are primarily insectivorous or consume undesirable rodents. Small species such as geckos, which tend to live around houses, are often welcomed because of their efficiency in destroying insects; they may transmit *Salmonella* bacteria, however. In general though, lizards are not disease vectors.

Only two species, the Gila monster of the southwestern United States (*Heloderma*) and a close relative in Mexico, are venomous. They bite man only when provoked and fatalities are very rare. Unfortunately, diabolical powers attributed to lizards have made them objects of fear in many countries. Lizards are valued as subjects for biological research: the varied modes of reproduction and ability to regulate body temperatures are only two of many areas studied by comparative physiologists; the great abundance and easy observability of numerous species make them ideal subjects for ecologists and ethologists; the ability of some species to regenerate broken tails has led to their use by developmental biologists. In addition, because they are clean and easy to keep, lizards are quite popular as house pets.

NATURAL HISTORY

Life cycle. Most lizards reproduce by laying eggs. In some small species the number of eggs is rather uniform for each laying or clutch. For example, all anoles lay but a single egg at a time; many geckos lay one or two eggs (depending upon the species), and some skinks have fixed clutches of two eggs. A more general rule is that clutch size varies with size, age, and condition of the mother. A clutch of four to eight eggs may be considered typical, but large species such as iguanas may lay 50 or more eggs at one time. Lizard eggs are usually leathery shelled and porous and can expand by absorption of moisture as the embryos grow. An exception occurs in the majority of egg-laying geckos, whose eggs have shells that harden soon after deposition and then show no further change in size or shape.

Some lizards bear live young. In the family Scincidae this is true for about one-third of the species, many of which are tropical. In most other families that have live-bearing representatives, the species that are exposed to cold—either at high altitude or at extreme latitude—generally are the live bearers. For example, all New Zealand geckos have live young, yet all other geckos lay eggs. Live bearers are divided into two categories. Ovoviviparous forms essentially retain eggs in the oviduct with no definite shell laid down, whereas truly viviparous forms have a chorio-allantoic placenta. Whether there is an actual exchange of nutrients across this placenta, as in mammals, is currently under study.

Sex in lizards is genetically and rigidly determined; a hatchling normally has either only male or female reproductive structures. In representatives of at least three diverse families (Iguanidae, Teiidae, Pygopodidae), the males have dissimilar sex chromosomes. This is similar to the sex-chromosome system of most mammals but differs

from snakes, in which sex-chromosome differences, when present, are found in the female.

Most lizard populations are evenly divided between females and males. Deviations from this pattern are found in parthenogenetic (all female) species, in which the young are produced from unfertilized eggs. In the Caucasus all-female races of *Lacerta* and in the southwestern United States and parts of Mexico all-female species of whiptailed lizards (*Cnemidophorus*) have interesting parallels. They appear to live in areas ecologically marginal for representatives of their genera. In the case of *Cnemidophorus*, there is convincing evidence that parthenogenetic forms arose through hybridization between two bisexual species.

Parental care among lizards tends to be minimal following egg deposition. Many species dig holes in which the eggs are placed; others bury them under leaf litter or utilize a cranny in a tree or cave. Some species, however, notably the five-lined skink (*Eumeces fasciatus*) of the United States, remain with their eggs throughout incubation time (about six weeks), leaving only infrequently to feed. These skinks turn the eggs regularly and, if the eggs are experimentally scattered, will return them to the nest cavity. As soon as the young disperse, family ties are severed.

Certain lizards, particularly some geckos, are known to be communal egg-layers, many females depositing their eggs at the same site. Whether this is due to social interaction or simply to ideal site conditions has not been determined.

Juvenile lizards are essentially miniature adults; they do not go through any larval phase nor any stage of dependence upon adults. They often differ from the adult in colour or pattern and in certain body proportions. For example, heads of hatchling lizards of some species tend to be proportionally larger than those of adults. Certain ornamental structures, such as the throat fan of the male American chameleon (*Anolis*) or the horns of some true chameleons, develop as the lizards become sexually mature.

Some of the smaller lizards mature very quickly, and population turnover is essentially an annual event. The small, side-blotched lizards of the iguanid genus *Uta* of western North America have this type of population dynamics. The young hatch in July and reach sexual maturity that autumn. At this time males undergo spermatogenesis and mating takes place. Females accumulate large quantities of fat, which appears to be utilized in the production of eggs the following spring. Losses of 90 percent or more adults per year may come from predation, inclement weather, or other environmental variables. A single species living under a variety of environmental conditions may have very different population dynamics in different regions. For example, in areas with long winters there are periods of hibernation, coupled with greater longevity and slower population turnover.

Large lizards may take several years to reach sexual maturity. Unfortunately, there is little information on the dynamics of natural populations of most lizard species. In captivity many species are long-lived. There is a report of a male slowworm (*Anguis fragilis*) 46 years old mating with a female 20 years old. Gila monsters (*Heloderma*) have been kept in captivity for more than 25 years, and even some small geckos have been kept for as long as 20 years.

Ecology. The most important environmental variable to a lizard is almost certainly temperature. Like fish and amphibians, lizards are ectothermic ("cold-blooded"); they tend to assume the temperature of their surroundings. Yet all temperatures are not equally acceptable to lizards. Most species seek out relatively specific body temperatures, called "preferred temperatures," mostly ranging from 28° to 38° C (82°–100° F). Although metabolic energy is not utilized to control body temperature, considerable thermoregulation can be accomplished largely through behavioral means, if the lizard has a choice. Typically, a diurnal lizard will emerge early in the morning and will sun itself, orienting the body to maximize exposure to the sun, until the preferred temperature is approached. The ability to absorb heat from solar radiation may permit the lizard to warm itself well above air temperatures. For example, *Liolaemus multiformis*, a small iguanid that lives high in

Parthenogenesis

Population turnover

Temperature regulation

Importance to man

the Andes, has the ability to raise its body temperature to 35° C (95° F), while air temperatures are at 10° C (50° F) or lower.

The preferred body temperature plays a critical physiological role in the life of a lizard. It has been demonstrated in the laboratory that animals kept without the opportunity to achieve the preferred temperature may be unable to attain the normal reproductive condition or may become sterilized. There is also evidence that enzymes catalyze reactions most efficiently at or near the preferred body temperature.

A lizard living in the tropics often will find the immediate environmental temperatures within its preferred range. To be successful in other habitats, a species must be able either to function at less than optimal temperature or, at least, to have less time at the optimal temperature and spend more time attaining this temperature. Thus it is not surprising that diversity of lizard species decreases with increasing latitude or with high altitude within the tropics.

Water is less of a problem to lizards than is temperature. All reptiles excrete uric acid and hence do not need great amounts of liquid to get rid of nitrogenous wastes. Many lizards have salt glands for active excretion of mineral salts. Deserts, therefore, do not pose severe problems to lizards and actually serve as a major habitat for the group. Lizards form a conspicuous portion of the fauna of oceanic islands, where amphibian and mammalian species' diversity is generally low. The ability of lizards to withstand desiccation may well account for their success at colonizing oceanic islands. They are believed to arrive on mats of floating vegetation washed up on the island shore. Hard-shelled gecko eggs seem to be particularly equipped for such journeys.

Other variables that affect lizards are day length (photoperiod) and rainfall. Lizards living far from the equator experience marked variation in photoperiod, with short winter days and long summer days. Certain species are adapted to respond to such cues. *Anolis carolinensis* of the southeastern United States ceases reproduction in the late summer and fattens up for winter hibernation. This change occurs while the days are still warm and appears to be triggered by decreasing day length. It is adaptive for the species because eggs laid in September would essentially be wasted, the young hatching in November when food is not readily available and temperatures are too low to permit efficient, rapid growth. Some tropical species respond to alternations between rainy and dry seasons, and egg-laying may cease during the driest months of the year. This may be adaptive for a variety of interrelated reasons. When food abundance is low, it is of direct advantage to the parent not to channel energy into production of eggs. Additionally, eggs might be less viable because of desiccation.

Lizards provide valuable models for the study of competition between species. On some Caribbean islands as many as ten species of *Anolis* may live in a single restricted area. For so many species to be accommodated, each must be specialized for a rather precise niche. The species come in a variety of sizes, feed on different sizes of prey, and have different preferences for structural and climatic niches. Some live in tree crowns, others on trunks, others in grass; some live in open sun, others in "filtered" sun, and still others in deep shade. Thus, with ten anoles in a single area, each species has its own characteristic microhabitat.

Behaviour. Most lizards are active during daylight hours, when acute binocular vision is necessary for most nonburrowing species. The family Gekkonidae, however, is composed predominantly of species that are most active from dusk to dawn. In conjunction with night activity, geckos are highly vocal and communicate by sound, whereas most other lizards are essentially mute.

Lizards spend considerable time obtaining food, usually insects. Iguanids and agamids tend to perch motionless at familiar sites and wait for prey. They are attracted by motion and dart suddenly for the capture. The true chameleons move slowly, carefully observant, each eye moving independently, and capture their prey by shooting out the sticky tongue. Lizards of other groups actively search for prey by probing and digging, using scent as well

as visual cues. Plants are eaten by many of the largest lizards, such as the iguanas and the spiny-tailed agamid (*Uromastix*).

Lizards themselves are food for many birds, mammals, and reptiles, and they have many defensive mechanisms. The chuckwalla (*Sauromalus*) remain close to rock piles. When danger threatens, they move into crevices and puff themselves up so that extrication is most difficult. A number of spiny-tailed forms also move into crevices and expose only the formidable tail. Perhaps the highest development of this sort of defense is found in the African armadillo lizard (*Cordylus*), which holds its tail in its mouth with the forefeet and presents a totally spiny appearance to an attacker. To intimidate intruders on its territory, the frilled lizard of Australia (*Chlamydosaurus*) extends a throat frill almost as wide as the lizard is long. The tails of many lizards break off (autotomize) easily. The broken-off section wriggles rapidly, distracting the predator as the tailless lizard scurries for cover.

Social interactions among lizards are best understood for the species that respond to visual stimuli. Many lizards defend certain areas against intruders of the same or

Defense

Hiberna-
tion

closely related species. Territorial defense does not always involve actual combat. Elaborate, ritualized displays have evolved, presumably to avoid physical harm. The displays often involve erection of crests along the back and neck, increasing apparent size; showing bright colours, either by extending a throat fan or exposing a coloured patch of skin; and stereotyped movements such as pushups, head bobbing, and tail waving. Impressive ornamentation is often restricted to males, but females of many species defend territories by stereotyped movements similar to those of males. Energy is expended in territorial defense, and a displaying male is very conspicuous and vulnerable to predation; but territoriality is evidently advantageous and has evolved through natural selection. Successful defense of a territory increases the chances of obtaining the necessary amount of food and at the same time increases the probability of a successful mating with any females living within the defended area. Thus a successful territorial male has a higher probability of reproductive success than one living in a marginal area. The displays used by males in establishing territories also may function to "advertise" their presence to females; in species that breed seasonally, territoriality diminishes during the nonbreeding season. In iguanids, actual courtship displays differ from territorial displays in that males approach females with pulsating, jerky movements. In addition to visual cues used for bringing the sexes together, there are undoubtedly chemical stimuli, but these have not been well studied. Numerous lizard species have femoral pores, which are small blind tubes along the inner surface of the thighs, whose function may be the secretion of chemical attractants and territorial markers.

Courtship

Copulation follows a common pattern. The male grasps the female by the skin, often of the neck or side of the head, places the fore and rear legs on the near side over the female, pushes his tail beneath hers, and twists his body to bring the cloacae together. One hemipenis is then everted and inserted into the cloaca of the female. Depending upon the species, copulation may last from seconds to 15 minutes or more.

FORM AND FUNCTION

Rather than present a detailed anatomical report of a lizard, this section discusses certain structures that are either characteristic of lizards in general or specializations of certain groups.

Skull and jaws. The skull is derived from the primitive diapsid condition (see below *Paleontology*); but the lower bar leading back to the quadrate bone is absent, however, giving greater flexibility to the jaw. In some burrowers, for example *Anniella* and the amphisbaenians, as well as some surface-living forms including the geckos, the upper as well as lower temporal bar has been lost. The small burrowers have thick, tightly bound skulls, with braincases well protected by bony walls. In most lizards the front of the braincase is made up of thin cartilage and membrane. The eyes are separated by a thin vertical interorbital septum. In burrowing forms with degenerate eyes, the septum is reduced, adding to the compactness of the skull. Most lizard skulls are kinetic; *i.e.*, the upper jaw can move in relation to the rest of the cranium. Since the anterior part of the braincase is cartilaginous and elastic, the entire front end of the skull can move as a single segment on the back part, which is solidly ossified. This increases the gape of the jaws and probably assists in pulling struggling prey into the mouth.

Teeth. Most lizards are insectivores (insect eaters), with sharp, tricuspid teeth adapted for grabbing and holding. Some herbivorous (plant-eating) species, for example, iguanas, have tooth crowns expanded to a leaf shape with serrated cutting edges. The teeth of some large predators are conical and slightly recurved. Mollusk and crustacean feeders, such as the caiman lizard (*Dracaena*), may have blunt, rounded teeth in the back of the jaw designed for crushing. The venomous lizards (*Heloderma*) have a longitudinal groove or fold on the inner side of each mandibular tooth. These grooves conduct the venom. In most lizards, teeth are present along the jaw margin (on the maxilla, premaxilla, and dentary bones) and, in some

Figure 12: Specialized eyes of two lizards. (Top) Turreted eye of chameleon (*Chamaeleo*). (Bottom) Slit pupil of gecko (*Gekko*).

forms, on the palate. In the embryo, an egg-tooth develops on the premaxilla and projects forward from the snout. It aids in piercing the shell and is lost soon after hatching. This is a true tooth, unlike the horny epidermal point in turtles and crocodilians.

The egg-tooth

The common mode of tooth implantation is pleurodonty, in which the teeth are fused to the inner side of the labial wall. In the other mode, acrodonity, teeth are fused to the tooth-bearing bone, often to the crest of the bone. Acrodon teeth are rarely replaced, once a certain growth stage is reached. The dentition of the Agamidae is usually described as acrodon, but most species have several pleurodon teeth at the front of the upper and lower jaws.

Locomotion and limb adaptations. The majority of lizards are quadrupedal, with powerful limb musculature. They are capable of rapid acceleration and possess great ability to change direction of motion rapidly. The racerunners (*Cnemidophorus*) can attain speeds of 24 kilometres (15 miles) per hour, which, in terms of their own body length, puts them in a class with fast terrestrial mammals. A tendency toward elongation of the body is found in some families, often accompanied by reduction of limb length and, not infrequently, complete loss of limbs. Such lizards propel themselves entirely by lateral undulations emanating from highly complicated ventral abdominal musculature. Limbless lizards that move quickly on the surface or through sand tend to have elongate tails (*Ophisaurus*, the glass "snake"), whereas the burrowers have extremely reduced tails (amphisbaenians). The burrowers (amphisbaenians in particular) dig by ramming the head into the substrate, then rotating the head around the head joint, compacting the substrate.

Many modifications of the toes are to be seen in lizards. Some desert geckos, the iguanid *Uma*, and the lacertid *Acanthodactylus* have fringes on the toes that provide increased surface area and prevent sinking into loose desert sand. Arboreal geckos and anoles have lamellae (fine plates) on the undersides of the toes. Each lamella is made up of brushlike setae, each double; and the tips divide several times, the final strand less than .25 micrometre (1/100,000 in.) in diameter. These fine hairlike processes greatly enhance the clinging ability of the lizards, as they are able to find purchase in the smallest irregularities of

Figure 13: Fine structure of gecko foot. (Top left) Foot of gecko (*Gekko gekko*) showing chevron-shaped ridges or lamellae (about life size). White rectangle indicates the area covered by the photograph at the next larger magnification. (Top right) More detailed view of six of the lamellae (magnified 25 \times). Joseph F. Gennaro, Jr.

the substrate. Geckos and anoles can easily climb vertical panes of glass.

The true chameleons (Chamaeleontidae), a predominantly arboreal family, have a different type of highly specialized limb. The digits on each foot are divided into two groups by webs of skin. On the hind limb, three of the toes are on the outside, two on the inside (a form of zygodactyl); on the forelimb the pattern is reversed. Each foot is thus divided into an outer and an inner portion, which can be opposed as the branch is gripped. In addition, these and some other lizards have prehensile tails, which aid in grasping branches.

Several terrestrial iguanids and agamids are able to run bipedally. Basilisks are actually able to run across water for short distances. During bipedal locomotion the tail is held out backward and upward and acts as a counterweight.

Some lizards are able to parachute or glide through the air and make soft landings. The most highly adapted of these are the agamid lizards called flying lizards (*Draco*), which have extensible lateral expansions of the skin, supported by elongate ribs.

Skin and colour change. Except for openings of nostrils, mouth, eyes, and cloaca, most lizards are completely covered in scales, which vary among species and on different parts of the body of the individual. Scales may be smooth and overlapping, form a mosaic of flat plates, or have keels or tubercles. Osteoderms, bony plates that develop in

the dermis, underlie head and body scales of some lizards. The outer parts of the scales are composed of dead horny tissue made up largely of the protein keratin. The dead layer is shed at intervals and is replaced by proliferating cells in the deep part of the epidermis. Certain lizards have scale organs, with a stiff projecting seta emerging from the serrated edge of the scale and presumably responsive to tactile stimuli.

Many lizards can show some colour change. Two groups, the chameleons and the anoles, are particularly noteworthy in this ability. They can change from bright green to deep, chocolate brown, and patterns such as lines and bars may appear and disappear. The pigment cells that permit colour change are melanophores. Within these cells, pigment granules are able to migrate. In general, the animal is light when pigment is concentrated and dark when it is dispersed throughout the cells. The actual colour state, complexly controlled, is not simply matching of background but seems to be controlled by an interaction of hormones, temperature, and the nervous system.

PALEONTOLOGY

Lizards belong to the diapsid reptiles, a group characterized by the presence of an opening in the temporal bone of the skull, both above and below a bar formed by the postorbital and squamosal bones. The diapsids comprise two subclasses of reptiles: the Archosauria (crocodiles, pterosaurs, dinosaurs) and the more primitive Lepidosauria (lizards, snakes, eosuchians, and rhynchocephalians). The earliest known Lepidosaurian order (Eosuchia) appeared in the Late Permian (about 230,000,000 years ago) and almost undoubtedly was ancestral to lizards. Modern lizards differ from their ancestors in several skeletal features, the most diagnostic differences being in the construction of the upper temporal and quadrate regions of the skull. A.S. Romer divides true lizards from their ancestors on the basis of the quadrate region. Among true lizards the quadrate articulates flexibly with the squamosal above it. This occurred through loss of the lower temporal arch and reduction of squamosal development. The oldest fossil true lizards appeared in the Late Triassic (200,000,000 years ago). These were not primitive but highly specialized, having ribs that could be projected outward to provide a gliding ability. Thus it is possible that even older lizards will be found. Representatives of many modern lizard families have been found in Cretaceous deposits (from 136,000,000 to 65,000,000 years ago); and representatives of modern genera, virtually indistinguishable from living forms, were common from the Oligocene (38,000,000 to 26,000,000 years ago) on.

CLASSIFICATION

Distinguishing taxonomic features. Lizards differ from other reptilian groups in several anatomical characters, including the possession of not more than a single bony arch across the temple and paired reversible copulatory organs, the hemipenes.

G. Underwood (1967) summarized the differences between snakes and lizards. Lizards have the eyes separated by a thin vertical interorbital septum, whereas in snakes this septum is absent and the entire width of the bony braincase separates the orbits. Other features that distinguish lizards from snakes include: (1) the pectoral (shoulder) girdle, absent even as a trace in all snakes, present in all lizards; (2) the histological structure of the adrenal glands; (3) the placement of the thymus bodies. M.R. Miller (1968) found that the internal ear of snakes is considerably different from and more primitive than that of any lizard. The families of lizards are defined primarily by osteology and dentition, as well as presence or absence of the rectus superficialis muscle. When this muscle is absent in a group, there is not the slightest tendency for limb reduction and serpentine locomotion. The limits of the families seem to be agreed upon by most systematists, although relationships among the families are not always so clear.

Annotated classification. The classification presented here is adapted from Underwood (1957), which is an updating of C.L. Camp (1923). Definitions of taxa follow

Lizards and snakes distinguished

Bipedal locomotion

Figure 14: Comparison of heads of a typical lizard and a typical snake. (Top) Legless lizard (*Ophisaurus*). (Bottom) Green rat snake (*Elaphe triaspis*).

Camp where feasible. The classification of the Gekkonidae follows A.G. Kluge (1967). The dates of earliest fossils are from R. Hoffstetter (1962).

SUBORDER SAURIA

Reptiles with a single temporal opening lying above the bar formed by postorbital and squamosal bones. Pectoral girdle and interorbital septum always present. About 3,000 species.

Infraorder Ascalabota

Rectus superficialis rarely present; usually more than four transverse rows of ventral scales found over each body segment; body is covered by scales that overlap by a wide margin ("deciduous").

Superfamily Gekkonidea

Family Gekkonidae (geckos). No supratemporal arch; well defined limbs. Jurassic to present. Eighty-two genera, 650 species. Virtually worldwide in subtropical and tropical regions. Adult total length from slightly under 4 cm to 35 cm (1.5–14 in.). Most with soft, granular skin, easily autotomized tails, no movable eyelids, and toes with fine setae.

Family Pygopodidae (flap-footed lizards). Australia and New Guinea. Some burrowers, others surface dwelling; hind limbs represented by scaly flaps. Eight genera, 15 species.

Family Dibamidae. Philippines and Vietnam, to New Guinea. Burrowers; females limbless, males with flaplike hind limbs. One genus, 3 species.

Family Anelytropsidae. Eastern Mexico. Limbless; one species.

Superfamily Iguanoidea

Family Iguanidae. Dentition pleurodont. Teeth replaced when lost. Well-developed limbs. Movable eyelids. Oligocene, possibly late Eocene to present. Dominant family of North, Central, and South America, West Indies, and Galápagos Islands. One genus on Fiji and Tonga, two genera on Madagascar. Adult lengths from 10 cm (4 in.; *Uta*) to 2 m (6.6 ft; *Iguana*). A family of diverse forms including spiny desert dwellers (*Phrynosoma*), arboreal species (*Anolis*), and sea-going iguanas (*Amblyrhynchus*). Fifty genera, 600 species (200 in one genus, *Anolis*).

Family Agamidae. Most teeth acrodont. Many examples of convergent evolution with iguanids, but tooth difference absolute. Late Cretaceous to present. Old World tropics and subtropics, except Madagascar. Thirty-three genera, 300 species (60 in genus *Agama*).

Superfamily Rhiptoglossidea

Family Chamaeleontidae (Old World chameleons). Feet zygodactylous, grasping. Dentition acrodont. Tongue long, slender, extensible. Two genera, *Brookesia* 16 species, *Chamaeleo* 68 species. About half restricted to Madagascar, remainder primarily African, two species in western Asia, one in India, one reaching Mediterranean region. Most are insectivores 17–25 cm (7–10 in.); the largest, reaching 60 cm (24 in.), will eat birds.

Infraorder Autarchoglossa

Superfamily Scincomorphoidea

Family Scincidae (skinks). Skull arches present, osteoderms (dermal bone) present. Late Cretaceous to present. Worldwide (except in polar and subpolar regions), greatest diversity in Old World tropics. Typically with conical heads, cylindrical bodies, tapering tails. Less variable than the other large families. Primarily ground dwelling or burrowing, some arboreal.

Limb reduction common. Majority below 12 cm (5 in.), largest reaches 60 cm (24 in.). About 50 genera, 800 species.

Family Cordylidae (girdle-tailed lizards). Femoral pores and osteoderms present. Supratemporal fossa roofed over. Late Jurassic to present. Southern Africa and Madagascar. 20–60 cm (8–24 in.). About 10 genera, 50 species.

Family Lacertidae. Osteoderms absent, supratemporal fossa roofed over. Eocene (possibly Cretaceous) to present. Europe, Asia, and Africa. Morphologically uniform, conical heads, scaly bodies, movable eyelids, well developed limbs and tail. Length 15–60 cm (6–24 in.). Approximately 20 genera, 150 species.

Family Teiidae. Osteoderms absent, supratemporal fossa open. Late Cretaceous to present. New World only, primarily in tropics and subtropics. Great variation in the family, including large terrestrial predators (*Tupinambis*), large semiaquatic snail eaters (*Dracaena*), lacertid-like "racers" (*Cnemidophorus*), and small burrowers. Size range 7–120 cm (3–48 in.). Forty genera, 200 species.

Superfamily Anguinomorphoidea

Family Anguinae. Skull arches, osteoderms present. Six mandibular bones. Late Cretaceous to present. Most in Americas, a few Eurasian. Glass lizards (*Ophisaurus*) are limbless "grass swimmers" reaching 120 cm (48 in.). Alligator lizards (*Gerrhonotus*) and galliwasp (*Diploglossus*) have four limbs, somewhat elongate bodies, and reach 37 cm (15 in.). Seven genera, 67 species.

Family Anniellidae (California legless lizards). Limbless burrowers. No skull arches. Length 11–25 cm (4–10 in.). California and Baja California. One genus, two species.

Family Xenosauridae. Shape of interclavicle bone and presence of tubercles in the osteoderms distinguishes the family. Late Cretaceous from North America. Presently, two genera, one in Mexico, one in China; four species.

Family Helodermatidae (Gila monster and beaded lizard). Venomous; grooved hollow fangs in lower jaw; heavy-bodied. Skin texture "beaded." Oligocene to present; southwest United States and Mexico. Adult length to 50 cm (20 in.) in Gila monster, 80 cm (32 in.) in beaded lizard. One genus, two species.

Family Varanidae (monitor lizards). Osteoderms reduced, seven cervical vertebrae, postorbital arch incomplete. Restricted to Old World tropics and subtropics. Fossils from Cretaceous of North America. Smallest species is adult at 20 cm (8 in.), largest exceeds 3 m (10 ft). General uniformity of appearance with elongate head and neck, relatively heavy body, long tail, well developed limbs. One genus, 30 species.

Family Lanthanotidae (earless monitor lizard). Fossils from Recent only. No external ear. Restricted to Borneo; rare and little known. Length to 40 cm (16 in.). One genus and species.

Family Xantusiidae (night lizards). Vertebrae procoelous, supratemporal arch present. No movable eyelid. Relationships to other lizards unclear, even as to assignment within suborder. Share some features with gekkonids, others with skinks. Four genera, 12 species, California through Central America, and Cuba. All moderately small; bodies covered with small scales; ventral surfaces and head with larger platelike scales.

SUBORDER AMPHISBAENIA

Family Amphisbaenidae (amphisbaenians or worm lizards). Long cylindrical bodies with shallow grooves. No external ears, no readily visible eyes. Burrowers. Eocene to present. Primarily tropical, one species reaches Florida, and one reaches Spain. All genera lack hind limbs, and all but three lack forelimbs. Fifteen genera, about 100 species.

Critical appraisal. The boundaries of most lizard families have been stable for the past half-century, with several exceptions. The most important involves Gekkonidae, which Underwood (1954) divided into three families but which Kluge (1967) reunited into a single family with four subfamilies. C. Gans (1960) considers the Amphisbaenia so distinct that he raised them to ordinal status, equivalent in rank to lizards and snakes, and raised the two amphisbaenid subfamilies to family status. Studies by M.R. Miller (1966, 1968) on the internal ear, and A.E. Greer (1970) on cranial osteology clarify the relationships of some of the obscure burrowers and demonstrate that members of the so-called family Feylinidae are merely specialized skinks and are not closely related to the superficially similar Anelytropsidae. Perhaps of greatest significance is the finding that the cochlear duct of all snakes is more primitive than that of any lizard. This throws doubt on the theory that snakes are derived from highly advanced lizards (varanid relatives). (G.C.G.)

Serpentes (snakes)

Serpentes, one of three suborders of the order Squamata, includes only the snakes, a widely known and much misunderstood group. The closest relatives of the snakes are the lizards (suborder Sauria) and the wormlike amphisbaenians (suborder Amphisbaenia).

Arms and legs gone, no ears, only one functional lung, voiceless, eyelids missing—a human being in such condition would be institutionalized and under constant care. Snakes have not only survived these losses but have become highly successful in a great variety of ecological roles. Fearless, independent, and usually solitary, the snake has capitalized upon these apparent deficiencies to become an efficient second- and third-level predator, focussing perhaps 70 percent of its existence on tracking down, catching, and digesting its living prey. The elongate, limbless body of the snake permits it to be soundless in motion, invisible at rest, and almost unlimited in its access to hiding places, such as nests, tree holes, crevices, briar patches, gopher tunnels, and other shelters where small vertebrated animals seem to feel themselves safe from their enemies. Most of the remainder of the snake's existence is dedicated to continued survival in an antagonistic world that is usually either too hot or too cold and is full of other organisms challenging the snake's right to live. With its body temperature almost totally dependent upon the surroundings, the snake must seek out both nightly and seasonal resting places where rising temperatures eventually can be relied upon to rekindle its abilities to move, to sense, and to reproduce. Reproduction demands only a few percent of the male snake's existence, for it consists of little more than a sudden burst of highly seasonal activity followed by an immediate return to the more pressing activities of food search. The female devotes slightly more time to reproductive activities, because she must eventually seek out a suitable place to deposit the eggs

or to give birth to a usually good-sized brood. This, too, however, is an act of short duration, followed immediately by return to the continuing problems of daily existence.

Snakes are found around the world in practically every kind of habitat and in all regions except near the poles. They are not successful competitors with man, and only a few diminutive species with very secretive habits find it possible to share living space with humans. When man moves in, practically all reptiles share the fate of large mammals and predatory birds—they must move out or die, because man is not and never has been a particularly good coexisting species except with those organisms that he bends to his will, such as corn or horses, or with those capable of capitalizing upon his presence, such as pigeons and rats. Of the reptiles, the snake is the most distasteful to man, and snake species are quickly wiped out. In rural areas, man pays the penalty for this eradication in an inevitable increase in the natural prey of the snakes, including rats, mice, and other rodents.

IMPORTANCE

After the unfortunate episode in the Garden of Eden, perhaps the first relationship between man and snakes that one thinks of is envenomation from poisonous snakebite. The likelihood of any individual human encountering a venomous snake during his lifetime has been reduced to almost zero as a result of the tremendously increased world population, the concentration of humans in cities, where poisonous snakes cannot survive, and the reduction in overall numbers of snakes as a consequence of the invasion and destruction of their habitats by man. At the same time, the likelihood of any one poisonous snake, sometime during its life, finding itself in a position in which it must bite a human in self-defense increases geometrically, as a consequence of the enormously inflated human population, man's ever-increasing mobility, and the increased utilization of remote areas for recreation purposes of all sorts. One of these likelihoods is offset by the other, and the overall number of bites per year by venomous snakes around the world remains rather constant, at about 1,000,000 per year. Of this 1,000,000, perhaps 30,000 to 40,000 result in death, with most of the deaths occurring in areas such as tropical Africa and Asia because of the inadequate medical facilities for proper treatment. It has been estimated that in the United States about 1,000 bites occur each year, with approximately 15 resulting in death. Records for bites by the viper in England indicate that only seven deaths occurred between 1899 and 1945 and only one death between 1945 and 1960, with the latter a consequence of treatment rather than of the bite. A large percentage of the bites in the United States occur when the snakes are handled for various reasons. These reasons include care in zoos, the extraction of venoms, exhibition by showmen in carnivals and sideshows, the maintenance of snakes as pets or curiosities, and their inclusion in religious ceremonies by various sects. Practically all of the time-honoured remedies or first-aid measures for snakebite treatment are more dangerous in the hands of the inexperienced than is the bite itself. If any kind of medical care is available within an hour or less, nothing more than a light tourniquet is needed as emergency treatment.

No snake has ever regularly hunted man, but man continues to engage in seeking out the snake. The uses that man finds for snakes are not extensive, but each of them results in the decimation of wild populations. Snakes are collected as a source of rare and exceedingly expensive leather for belts, pocketbooks, shoes, and gloves. There is a phenomenal traffic in live snakes for purposes of display or as pets, including the flow to zoos, circuses, carnivals, or roadside "snake farms," as well as to the amateur snake fancier with a large collection in his basement. There are perhaps 40–50 research laboratories and antivenin institutes around the world, in which either snakes or snake venoms are used, and live snakes are needed in fairly large numbers for the work. An indication of the numbers of animals involved in this kind of traffic is given by data from the United States Department of the Interior on importations, taken from customs reports. During 1968 and 1969, more than 3,344,000 specimens of living reptiles

Snakebite

Figure 15: Variation of snake head shapes.

(including snakes) were brought into the United States. It is difficult to determine how many of these reptiles were snakes, but perhaps a quarter to a third of the total would be a reasonable estimate, which would mean that almost 1,000,000 snakes were shipped into the United States in those two years. The mortality rate among such snakes is high, but those that survive bring prices from about \$5 to as much as \$1,500, and, therefore, this is a multimillion-dollar business. The snake roundup, or snake rodeo, has become recognized as a tourist attraction in the United States, and such events take place in about a dozen different cities each year. The emphasis is on capturing and killing rattlesnakes or copperheads, but usually any snake will do, and the slaughter is always extensive. This phenomenon will die out as the number of available snakes decreases. Distaste for snakes has often led legislatures or monarchs to promise bounties for those killed in areas under their jurisdiction, and such bounties invariably result in the importation of animals from many miles away. In a single year, 1889, 578,415 snakes were turned in for bounties in India. Although Western cultures have never developed the taste, in some parts of Asia the snake is considered a choice delicacy and, by some, even as somewhat of an aphrodisiac.

Snakes as
symbols

The serpent is a recurrent figure in religious beliefs, ceremonies, activities, and legends. The decidedly unhuman appearance of the snake, its unwinking eye, its reputed ability to deliver unexpected and sudden death, the fear, hatred, and loathing with which it is regarded by many, the folktales and legends that have surrounded it in practically every culture, all have combined to produce religious overtones in many different parts of the world. While in many religions the snake is primarily a symbol, direct worship of the snake as a godlike creature (not as an indirect representation) is not uncommon. Python worshippers are found in Africa, and the cobra cults of India are well known. Quetzalcoatl was the feathered serpent of the Aztecs. The serpent is a symbol for the snake-handling Protestant sects of the United States, the snake dancers of the Hopi Indians, and perhaps the Burmese snake charmers, who end their ceremonies with a kiss on the top of a cobra's head. Handling of snakes is done both as a gesture of belief and faith in the power of the gods and as an act of defiance of the same power. Bites and fatalities are about equally distributed in both cases.

NATURAL HISTORY

Interaction with the environment. While not exactly at the mercy of the environment, the snake is largely dependent upon it and must devote much of its day-to-day existence to coping with the vagaries and changes taking place in its surroundings. The problem varies with latitude and altitude, for the actions and reactions of a snake in temperate North America are distinct from those of one living in the American tropical lowlands but are similar to those of another living at higher altitudes in the Andes of Ecuador. No matter where they live, snakes are subjected to pressures from the biotic, or living, parts of the environment as well as from the abiotic, the physical, or nonliving, parts. But the amount or degree of challenge to the snake from different segments of the environment changes drastically depending upon the region it inhabits. The individual living in the hot, humid tropics of Africa, with comparatively constant temperatures close to optimum throughout the year and ample moisture from both rainfall and the surroundings, finds that its environmental problems involve competition with other members of its own species for food supply, the challenge of other species of snakes and perhaps other vertebrates for possession of the ecological niche, and the constant pressure of the predator that finds it a tasty morsel. The viper (*Vipera berus*) living within the Arctic Circle of Europe, on the other hand, is the only snake species present in the area and lives practically unchallenged in its niche but is faced permanently with situations in its physical environment that are substandard for survival, so that death from overheating, freezing, or dehydration is a repetitive threat. These differences among animals from different parts of the world are reflected in their life histories, and it is

neither possible nor legitimate to speak of the "life history of the snake" unless one speaks only of a single region or, perhaps, of a single species.

In the tropical regions, life continues at approximately the same activity level year after year. The only break in the rhythm comes in the dry season and this only when the dry season is not just a period of slightly less rainfall. Snakes may enter a short period of dormancy at such times, which is, at least in part, a consequence of the effect the dry season has upon their prey. This dormant period is similar to the hibernation in winter by temperate-area snakes, although little is known about the physiological changes that may or may not take place in tropical dormancy. At higher latitudes and altitudes, during periods of maximum stress, which for most snakes are the cold months, the animals must seek out a place where they can be completely inactive and nonreactive, where their inability to respond to the stimulus of danger is compensated for by the absence of danger, and where the surrounding extremes of low temperature and low humidity are mitigated to the point that they remain within the limits of the tolerance capacity of snakes. Such places are few and far between, and good hibernacula (dens used for hibernation) are recognized and utilized year after year, with snakes of several different species often sharing a den. It seems likely that the snakes do not remember the location of a hibernaculum but utilize the simple expedient of following a scent trail left by other snakes randomly seeking a den, with the scent growing more and more strong as successive snakes arrive from greater and greater distances. Many of the changes that occur in the individual snake after arriving at the hibernaculum are direct results of its dependence upon the environment, and, as its body cools, the heartbeat and respiration slow almost to a stop and there is no muscular activity, little digestion, and no defecation. Physiological changes that are not correlated with or responsive to the surroundings also take place, but not to a degree comparable to those occurring in a hibernating mammal, and there is no "alarm system" to stir the snake into activity if a tolerance limit is passed. In such a case, the snake simply dies. At the end of the cold season, the snake is totally dependent upon the changes in its surroundings to bring it back to activity; it cannot rouse itself. The stimuli are felt by all almost simultaneously, and snakes emerge by the dozens or even by the hundreds from some denning places. In some species, copulation takes place immediately after enough of the sun's rays have been absorbed to permit the development of an interest in the surroundings; in others, copulation is the final act before entering hibernation, and the sperm lie dormant in the dormant female. Fertilization of the egg can take place immediately after copulation, but in some species at least, the female can store the sperm for several years, using them to fertilize successive batches of eggs.

Behaviour. *Interactions between individuals.* Snakes in both tropical and temperate regions tend to be solitary in their habits. The denning and mating aggregations are, for the most part, the only social events of the season. Sea snakes differ in this respect, sometimes being seen travelling in large troops, which seems to indicate an urge to aggregate. Female sea snakes (Hydrophiidae) also congregate in large numbers in seawall caves at parturition time, but this may have no social significance, since it seems to be a consequence of availability of a safe place for the young to be born rather than aggregational behaviour per se. There is some tendency for females of certain species in temperate areas to use a single site for egg deposition. Hunting of food is strictly an individual act for snakes; there are no known instances of cooperative hunting, as seen in some mammal and bird species. Hiding places and basking sites are occasionally shared; this again is a consequence of availability, and in the tropics, where hiding places abound, it is rare to find more than one snake at a time under a log or a rock. Except for these few weak instances, there is no development in snake populations of social behaviour. There is no establishment of social hierarchies, no territoriality, and perhaps no dominance. The combat dance engaged in by two males of the same species, where the bodies are entwined anteriorly and raised higher and

Hiber-
nation

Combat
dances

higher off the ground until finally one snake overthrows the other, certainly establishes a dominant individual, but there is no indication that awareness of this dominance is retained by either snake. A dominance that must be reestablished at every encounter does not contribute to a social structure. It has been suggested that the combat dance is essentially a homosexual encounter, with each male attempting to copulate with the other.

Reproduction. The occurrence of mating immediately after emergence from hibernation allows snakes to take advantage of the fact that the females are accessible, concentrated, and receptive. The males are equally concentrated, so pair formation and copulation is a simple matter. Males of some species have nuptial tubercles on various parts of the body, used to stroke or massage the female and, presumably, to arouse her sexually. Even when obvious tubercles are absent, the male uses a rubbing technique to stimulate the female, and in some species a muscle ripple moving along the male's body will provide a lateral caress. There are many descriptions in the literature of courtship dances done by snakes, in which the bodies are entwined and as much as one-third lifted off the ground, the coils ebbing and flowing with silent grace. Unfortunately, in many of these reports, the snakes were not captured and sexed, and the observer simply assumed that a male and female were involved. Recent work, where the snakes have been sexed, tends to indicate that the dance often, if not always, involves two males and is of little or no significance in reproduction. In any event, copulation is achieved after a comparatively brief courtship through the insertion of a hemipenis in the female's cloaca (a common urogenital chamber, lying just anterior to the anus). The hemipenis is one of a pair of mirror-image intromittent organs lying in the base of the male's tail, posterior to the anus, and strictly reserved for mating, for the urinary passages empty directly into the cloaca of the male. Either hemipenis can be used in copulation and must be everted, through a process of turning itself inside out. This is achieved primarily by engorgement of the organ with blood.

The everted organ is heavily armed with spines, spinules (minute spines), flounces, calyces, and other ornaments, all of which appear to play a role in ensuring that the male is securely attached to the female for the entire period until the sperm have been deposited. The sperm pass along a deep groove in the hemipenis, which, although open along one margin when examined in a dead snake, clearly forms a tubular passage as a result of the pressures of the engorged margins of the groove. After release, the sperm may immediately move up the oviducts and fertilize eggs just released from the ovary, or they may be stored by the female and released later to achieve fertilization. Once fertilization has occurred, the egg begins to accumulate additional layers from the shell glands in the oviduct. In some species, this continues until a firm yet pliable, leathery shell has been formed, permeable to both gases and liquids but capable of retaining much of its liquid content unless in a very dry place. The female then deposits the entire clutch of eggs in a protected, damp, warm, and usually dark place, often along with clutches from other females of the same species, for the same stimuli that lead snakes to congregate for hibernation also bring them to the same places for egg laying. Many species immediately abandon the eggs, some remain with the clutch and certainly appear to be protecting them from external danger, and a very few actually assume the role of a brood hen, maintaining a body temperature measurably higher than the surroundings, presumably assisting in incubation. In certain species, additional layers of membranous material are deposited around the embryo, but the calcareous (calcium-containing) shell does not form. Instead, the embryo is retained in the oviduct and continues its development there.

This is termed ovoviviparous development, since it is simply an egg retained in the oviduct, in contrast to viviparous, the condition seen in mammals, where the fetus develops in the uterus and establishes a placental connection with the uterine wall to permit exchange of materials with the maternal circulation. But, while an umbilical connection does not develop, there is now considerable evidence of exchange of materials between

mother and fetus across their contiguous, highly vascularized membranous surfaces, and the distinction between the two types of development is so blurred in some species as to become specious.

Regardless of the devices used to provide it with protection, the snake fetus is always brought to term before the onslaught of environmental conditions that could result in its death. The embryonic turtle can sleep away its first winter in the egg and hatch the following spring none the worse for the experience, but there is as yet no evidence that snakes can do the same. The contrast may result from the fact that the female turtle can scoop out a hole deeply enough that freezing temperatures may not affect her brood, but the female snake is restricted, both by her limblessness and by the nature of the egg itself, to egg laying on or near the surface, where below-freezing temperatures are unavoidable. In the tropics, evidence is scanty, but it would appear that there is an endogenous (*i.e.*, controlled from within) rhythm there as well, since young are not produced throughout the year.

Early development and growth. The young snake, whether from an egg or born alive, comes equipped with a sharp cutting device on its upper lip, the egg tooth. It slashes its way out of the rubbery eggshell with this tooth or, in the case of the live-born, cuts its way out of the soft membranes and is instantly competent to cope with its surroundings. Almost invariably, the first act of a newborn snake is to extend its tongue and taste the surroundings, conveying to the Jacobson's organ (a sensitive region in the roof of the mouth) chemical information perhaps more significant than the visual cues picked up by the pair of very inexperienced eyes. Young snakes begin to feed immediately after hatching, displaying considerable ability in the capture and consumption of prey. Venomous snakes are born with functional venom glands and fangs and are capable of immediate utilization of their most formidable weapons. Some of the viperid snakes are born with a bright-green tail tip (contrasting strongly with the rest of the body colour), which they are capable of waving and shaking in a way that attracts the attention of possible prey. Within a very short time after birth, the first sloughing of the skin takes place, and the egg tooth is shed at about the same time.

The rate of growth is correlated with availability of food and temperatures high enough to permit full metabolic activity. When all factors are optimum, snakes grow surprisingly fast. A brood of California rosy boas born on October 26, 1965, more than doubled their lengths by July 26, 1966. In this nine-month period they had reached lengths only a few inches shorter than their mother, an adult close to maximum length for the species. It has been suggested that all snakes grow rapidly until they reach sexual maturity, after which time growth slows but very seldom stops completely. Snakes have indeterminate growth, which means there is no terminal point in time or size for growth in their lifetime, but they can continue to increase in length until they die. Sexual maturity is reached in about two years by many snakes. In the larger species, sexual maturity comes later, after four or five years or more.

Molt. A regularly recurrent event during the activity period of all snakes is the shedding, or molting, of the skin. Dormant individuals do not shed, but quite often this is one of the first events to take place after the end of dormancy. The integument of all animals represents the primary buffer between internal structures and the environment, and it is constantly subject to wear, tear, and other damage. The first line of defense against damage, especially when the skin is completely broken, is the formation of a blood clot, a scab, cellular reorganization, and scar formation. The second line of defense is the constant production of new cells in the deeper layers of the skin to provide replacement cells on the surface for those lost or worn away. In snakes, the replacement procedure has been modified to a considerable degree. The replacement cells are not constantly produced independently of each other but are all on the same cycle and are cohesive into a complete unit. When this unit is functional, the old skin lying external to it becomes a threat to continued good

Egg
laying

Growth
rates

health. At this point, the snake's eyes become a milky blue, an indication of a physiological loosening of the skin that forms the eye cap. This loosening is duplicated all over the body, although not so obviously. Shortly, the eyes clear, and the snake rubs loose the skin around the mouth and nose and crawls out of it completely, leaving a new, functional skin resplendent in fresh, bright colours. The rattlesnake sheds its skin in the same fashion as all other snakes, but the process is highly modified at the tail tip, where successive layers of keratinized, hardened epidermis are interlocked, or nested, to form the rattle, a device used to ward off death or injury to the snake caused by large mammals, including man. The use of the rattle is reasonably successful with buffalo, cattle, or horses but spectacularly unsuccessful with man, because, through this advertising, the rattling snake precipitates either its death or capture but seldom its escape.

Locomotion. The snake has overcome the handicap of absence of limbs by developing several different methods of locomotion, some of which are seen in other limbless animals, others being unique. The first method, called serpentine locomotion, is shared with almost all legless animals, such as some lizards, the caecilians, earthworms, and others. This is the way most snakes move and has been seen by any zoo visitor. The body assumes a position of a series of S-shaped horizontal loops, and each loop pushes against any resistance it can find in the environment, rocks, branches, twigs, dust, sand, pebbles, etc. The environment almost always provides sufficient resistance to make movement possible, and many snake species never use any other method of locomotion than this. Such

with the substrate and, in fact, was developed because of the failure of the substrate to provide sufficient resistance for any of the previously described methods. This method, called sidewinding, characterizes snakes living in the desert, where the sand simply gives way under any kind of push. The sidewinder does not progress forward when in motion but actually goes sideways. The snake, lying extended on the sand, lifts the anterior part of the body, moves it five to six inches to the side, and rests that part on the sand, maintaining a lifted loop to the rest of the body. This lifted loop is then progressively shifted along the body to the end of the tail, at which time the entire snake has moved five to six inches to the side from its previous position. By the time the first loop reaches the end of the tail, a new loop has already lifted the head and started down the body, and the snake looks like a coiled spring rolling across the sand. There is no rolling involved, however, since the ventral surface is always in contact with a substrate and usually leaves its impression behind in the sand, like a footprint. A nonterrestrial method of locomotion is swimming. Most snakes use a somewhat frantic serpentine locomotion in water, and the water provides enough resistance to allow progress, but one would be hard put to say whether snakes are natural swimmers or cannot swim at all but simply take advantage of their natural buoyancy to crawl through the water. The true sea snakes, however, have a morphological adaptation that gives rise to a clearly distinct method of locomotion. The tail is compressed from side to side to form an oar, or paddle, and swimming efficiency is not only improved but raised almost to the level of an art by these snakes.

Side-winding

San Diego Zoo

In typical method of locomotion, Bahaman boa (*Epicrates striatus*) extending itself to reach branch at right (not shown).

species, when placed on a surface providing no resistance, such as smooth glass, are unable to move, whipping and thrashing around without progress. Other methods of terrestrial movement also involve at least some resistance by the environment but usually less than the first. One of these is known as "concertina" locomotion, because the snake in action resembles the opening and closing of an accordion or concertina. First the tail and the posterior-most part of the body are securely anchored, then the head and the rest of the body are extended as far forward as possible from that secure base. At the maximum extension, the head and the fore part of the body are anchored and the posterior part drawn up as close as possible in the accordion-like folds. A second cycle follows the first, and the snake progresses. Tree snakes, such as *Imantodes* and *Oxybelis*, modify this technique to move from branch to branch and have a strongly compressed body that permits surprising amounts of the body to be stiffened and extended, using a modified I-beam effect for rigidity. The third method is called "caterpillar" or "rectilinear" locomotion, because the body moves in a straight line, using a flow of muscle contractions along the sides that looks like a caterpillar in motion. The body musculature is used for sequential lifting, anchoring, and pushing against individual ventral scales, which results in an inching along. It is used by large, heavy-bodied snakes, such as the boas and some of the vipers.

The fourth method is the least dependent on friction

FORM AND FUNCTION

General features. The most characteristic aspect of the snake form is the elongate body and tail and the absence of limbs. Fragments of limbs and girdles still survive in a few species of snakes, and in some snakes of the family Boidae the remnant forms a tiny, external spur on either side of the body at the anus, which is used by the male during courtship to stimulate the female. There is no snake in which the limb remnants still retain a function in locomotion. The body is usually slender, although there are some very heavily bodied species. The body shape is correlated with activity level, with the slender species moving about all the time and the heavy forms leading a sedentary life. The pit vipers, for example, while not always long snakes, are often big snakes. It seems likely that these snakes evolved in the direction of heaviness only after the development of a heat-sensitive depression, the loreal pit, located between the eye and the nostril, and the venom apparatus, which enabled them to stay in one place and wait for their prey to approach, rather than engaging in a continuous, active search for food. Similarly, some of the largest boid snakes (boas, anacondas, and pythons) have labial pits that function in the same way as the loreal pit of the vipers, so they, too, can be sedentary and grow fat. Arboreal snakes are the most elongated and slender of all, with the tail (the region posterior to the anus) often longer than the body and the body often strongly compressed laterally, which permits greater rigidity of the body frame while crawling from branch to branch. Burrowing snakes are seldom large, and the true burrowers, the Typhlopidae and Leptotyphlopidae, living all their lives like earthworms, are the tiniest snakes of all. The burrowers have almost no tail, although some of them retain a spiny tail tip, which probably serves the animal as an anchoring point when crawling through the soil. The tail in the sea snakes is flattened to form an oar, used to scull through the water. Sea snakes are almost totally helpless on land, locomoting only with the utmost of difficulty.

The skin. The entire body and tail in snakes are covered with scales, which are cornified folds in the epidermal layers of the skin. These scales are usually arranged in longitudinal rows, the numbers and arrangement of which are characteristic of the species. The scales may be large and shield shaped, in which case the number of rows is low, from eight to 29 or 30, or they may be very small, rounded, and occasionally with the centre raised, in which case the number of rows can be as high as 90 or 100. A sin-

Body proportions

gle scale may be very smooth and shiny (as in the rainbow snakes), it may have a raised ridge (keel) along its centre, it can be heavily striated, or it may even have a raised spine in the centre, as in the Javanese wart snake. The scales in some species have sensory structures on the posterior margins called apical pits, and all scales have various micro-ornamentations, consisting of hairlike projections, holes, spinules (small spines), and other specializations visible only through an electron microscope. The scales on the ventral surface of the body are modified into broad plates in the majority of species and are used in locomotion. The sea snakes and the blind snakes lack such ventrals, the scales being small, as on the dorsal surface, and there are several other species, such as the anaconda, in which the ventrals are very reduced in size. This appears to be a secondary loss of the enlarged ventrals, correlated with life in an environment where locomotion is achieved in other ways, such as swimming or movement in burrows.

Coloration. The colours and colour patterns seen in snakes are often bright, occasionally spectacular, and in some species even beautiful. Snake colours are produced in two ways, either by pigment deposited in the skin or by differential diffraction of light as a consequence of the physical properties of the skin itself. When seen on a uni-colour or uniform background, most snakes are obvious, and their colour patterns seem bold and prominent. When the animals are placed in their natural habitat, however, the significance of the colour patterns becomes obvious. The many lines running at sharp angles to the elongated lines of the body, the triangles or rectangles of colour, the blotches, spots, bands, or lozenges, all become highly disruptive to the eye, and the snake disappears into its surroundings. Blotched or spotted snakes tend to be sedentary and heavy bodied, while striped and the occasional uni-colour snakes are usually active species. In both cases, the coloration is protective, since a coiled, sedentary snake has its body outline completely obscured by the overlapping patterns, while the stripes on a crawling snake eliminate the sensation of motion until they suddenly narrow at the tip of the tail and the snake disappears.

Warning
coloration

Although in most snakes the colours are such that they help the animal to hide, there are some species that seem to be advertising their presence rather than trying to hide it. Their patterns are aposematic, or warning, in nature, and let a possible enemy or predator know that he runs some risk in an encounter with the snake. The warning is effective, of course, only if the intruder is knowledgeable concerning its significance and can take heed. This implies a teaching and learning sequence, with the dangerous snake as "teacher" and the predator as "student." For this reason, it has been suggested that the bright colours of the highly (and often fatally) venomous coral snakes did not evolve as warnings of the snakes' own poison but as mimics of some other venomous species, less dangerous, but still able to teach the predator the significance of the warning coloration. There is no evidence that avoidance of aposematic species is instinctive; on the contrary, naive predators readily attempt to take aposematic forms. A predator that dies in its first encounter with a dangerous species cannot act as a selective force favouring the coloration of that species. There are quite a few mildly poisonous rear-fanged snakes, brightly banded in red, black, and yellow (colours found in the coral snakes), that can make a predator suffer a sufficiently painful lesson that it will avoid contact with all similarly coloured snakes, including the fatally venomous coral snakes and the completely harmless milk snakes (*Lampropeltis*). (For a complete discussion of the evolution of mimicry, see MIMICRY.)

Skull and sense organs. Snakes rely on several senses to inform them of their surrounding. The pits, found in the region between the nostril and the eye in the pit vipers (the viperid subfamily Crotalinae) and in the scales of the lip line in some boids, are sensitive to very slight changes in temperature in their surroundings. These snakes feed almost exclusively on animals, such as birds and mammals, that maintain a constant body temperature and can therefore be located by the snake through the reception of the heat of the warm body. The heat lost by even a small rodent is sufficient to alert a waiting viper and enable it

Tempera-
ture
detection

to direct a fast strike at the animal as it passes by. Death follows rapidly, and the snake follows the dying animal at a leisurely pace, perhaps in full awareness that it will not go far. The boids use the same technique for detecting warm prey, but after striking they retain the grip, killing by constriction.

The eye of the snake is lidless and covered by a transparent cap of epidermis, which is shed with the rest of the skin at each molt. Animals active during the day usually have round pupils, while the nocturnal species have a vertical or slit pupil that opens up in the dark, as does that of a cat, but closes more effectively in bright light, protecting the sensitive, dark-adapted retina. The eye has been almost completely lost in the burrowing families, in which it is visible only as a black spot buried under the flesh and bone of the head. Arboreal snakes often have a bulging, laterally placed eye, permitting them to see activities directly below as well as above and around them. The structure of the eye in snakes indicates that their lizard ancestor was probably a burrower and that all aboveground activity by snakes is a secondary invasion from an ancestral life underground.

The reception of sound is entirely by bone conduction within the skull. The snake has no external ear, but it still retains a few of the vestiges of the internal ear, which are connected to other skull bones in such a way as to permit transmission of some earth-borne, and perhaps a few aerial, sound waves of low frequency.

The skull of snakes is characterized by mobility. It is light, with a reduced number of bones, and there are hinge joints at several levels that permit slight rotation or movement of one segment upon another. The only compact unit is the central braincase, with all other skull bones little more than attachments to it. The flexibility of the skull and the jawbones attached to it is a major compensatory factor to balance the loss of limbs. The snake replaces manipulation of digits with manoeuvrability of skull bones.

The jaws of snakes are highly mobile and are usually heavily armed with teeth. The upper jaw can move to and fro on hinged joints and can also rotate slightly. In most snakes, the upper jaw is connected to the lower jaw by a joint that acts as a pivot point, and, in eating, all toothed bones on one side of the mouth move forward as a unit. In some tree snakes (the colubrid subfamilies Dipsadinae and Pareinae), the connection between the

Teeth
and
fangs

Drawing by M. Moran

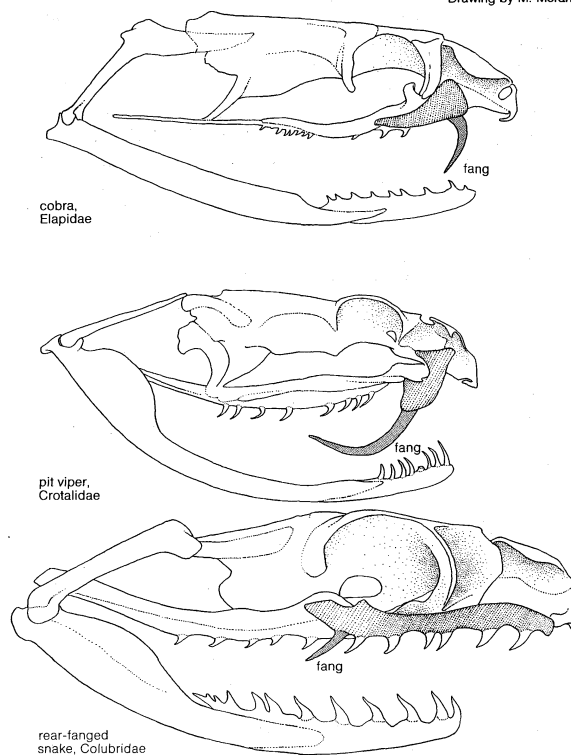

Figure 16: Skulls of representative poisonous snakes.

upper jaw and the quadrate is lost, and there are four independent units rather than two. These snakes feed exclusively on small, slippery prey, such as slugs and snails, and this jaw modification permits them to hold their food with three jaws while the fourth is advanced. The maxillary bone (the main bone of the upper jaw) of most snakes is elongated, with many teeth, but in the Viperidae (Old World vipers, New World rattlesnakes, and other pit vipers) only one functional fang remains, on a short, blunt, rotatable maxillary. The position usually occupied by the maxillary has been taken by the pterygoid bone. In the Elapidae (cobras and relatives) the maxillary bears a single fang in a fixed position, sometimes followed by a few smaller, solid teeth. In several different evolutionary lines of snakes, the posterior one or two teeth on the maxillary have enlarged and changed, usually in the direction of developing a groove or canal on the anterior edge to conduct a flow of venom. These are the rear-fanged snakes, usually (although not always) nonlethal to man. Snake teeth are usually long, slightly recurved, and needle-sharp. This facilitates swallowing and prevents loss of food, because the only direction in which a food item, which may be alive when swallowed, can go to escape the teeth is down the throat. Modifications in food habits have often been accompanied by changes in tooth structure or the loss of teeth. The egg-eating snakes, for example, have only a few peglike teeth left. The burrowing blind snakes have very reduced dentition and have often lost the teeth of one jaw entirely.

The vertebral column of snakes is highly elongated and includes many more vertebrae than almost any other kind of vertebrate animal. Since there are no limb girdles associated with the skeleton, there are no good delimiters of regions, and snakes are generally regarded as having only two kinds of vertebrae, precaudal and caudal. A pair of ribs is associated with each precaudal vertebra except for a few immediately behind the head, but, by definition, there are no ribs on caudal vertebrae. Each vertebra articulates with its neighbours at five different points; first, at the contact point between the centra (the main, central bodies of the bones), which is a ball-and-socket joint; then two points at the zygapophyses (projections from the centra), with articulating surfaces that lie dorsally and ventrally; and finally the zygosphenes and zygantra, found almost exclusively in snakes, the zygosphenes being a projecting shelf on the neural arch (the upper part of the vertebra) and the zygantrum, a pocket into which the zygosphenes fits and within which it can swivel. These five points permit lateral and vertical rotation while preventing almost entirely any twisting of the vertebral column, thus achieving both flexibility and rigidity. The vertebra may bear on its ventral surface a long, posteriorly directed projection called a hypapophysis. The presence or absence of this structure on the vertebrae of the posterior third of the body has been of considerable importance in snake classification, because large groups of species show this as a common characteristic. In the egg-eating snakes (members of the colubrid subfamily Dasypeltinae), the hypapophyses of a series of vertebrae a short distance behind the head have developed anteriorly directed tips that have a distinct coating of enamel-like substance. These serve as eggshell breakers, projecting through a gap in the dorsal intestinal wall, where they can rip into an egg when the snake constricts the muscles of the body as it passes the hypapophyseal points. The crushed shell is regurgitated, and the contents of the egg pass on to the stomach. The vertebrae of the tail tip in the rattlesnake are highly modified to form a "shaker" for the rattle.

Urogenital system. The urogenital system in snakes is not very distinctive from that of other vertebrates. The testes and ovaries tend to be staggered as a consequence of the elongation of the body, with the right usually lying anterior to the left. Snakes do not have a urinary bladder, and kidney wastes are excreted in a solid state as uric acid. As mentioned above, the male snake has two separate intromittent organs, the hemipenes. This structure is not homologous with the penis of mammals but seems to represent a completely different solution to the problem of internal fertilization. It is a saclike structure that must

Figure 18: (Top left, top right, bottom left) Egg-eating snake (*Dasypeltis*) approaching and swallowing egg of a hen. (Bottom right) Eggshell that has been regurgitated after snake has consumed its contents.

Carl Gans

be turned inside out to be inserted in the cloaca of the female and can be removed only by turning it back to inside in, because to draw it out directly would damage the female considerably. The hemipenis is extremely variable in its overall appearance and structure; the cloaca of the female is often similarly constructed, thus preventing cross-fertilization by males of related species.

Specializations for securing food. The most essential and time-consuming activity for a snake during nondormant periods, regardless of its habitat, is the pursuit, capture, and digestion of food. There are many morphological and behavioral modifications to be observed in snakes that facilitate food gathering. Some of these changes are widespread and found in practically every kind of snake. Jacobson's organ, for example, is located in the roof of the mouth and is capable of detecting minute quantities of various chemical substances when they are picked up externally on the delicate, double-tipped tongue and thrust into the organ for analysis. It is so significant and useful that it has never been lost by any snake species. While important primarily in trailing and recognition of prey, the Jacobson's organ is also used in detection of enemies, in trailing other snakes of the same species, and in courtship.

Some snakes have specialized salivary glands that elaborate a potent poison, along with either grooved or tubular teeth to permit internal injection of the venom. This device for rapid immobilization of prey has proven successful whenever it has occurred, and several different lines of evolution can be detected both in the type of injector tooth and in the chemical composition or mode of action of the venoms. The types of injector tooth include the long, tubular fang of the viperids; the short, hollow fang on a fixed maxillary seen in the elapids; and the several kinds of grooved tooth on the posterior end of the maxillary. In the latter case, there is little doubt but that the development of grooving has taken place several different times in different places. As for the venoms, it is true that the terms neurotoxic, hemotoxic, and cardiotoxic, once used to describe the different effects, are clearly misleading and are too simple for accurate statements concerning venom composition, but it is still accurate to say that some of the components of venoms cause changes in the red blood cells, coagulation defects, and blood-vessel injury, while others produce deleterious changes in sensory and motor functions and in respiration, and still others have a direct effect on the heart. Some venoms kill very rapidly, such as that of *Bothrops insularis* of Queimada Island, off the Brazilian coast, which would lose as prey most of the birds it bites if they could fly very far away. Other venoms kill

Types of
venom

The
hypapo-
physis

more slowly, and the snake bites, retires, and waits, finally trailing the bitten prey, using the tongue and the Jacobson's organ until it finds the already stiffening body. Some snakes, in particular the rear-fanged species, bite, chew, and hold on, eventually bringing the hindmost maxillary teeth into play, which permits the injection of toxins.

Constriction

Other feeding specializations are not so widespread among species, and some are restricted to a single group. Many of the boids and some of the colubrids utilize a constriction method for killing their food. The prey is struck and held by the teeth, and a series of body coils are rapidly thrown around it. These coils tighten until respiration is impossible and suffocation results, but very seldom are bones crushed or broken. The snail-eating snakes have a series of modifications of the teeth, the toothed bones, and the lower jaw that permit the insertion of the lower jaw into a shell to pull out the snail's body. One genus of sea snakes, *Microcephalophis*, has a tiny head and a long neck with the same diameter as the head, which can be inserted deeply into very narrow holes inhabited by its prey. An Asiatic water snake, *Erpeton*, has a pair of elongate tentacles on its snout that appear to function as sighting devices to guide the strange, stiff-bodied strike at a passing fish. There is a great correlation between the difficulty in catching a particular kind of prey and the development of morphological and behavioral devices to help solve the problem. The blind snake living in a termite nest needs no more than its tongue and Jacobson's organ to permit it to recognize the soft-bodied, defenseless termites, and its eyes and most of its teeth have been lost. But the rattlesnake, seeking the most elusive prey of all in the agile, aware, sensorily acute small mammal, has a full armament of equipment, including the facial pit, the venom gland, the rotatable maxillary bone, the tubular fang, and two functional eyes.

EVOLUTION AND CLASSIFICATION

Evolutionary origins. The oldest fossil definitely identifiable as a snake is *Dinilysia*, from the Upper Cretaceous (about 80,000,000 years ago) of Argentina, considered to be most closely related to the aniliids and others in the superfamily Booidea. Some fossils from earlier deposits have been called snakes, but American paleontologist Alfred S. Romer has tentatively regarded them as lizards. Snake bones are delicate and do not tend to fossilize well. Most snakes are small, and fossil hunters in the past tended to concentrate on larger, more spectacular specimens. Modern techniques have begun to turn up a wealth of material, much of very small size, including snake skull bones and vertebrae. Much of this material is from Pliocene, Pleistocene, and older Recent deposits, and it often either is identifiable with modern genera or else shows close resemblance to them.

Relation to lizards

Snakes are, thus, a comparatively young group of animals. They arose from a lizard ancestor probably very similar to the modern varanids (monitor lizards). *Dinilysia* shows certain characters very similar to those found in the Bornean lizard *Lanthanotus*, a platynotan lizard related to the Varanidae. Several theories have been proposed as to the habitat preference of the snake ancestor, including aquatic, terrestrial in savanna-like situations, or burrowing. Strong support for the burrowing hypothesis has come from study of the eye. Losses (such as the movable eyelid) caused by ancestral adaptation to burrowing were not regained by the descendant nonburrowing snakes, and other devices to cope with vision problems were developed and refined.

The phenomenal adaptive radiation that produced the many different species of colubrid snakes (a category that includes the vast majority of familiar snakes), now found in practically every kind of habitat and efficiently capitalizing upon almost every kind of terrestrial animal as food, was a very recent event. It probably took place entirely within the Tertiary (from about 65,000,000 to 2,500,000 years ago), and represents a triumph over the handicap of limb loss, which is often a blind alley in evolution. The development of more than 2,000 species of snakes occupying practically all available niches is an achievement equivalent to the concomitant emergence

and differentiation of the birds or perhaps even that of the mammals.

Distinguishing taxonomic features. Herpetologists have used a variety of characteristics in the recognition of higher taxonomic units within the snakes, but one tendency has characterized most of the classifications set up by different authors over the years. This has been to base the classification on contrasting conditions of a very few characteristics, occasionally only one. Characteristics used either by themselves or in combinations with one or two others have included the following: the manifold variations in the structure of the hemipenis; the presence or absence of various projections, knobs, folds, shelves, and other modifications of the individual vertebrae; the different types of maxillary teeth and their arrangement on the bone; arrangement and relationships of bones in the skull; presence or absence, location, origin, and insertion of muscles, primarily cranial, but occasionally those of the body; and the type of retina in the eye. If any one of these is emphasized over most others in a classification, that classification will be very different from other systems, because these characteristics are not closely associated genetically and do not tend to group themselves together but vary quite independently. Taxa at the lower levels of classification (genera and species) are usually recognized on the basis of external characteristics that permit easy identification, even though these cannot be used to indicate phylogenetic relationships. These characteristics include the shape, presence or absence, fusion, division, and relationships of the plates of the head; the numbers of rows of dorsal scales and their ornamentation with keels, striae, pits, etc.; the size, number, and condition of ventral, anal, and subcaudal scales; shape of body or head or both; and, in some cases, coloration.

Annotated classification. The classification presented here represents a conservative summary of the views expressed by G. Underwood, H.W. Parker, H.G. Dowling, A.S. Romer, A. Bellairs, and other prominent herpetologists in the recent literature. Careful analysis of the classifications offered by these authors shows that the major differences are in the level of taxonomic recognition given to a particular group rather than in the allocation of a group with regard to phylogenetic position.

SUBORDER SERPENTES

Reptiles without limbs and with the body greatly elongated; with a very high number of vertebrae in both body and tail, each individual vertebra with zygosphenes and zygantrum and almost all those of the body with a pair of attached ribs. Pectoral girdle completely absent; pelvic girdle usually absent, but present as a vestige in primitive species. Outer ear and tympanum lacking, sound reception entirely by bone conduction. Bones of both jaws usually flexible, loosely attached to the skull and to each other, plentifully supplied with teeth in most species, forming poison fangs in some. The braincase is platytrabic.

Superfamily Typhlopoidea (or Scolecophidia)

Diminutive, wormlike snakes that usually retain vestiges of the pelvic girdle and 2 common carotid arteries. Skull compact, with the bones solidly united, which facilitates burrowing; dentition very reduced, with no teeth on the pterygoid, premaxillary, or palatine bones. Intercostal arteries to almost all body segments.

Family Typhlopidae (blind snakes or worm snakes)

Maxillary bone bears teeth arranged transversely and can be rotated slightly on its attachment to the skull; dentary bone usually lacks teeth (present in anomalepine species). Either there is a single pelvic bone or the girdle is absent entirely. Circumtropical in distribution; practically no fossils are known, except for a few specimens from the Tertiary of Europe.

Family Leptotyphlopidae (slender blind snakes)

Maxillary bone bears no teeth and is quite firmly united with the skull; teeth are always present on the dentary. The pelvic girdle made of 3 bones. Tropics of Latin America to southwestern United States, Africa, and southwestern Asia. No fossils are known.

Superfamily Booidea (or Henophidia)

Moderate-sized to very large snakes. Often with vestiges of the pelvis and associated bones, sometimes visible externally as a rudimentary hind limb. There are two common carotid arteries. The coronoid bone of skull usually present; parasphenoid bone does not form part of the optic foramen; supraorbital bone absent in all except some members of the Boidae. Den-

tion well developed on all jawbones, usually including the premaxillary. Intercostal arteries running to almost all body segments are present.

Family Aniliidae

The femur present as an anal spur in males, and pelvis made up of a single bone. No hypapophyses on the body vertebrae. Ventral scales only slightly larger than dorsal scales, not extending across the full width of the belly. Premaxillary bone with teeth; forms a suture (tight seam) with the maxillary; dentary immovable. One genus, *Anilius*; known only from the Recent of South America; a brightly coloured snake, with red, black, and yellow rings around the body.

Family Xenopeltidae (sunbeam snakes)

Femur absent; no trace of the pelvic girdle. Hypapophyses on the anterior vertebrae. The ventral scales enlarged. Premaxillary bone toothed; forms a suture with the maxillary. Dentary hinged on the surangular bone and movable. One genus, *Xenopeltis*, burrowing snakes from India and elsewhere in Asia. No fossils known.

Family Uropeltidae (shieldtail snakes)

Femur absent; there may or may not be pelvic rudiments. No hypapophyses on the vertebrae. Ventral scales usually not more than twice as broad as the neighbouring dorsal scales. No teeth on the premaxillary, which forms a suture with the maxillary. Dentary fixed on the surangular and, thus, immovable. A family of burrowing snakes, found only in southern Asia. No fossils known.

Family Boidae (pythons, boas, and wood snakes)

Femur often present; pelvic vestiges occurring in all but a few genera. Hypapophyses present on vertebrae. Ventral scales broad, extending across the entire belly, except in a very few groups. Premaxillary may or may not bear teeth; does not form a suture with the maxillary. Circumtropical; it includes all of the giant snakes as well as several genera of small, secretive snakes. Bones from apparent boids have been found in Tertiary deposits around the world. The family is divided into subfamilies in different ways by different authors. The subfamilies Boinae, for the large New World constrictors, and the Pythoninae, for the Old World pythons, are almost universally recognized.

Family Acrochordidae (wart snakes)

Femur and all pelvic vestiges absent; hypapophyses present throughout the vertebral column. Ventral scales cannot be differentiated from dorsals. Premaxillary bone toothless and free of maxillary bone; dentary not hinged or any part of it free. One genus, *Acrochordus*; aquatic snakes found in Australia, the East Indies, and southeastern Asia. No fossils known.

Superfamily Colubroidea (or Caenophidia)

This superfamily includes the major number of snakes, which have in common the complete absence of any vestiges of the limb girdles and have only the left common carotid artery. Skull quite flexible, with several joints and sutures that permit movement of one part on another. Coronoid bone absent. No teeth on the premaxillary; characteristically, maxillary, palatine, pterygoid, and dentary bones all are toothed; some groups have a fang, or grooved tooth, at the posterior end of the maxillary. Intercostal arteries occur at intervals of several body segments.

Family Colubridae

Maxillary bone comparatively fixed in position, cannot be rotated; usually elongate and armed with teeth throughout its length. Posteriormost maxillary teeth grooved or hollow in some groups, but these fangs are preceded by a series of normal teeth in practically every instance. Hypapophyses may be present on vertebrae throughout the body or may be absent posteriorly, and this character has been used to divide the family into smaller groups. Tail usually long and ending in a point. Found all over the world where snakes occur; species make up the majority of snakes everywhere except Australia. Most of the following subfamilies are recognized by herpetologists, and some authors raise several of them to familiar status.

Subfamily Dasyptelinae (egg-eating snakes). Perforated esophagus and a series of elongated, enamel-tipped vertebral hypapophyses, which pass through the perforations and can crush eggshells. Teeth extremely reduced and peglike. Two genera, found in Africa and Asia.

Subfamilies Pareinae and Dipsadinae. Two small subfamilies of arboreal snakes, specialized for snail eating. These adaptations, including specially modified lower jaw, have evolved separately in the Asian Pareinae and the South American Dipsadinae.

Subfamily Xenodontinae. Large, bladelike posterior maxillary teeth, a large adrenal gland, and several other characters. Two of the genera, *Lystrophis* and *Heterodon*, have pointed, recurved, digging snouts not seen in *Xenodon*.

Subfamily Homalopsinae. Aquatic, fish-eating snakes, lacking grooved teeth. Stout body with a short tail. Southeast Asia, the East Indies, and Australia.

Subfamily Colubrinae. Widespread and often abundant group; contains most of the familiar harmless snakes of Europe and North America. Highly variable in coloration, size, and structure. Many nonpoisonous; some rear-fanged (but rarely dangerous to man); many kill by constriction. About 1,500 species.

Family Viperidae (vipers, rattlesnakes, moccasins, and relatives)

The maxillary bone rides on a hinged joint and is armed with a long, sharp tooth with a canal through it for injection of poison; no other teeth on the maxillary except for replacement fangs. Hypapophyses present on the vertebrae throughout the body.

Subfamily Viperinae (Old World vipers). No heat-sensitive pit or excavation in the maxillary bone. Found throughout Europe, Asia, and Africa but not in Australia. Fossils from Miocene of Europe.

Subfamily Crotalinae (pit vipers). Heat- or infrared-sensitive pit present on the side of the head between the nostril and the eye; maxillary bone with deep excavation in its outer surface to accommodate the pit organ. Widely distributed in the New World; one of the larger groups includes rattlesnakes. A few species also known from Asia. Fossils from Pliocene and Pleistocene of North America.

Family Elapidae (cobras, mambas, coral snakes and relatives)

Maxillary bone is shortened, fixed in position; cannot be rotated. Anteriormost tooth on the maxillary a short, fixed, hollow poison fang, usually but not always followed by a few other teeth. Hypapophyses are present on all body vertebrae. Tail rounded and normal, ending in a narrow tip. Elapids are also found abundantly in Asia, Africa, Central America, and South America; especially numerous in Australia, comprising, with sea snakes, more than two-thirds of snake species; rarely enter the United States; do not occur in Europe except as possible fossils.

Family Hydrophiidae (sea snakes)

The maxillary bone much like that of the elapids. Hypapophyses are present on the vertebrae throughout the body. The tail and part of the body compressed vertically into a large, oarlike swimming device. Found in the tropical western Pacific and Indian oceans; only one genus proven to have reached the Pacific coast of the New World.

Critical appraisal. The classification of snakes cannot yet be considered to have achieved the relative stability that characterizes bird and mammal classification. Authorities continue to disagree both on the taxonomic rank to be accorded certain groups and on the relationships of many groups. Romer, for example, recognizes the Xenopeltinae and Loxoceminae as subfamilies of the Aniliidae. Underwood, on the other hand, treats the first as a family, Xenopeltidae, and considers the Loxoceminae to be a subfamily of the Boidae. The Anomalepinae are regarded by some authors as sufficiently distinct from the Typhlopinae to warrant family status.

Emphasis on one characteristic, such as the presence or absence of a pelvis, profoundly affects the classification. Some authorities remove from the Uropeltidae all genera with pelvic remnants, placing them in the Aniliidae. Others have excluded from the Boidae all genera that lack pelvic remnants.

The family Colubridae has troubled taxonomists for nearly two centuries, many attempts having been made to break it into workable groups. The conservative view still recognizes only a few small, distinct subfamilies and several large grab-bag subfamilies. Many groups have been separated from the Colubrinae as subfamilies within the Colubridae or even as distinct families.

In older classifications, the pit vipers have sometimes been separated from the Old World vipers as the family Crotalidae. (J.A.P.)

Crocodylia (crocodiles)

The crocodiles constitute an order of the vertebrate class Reptilia. They are generally large, ponderous, amphibious animals, somewhat lizardlike in appearance, and carnivorous in habit. They have powerful jaws with many conical teeth and short legs with clawed, webbed toes. The tail is long and massive and the skin thick and plated. About 20 species are recognized.

The group is of particular interest because of its evolutionary position: the crocodiles are the last living link with the dinosaur-like reptiles of prehistoric times. They are, at the same time, the nearest living relatives of the birds. A large variety of crocodile fossils have been discovered; three of the four suborders of Crocodylia are extinct. On the basis of this extensive fossil record, it has been possible to establish well-defined relationships between the crocodiles and other vertebrate groups.

GENERAL FEATURES

Size range and diversity of structure. The crocodiles are the largest and the heaviest of present-day reptiles. In former times the Nile crocodile (*Crocodylus niloticus*) and the estuarine crocodile (*Crocodylus porosus*) attained a length of almost nine metres (about 30 feet), but today, specimens rarely exceed six metres (20 feet). Other species, for example, the smooth-fronted caiman (*Paleosuchus*) and the dwarf crocodile (*Osteolaemus tetraspis*) are about 1.7 metres (six feet) in length.

All crocodiles have a relatively long snout, or muzzle, which varies considerably in proportions and shape. The large horny plates that cover most of the body generally are arranged in a regular pattern. Thick, bony plates occur on the back. The families and genera may be distinguished by anatomical features, principally those of the skull. Species are identified principally by the proportions of the snout; by the bony structures on the dorsal, or upper, surface of the snout; and by the number and the arrangement of the large neck scutes.

From Mitteilungen aus dem Zoologischen Museum in Berlin

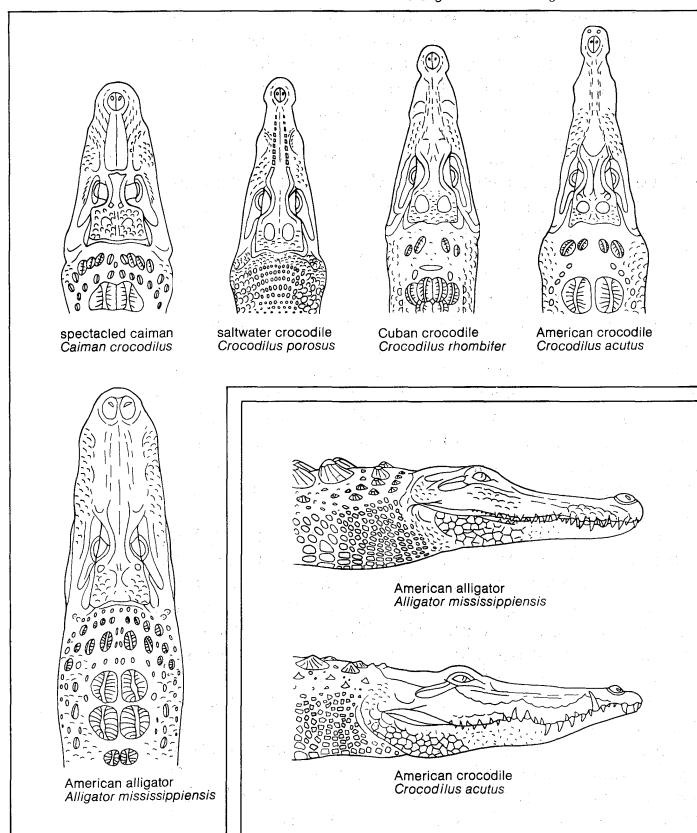

Figure 17: Heads of representative Crocodylia.

Distribution and abundance. The habitat of the crocodile is mainly the tropics and subtropics of the northern and southern hemispheres. The Mississippi, or American, alligator (*Alligator mississippiensis*), the American crocodile (*Crocodylus acutus*), and the Chinese alligator (*Alligator sinensis*) are the only species found outside the tropics.

The true crocodiles (family Crocodylidae) occur in most of Africa south of the Sahara, Madagascar, India, Sri Lanka, Southeast Asia, the East Indies, northern Australia, Mexico and Central America, the West Indies, and most of South America east of the Andes and north of the

mouth of the Río de la Plata. The caimans are confined to South America. The gaviail occurs in India.

As recently as several decades ago, crocodiles were plentiful in much of the tropics and subtropics, but today they are almost extinct in many areas, as the inroads of civilization continue to limit their natural habitat. Thousands are killed annually by man, either for sport or for their valuable skins, which provide leather for handbags, luggage, shoes, belts, and other articles. In some localities they are killed because of their depredation of domestic cattle. The governments of some countries have sought by legislation to protect the remaining crocodile populations from hunters.

The disappearance of the Nile crocodile from parts of Africa has resulted in an overabundance of the catfish *Clarias*, which in turn has greatly diminished the supply of popular food fishes. In an attempt to restore the original balance, crocodiles are bred and raised on farms. When they have grown to a length of about 1.5 metres (five feet) the crocodiles are released to their natural habitat.

NATURAL HISTORY

Life cycle. The young crocodile emerges from the egg with a length of 20–25 centimetres (eight to 10 inches). At first it remains concealed at the edge of its water habitat in order to avoid various predators. Principal among these are fishes and birds, but larger crocodiles also prey upon the young. During the first three to four years, the young increase in length by about 30 centimetres (about one foot) per year. The growth rate then gradually decreases, but growth can continue throughout life. Sexual maturity occurs at about ten years of age and at a body length of about 1.5 metres (five feet).

Of the little information available on the longevity of crocodiles, most has been gained from observation of animals in captivity. Captive animals seldom live more than 40 years, possibly because of lack of proper exercise and diet. Statistics on the growth of the Nile crocodile suggest, however, that specimens about six metres (20 feet) long are probably much more than 100 years old.

Behaviour. Crocodiles are predators, mostly nocturnal (*i.e.*, active at night), and spend most of their time in the water; they are also known to take rather long journeys over land. In their first weeks of life crocodiles eat mostly worms and water insects, then frogs and tadpoles; finally, their main diet is fish. Older crocodiles are more apt to prey upon waterfowl and on mammals, and occasionally a member of one of the larger species eats a human. This happens so infrequently, however, that crocodiles cannot be generally regarded as man-eaters.

Crocodiles capture water animals in their jaws with a sideways movement of the muzzle. To catch land animals they remain motionless at the edge of a water hole from which the prey habitually drink, or they float passively in the water, resembling a drifting log. With a swift blow of the tail, they knock unsuspecting prey into the water. A number of crocodile species grip the legs of the victim in their jaws, then rotate themselves rapidly in the water, thus tearing the prey apart. When a crocodile cannot consume all of a victim at one time, it drags the carcass into its burrow.

The burrow is dug more or less horizontally at or just above the waterline and may extend for several metres, eventually ending in a chamber. The Mississippi alligator and the China alligator enter a state of inactivity (*i.e.*, hibernate) in these chambers during cold periods.

During the day, crocodiles often lie at the water's edge to sun themselves, frequently in large numbers. Otherwise, crocodiles live as lone individuals and establish individual territories. The extent of the territory is apparently defined for the animal's neighbours by its loud, vibrant roar, answered in kind by the crocodiles in adjacent territories.

When it roars, the crocodile tenses the musculature of its body so that the head and tail rise high out of the water; the flanks may vibrate so violently that water is sprayed high into the air from each side. Roaring can be provoked by similar noises, such as a deep note from a trumpet or the sound of artillery or supersonic aircraft. Crocodiles are also capable of deep grunting sounds, which apparently

Declining populations

Diet

Intelligence

play a role during courtship, and a warning hiss. The young make squeaking sounds.

Of all reptile brains, the crocodile brain is the most highly developed. Crocodiles often show curiosity and are capable of being developed into tame animals—both attributes being measures of intelligence. If kept in captivity from birth, individuals of some species are known to recognize their keepers, show neither fear nor aggressiveness, beg for food, and permit themselves to be petted. In other words, they learn to adapt their behaviour to the unnatural captive environment.

Locomotion. The principal style of locomotion is that of swimming, in which the crocodile places its legs back against the sides of the body and moves forward by means of lateral wavelike motions of the tail. In walking on land, crocodiles hold themselves high on all four legs, and the body moves in waves, with a lateral swinging motion. When startled, crocodiles are able to run short distances, the two front legs moving forward and backward together as do also the two hindlegs, somewhat in the manner of a hopping rabbit. When moving quickly into the water from a bank, crocodiles slide on their bellies, pushing with the feet.

Reproduction. The sexes are outwardly different only in the Indian gavial (*Gavialis gangeticus*), in which the males, during the reproductive period, have a bulbous knob at the tip of the muzzle. Copulation occurs in the water and lasts about ten minutes. It is preceded by a courtship in which the animals rub their muzzles against each other and over the neck of the partner. The male then mounts the back of the female, and both animals rotate their tails so that the respective bodily openings are brought into contact. The distensible male reproductive organ is then inserted into the female.

All crocodiles lay hard-shelled eggs, which may number more than 100, depending upon the age and size of the female. The female builds a nest as a shelter for the eggs. The Nile crocodile female digs a trench, which it refills with dirt after laying the eggs. The female estuarine crocodile builds a mound of mud and decaying plant material, in the centre of which are the eggs. With her tail the female splashes water onto the nest. This promotes the heat-generating process of vegetative decay. The trench and mound types of nest are extremes, between which intermediate types are made by the various other species. In every case the female remains close to the nest and protects the eggs from predators until the eggs hatch.

After two or three months the young are fully developed and ready to hatch. While still in the egg they utter squeaking sounds, perhaps signalling that they are ready to emerge. The female then removes the dirt or other debris from the eggs but thereafter provides no further care for her offspring.

Ecology. Crocodiles are mainly inhabitants of swamps, lakes, and rivers, although some species make their way to brackish water or to the sea. The estuarine (or saltwater) crocodile (*C. porosus*), which lives almost entirely in the ocean, may swim miles out to sea. Such crocodiles venture upriver only as far as the limit of the salt water. The smooth-fronted caiman (*Paleosuchus*) in South America prefers rocky, fast-flowing rivers. In West Africa the dwarf crocodile (*Osteolaemus tetraspis*) is found principally in the rivers of the forest regions.

FORM AND FUNCTION

The form of the crocodile is adapted to its amphibious way of life. The elongated body with its long, muscular paddle tail is well suited to rapid swimming. Other features, enumerated below, are also adapted to the animal's amphibious habit.

The external nostril openings, the eyes, and the ear openings are the highest parts of the upper side of the head. These important sense organs thus remain above the water surface even when the rest of the head is submerged. The two nostril openings are close together on a raised portion of the point of the muzzle and may be closed by membranous flaps so that no water can enter when the animal dives. A long nasal passage enclosed in bone leads from the exterior nostril openings to the interior

nostril openings, or choanae, located at the extreme posterior end of the palate; a membranous flap in front of the choanae constitutes the posterior closure of the mouth cavity. Thus, the crocodile can breathe even if its mouth is open under water.

Like many nocturnal animals, crocodiles have eyes with vertical, slit-shaped pupils; these narrow in bright light and widen in darkness, thus controlling the amount of light that enters. On the back wall of the eye the so-called tapetum lucidum reflects the incoming light, thus utilizing small amounts of light to the best advantage. In addition to the protection provided by the upper and lower eyelids, the nictitating membrane, a thin, translucent structure, may be drawn over the eye from the inner corner while the lids are open. The delicate eyeball surface is thus protected under water, but a certain degree of vision is still possible.

Unlike the ears of other modern Reptilia, those of the crocodile have a movable, external membranous flap. By means of this structure the crocodile is able to protect its ears from the water.

The crocodile's relatively flat snout is usually quite long; in some species it is extremely elongated. The outer margin of the jaws in most species is jagged. Each jaw carries a row of sharp teeth, which may number more than 100 in species with very long muzzles. The teeth are held in sockets and replaced continuously, new ones growing from below and old ones being forced out. On the floor of the mouth is the thick, fleshy tongue, firmly attached and therefore almost immobile.

The posterior portion of the head forms a flat plate. Here the short, powerful neck is attached. On its upper side are two groups of knobby scales: the smaller postoccipital knobs (absent only in the estuarine crocodile); and the large nuchal knobs, which in some species may be connected to the adjacent horny plates of the back.

The upper surfaces of the back and tail are covered with large, rather rectangular horny plates arranged regularly in longitudinal and transverse rows. Most of the dorsal plates have a longitudinal ridge, or keel. Under these plates lie bony plates of about the same size, except in the estuarine crocodile, in which the bony plates are much smaller.

The entire underside of the crocodile usually also has regularly arranged horny plates, which are smaller than those on the upper surface, entirely smooth, rectangular, and contain little or no bone material. An exception to this condition occurs in caimans of the genera *Melanosuchus*, *Caiman*, and *Paleosuchus*, in which the surface plates on the lower side are just as bony as those on the back. Slightly posterior to the attachment of the hindlegs, on the underside of the base of the tail, lies the anus, which extends longitudinally, surrounded by an oval area of small scales.

In contrast to the back and belly, the sides of the body have mostly small knobby scales. The flanks are thus distensible, a necessary condition for breathing and for the expansion of the body that occurs in the pregnant female.

The legs are short but powerful. The forefeet have five toes—the usual number for Reptilia. In their anatomical structure, however, the forelegs differ markedly from those of other reptiles. This departure suggests that crocodiles developed from ancestors with degenerate forelegs; it also supports the possibility of a close evolutionary relationship between the crocodiles and the birds, in which the forelimbs have been considerably modified. The hindlegs are more powerfully developed than the front pair. The hind feet have only four toes, which are wholly or partially webbed.

On its flat upper side the tail carries a comb which, in the anterior portion, is double, consisting of high leaf-shaped scales. Near the middle of the tail the two combs merge.

The heart of the crocodile is markedly different in structure from that of other reptiles: the two auricles and the two ventricles are completely separate.

There exists, nevertheless, a connection between the arterial and venous circulation by way of the so-called Panizzae foramen, which opens between the two vessels leading separately from the ventricles. This connection is necessary for equalization of pressure differences between

The nest

Body plates

Sensory structures

Arterial-venous connection

the arterial and venous circulatory systems that arise during long dives in deep water.

EVOLUTION AND CLASSIFICATION

Paleontology. The crocodile skull exhibits distinctly developed upper and lower temporal (*i.e.*, behind the eye sockets) openings; the teeth arise from sockets, and the roof of the skull lacks an opening for the parietal organ, a median, dorsal outgrowth of the brain. The crocodiles thus show the most important characteristics of the group that includes the dinosaurs (Archosauria). Within the Archosauria the crocodiles are a separate order, since they have developed a secondary bony palate, which encloses the nasal passage from the exterior nasal openings to the choanae (internal nostrils).

These features occur even in the most primitive representatives of the crocodile group, namely the Protosuchia of the Upper Triassic Period (about 190,000,000–200,000,000 years ago); but their muzzles were very short, and the choanae were relatively far forward on the palate. As the crocodiles continued to evolve, the openings of the choanae tended to move further back. In the Mesosuchia of the Jurassic (136,000,000–190,000,000 years ago) and Cretaceous periods (65,000,000–136,000,000 years ago)—to which the long-snouted ocean crocodiles also belong—the choanae had already moved to the posterior part of two bones of the skull (palatines). In the true crocodiles (Eusuchia), which appear in the Upper Jurassic, the choanae are entirely enclosed by the pterygoids. In modern species they have moved to the posterior border of the palate. In the Sebecosuchia of the Upper Cretaceous to the Miocene Epoch (7,000,000–26,000,000 years ago), a branch collateral to that of the crocodiles, the skull is laterally flattened, and the choanae lie in a depression in the anterior part of the pterygoids.

Distinguishing taxonomic features. The families and genera of the order Crocodilia are differentiated primarily by the anatomical peculiarities of their skulls. The classification of the species is based mainly upon external characteristics, such as the proportions of the snout, the bony structures on the dorsal side of the snout, the number of teeth, the number and arrangement of the large knobs on the nape of the neck, and the characteristics of the dorsal plates.

Annotated classification. Extinct groups represented only by fossils are indicated by a dagger (†).

ORDER CROCODILIA

Heavy cylindrical body; large, triangular head; legs short, toes webbed; long, muscular tail; large flat plates on belly, keeled ones on back; heart 4-chambered.

†Suborder Protosuchia

Upper Triassic; muzzle very short; choanae (internal nostrils) in region of palatine bones.

†Suborder Mesosuchia

Jurassic to Upper Cretaceous; choanae in posterior part of palatine bones.

†Suborder Sebecosuchia

Upper Cretaceous to Miocene; skull laterally flattened; choanae in depression in anterior part of pterygoids.

Suborder Eusuchia

Upper Jurassic to Recent; choanae entirely enclosed by pterygoids.

Family Alligatoridae (alligators)

Four genera and 7 species; teeth of lower jaw fit inside those of upper jaw.

Family Crocodylidae (true crocodiles)

Three genera and 13 species; teeth of upper and lower jaws form one interdigitating row when mouth is closed.

Family Gavialidae (gavial)

One genus and 1 species; extremely long snout, more than 22 teeth in each jaw; nasal bones separated from premaxillaries.

Critical appraisal. One authority has separated the order Crocodylomorpha into two suborders, Crocodilia and Paracrocodylia. According to this scheme the Crocodilia include as infra-orders those groups given above as suborders. This scheme also contains a suborder, Thalattosuchia.

Widely different views prevail concerning the classification of the living groups of Eusuchia—*i.e.*, the alligators,

the true crocodiles, and the gavials. Of these, the alligators and the true crocodiles, without doubt more closely related to each other than to the gavials, are sometimes regarded as constituting two subfamilies of the family Crocodylidae. Some authors regard the gavials as a third subfamily. Others give the false gavial, or Sunda gavial, a special position with respect to the true crocodiles. For conciseness, these three groups have been treated here as distinct families.

Sauria: General surveys of the species of lizards and their life histories, with many photographs, are found in K.P. SCHMIDT and R.F. INGER, *Living Reptiles of the World* (1957); A.F. CARR, *The Reptiles* (1963); R. MERTENS, *La vie des amphibiens et reptiles* (1959; Eng. trans., *The World of Amphibians and Reptiles*, (1960); and H.M. SMITH, *Handbook of Lizards: Lizards of the United States and Canada* (1946). V.A. HARRIS, *The Anatomy of the Rainbow Lizard* (1963), provides a dissection manual for students, moderately technical but very readable. Of a more technical nature is a work by A.S. ROMER: *Osteology of the Reptiles* (1956). W.W. MILSTEAD (ed.), *Lizard Ecology: A Symposium* (1967), contains summaries of research in population ecology, physiological ecology, and social behaviour, with panel discussions of the reports; an excellent source for understanding trends in research.

Important taxonomic books and papers, not easily read by the layman, but fundamental to an understanding of the classification are: C.L. CAMP, "Classification of the Lizards," *Bull. Am. Mus. Nat. Hist.*, 48:289-480 (1923); R. HOFFSTETTER, "Revue des récentes acquisitions concernant l'histoire et la systématique des squamates," in *Problèmes actuels de paléontologie (évolutions des vertébrés)*, pp. 243-279 (1962); A.G. KLUGE, "Higher Taxonomic Categories of Gekkonid Lizards, and Their Evolution," *Bull. Am. Mus. Nat. Hist.*, 135:1-59 (1967); S.B. MCDOWELL and C.M. BOGERT, "The Systematic Position of *Lanthanotus* and the Affinities of the Anguimorph Lizards," *ibid.*, 105:1-142 (1954); M.R. MILLER, "The Cochlear Duct of Lizards," *Proc. Calif. Acad. Sci.*, 4th series, 33:255-359 (1966), and "The Cochlear Duct of Snakes," *ibid.*, 35:425-476 (1968); G. UNDERWOOD, "On the Classification and Evolution of Geckoes," *Proc. Zool. Soc., Lond.*, 124:469-492 (1954), "On Lizards of the Family Pygopodidae, a Contribution to the Morphology and Phylogeny of the Squamata," *J. Morph.*, 100:207-268 (1957), and "A Contribution to the Classification of Snakes," *Publ. Br. Mus. Nat. Hist.*, no. 635 (1967); A.E. GREER, "A Sub-familial Classification of Scincid Lizards," *Bull. Mus. Comp. Zool. Harv.*, 139:151-183 (1970).

Serpentes: CARL GANS *et al.* (eds.), *Biology of the Reptilia* (1969-), a multivolume work, made up of contributions by specialists, that will eventually summarize current knowledge about the class Reptilia, with emphasis on morphology, embryology and physiology, and ecology and behaviour; GEORGE A. BOULENGER, *Catalogue of the Snakes in the British Museum, Natural History*, 3 vol. (1893-96), a classic work, the only attempt ever made in the English language to list, describe, and help identify all the snakes of the world; GARTH UNDERWOOD, *A Contribution to the Classification of Snakes* (1967), a highly technical discussion of relationships among the various kinds of snakes; JAMES A. PETERS, *Dictionary of Herpetology* (1964), contains extensive information about snakes and other reptiles, in a readily accessible form; ROGER CONANT, *A Field Guide to Reptiles and Amphibians of the United States and Canada East of the 100th Meridian* (1958), and ROBERT C. STEBBINS, *A Field Guide to Western Reptiles and Amphibians* (1966), extensively illustrated manuals for field identification of snakes, as well as other reptiles; CLIFFORD H. POPE, *The Giant Snakes* (1961), an entertaining discussion of the very large snakes, and *Snakes Alive and How They Live* (1937, reprinted 1958), although somewhat outdated, still a readable account of snake natural history; ALBERT H. and ANNA A. WRIGHT, *Handbook of Snakes of the United States and Canada*, 2 vol. (1957), detailed descriptions of all the kinds of snakes known on the North American continent, with many photographs; COLEMAN J. and OLIVE B. GOIN, *Introduction*

to Herpetology (1962), a textbook designed for undergraduate classes at the college level; KARL P. SCHMIDT and ROBERT F. INGER, *Living Reptiles of the World*, pp. 175-279 (1957), a popular account, aimed at the general public, profusely illustrated with colour photographs; RAMONA and DESMOND MORRIS, *Men and Snakes* (1965), a thorough review of man's relationships with snakes, including culture, mythology, medicine, and exploitation; H.W. PARKER, *Natural History of Snakes* (1965), one of the handbook guides to the British Museum, and *Snakes* (1963), a factual account of the general biology of snakes; LAURENCE M. KLAUBER, *Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind*, 2 vol. (1956; abridged ed., 1982), a thorough summary, not only of rattlesnakes but of all snakes, their biology and relationships with man; HOBART M. SMITH, *Snakes As Pets* (1965), a guide to the care and feeding of snakes in captivity; JAMES A. OLIVER, *Snakes in Fact and Fiction* (1958), a popular account of the snake, with both true and imaginative stories about size, food, numbers, and other bits of natural history; WOLFGANG BUCHERL, E.E. BUCKLEY, and V. DEULOFEU (eds.), *Venomous Animals and Their Venoms*, 2 vol. (1968-71), a discussion of the classification, distribution, and biology of venomous snakes, with detailed discussions of their venoms as well as treatment of snakebite; SHERMAN A. and MADGE R. MINTON, *Venomous Reptiles* (1969), an entertaining and often anecdotal account of venoms, venomous reptiles, their bites and the treatment of bites, and the intricate relationships of snakes with man and his cultures; TONY PHELPS, *Poisonous Snakes* (1981), a treatment of the rear-fanged colubrids, the elapids, and the vipers.

Crocodylia: M.M. COHEN and C. GANS, "The Chromosomes of the Order Crocodylia," *Cytogenetics*, 9:81-105 (1970), pictures of karyotypes of all recent species of crocodiles and an attempt to interpret them from the viewpoint of evolution; H.B. COTT, "Scientific Results of an Inquiry into the Ecology and Economic Status of the Nile Crocodile (*Crocodilus niloticus*) in Uganda and Northern Rhodesia," *Trans. Zool. Soc. Lond.*, 29:211-356 (1961), one of the most comprehensive accounts of the behaviour and territorialism of the Nile crocodile; O. KUHN, *Die vorzeitlichen Krokodile* (1968), a survey of all recent and fossil crocodiles and a proposal of a common classification for both; F.J. Aquar.-Terrar.-Z.*, 16:90-92 (1963), observations on the intelligence of a tame, seven-foot, spectacled caiman; O. VON WETTSTEIN, "Crocodylia," *Handb. Zool.*, 7:236-424 (1931), a complete monograph of the recent crocodiles, with an extensive bibliography.

Respiration and Respiratory Systems

Respiration is the process by which animal organisms take up oxygen and discharge carbon dioxide in order to satisfy their energy requirements. In the living organism, energy is liberated, along with carbon dioxide, through the oxidation of molecules containing carbon. The term respiration also denotes the exchange of the respiratory gases (oxygen and carbon dioxide) between the organism and the medium in which it lives and between the cells of the body and the tissue fluid that bathes them.

With the exception of energy used by animal life in the deep ocean, all energy used by animals is ultimately derived from the energy of sunlight. The carbon dioxide in the atmosphere in conjunction with the energy of sunlight is used by plants to synthesize sugars and other components. Animals consume plants or other organic material

to obtain chemical compounds, which are then oxidized to sustain vital processes.

This article first considers the gaseous components of air and water, the natural respiratory habitats of animals, and the basic types of respiratory structures that facilitate gas exchange in these environments. After this general survey, the human respiratory system and human respiration are examined in detail, followed by an overview of diseases and disorders affecting respiration. For a depiction of some of the structures that make up the human respiratory system, shown in relation to other parts of the gross anatomy, see the colour Trans-Vision in the *Propædia*, Part Four, Section 421.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 336, 421, and 423. The article is divided into the following sections:

General features of the respiratory process	725	Gas exchange in the lung	
The gases in the environment	725	Abnormal gas exchange	
Basic types of respiratory structures	726	Interplay of respiration, circulation, and metabolism	743

Transport of carbon dioxide			

General features of the respiratory process

Although the acquisition of oxygen and the elimination of carbon dioxide are essential requirements for all animals, the rate and amount of gaseous exchange vary according to the kind of animal and its state of activity. In the Table the oxygen consumption of various animals is expressed in terms of millilitres of oxygen per kilogram of body weight per hour, reflecting the gas demands of different species at rest and in motion. A change in the chemical composition of the body fluids elicits a response from the central nervous system, which then excites or depresses the machinery of external respiration.

THE GASES IN THE ENVIRONMENT

The range of respiratory problems faced by aquatic and terrestrial animals can be seen from the varying composition and physical characteristics of water and air. Air contains about 20 times the amount of oxygen found in air-saturated water. In order to extract an equivalent amount of oxygen as an air breather, an aquatic animal may find it necessary to pass across the respiratory surfaces a relatively larger volume of the external medium. Moreover, the diffusion rate of oxygen is much lower in water than in air. The problem is further compounded by the higher

density (1,000 times air) and viscosity (100 times air) of water, which impose on the machinery of aquatic respiration a much greater work load. Thus, fish may expend about 20 percent of their total oxygen consumption in

Oxygen Consumption of Various Animals and Its Variation with Rest and Activity

	weight (grams)	oxygen consumption (millilitres per kilogram of weight per hour)
Paramecium	0.000001	500
Mussel (<i>Mytilus</i>)	25	22

running the respiratory pump, as compared with about 1 to 2 percent in mammals, including humans.

The carbon dioxide content of most natural waters is low compared with air, often almost nil. In contrast to oxygen, carbon dioxide is extremely soluble in water and diffuses rapidly. Most of the carbon dioxide entering water combines either with the water (to form carbonic acid) or with other substances (to form carbonates or bicarbonates). This buffering capacity maintains a low level of free carbon dioxide and facilitates the maintenance of a favourable diffusion gradient for carbon dioxide exchange by water breathers. In general, oxygen exchange, which is strongly dependent on the oxygen content of the water, is more critically limiting for aquatic forms than is the exchange of carbon dioxide.

Temperature exerts a profound effect on the solubility of gases in water. A change from 5° to 35° C (41° to 95° F) reduces the oxygen content of fresh water by nearly half. At the same time, a rise in body temperature produces an increase in oxygen consumption among animals that do not closely regulate their body temperatures (so-called cold-blooded animals). A fish experiencing both rising water and body temperatures is under a double handicap: more water must be pumped across its gill surfaces to extract the same amount of oxygen as was needed at the lower temperature; and the increased metabolism requires greater quantities of oxygen.

The amount of oxygen available in natural waters is also limited by the amount of dissolved salts. This factor is a determinant of oxygen availability in transitional zones between sea and fresh water. Pure water, when equilibrated with oxygen at 0° C, for example, contains about 50 millilitres of oxygen per litre; under the same conditions, a solution containing 2.9 percent of sodium chloride contains only 40 millilitres of oxygen per litre. Bodies of water may have oxygen-poor zones. Such zones are especially evident in swamps and at the lower levels of deep lakes. Many animals are excluded from such zones; others have become remarkably adapted to living in them.

The Earth's atmosphere extends to a height of many miles. It is composed of a mixture of gases held in an envelope around the globe by gravitational attraction. The atmosphere exerts a pressure proportional to the weight of a column of air above the surface of the Earth extending to the limit of the atmosphere: atmospheric pressure at sea level is on average sufficient to support a column of mercury 760 millimetres in height (abbreviated as 760 mm Hg—the latter being the chemical symbol for mercury). Dry air is composed chiefly of nitrogen and inert gases (79.02 percent), oxygen (20.94 percent), and carbon dioxide (0.03 percent), each contributing proportionately to the total pressure. These percentages are relatively constant to about 80.5 kilometres in altitude. At sea level and a barometric pressure of 760 millimetres of mercury, the partial pressure of nitrogen is 79.02 percent of 760 millimetres of mercury, or 600.55 millimetres of mercury; that of oxygen is 159.16 millimetres of mercury; and that of carbon dioxide is 0.20 millimetres of mercury.

The existence of water vapour in a gas mixture reduces the partial pressures of the other component gases but does not alter the total pressure of the mixture. The importance of water-vapour pressure to gas composition can be appreciated from the fact that at the body temperature of humans (37° C, or 98.6° F) the atmospheric air drawn into the lungs becomes saturated with water vapour. The water-vapour pressure at 37° C is 47 millimetres of mercury. To calculate the partial pressures of the respiratory gases, this value must be subtracted from the atmospheric pressure. For oxygen, 760 (the atmospheric pressure) - 47 = 713 millimetres of mercury, and 713×0.209 (the percentage of oxygen in the atmosphere) = 149 millimetres of mercury; this amounts to some 10 millimetres of mercury lower than the partial pressure of oxygen in dry air at 760 millimetres of mercury total pressure.

Atmospheric pressures fall at higher altitudes, but the composition of the atmosphere remains unchanged. At 7,600 metres (25,000 feet) the atmospheric pressure is 282 millimetres of mercury and the partial pressure of oxygen is about 59 millimetres of mercury. Oxygen continues to

constitute only 20.94 percent of the total gas present. The rarefaction of the air at high altitudes not only limits the availability of oxygen for the air breather, it also limits its availability for aquatic forms, since the amount of dissolved gas in water decreases in parallel with the decline in atmospheric pressure. Lake Titicaca in Peru is at an altitude of about 3,810 metres; one litre of lake water at this altitude (and at 20° C, or 68° F) holds four millilitres of oxygen in solution; at sea level, it would hold 6.4.

The variations in the characteristics of air and water suggest the many problems with which the respiratory systems of animals must cope in procuring enough oxygen to sustain life.

BASIC TYPES OF RESPIRATORY STRUCTURES

Respiratory structures are tailored to the need for oxygen. Minute life-forms, such as protozoans, exchange oxygen and carbon dioxide across their entire surfaces. Multicellular organisms, in which diffusion distances are longer, generally resort to other strategies. Aquatic worms, for example, lengthen and flatten their bodies to refresh the external medium at their surfaces. Sessile sponges rely on the ebb and flow of ambient water. By contrast, the jellyfish, which can be quite large, has a low oxygen need because its content of organic matter is less than 1 percent and its metabolizing cells are located just beneath the surface, so that diffusing distances are small.

Organisms too large to satisfy their oxygen needs from the environment by diffusion are equipped with special respiratory structures in the form of gills, lungs, specialized areas of the intestine or pharynx (in certain fishes), or tracheae (air tubes penetrating the body wall, as in insects).

Respiratory structures typically have an attenuated shape and a semipermeable surface that is large in relation to the volume of the structure. Within them there is usually a circulation of body fluids (blood through the lungs, for example). Two sorts of pumping mechanisms are frequently encountered: one to renew the external oxygen-containing medium, the other to ensure circulation of the body fluids through the respiratory structure. In air-breathing vertebrates, alternately contracting sets of muscles create the pressure differences needed to expand or deflate the lungs, while the heart pumps blood through the respiratory surfaces within the lungs. Oxygenated blood returning to the heart is then pumped through the vascular system to the various tissues where the oxygen is consumed.

Respiratory organs of invertebrates. Two common respiratory organs of invertebrates are trachea and gills. Diffusion lungs, as contrasted with ventilation lungs of vertebrates, are confined to small animals, such as pulmonate snails and scorpions.

Trachea. This respiratory organ is a hallmark of insects (Figure 1). It is made up of a system of branching tubes that deliver oxygen to, and remove carbon dioxide from, the tissues, thereby obviating the need for a circulatory system to transport the respiratory gases (although the circulatory system does serve other vital functions, such as the delivery of energy-containing molecules derived from food). The pores to the outside, called spiracles, are typically paired structures, two in the thorax and eight in the abdomen. Periodic opening and closing of the spiracles prevents water loss by evaporation, a serious threat to insects that live in dry environments. Muscular pumping motions of the abdomen, especially in large animals, may promote ventilation of the tracheal system.

Although tracheal systems are primarily designed for life in air, in some insects modifications enable the tracheae to serve for gas exchange under water (Figure 2). Of special interest are the insects that might be termed bubble breathers, which, as in the case of the water beetle *Dytiscus*, take on a gas supply in the form of an air bubble under their wing surfaces next to the spiracles before they submerge. Tracheal gas exchange continues after the beetle submerges and anchors beneath the surface. As oxygen is consumed from the bubble, the partial pressure of oxygen within the bubble falls below that in the water; consequently oxygen diffuses from the water into the bubble to replace that consumed. The carbon dioxide produced by the insect diffuses through the tracheal system into

Buchsbaum, *Animals Without Backbones*, 2nd ed. (1948), The University of Chicago Press

the bubble and thence into the water. The bubble thus behaves like a gill. There is one major limitation to this adaptation: As oxygen is removed from the bubble, the partial pressure of the nitrogen rises, and this gas then diffuses outward into the water. The consequence of outward nitrogen diffusion is that the bubble shrinks and its oxygen content must be replenished by another trip to the surface. A partial solution to the problem of bubble renewal has been found by small aquatic beetles of the family Elmidae (e.g., *Elmis*, *Riolus*), which capture bubbles containing oxygen produced by algae and incorporate this gas into the bubble gill. Several species of aquatic beetles also augment gas exchange by stirring the surrounding water with their posterior legs.

An elegant solution to the problem of bubble exhaustion during submergence has been found by certain beetles that have a high density of cuticular hair over much of the surface of the abdomen and thorax. The hair pile is so dense that it resists wetting, and an air space forms below it, creating a **plastron**, or air shell, into which the tracheae open. As respiration proceeds, the outward diffusion of nitrogen and consequent shrinkage of the gas space are prevented by the surface tension—a condition manifested by properties that resemble those of an elastic skin under tension—between the closely packed hairs and the water. The plastron becomes “permanent” in the sense that further bubble trapping at the surface is no longer necessary,

Plastron

and the beetles may remain submerged indefinitely. Since the plastron hairs tend to resist deformation, the beetles can live at considerable depths without compression of the plastron gas.

One extraordinary strategy used by the hemipteran insects *Buenoa* and *Anisops* is an internal oxygen store that enables them to lurk for minutes without resurfacing while awaiting food in relatively predator-free but oxygen-poor mid-water zones. The internal oxygen store is in the form of hemoglobin-filled cells that constitute the first line of oxygen delivery to actively metabolizing cells, sparing the small air mass in the tracheal system while the hemoglobin store is being depleted.

The respiratory structures of spiders consist of peculiar “book lungs,” leaflike plates over which air circulates through slits on the abdomen. The book lungs contain blood vessels that bring the blood into close contact with the surface exposed to the air and where gas exchange between blood and air occurs. In addition to these structures, there may also be abdominal spiracles and a tracheal system like that of insects.

The “book lungs” of spiders

Since spiders are air breathers, they are mostly restricted to terrestrial situations, although some of them regularly hunt aquatic creatures at stream or pond edges and may actually travel about on the surface film as easily as on land. The water spider *Argyroneta aquatica*, the frogman of the spider world, utilizes the water-beetle method of capturing air bubbles at the surface. The bubble is pressed against the respiratory openings on the abdomen, but, because there is no permanent plastron, trips must be made to the surface for bubble renewal. Most of the life cycle of the water spider, however, including courtship and breeding, prey capture and feeding, and the development of eggs and embryos, occurs below the water surface. Many of these activities take place in a kind of diving bell formed by silk. The spider weaves an inverted basketlike web that is anchored to underwater plants or other objects. Bubbles captured at the surface are ejected into the interior, inflating the underwater house with air. The combination of bubble trapping and web building has given *Argyroneta aquatica* access to an environment denied most of its relatives.

Many immature insects have special adaptations for an aquatic existence. Thin-walled protrusions of the integument, containing tracheal networks, form a series of gills (tracheal gills) that bring water into close contact with the closed tracheal tubes (see Figure 2). The nymphs of mayflies and dragonflies have external tracheal gills attached to their abdominal segments, and certain of the gill plates may move in a way that sets up water currents over the exchange surfaces. Dragonfly nymphs possess a series of tracheal gills enclosed within the rectum. Periodic pumping of the rectal chamber serves to renew water flow over the gills. Removing the gills or plugging the rectum results in lower oxygen consumption. Considerable gas exchange also occurs across the general body surface in immature aquatic insects.

The insect tracheal system has inherent limitations. Gases diffuse slowly in long narrow tubes, and effective gas transport can occur only if the tubes do not exceed a certain length. It is generally thought that this has imposed a size limit upon insects.

Gills of invertebrates. Gills are evaginations of the body surface. Some open directly to the environment; others, as in fishes, are enclosed in a cavity. In contrast, lungs represent invaginations of the body surface that comes in contact with the environmental medium and across which gas exchange occurs can be viewed as a gill. Gills usually have a large surface area in relation to their mass; pumping devices are often employed to renew the external medium. Although gills are generally used for water breathing, and lungs for air breathing, this association is not invariable, as exemplified by the water lungs of sea cucumbers.

The marine polychaete worms use not only the general body surface for gas exchange but also a variety of gill-like structures: segmental flaplike parapodia (in *Nereis*) or

Varieties of gill-like structures

Figure 2: Ways by which aquatic insects obtain oxygen.

This figure first appeared in *New Scientist*, the weekly review of science and technology, 128 Long Acre, London W.C. 2

elaborate branchial tufts (among the families Terebellidae and Sabellidae). The tufts, used to create both feeding and respiratory currents, offer a large surface area for gas exchange.

In echinoderms (starfish, sea urchins, brittle stars), most of the respiratory exchange occurs across tube feet (a series of suction-cup extensions used for locomotion). However, this exchange is supplemented by extensions of the coelomic, or body-fluid, cavity into thin-walled "gills" or dermal branchiae that bring the coelomic fluid into close contact with seawater. Sea cucumbers (Holothuridae), soft-bodied, sausage-shaped echinoderms that carry on some respiration through their oral tentacles, which correspond to tube feet, also have an elaborate "respiratory tree" consisting of branched hollow outpouchings off the cloaca (hindgut). Water is pumped in and out of this system by the action of the muscular cloaca, and it is probable that a large fraction of the animals' respiratory gas is exchanged across this system.

The gills of mollusks have a relatively elaborate blood supply, although respiration also occurs across the mantle, or general epidermis. Clams possess gills across which water circulates, impelled by the movements of millions of microscopic whips called cilia. In the few forms studied, the extraction of oxygen from the water has been found to be low, on the order of 2 to 10 percent. The currents produced by ciliary movement, which constitute ventilation, are also utilized for bringing in and extracting food. At low tide or during a dry period, clams and mussels close their shells and thus prevent dehydration. Metabolism then shifts from oxygen-consuming (aerobic) pathways to oxygen-free (anaerobic) pathways, which causes acid products to accumulate; when normal conditions are restored, the animals increase their ventilation and oxygen extraction in order to rid themselves of the acid products. In snails, the feeding mechanism is independent of the respiratory surface. A portion of the mantle cavity in the form of a gill or "lung" serves as a gas-exchange site. In air-breathing snails, the "lung" may be protected from drying out through contact with the air by having only a pore in the mantle as an opening to the outside. Cephalopod mollusks, such as squid and octopus, actively ventilate a

protected chamber lined with feathery gills that contain small blood vessels (capillaries); their gills are quite effective, extracting 60 to 80 percent of the oxygen passing through the chamber. In oxygen-poor water, the octopus may increase its ventilation 10-fold, indicating a more active control of respiration than appears to be present in other classes of mollusks.

Many crustaceans (crabs, shrimps, crayfish) are very dependent on their gills. As a rule, the gill area is greater in fast-moving crabs (*Portunids*) than in sluggish bottom dwellers; decreases progressively from wholly aquatic, to intertidal, to land species; and is greater in young crabs than in older crabs. Often the gills are enclosed in protective chambers, and ventilation is provided by specialized appendages that create the respiratory current. As in cephalopod mollusks, oxygen utilization is relatively high—up to 70 percent of the oxygen is extracted from the water passing over the gills in the European crayfish *Astacus*. A decrease in the partial pressure of oxygen in the water elicits a marked increase in ventilation (the volume of water passing over the gills); at the same time, the rate of oxygen utilization declines somewhat. Although more oxygen is extracted per unit of time, the increased ventilation increases the oxygen cost of breathing. The increased oxygen cost, together with the decrease in extraction per unit of volume, probably limits aquatic forms of crustaceans to levels of oxidative metabolism lower than those found in many air-breathing forms. This is largely due to the lower relative content of oxygen in water and the higher oxidative cost of ventilating a dense and viscous medium compared with air. Not all crustaceans meet a reduction in oxygen with increased ventilation and metabolism. The square-backed crabs (*Sesarma*) become less active, reducing their oxidative metabolism until more favourable conditions prevail.

Respiratory organs of vertebrates. In most vertebrates the organs of external respiration are thin-walled structures well supplied with blood vessels. Such structures bring blood into close association with the external medium so that the exchange of gases takes place across relatively small distances. There are three major types of respiratory structures in the vertebrates: gills, integumentary exchange areas, and lungs. The gills are totally external in a few forms (as in *Necturus*, a neotenic salamander), but in most they are composed of filamentous leaflets protected by bony plates (as in fish). Some fishes and numerous amphibians also use the body integument, or skin, as a gas-exchange structure. Both gills and lungs are formed from outpouchings of the gut wall during embryogenesis. Such structures have the advantage of a protected internal location, but this requires some sort of pumping mechanism to move the external gas-containing medium in and out.

The quantity of air or water passing through the lungs or gills each minute is known as the ventilation volume. The rate or depth of respiration may be altered to bring about adjustments in ventilation volume. The ventilation volume of humans at rest is approximately six litres per minute. This may increase to more than 100 litres per minute with increases in the rate of respiration and the quantity of air breathed in during each respiratory cycle (tidal volume). Certain portions of the airways (trachea, bronchi, bronchioles) do not participate in respiratory exchange, and the gas that fills these structures occupies an anatomical dead space of about 150 millilitres in volume. Of a tidal volume of 500 millilitres, only 350 millilitres ventilate the gas-exchange sites.

The maximum capacity of human lungs is about six litres. During normal quiet respiration, a tidal volume of about 500 millilitres is inspired and expired during every respiratory cycle. The lungs are not collapsed at the close of expiration; a certain volume of gas remains within them. At the close of the expiratory act, a normal subject may, by additional effort, expel another 1,200 millilitres of gas. Even after the most forceful expiratory effort, however, there remains a residual volume of approximately 1,200 millilitres. By the same token, at the end of a normal inspiration, further effort may succeed in drawing into the lungs an additional 3,000 millilitres.

The gills. The gills of fishes are supported by a series

Gills of crustaceans

Ventilation volume

Fish gills

of gill arches encased within a chamber formed by bony plates (the operculum). A pair of gill filaments projects from each arch; between the dorsal (upper) and ventral (lower) surfaces of the filaments, there is a series of secondary folds, the lamellae, where the gas exchange takes place (Figure 3). The blood vessels passing through the gill arches branch into the filaments and then into still smaller vessels (capillaries) in the lamellae. Deoxygenated blood from the heart flows in the lamellae in a direction counter to that of the water flow across the exchange surfaces. In a number of fishes the water-to-blood distance across which gases must diffuse is 0.0003 to 0.003 millimetre, or about the same distance as the air-to-blood pathway in the mammalian lung.

The countercurrent flow of blood through the lamellae in relation to external water flow has much to do with the efficiency of gas exchange. Laboratory experiments in which the direction of water flow across fish gills was reversed showed that about 80 percent of the oxygen was extracted in the normal situation, while only 10 percent was extracted when water flow was reversed. The uptake of oxygen from water to blood is thus facilitated by countercurrent flow; in this way, greater efficiency of oxygen uptake is achieved by an anatomical arrangement that is free of energy expenditure by the organism. Countercurrent flow is a feature of elasmobranchs (sharks, skates) and cyclostomes (hagfishes, lampreys) as well as bony fishes.

A number of vertebrates use externalized gill structures. Some larval fishes have external gills that are lost with the appearance of the adult structures. A curious example of external gills is found in the male lungfish (*Lepidosiren*). At the time the male begins to care for the nest, a mass of vascular filaments (a system of blood vessels) develops as an outgrowth of the pelvic fins. The fish meets its own needs by refilling its lungs with air during periodic excursions to the water surface. When it returns to the nest, its pelvic-gill filaments are perfused with well-oxygenated blood, providing an oxygen supply for the eggs, which are more or less enveloped by the gill filaments.

It is theoretically possible for a skin that is well supplied

with blood vessels to serve as a major or even the only respiratory surface. This requires a thin, moist, and heavily vascularized skin, which increases the animal's vulnerability to enemies. In terrestrial animals a moist integument also provides a major avenue of water loss. A number of fishes and amphibians rely on the skin for much of their respiratory exchange; hibernating frogs utilize the skin for practically all their gas exchanges.

The lung. The lungs of vertebrates range from simple saclike structures found in the Dipnoi (lungfishes) to the complexly subdivided organs of mammals and birds. An increasing subdivision of the airways and the development of greater surface area at the exchange surfaces appear to be the general evolutionary trend among the higher vertebrates.

In the embryo, lungs develop as an outgrowth of the forward portion of the gut. The lung proper is connected to the outside through a series of tubes; the main tube, known as the trachea (windpipe), exits in the throat through a controllable orifice, the glottis. At the other end the trachea subdivides into secondary tubes (bronchi), in varying degree among different vertebrate groups.

The trachea of amphibians is not divided into secondary tubes but ends abruptly at the lungs. The relatively simple lungs of frogs are subdivided by incomplete walls (septa), and between the larger septa are secondary septa that surround the air spaces where gas exchange occurs. The diameter of these air spaces (alveoli) in lower vertebrates is larger than in mammals: The alveolus in the frog is about 10 times the diameter of the human alveolus. The smaller alveoli in mammals are associated with a greater surface for gas exchange: although the respiratory surface of the frog (*Rana*) is about 20 square centimetres per cubic centimetre (50.8 square inches per one cubic inch) of air, that of humans is about 300 square centimetres.

An important characteristic of lungs is their elasticity. An elastic material is one that tends to return to its initial state after the removal of a deforming force. Elastic tissues behave like springs. As the lungs are inflated, there is an accompanying increase in the energy stored within the elastic tissues of the lungs, just as energy is stored in a stretched rubber band. The conversion of this stored, or potential, energy into kinetic, or active, energy during the deflation process supplies part of the force needed for the expulsion of gases. A portion of the energy put into expansion is thus recovered during deflation. The elastic properties of the lungs have been studied by inflating them with air or liquid and measuring the resulting pressures. Muscular effort supplies the motive power for expanding the lungs, and this is translated into the pressure required to produce lung inflation. It must be great enough to overcome (1) the elasticity of the lung and its surface lining; (2) the frictional resistance of the lungs; (3) the elasticity of the thorax or thoraco-abdominal cavity; (4) frictional resistance in the body-wall structures; (5) resistance inherent in the contracting muscles; and (6) the airway resistance. The laboured breathing of the asthmatic is an example of the added muscular effort necessary to achieve adequate lung inflation when airway resistance is high, owing to narrowing of the tubes of the airways.

Studies of the pressure-volume relationship of lungs filled with salt solution or air have shown that the pressure required to inflate the lungs to a given volume is less when the lungs are filled with liquid than when they are filled with air. The differences in the two circumstances have been thought to result from the nature of the environment-alveolar interface, that interface being liquid-liquid in the fluid-filled lung and gas-liquid in the air-filled lung. In the case of the latter, the pressure-volume relationship represents the combined effects of the elastic properties of the lung wall plus the surface tension of the film, or surface coating, lining the lungs. Surface tension is the property, resulting from molecular forces, that exists in the surface film of all liquids and tends to contract the volume into a form with the least surface area; the particles in the surface are inwardly attracted, thus resulting in tension. Surface tension is nearly zero in the fluid-filled lung.

The alveoli of the lungs are elastic bodies of nonuniform size. If their surfaces had a uniform surface tension, small

Characteristics of lungs

Elasticity of alveoli

alveoli would tend to collapse into large ones. The result in the lungs would be an unstable condition in which some alveoli would collapse and others would overexpand. This does not normally occur in the lung because of the properties of its surface coating (surfactant), a complex substance composed of lipid and protein. Surfactant causes the surface tension to change in a nonlinear way with changes in surface area. As a result, when the lungs fill with air, the surface tensions of the inflated alveoli are less than those of the relatively undistended alveoli. This results in a stabilization of alveoli of differing sizes and prevents the emptying of small alveoli into larger ones. It has been suggested that compression wrinkles of the surface coating and attractive forces between adjacent wrinkles inhibit expansion. Surfactants have been reported to be present in the lungs of birds, reptiles, and amphibians.

DYNAMICS OF VERTEBRATE RESPIRATORY MECHANISMS

Organs in
primitive
vertebrates

Fishes. Among the most primitive of present-day vertebrates are the cyclostomes (lampreys and hagfishes), the gill structures of which are in the form of pouches that connect internally with the pharynx (throat) and open outward through slits, either by a fusion of the excurrent gill ducts into a single tube (in *Myxine*) or individually by separate gill slits (in *Petromyzon*). The gill lamellae of cyclostomes form a ring around the margins of the gill sac, and the series of sacs is supported in a flexible branchial skeleton. The number of paired pouches varies in different forms from six to 14. The pharynx of lampreys divides into an esophagus above and a blind tube below, from which the gill pouches arise. The upper pharynx of hagfishes communicates to the exterior through a nostril, a structure absent in lampreys. When the parasitic lampreys are embedded in the flesh of fish, upon which they live, they maintain a flow of water through the gills by alternate contractions of the gill pouches. When the gill-pouch muscles relax, the pouches expand, and water is sucked in. The water is forced out through the gills by muscular contraction; the branchial musculature apparently prevents reflux of the water into the pharynx while the head of the lamprey is embedded in the flesh of its prey.

In the hagfish *Myxine glutinosa*, the major oxygen supply is derived from water drawn in through the nostril that opens into the pharynx. A peculiar respiratory structure, the velum, just behind the nostril opening, dangles from the upper midline of the pharynx, resembling an inverted T. Membranous scrolls attached to this horizontal bar can extend downward and then roll upward like window shades. A combination of velar and gill-pouch contractions directs the flow of water through the gill pouches. Foreign material entering the nostril is expelled from both the mouth and nostril by a violent "sneeze." This reaction probably protects the respiratory surfaces, since the animals have common respiratory and alimentary ducts. Blood flow in the gills of cyclostomes, as in those of bony fishes, is in a direction counter to that of water flow—an arrangement that increases the efficiency of gas exchange across the respiratory surface (Figure 4).

Cartilaginous fishes (sharks and rays) and bony fishes employ a double-pumping mechanism to maintain a relatively constant flow of water over the gill exchange surfaces. In sharks and rays a small forward gill slit, the spiracle, also provides a channel for water flow into the gill chamber. Bottom-dwelling forms (e.g., skates) have relatively larger spiracles, and the major portion of the water flow passes through them rather than through the downward-oriented mouth.

The pumping mechanism is not the only method of ventilation; sharks have been observed to keep both mouth and gill flaps open while swimming, ensuring a constant water flow across the gill surfaces. When they slow down or settle to the bottom, the pumping activity is resumed. Tunas and mackerel cannot stop swimming: They have no active respiratory mechanism and are dependent for their gill ventilation on the current that results from their forward motion through the water.

A number of fishes depend in varying degree on aerial respiration. The ability to breathe air enables them to live in places where the oxygen content of water may be low or

Figure 4: Blood and water flow through gill body of hagfish. Note that water flow is counter to blood flow, an arrangement facilitating gas exchange.

nil. Two general means of acquiring oxygen are employed. Some fishes stay near the surface of the water, where the oxygen pressure resulting from surface diffusion is highest. Others have developed ancillary respiratory structures in the pharynx or the stomach; the gulping of air at the surface is a means of charging these respiratory surfaces (such as the pharyngeal epithelium in *Electrophorus* or the stomach in *Plecostomus*). The frequency with which these fishes rise to the surface to gulp air corresponds to their current need for oxygen.

The swamp-dwelling *Erythrinus* of Guyana uses both aquatic and aerial respiration, varying them according to the gaseous composition of the water. When the oxygen content is low, respiration through the gills ceases; when the oxygen content of the water is high, the fish relies primarily upon its gills except when the carbon dioxide content is also high—when, again, aerial respiration predominates. In other conditions it uses both modes of respiration. This apparently extends the range of conditions in which *Erythrinus* can survive.

Eels (*Anguilla*) use their skin as a major respiratory surface in addition to their gills. In water, about 15 percent of their oxygen uptake is across the skin, and this rises to around 50 percent when in air. They are capable of making extensive overland migrations during which, in the first few hours, they draw upon oxygen in the swim bladder. Like most fishes, eels when out of water exhibit a reduced heart rate and less oxygen consumption. When they return to water, their heart rate rises, and both oxygen consumption and blood lactic-acid levels rise. Lactic-acid production results from metabolism without oxygen, and such acid products must themselves be metabolized through higher oxygen consumption. Such patterns have been observed in grunions of the California coast that come ashore to breed, and even in flying fishes during their brief aerial excursions.

The lungfishes (Dipnoi) are remnants of the Devonian period and a transitional form between water and air breathers. Like amphibians, they rely on the buccal force pump mechanism to inflate the lung. They are adapted for bimodal respiration so that oxygenated blood leaving the air-exchange organ, either gills or lung, can pass to the afferent branchial circulation and then to the body tissues or can be dispatched to the lungs (Figure 5). The three dipnoan genera differ with respect to their reliance on the gills or lungs. In the Australian lungfish (*Neoceratodus*), the bulk of oxygen uptake and carbon dioxide elimination is by way of well-developed gills; in the African lungfish (*Protopterus*) and the South American lungfish (*Lepidosiren*), the gills are reduced and ventilation depends heavily on the lungs. In the latter two, which rely primarily on lung ventilation, separation of oxygenated

Figure 5: Rearrangements of the circulation in a fish during (A) air breathing and (B) prolonged submersion. (A) During air breathing, the gill shunts are open, the ductus closed, and the pulmonary arterial vasomotor segment open. This arrangement clearly favours blood flow to the lungs. (B) During prolonged submersion, the gill shunts are closed, the ductus open, and the pulmonary arterial vasomotor segment closed. This arrangement diverts blood flow from the pulmonary to systemic circulations.

Modified after A.P. Fishman, R.G. DeLaney, P. Laurent, and J.P. Szidon in K. Johansen and W.W. Burggren (eds.), *Cardiovascular Shunts: Phylogenetic, Ontogenetic, and Clinical Aspects*, p. 89, © 1985 Munksgaard International Publishers Ltd., Copenhagen, Denmark

and deoxygenated blood is much more complete than in the Australian lungfish.

Adaptation to drought During long periods of drought, both *Protopterus* and *Lepidosiren* build a subterranean cocoon that opens to the surface via a thin tunnel. They then enter into a state of estivation in which metabolism, respiration, and heart rate fall to low levels. This state of diminished oxygen requirement enables the lungfish to remain viable without food or water for months or years, until the waters return.

The bowfin, *Amia calva*, has both gills and an air bladder that may be used for respiration. It is almost exclusively a water breather at 10° C (50° F), a temperature at which it shows low physical activity. Its air-breathing rate increases with temperature and activity, and, at around 30° C (86° F), it draws about three times as much oxygen from air as from water. As in lungfishes, carbon dioxide elimination is predominantly across the gills. The bowfin's air-breathing frequency varies inversely with the oxygen content of the water; when oxygen tensions in water decline below 40 or 50 millimetres of mercury at 20° C (68° F), air breathing largely replaces water breathing. When an exchange surface (gill or air bladder) is not being utilized as the primary oxygen-exchange site, there is a tendency for blood to bypass it.

The so-called electric eel of South America (*Electrophorus electricus*) inhabits muddy streams that may become severely oxygen deficient. It is an obligatory air breather that depends upon the exchange of oxygen across the membranes of its mouth, expelling the air through its gill slits. Its blood has a high percentage of red corpuscles, is high in hemoglobin, and has an oxygen-absorbing capacity similar to that of mammals. Carbon dioxide elimination is primarily across the skin and, to a lesser extent, through the vestigial gills. (F.N.W./A.P.F.)

Amphibians. The living amphibians (frogs, toads, salamanders, and caecilians) depend on aquatic respiration to

a degree that varies with species, stage of development, temperature, and season. With the exception of a few frog species that lay eggs on land, all amphibians begin life as completely aquatic larvae. Respiratory gas exchange is conducted through the thin, gas-permeable skin and the gills. In addition to these structures, frog tadpoles use their large tail fins for respiration; the tail fins contain blood vessels and are important respiratory structures because of their large surface area. As amphibian larvae develop, the gills (and in frogs, the tail fin) degenerate, paired lungs develop, and the metamorphosing larvae begin making excursions to the water surface to take air breaths.

The lungs of amphibians (Figure 6) are simple saclike structures that internally lack the complex spongy appearance of the lungs of birds and mammals. The lungs of most amphibians receive a large proportion of the total blood flow from the heart. Even though the amphibian ventricle is undivided, there is surprisingly little mixture of blood from the left and right atrial chambers within the single ventricle. As a consequence, the lungs are perfused primarily with deoxygenated blood from the systemic tissues.

By the time the larva has reached adult form, the lungs have assumed the respiratory function of the larval gills. A few species of salamanders (for example, the axolotl) never metamorphose to the adult stage, and although they may develop lungs for air breathing, they retain external gills throughout life. Another exception to the usual pattern of respiratory development is seen in the Plethodontidae family of salamanders, which lose their gills upon metamorphosis but never develop lungs as adults; instead, gas exchange is conducted entirely across the skin. In almost all amphibian species, the skin in adults continues to play an important role in gas exchange.

The relative contributions of lungs and skin, and even local areas of skin, to gas exchange differ in different species and in the same species may change seasonally. In frogs, the skin of the back and thighs (the areas exposed to air) contains a richer capillary network than the skin of the underparts and therefore contributes more to gas exchange. The aquatic newt *Triton* utilizes both lung and skin respiration, the skin containing about 75 percent of the respiratory capillaries. At the other extreme, the tree frog *Hyla arborea* is much less aquatic, and its lungs contain over 75 percent of the respiratory capillary surface area. Similar differences are found even in closely related forms: In the relatively more terrestrial frog *Rana temporaria*, uptake of oxygen across the lung is about three times greater than across the skin; in *R. esculenta*, which is more restricted to water, the lungs and skin function about equally in the uptake of oxygen. Carbon dioxide is eliminated mainly through the skin in both these species; in fact, the skin appears to be a major avenue for carbon dioxide exchange in amphibians generally.

In temperate climates, as winter approaches, the colder environmental temperature (and thus lower body temperature) induces a marked lowering of the metabolic rate in amphibians. Terrestrial forms (e.g., toads and some

Variation from higher vertebrates

Seasonal changes in gas exchange

salamanders) may burrow into the ground to overwinter. Aquatic species burrow into the mud at the bottom of lakes or ponds. Because their metabolic rate is much lower during winter, adequate gas exchange can be provided entirely by the skin in either terrestrial or aquatic habitats.

The mechanism of lung inflation in amphibians is the buccal cavity (mouth-throat) pumping mechanism that also functions in air-breathing fishes. To produce inspiration, the floor of the mouth is depressed, causing air to be drawn into the buccal cavity through the nostrils. The nostrils are then closed, and the floor of the mouth is elevated. This creates a positive pressure in the mouth cavity and drives air into the lungs through the open glottis. Expiration is produced by contraction of the muscles of the body wall and the elastic recoil of the lungs, both acting to drive gas out of the lungs through the open glottis. In aquatic amphibians the pressure of water on the body wall can also assist expiration. Many amphibians show rhythmic oscillations of the floor of the mouth between periods of lung inflation; these oscillations are thought to be involved in olfaction by producing a flow of gas over the olfactory epithelial surfaces.

Adaptation
to land

Reptiles. To survive on land, the reptiles had to develop a skin relatively impermeable to water, so as to prevent desiccation, and hence not well suited for respiration. Thus, while a few specialized reptiles (for example, sea snakes) can acquire nearly half of their oxygen supply through their skin, most reptiles depend almost entirely on the lungs for gas exchange. Reptilian lungs are considerably more complex than those of amphibians, showing much more internal partitioning to provide additional surface area for gas exchange between lung gas and blood. The most complex reptilian lungs are found in sea turtles such as *Chelonia mydas*, the green turtle. This species can develop a high metabolic rate associated with its prolific swimming ability. Its lungs are suited to providing a high rate of gas exchange, with extensive branching of the airways leading to the numerous gas sacs of the lungs.

The mechanism for lung inflation in reptiles is an aspiration (suction) pump, which is the same in general principle as the lung inflation mechanism in birds and mammals. In most reptiles inspiration is produced by muscular expansion of the rib cage and body wall, creating a subatmospheric pressure within the lungs that causes air to flow in. Crocodiles and alligators have a specialized muscle attached to the posterior surface of the liver; the anterior surface of the liver in turn is attached to the posterior surface of the lungs. Contraction of this muscle pulls on the liver and results in expansion of the lungs.

Respiration
in turtles

The adoption of a rigid shell by turtles and tortoises necessitated the development of highly specialized skeletal muscles to inflate the lungs. In the tortoise *Testudo graeca*, lung ventilation is achieved by changing the volume of the body cavity. Expiration is brought about by the activity of muscles that draw the shoulder girdle back into the shell, compressing the abdominal viscera. The increased pressure in the body cavity is transmitted to the lungs. Inspiration involves opposite muscular actions that produce an increase in the volume of the body cavity and thus a subatmospheric lung pressure. Because of the rigidity of its shell, the tortoise, unlike other reptiles, cannot use the potential energy of abdominal wall structures to assist in respiration, and hence both expiration and inspiration are active energy-consuming events. In aquatic turtles, however, the pressure of water on the front and rear limbs assists expiration.

The breathing patterns of most reptiles are not regular, usually consisting of a series of active inspirations and expirations followed by relatively long pauses. In aquatic reptiles diving occurs during these pauses, which may last an hour or more in some turtles and aquatic snakes. Even terrestrial reptiles show intermittent periods of breathing and breath holding. The metabolic rate of most reptiles is one-fifth to one-tenth that of birds or mammals, and constant lung ventilation is unnecessary in most reptiles.

Birds. Birds must be capable of high rates of gas exchange because their oxygen consumption at rest is higher than that of all other vertebrates, including mammals, and it increases many times during flight. The gas volume of

the bird lung is small compared with that of mammals, but the lung is connected to voluminous air sacs by a series of tubes, making the total volume of the respiratory system about twice that of mammals of comparable size (Figure 7). The trachea divides into primary bronchi, each of which passes through a lung and onward to the paired abdominal air sacs; they also give rise to secondary bronchi supplying the other air sacs. Tertiary bronchi penetrate the lung mass and, from the walls of the tertiary bronchi, rather fine air capillaries arise. These air capillaries have a large surface area; their walls contain blood capillaries connected with the heart. Gas exchange takes place between the air capillaries and blood capillaries, making this surface analogous to the alveolar surface in mammals.

Figure 7: Respiratory system of a bird.

There are several important differences in the mechanism and pattern of lung ventilation in birds compared with other vertebrates with lungs. The lungs of birds do not inflate and deflate but rather retain a constant volume. Also, the lungs are unidirectionally ventilated rather than having a tidal, bidirectional flow, as in other vertebrates with lungs. To achieve this unidirectional flow, the various air sacs are inflated and deflated in a complex sequence, like a series of interconnected bellows. The lungs, which are located midway between air sacs in terms of the flow of gas, are continuously ventilated in a single direction with freshly inspired air during both inspiration and expiration at the nostrils. Aspiration into the air sacs is produced by expansion of the chest and abdominal cavity. The sternum (breastbone) swings forward and downward, while the ribs and chest wall move laterally. Expiration is caused by compression of the air sacs by skeletal muscle.

Uni-
directional
airflow in
birds

As a consequence of the continual, unidirectional airflow, the lungs of birds are more completely ventilated than the lungs of mammals. The flow of gas and blood within the bird lung is carefully arranged to maximize gas exchange, which is far more efficient than in the mammalian lung: Himalayan geese have been observed not only to fly over Mount Everest, but to honk as they do so. The ventilation of pigeons increases around 20-fold during flight, brought about by more rapid breathing and not by taking in more air at a breath. There is a precise synchrony between breathing and wing motion: the peak of expiration occurs at the downstroke of the wingbeat. The pigeon's in-flight ventilation is about two and one-half times that needed to support metabolism; around 17 percent of the heat production during flight is lost through evaporative cooling, suggesting that the excess ventilation is for regulating body heat. Studies of evening grosbeaks and ring-billed gulls show that their ventilation, in contrast to that of pigeons, increases in proportion to oxygen consumption. The increased ventilation in these birds is brought about by deeper as well as by more rapid breathing.

Efficiency
of bird
ventilation

The respiratory system of birds is also used for commu-

nication through song. The “voice box” is the syrinx, a membranous structure at the lower end of the trachea. Sound is produced only when air flows outward across the syrinx. In canaries, notes or pulses are synchronous with chest movements; the trills, however, are made with a series of shallow breaths. The song of many small birds is of long duration relative to their breathing frequencies.

Mammals. To provide the gas exchange necessary to support the elevated metabolic rate of mammals, mammalian lungs are subdivided internally. The repetitive subdivisions of the lung airways provide gas to the tiny alveoli (gas sacs) that form the functional gas-exchange surface area of the lungs. Human lungs have an estimated 300,000,000 alveoli, providing in an adult a total surface area approximately equivalent to a tennis court.

Ventilatory
pump in
humans

Inspiration in mammals, as in reptiles, is powered by an aspiration (suction) pump. Expansion of the chest lowers the pressure between the lungs and the chest wall, as well as the pressure within the lungs. This causes atmospheric air to flow into the lungs. The chief muscles of inspiration are the diaphragm and the external intercostal muscles. The diaphragm is a domelike sheet of muscle separating the abdominal and chest cavities that moves downward as it contracts. The downward motion enlarges the chest cavity and depresses the organs below. As the external intercostal muscles contract, the ribs rotate upward and laterally, increasing the chest circumference. During severe exercise other muscles may also be used. Inspiration ends with the closing of the glottis.

In expiration, the glottis opens, and the inspiratory muscles relax; the stored energy of the chest wall and lungs generates the motive power for expiration. During exercise or when respiration is laboured, the internal intercostal muscles and the abdominal muscles are activated. The internal intercostals produce a depression of the rib cage and a decrease in chest circumference. (F.N.W./W.W.Bu.)

Human respiration

THE DESIGN OF THE RESPIRATORY SYSTEM

The human gas exchanging organ, the lung, is located in the thorax, where its delicate tissues are protected by the bony and muscular thoracic cage. The lung provides the organism with a continuous flow of oxygen and clears the blood of the gaseous waste product, carbon dioxide. Atmospheric air is pumped in and out regularly through a system of pipes, called conducting airways, which join the gas exchange region with the outside of the body (Figure 8). The airways can be divided into upper and lower airway systems. The transition between the two systems is located where the pathways of the respiratory and digestive systems cross, just at the top of the larynx.

Figure 8: The respiratory system and its location.

The upper airway system comprises the nose and the paranasal cavities, called sinuses, the pharynx, or throat, and partly also the oral cavity, since it may be used for breathing. The lower airway system consists of the larynx, the trachea, the stem bronchi, and all the airways ramifying intensively within the lungs, such as the intrapulmonary bronchi, the bronchioles, and the alveolar ducts. For respiration, the collaboration of other organ systems is clearly essential. The diaphragm, as the main respiratory muscle, and the intercostal muscles of the chest wall play an essential role by generating, under the control of the central nervous system, the pumping action on the lung. The muscles expand and contract the internal space of the thorax, whose bony framework is formed by the ribs and the thoracic vertebrae. The contribution of the lung and chest wall (ribs and muscles) to respiration is described below in *The mechanics of breathing*. The blood, as a carrier for the gases, and the circulatory system (*i.e.*, the heart and the blood vessels) are mandatory elements of a working respiratory system (see BLOOD and CIRCULATION AND CIRCULATORY SYSTEMS).

Morphology of the upper airways. *The nose.* The nose is the external protuberance of an internal space, the nasal cavity (Figure 9). It is subdivided into a left and right canal by a thin medial cartilaginous and bony wall, the nasal septum. Each canal opens to the face by a nostril and into the pharynx by the choana. The floor of the nasal cavity is formed by the palate, which also forms the roof of the oral cavity. The complex shape of the nasal cavity is due to projections of bony ridges, the superior, middle, and inferior turbinate bones (or conchae), from the lateral wall. The passageways thus formed below each ridge are called the superior, middle, and inferior nasal meatuses.

On each side, the intranasal space communicates with a series of neighbouring air-filled cavities within the skull (the paranasal sinuses) and also, via the nasolacrimal duct, with the lacrimal apparatus in the corner of the eye. The duct drains the lacrimal fluid into the nasal cavity. This fact explains why nasal respiration can be rapidly impaired or even impeded during weeping: the lacrimal fluid is not only overflowing into tears, it is also flooding the nasal cavity.

The paranasal sinuses are sets of paired single or multiple cavities of variable size. Most of their development takes place after birth, and they reach their final size toward the age of 20 years. The sinuses are located in four different skull bones—the maxilla, the frontal, the ethmoid, and the sphenoid bones. Correspondingly, they are called the maxillary sinus, which is the largest cavity; the frontal sinus; the ethmoid sinuses; and the sphenoid sinus, which is located in the upper posterior wall of the nasal cavity. The sinuses have two principal functions: because they are filled with air, they help keep the weight of the skull within reasonable limits, and they serve as resonance chambers for the human voice.

Paranasal
sinuses

The nasal cavity with its adjacent spaces is lined by a respiratory mucosa. Typically, the mucosa of the nose contains mucus-secreting glands and venous plexuses; its top cell layer, the epithelium, consists principally of two cell types, ciliated and secreting cells. This structural design reflects the particular ancillary functions of the nose and of the upper airways in general with respect to respiration. They clean, moisten, and warm the inspired air, preparing it for intimate contact with the delicate tissues of the gas-exchange area. During expiration through the nose, the air is dried and cooled, a process that saves water and energy.

Two regions of the nasal cavity have a different lining. The vestibule, at the entrance of the nose, is lined by skin that bears short thick hairs called vibrissae. In the roof of the nose, the olfactory organ with its sensory epithelium checks the quality of the inspired air. About two dozen olfactory nerves convey the sensation of smell from the olfactory cells through the bony roof of the nasal cavity to the central nervous system.

The pharynx. For the anatomical description, the pharynx can be divided into three floors (see Figure 9). The upper floor, the nasopharynx, is primarily a passageway for air and secretions from the nose to the oral pharynx. It is also connected to the tympanic cavity of the middle ear

Figure 9: Upper airways with nasal and oral cavities, pharynx, and larynx.

through the auditory tubes that open on both lateral walls. The act of swallowing opens briefly the normally collapsed auditory tubes and allows the middle ears to be aerated and pressure differences to be equalized. In the posterior wall of the nasopharynx is located a lymphatic organ, the pharyngeal tonsil. When it is enlarged (as in tonsil hypertrophy or adenoid vegetation), it may interfere with nasal respiration and alter the resonance pattern of the voice.

The middle floor of the pharynx connects anteriorly to the mouth and is therefore called the oral pharynx or oropharynx. It is delimited from the nasopharynx by the soft palate, which roofs the posterior part of the oral cavity.

The lower floor of the pharynx is called the hypopharynx. Its anterior wall is formed by the posterior part of the tongue. Lying directly above the larynx, it represents the site where the pathways of air and food cross each other: Air from the nasal cavity flows into the larynx, and food from the oral cavity is routed to the esophagus directly behind the larynx. The epiglottis, a cartilaginous, leaf-shaped flap, functions as a lid to the larynx and, during the act of swallowing, controls the traffic of air and food.

Morphology of the lower airways. The larynx. The larynx is an organ of complex structure that serves a dual function: as an air canal to the lungs and a controller of its access, and as the organ of phonation (see Figure 10). Sound is produced by forcing air through a sagittal slit formed by the vocal cords, the glottis. This causes not only the vocal cords but also the column of air above them to vibrate. As evidenced by trained singers, this function can be closely controlled and finely tuned. Control is achieved by a number of muscles innervated by the laryngeal nerves. For the precise function of the muscular apparatus, the muscles must be anchored to a stabilizing framework (Figure 10). The laryngeal skeleton consists of almost a dozen pieces of cartilage, most of them very small, interconnected by ligaments and membranes. The largest cartilage of the larynx, the thyroid cartilage, is made of two plates fused anteriorly in the midline. At the upper end of the fusion line is an incision, the thyroid notch; below it is a forward projection, the

laryngeal prominence. Both of these structures are easily felt through the skin. The angle between the two cartilage plates is sharper and the prominence more marked in men than in women, which has given this structure the common name of Adam's apple. Behind the shieldlike thyroid cartilage, the vocal cords span the laryngeal lumen. They correspond to elastic ligaments attached anteriorly in the angle of the thyroid shield and posteriorly to a pair of small pyramidal pieces of cartilage, the arytenoid cartilages. The vocal ligaments are part of a tube, resembling an organ pipe, made of elastic tissue. Just above the vocal cords, the epiglottis is also attached to the back of the thyroid plate by its stalk. The cricoid, another large cartilaginous piece of the laryngeal skeleton, has a signet-ring shape. The broad plate of the ring lies in the posterior wall of the larynx and the narrow arch in the anterior wall. The cricoid is located below the thyroid cartilage, to which it is joined in an articulation reinforced by ligaments. The transverse axis of the joint allows a hingelike rotation between the two cartilages. This movement tilts the cricoid plate with respect to the shield of the thyroid cartilage and hence alters the distance between them. Because the arytenoid cartilages rest upright on the cricoid plate, they follow its tilting movement. This mechanism plays an important role in altering length and tension of the vocal cords. The arytenoid cartilages articulate with the cricoid plate and hence are able to rotate and slide to close and open the glottis.

Viewed frontally, the lumen of the laryngeal tube has an hourglass shape, with its narrowest width at the glottis. Just above the vocal cords there is an additional pair of mucosal folds called the false vocal cords or the vestibular folds. Like the true vocal cords, they are also formed by the free end of a fibroelastic membrane. Between the vestibular folds and the vocal cords, the laryngeal space enlarges and forms lateral pockets extending upward. This space is called the ventricle of the larynx. Because the gap between the vestibular folds is always larger than the gap between the vocal cords, the latter can easily be seen from above with the laryngoscope, an instrument designed for visual inspection of the interior of the larynx.

The muscular apparatus of the larynx comprises two functionally distinct groups. The intrinsic muscles act directly or indirectly on the shape, length, and tension of the vocal cords. The extrinsic muscles act on the larynx as a whole, moving it upward (e.g., during high-pitched phonation or swallowing) or downward. The intrinsic muscles attach to the skeletal components of the larynx itself; the

Figure 10: Larynx with major cartilages, hyoid bone, and vocal cords.

Middle and lower floors

extrinsic muscles join the laryngeal skeleton cranially to the hyoid bone or to the pharynx and caudally to the sternum (breastbone).

The trachea and the stem bronchi. Below the larynx lies the trachea, a tube about 10 to 12 centimetres long and two centimetres wide. Its wall is stiffened by 16 to 20 characteristic horseshoe-shaped, incomplete cartilage rings that open toward the back and are embedded in a dense connective tissue. The dorsal wall contains a strong layer of transverse smooth muscle fibres that spans the gap of the cartilage. The interior of the trachea is lined by the typical respiratory epithelium. The mucosal layer contains mucous glands.

At its lower end, the trachea divides in an inverted Y into the two stem (or main) bronchi, one each for the left and right lung. The right main bronchus has a larger diameter, is oriented more vertically, and is shorter than the left main bronchus. The practical consequence of this arrangement is that foreign bodies passing beyond the larynx will usually slip into the right lung. The structure of the stem bronchi closely matches that of the trachea.

Figure 11: Model of airway branching in the human lung, assuming regular dichotomy (see text).

Structural design of the airway tree. The hierarchy of the dividing airways, and partly also of the blood vessels penetrating the lung, largely determines the internal lung structure. Functionally the intrapulmonary airway system can be subdivided into three zones, a proximal, purely conducting zone, a peripheral, purely gas-exchanging zone, and a transitional zone in between, where both functions grade into one another (Figure 11). From a morphological point of view, however, it makes sense to distinguish the relatively thick-walled, purely air-conducting tubes from those branches of the airway tree structurally designed to permit gas exchange.

The structural design of the airway tree is functionally important because the branching pattern plays a role in determining air flow and particle deposition. In modeling the human airway tree, it is generally agreed that the airways branch according to the rules of irregular dichotomy. Regular dichotomy means that each branch of a treelike structure gives rise to two daughter branches of identical dimensions. In irregular dichotomy, however, the daughter branches may differ greatly in length and diameter. The models calculate the average path from the trachea to the lung periphery as consisting of about 24–25 gener-

ations of branches. Individual paths, however, may range from 11 to 30 generations. The transition between the conductive and the respiratory portions of an airway lies on average at the end of the 16th generation, if the trachea is counted as generation 0. The conducting airways comprise the trachea, the two stem bronchi, the bronchi, and the bronchioles. Their function is to further warm, moisten, and clean the inspired air and distribute it to the gas-exchanging zone of the lung. They are lined by the typical respiratory epithelium with ciliated cells and numerous interspersed mucus-secreting goblet cells. Ciliated cells are present far down in the airway tree, their height decreasing with the narrowing of the tubes, as does the frequency of goblet cells. In bronchioles the goblet cells are completely replaced by another type of secretory cells named Clara cells. The epithelium is covered by a layer of low-viscosity fluid, within which the cilia exert a synchronized, rhythmic beat directed outward. In larger airways, this fluid layer is topped by a blanket of mucus of high viscosity. The mucus layer is dragged along by the ciliary action and carries the intercepted particles toward the pharynx, where they are swallowed. This design can be compared to a conveyor belt for particles, and indeed the mechanism is referred to as the mucociliary escalator.

Whereas cartilage rings or plates provide support for the walls of the trachea and bronchi, the walls of the bronchioles, devoid of cartilage, gain their stability from their structural integration into the gas-exchanging tissues. The last purely conductive airway generations in the lung are the terminal bronchioles. Distally, the airway structure is greatly altered by the appearance of cuplike outpouchings from the walls (see Figure 11). These form minute air chambers and represent the first gas-exchanging alveoli on the airway path. In the alveoli, the respiratory epithelium gives way to a very flat lining layer that permits the formation of a thin air–blood barrier. After several generations (Z) of such respiratory bronchioles, the alveoli are so densely packed along the airway that an airway wall proper is missing; the airway consists of alveolar ducts. The final generations of the airway tree end blindly in the alveolar sacs.

The lungs. *Gross anatomy.* The organ lung is parted into two slightly unequal portions, a left lung and a right lung, which occupy most of the intrathoracic space (see Figure 8). The space between them is filled by the mediastinum, which corresponds to a connective tissue space containing the heart, major blood vessels, the trachea with the stem bronchi, the esophagus, and the thymus gland. The right lung represents 56 percent of the total lung volume and is composed of three lobes, a superior, middle, and inferior lobe, separated from each other by a deep horizontal and an oblique fissure. The left lung, smaller in volume because of the asymmetrical position of the heart, has only two lobes separated by an oblique fissure. In the thorax, the two lungs rest with their bases on the diaphragm, while their apices extend above the first rib. Medially, they are connected with the mediastinum at the hilum, a circumscribed area where airways, blood and lymphatic vessels, and nerves enter or leave the lungs. The inside of the thoracic cavities and the lung surface are covered with serous membranes, respectively the parietal pleura and the visceral pleura, which are in direct continuity at the hilum. Depending on the subjacent structures, the parietal pleura can be subdivided into three portions: the mediastinal, costal, and diaphragmatic pleurae. The lung surfaces facing these pleural areas are named accordingly, since the shape of the lungs is determined by the shape of the pleural cavities. Because of the presence of pleural recesses, which form a kind of reserve space, the pleural cavity is larger than the lung volume (Figure 12).

During inspiration, the recesses are partly opened by the expanding lung, thus allowing the lung to increase in volume. Although the hilum is the only place where the lungs are secured to surrounding structures, the lungs are maintained in close apposition to the thoracic wall by a negative pressure between visceral and parietal pleurae. A thin film of extracellular fluid between the pleurae enables the lungs to move smoothly along the walls of the cavity during breathing. If the serous membranes become in-

Conducting

tree

flamed (pleurisy), respiratory movements can be painful. If air enters a pleural cavity (pneumothorax), the lung immediately collapses owing to its inherent elastic properties, and breathing is abolished on this side.

Pulmonary segments. The lung lobes are subdivided into smaller units, the pulmonary segments. There are 10 segments in the right lung and, depending on the classification, eight to 10 segments in the left lung. Unlike the lobes, the pulmonary segments are not delimited from each other by fissures but by thin membranes of connective tissue containing veins and lymphatics; the arterial supply follows the segmental bronchi. These anatomical features are important because pathological processes may be limited to discrete units, and the surgeon can remove single diseased segments instead of whole lobes.

Structure

The intrapulmonary conducting airways: bronchi and bronchioles. In the intrapulmonary bronchi, the cartilage rings of the stem bronchi are replaced by irregular cartilage plates; furthermore, a layer of smooth muscle is added between the mucosa and the fibrocartilaginous tunic. The bronchi are ensheathed by a layer of loose connective tissue that is continuous with the other connective tissue elements of the lung and hence is part of the fibrous skeleton spanning the lung from the hilum to the pleural sac. This outer fibrous layer contains, besides lymphatics and nerves, small bronchial vessels to supply the bronchial wall with blood from the systemic circulation. Bronchioles are small conducting airways ranging in diameter from three to less than one millimetre. The walls of the bronchioles lack cartilage and seromucous glands. Their lumen is lined by a simple cuboidal epithelium with ciliated cells and Clara cells, which produce a chemically ill-defined secretion. The bronchiolar wall also contains a well-developed layer of smooth muscle cells, capable of narrowing the airway. Abnormal spasms of this musculature cause the clinical symptoms of bronchial asthma.

The gas-exchange region. The gas-exchange region comprises three compartments: air, blood, and tissue. Whereas air and blood are continuously replenished, the function of the tissue compartment is twofold: it provides the stable supporting framework for the air and blood compartments, and it allows them to come into close contact with each other (thereby facilitating gas exchange) while keeping them strictly confined. The respiratory gases diffuse from air to blood, and vice versa, through the 140 square metres of internal surface area of the tissue compartment. The gas-exchange tissue proper is called the pulmonary parenchyma, while the supplying structures, conductive

airways, lymphatics, and non-capillary blood vessels belong to the non-parenchyma.

The gas-exchange region begins with the alveoli of the first generation of respiratory bronchioles. Distally, the frequency of alveolar outpocketings increases rapidly, until after two to four generations of respiratory bronchioles, the whole wall is formed by alveoli. The airways are then called alveolar ducts (Figure 13) and, in the last generation, alveolar sacs. On average, an adult human lung has about 300,000,000 alveoli. They are polyhedral structures, with a diameter of about 250 to 300 micrometres, and open on one side, where they connect to the airway. The alveolar wall, called the interalveolar septum, is common to two adjacent alveoli. It contains a dense network of capillaries, the smallest of the blood vessels, and a skeleton of connective tissue fibres (Figure 14). The fibre system is interwoven with the capillaries and particularly reinforced at the alveolar entrance rings. The capillaries are lined by flat endothelial cells with thin cytoplasmic extensions. The interalveolar septum is covered on both sides by the alveolar epithelial cells. A thin, squamous cell type, the type I pneumocyte, covers between 92 and 95 percent of the gas-exchange surface; a second, more cuboidal cell type, the type II pneumocyte, covers the remaining surface. The type I cells form, together with the endothelial cells, the thin air-blood barrier for gas exchange; the type II cells are secretory cells. Type II pneumocytes produce a surface-tension-reducing material, the pulmonary surfactant, which spreads on the alveolar surface and prevents the tiny alveolar spaces from collapsing. Before it is released into the airspaces, pulmonary surfactant is stored in the type II cells in the form of lamellar bodies. These granules are the conspicuous ultrastructural features of this cell type. On top of the epithelium, alveolar macrophages creep around within the surfactant fluid. They are large cells, and their cell bodies abound in granules of various content, partly foreign material that may have reached the alveoli, or cell debris originating from cell damage or normal cell death. Ultimately, the alveolar macrophages are derived from the bone marrow, and their task is to keep the air-blood barrier clean and unobstructed. The tissue space between the endothelium of the capillaries and the epithelial lining is occupied by the interstitium. It contains connective tissue and interstitial fluid. The connective tissue comprises a system of fibres, amorphous ground substance, and cells (mainly fibroblasts), which seem to be endowed with contractile properties. The fibroblasts are thought to control capillary blood flow or, alternatively,

Pulmonary surfactant

Figure 14: Electron micrograph of part of the interalveolar septum of the adult human lung. The lung capillary contains red blood cells interlaced with connective tissue fibres. The alveolar macrophage normally lies within the surfactant layer, which is not preserved here.

to prevent the accumulation of extracellular fluid in the interalveolar septa. If for some reason the delicate fluid balance of the pulmonary tissues is impaired, an excess of fluid accumulates in the lung tissue and within the airspaces. This pathological condition is called pulmonary edema. As a consequence, the respiratory gases must diffuse across longer distances, and proper functioning of the lung is severely jeopardized.

Blood vessels, lymphatic vessels, and nerves. With respect to blood circulation, the lung is a complex organ. It has two distinct though not completely separate vascular systems: a low-pressure pulmonary system and a high-pressure bronchial system. The pulmonary (or lesser) circulation is responsible for the oxygen supply of the organism. Blood, low in oxygen content but laden with carbon dioxide, is carried from the right heart through the pulmonary arteries to the lungs. On each side, the pulmonary artery enters the lung in the company of the stem bronchus and then divides rapidly, following relatively closely the course of the dividing airway tree. After numerous divisions, small arteries accompany the alveolar ducts and split up into the alveolar capillary networks. Because intravascular pressure determines the arterial wall structure, the pulmonary arteries, which have on average a pressure five times lower than systemic arteries, are much flimsier than systemic arteries of corresponding size. The oxygenated blood from the capillaries is collected by venules and drained into small veins. These do not accompany the airways and arteries but run separately in narrow strips of connective tissue delimiting small lobules. The interlobular veins then converge on the intersegmental septa. Finally, near the hilum the veins merge into large venous vessels that follow the course of the bronchi. Generally, four pulmonary veins drain blood from the lung and deliver it to the left atrium of the heart.

The bronchial circulation has a nutritional function for the walls of the larger airways and pulmonary vessels. The bronchial arteries originate from the aorta or from an intercostal artery. They are small vessels and generally do not reach as far into the periphery as the conducting airways. With a few exceptions, they end several generations short of the terminal bronchioles. They split up into capillaries surrounding the walls of bronchi and vessels

and also supply adjacent airspaces. Most of their blood is naturally collected by pulmonary veins. Small bronchial veins exist, however; they originate from the peribronchial venous plexuses and drain the blood through the hilum into the azygos and hemiazygos veins of the posterior thoracic wall.

The lymph is drained from the lung through two distinct but interconnected sets of lymphatic vessels. The superficial, subpleural lymphatic network collects the lymph from the peripheral mantle of lung tissue and drains it partly along the veins toward the hilum. The deep lymphatic system originates around the conductive airways and arteries and converges into vessels that mostly follow the bronchi and arterial vessels into the mediastinum.

Within the lung and the mediastinum, lymph nodes exert their filtering action on the lymph before it is returned into the blood through the major lymphatic vessels, called bronchomediastinal trunks. Lymph drainage paths from the lung are complex. The precise knowledge of their course is clinically relevant, because malignant tumours of the lung spread via the lymphatics.

The pleurae, the airways, and the vessels are innervated by afferent and efferent fibres of the autonomic nervous system. Parasympathetic nerve fibres from the vagus nerve (10th cranial nerve) and sympathetic branches of the sympathetic nerve trunk meet around the stem bronchi to form the pulmonary autonomic nerve plexus, which penetrates into the lung along the bronchial and vascular walls. The sympathetic fibres mediate a vasoconstrictive action in the pulmonary vascular bed and a secretomotor activity in the bronchial glands. The parasympathetic fibres stimulate bronchial constriction. Afferent fibres to the vagus nerve transmit information from stretch receptors, and those to the sympathetic centres carry sensory information (e.g., pain) from the bronchial mucosa.

Lung development. After early embryogenesis, during which the lung primordium is laid down, the developing human lung undergoes four consecutive stages of development, ending after birth. The names of the stages describe the actual morphology of the prospective airways. The pseudoglandular stage exists from five to 17 weeks; the canalicular stage, from 16 to 26 weeks; the saccular stage, from 24 to 38 weeks; and finally the alveolar stage, from 36 weeks of fetal age to about 1½ to two years after birth.

The lung appears around the 26th day of intrauterine life as a ventral bud of the prospective esophagus. The bud separates distally from the gut, divides, and starts to grow into the surrounding mesenchyme. The epithelial components of the lung are thus derived from the gut (i.e., they are of endodermal origin), and the surrounding tissues and the blood vessels are derivatives of the mesoderm.

Following rapid successive dichotomous divisions, the lung begins to look like a gland, giving the first stage of development (pseudoglandular) its name. At the same time the vascular connections also develop and form a capillary plexus around the lung tubules. Toward week 17, all the conducting airways of the lung are preformed, and it is assumed that, at the outermost periphery, the tips of the tubules represent the first structures of the prospective gas-exchange region.

During the canalicular stage, the future lung periphery develops further. The prospective airspaces enlarge at the expense of the intervening mesenchyme, and their cuboidal epithelium differentiates into type I and type II epithelial cells or pneumocytes. Toward the end of this stage, areas with a thin prospective air-blood barrier have developed, and surfactant production has started. These structural and functional developments give a prematurely born fetus a small chance to survive at this stage.

During the saccular stage, further generations of airways are formed. The tremendous expansion of the prospective respiratory airspaces causes the formation of saccules and a marked decrease in the interstitial tissue mass. The lung looks more and more "aerated," although it is filled with fluid originating from the lungs and from the amniotic fluid surrounding the fetus. Some weeks before birth, alveolar formation begins by a septation process that subdivides the saccules into alveoli. At this stage of lung development, the infant is born.

Filtering action of lymph nodes

First development

Lung vascular systems

Changes at birth

At birth the intrapulmonary fluid is rapidly evacuated and the lung fills with air with the first breaths. Simultaneously, the pulmonary circulation, which before was practically bypassed and very little perfused, opens up to accept the full cardiac output.

The newborn lung is far from being a miniaturized version of the adult lung. It has only about 20,000,000 to 50,000,000 alveoli, or 6 to 15 percent of the full adult complement. Therefore, alveolar formation is completed in the early postnatal period. Although it was previously thought that alveolar formation could continue to the age of eight years and beyond, it is now accepted that the bulk of alveolar formation is concluded much earlier, probably before the age of two years. Even with complete alveolar formation, the lung is not yet mature. The newly formed interalveolar septa still contain a double capillary network instead of the single one of the adult lungs. This means that the pulmonary capillary bed must be completely re-organized during and after alveolar formation; it has to mature. Only after full microvascular maturation, which is terminated sometime between the ages of two and five years, is the lung development completed, and the lung can enter a phase of normal growth. (P.H.Bu.)

CONTROL OF BREATHING

Breathing is an automatic and rhythmic act produced by networks of neurons in the hindbrain (the pons and medulla). The neural networks direct muscles that form the walls of the thorax and abdomen and produce pressure gradients that move air into and out of the lungs. The respiratory rhythm and the length of each phase of respiration are set by reciprocal stimulatory and inhibitory interconnection of these brain-stem neurons.

An important characteristic of the human respiratory system is its ability to adjust breathing patterns to changes in both the internal milieu and the external environment. Ventilation increases and decreases in proportion to swings in carbon dioxide production and oxygen consumption caused by changes in metabolic rate. The respiratory system is also able to compensate for disturbances that affect the mechanics of breathing, such as the airway narrowing that occurs in an asthmatic attack. Breathing also undergoes appropriate adjustments when the mechanical advantage of the respiratory muscles is altered by postural changes or by movement.

This flexibility in breathing patterns in large part arises from sensors distributed throughout the body that send signals to the respiratory neuronal networks in the brain. Chemoreceptors detect changes in blood oxygen levels and change the acidity of the blood and brain. Mechanoreceptors monitor the expansion of the lung, the size of the airway, the force of respiratory muscle contraction, and the extent of muscle shortening.

Although the diaphragm is the major muscle of breathing, its respiratory action is assisted and augmented by a complex assembly of other muscle groups. Intercostal muscles inserting on the ribs, the abdominal muscles, and muscles such as the scalene and sternocleidomastoid that attach both to the ribs and to the cervical spine at the base of the skull also play an important role in the exchange of air between the atmosphere and the lungs. In addition, laryngeal muscles and muscles in the oral and nasal pharynx adjust the resistance of movement of gases through the upper airways during both inspiration and expiration. Although the use of these different muscle groups adds considerably to the flexibility of the breathing act, they also complicate the regulation of breathing. These same muscles are used to perform a number of other functions, such as speaking, chewing and swallowing, and maintaining posture. Perhaps because the "respiratory" muscles are employed in performing nonrespiratory functions, breathing can be influenced by higher brain centres and even controlled voluntarily to a substantial degree. An outstanding example of voluntary control is the ability to suspend breathing by holding one's breath. Input into the respiratory control system from higher brain centres may help optimize breathing so that not only are metabolic demands satisfied by breathing, but ventilation is accomplished with minimal use of energy.

Non-respiratory functions of respiratory muscles

Central organization of respiratory neurons. The respiratory rhythm is generated within the pons and medulla. Three main aggregations of neurons are involved: a group consisting mainly of inspiratory neurons in the dorsomedial medulla, a group made up of inspiratory and expiratory neurons in the ventrolateral medulla, and a group in the rostral pons consisting mostly of neurons that discharge both in inspiration and expiration. It is currently thought that the respiratory cycle of inspiration and expiration is generated by synaptic interactions within these groups of neurons.

The inspiratory and expiratory medullary neurons are connected to projections from higher brain centres and from chemoreceptors and mechanoreceptors; in turn they drive cranial motor neurons, which govern the activity of muscles in the upper airways and the activity of spinal motor neurons, which supply the diaphragm and other thoracic and abdominal muscles. The inspiratory and expiratory medullary neurons also receive input from nerve cells responsible for cardiovascular and temperature regulation, allowing the activity of these physiological systems to be coordinated with respiration.

Neurally, inspiration is characterized by an augmenting discharge of medullary neurons that terminates abruptly. After a gap of a few milliseconds, inspiratory activity is restarted, but at a much lower level, and gradually declines until the onset of expiratory neuron activity. Then the cycle begins again. The full development of this pattern depends on the interaction of several types of respiratory neurons: inspiratory, early inspiratory, off-switch, post-inspiratory, and expiratory.

Early inspiratory neurons trigger the augmenting discharge of inspiratory neurons. This increase in activity, which produces lung expansion, is caused by self-excitation of the inspiratory neurons and perhaps by the activity of an as yet undiscovered upstream pattern generator. Off-switch neurons in the medulla terminate inspiration, but pontine neurons and input from stretch receptors in the lung help control the length of inspiration. When the vagus nerves are sectioned or pontine centres are destroyed, breathing is characterized by prolonged inspiratory activity that may last for several minutes. This type of breathing, which occasionally occurs in persons with diseases of the brain stem, is called "apneustic" breathing.

Post-inspiratory neurons are responsible for the declining discharge of the inspiratory muscles that occurs at the beginning of expiration. Mechanically, this discharge aids in slowing expiratory flow rates and probably assists the efficiency of gas exchange. It is believed by some that these post-inspiratory neurons have inhibitory effects on both inspiratory and expiratory neurons and therefore play a significant role in determining the length of the respiratory cycle and the different phases of respiration.

As the activity of the post-inspiratory neurons subsides, expiratory neurons discharge and inspiratory neurons are strongly inhibited. There may be no peripheral manifestation of expiratory neuron discharge except for the absence of inspiratory muscle activity, although in upright humans the lower expiratory intercostal muscles and the abdominal muscles may be active even during quiet breathing. Moreover, as the demand to breathe increases (for example, with exercise), more expiratory intercostal and abdominal muscles contract. As expiration proceeds, the inhibition of the inspiratory muscles gradually diminishes and inspiratory neurons resume their activity.

Chemoreceptors. One way in which breathing is controlled is through feedback by chemoreceptors. There are two kinds of respiratory chemoreceptors: arterial chemoreceptors, which monitor and respond to changes in the partial pressure of oxygen and carbon dioxide in the arterial blood, and central chemoreceptors in the brain, which respond to changes in the partial pressure of carbon dioxide in their immediate environment. Ventilation levels behave as if they were regulated to maintain a constant level of carbon dioxide partial pressure and to ensure adequate oxygen levels in the arterial blood. Increased activity of chemoreceptors caused by hypoxia or an increase in the partial pressure of carbon dioxide augments both the rate and depth of breathing, which restores partial pressures

Post-inspiratory neurons

of oxygen and carbon dioxide to their usual levels. On the other hand, too much ventilation depresses the partial pressure of carbon dioxide, which leads to a reduction in chemoreceptor activity and a diminution of ventilation. During sleep and anesthesia, lowering carbon dioxide levels three to four millimetres of mercury below values occurring during wakefulness can cause a total cessation of breathing (apnea).

Peripheral chemoreceptors. Hypoxia, or the reduction of oxygen supply to tissues to below physiological levels (produced, for example, by a trip to high altitudes), stimulates the carotid and aortic bodies, the principal arterial chemoreceptors. The two carotid bodies are small organs located in the neck at the bifurcation of each of the two common carotid arteries into the internal and external carotid arteries. This organ is extraordinarily well perfused and responds to changes in the partial pressure of oxygen in the arterial blood flowing through it rather than to the oxygen content of that blood (the amount of oxygen chemically combined with hemoglobin). The sensory nerve from the carotid body increases its firing rate hyperbolically as the partial pressure of oxygen falls. In addition to responding to hypoxia, the carotid body increases its activity linearly as the partial pressure of carbon dioxide in arterial blood is raised. This arterial blood parameter rises and falls as air enters and leaves the lungs, and the carotid body senses these fluctuations, responding more to rapid than to slow changes in the partial pressure of carbon dioxide. Larger oscillations in the partial pressure of carbon dioxide occur with breathing as metabolic rate is increased. The amplitude of these fluctuations, as reflected in the size of carotid body signals, may be used by the brain to detect changes in the metabolic rate and to produce appropriate adjustment in ventilation.

The carotid body communicates with medullary respiratory neurons through sensory fibres that travel with the carotid sinus nerve, a branch of the glossopharyngeal nerve. Microscopically, the carotid body consists of two different types of cells. The type I cells are arranged in groups and are surrounded by type II cells. The type II cells are generally not believed to have a direct role in chemoreception. Fine sensory nerve fibres are found in juxtaposition to type I cells, which, unlike type II cells, contain electron-dense vesicles. Acetylcholine, catecholamines, and neuropeptides such as enkephalins, vasoactive intestinal peptide, and substance P, are located within the vesicles. It is believed that hypoxia and hypercapnia (excessive carbon dioxide in the blood) cause the release of one or more of these neuroactive substances from the type I cells, which then act on the sensory nerve. It is possible to interfere independently with the responses of the carotid body to carbon dioxide and oxygen, which suggests that the same mechanisms are not used to sense or transmit changes in oxygen or carbon dioxide. The aortic bodies located near the arch of the aorta also respond to acute changes in the partial pressure of oxygen, but less well than the carotid body responds to changes in the partial pressure of carbon dioxide. The aortic bodies are responsible for many of the cardiovascular effects of hypoxia.

Central chemoreceptors. Carbon dioxide is one of the most powerful stimulants of breathing. As the partial pressure of carbon dioxide in arterial blood rises, ventilation increases nearly linearly. Ventilation normally increases by two to four litres per minute with each one millimetre of mercury increase in the partial pressure of carbon dioxide. Carbon dioxide increases the acidity of the fluid surrounding the cells but also easily passes into cells and thus can make the interior of cells more acid. It is not clear whether the receptors respond to the intracellular or extracellular effects of carbon dioxide or acidity.

Even if both the carotid and aortic bodies are removed, inhaling gases that contain carbon dioxide stimulates breathing. This observation shows that there must be additional receptors that respond to changes in the partial pressure of carbon dioxide. Current thinking places these receptors near the undersurface (ventral part) of the medulla. However, microscopic examination has not conclusively identified specific chemoreceptor cells in this region. The same areas of the ventral medulla also contain

vasomotor neurons that are concerned with the regulation of blood pressure. Some investigators argue that respiratory responses produced at the ventral medullary surface are direct and are caused by interference with excitatory and inhibitory inputs to respiration from these vasomotor neurons. They believe that respiratory chemoreceptors that respond to carbon dioxide are more diffusely distributed in the brain.

Muscle and lung receptors. Receptors in the respiratory muscles and in the lung can also affect breathing patterns. These receptors are particularly important when lung function is impaired, since they can help maintain tidal volume and ventilation at normal levels.

Changes in the length of a muscle affect the force it can produce when stimulated. Generally there is a length at which the force generated is maximal. Receptors, called spindles, in the respiratory muscles measure muscle length and increase motor discharge to the diaphragm and intercostal muscles when increased stiffness of the lung or resistance to the movement of air caused by disease impedes muscle shortening. Tendon organs, another receptor in muscles, monitor changes in the force produced by muscle contraction. Too much force stimulates tendon organs and causes decreasing motor discharge to the respiratory muscles and may prevent the muscles from damaging themselves.

Inflation of the lungs in animals stops breathing by a reflex described by the German physiologist Ewald Hering and the Austrian physiologist Josef Breuer. The Hering-Breuer reflex is initiated by lung expansion, which excites stretch receptors in the airways. Stimulation of these receptors, which send signals to the medulla by the vagus nerve, shortens inspiratory times as tidal volume (the volume of air inspired) increases, accelerating the frequency of breathing. When lung inflation is prevented, the reflex allows inspiratory time to be lengthened, helping to preserve tidal volume.

There are also receptors in the airways and in the alveoli that are excited by rapid lung inflations and by chemicals such as histamine, bradykinin, and prostaglandins. The most important function of these receptors, however, may be to defend the lung against noxious material in the atmosphere. When stimulated, these receptors constrict the airways and cause rapid shallow breathing, which inhibits the penetration of injurious agents into the bronchial tree. These receptors are supplied, like the stretch receptors, by the vagus nerve. Some of these receptors (called irritant receptors) are innervated by myelinated nerve fibres, others (the J receptors) by unmyelinated fibres. Stimulation of irritant receptors also causes coughing.

Variations in breathing. *Exercise.* One of the remarkable features of the respiratory control system is that ventilation increases sufficiently to keep the partial pressure of carbon dioxide in arterial blood nearly unchanged despite the large increases in metabolic rate that can occur with exercise, thus preserving acid-base homeostasis. A number of signals arise during exercise that can augment ventilation. Sources of these signals include mechanoreceptors in the exercising limbs; the arterial chemoreceptors, which can sense breath-by-breath oscillations in the partial pressure of carbon dioxide; and thermal receptors, because body temperature rises as metabolism increases. The brain also seems to anticipate changes in the metabolic rate caused by exercise, because parallel increases occur in the output from the motor cortex to the exercising limbs and to respiratory neurons. Changes in the concentration of potassium and lactic acid in the exercising muscles acting on unmyelinated nerve fibres may be another mechanism for stimulation of breathing during exercise. It remains unclear, however, how these various mechanisms are adjusted to maintain acid-base balance.

Sleep. During sleep, body metabolism is reduced, but there is an even greater decline in ventilation so that the partial pressure of carbon dioxide in arterial blood rises slightly and arterial partial pressure of oxygen falls. The effects on ventilatory pattern vary with sleep stage. In slow-wave sleep, breathing is diminished but remains regular, while in rapid eye movement sleep, breathing can become quite erratic. Ventilatory responses to inhaled car-

bodies

bon dioxide and to hypoxia are less in all sleep stages than during wakefulness. Sufficiently large decreases in the partial pressure of oxygen or increases in the partial pressure of carbon dioxide will cause arousal and terminate sleep.

During sleep, ventilation may swing between periods when the amplitude and frequency of breathing are high and periods in which there is little attempt to breathe, or even apnea (cessation of breathing). This rhythmic waxing and waning of breathing, with intermittent periods of apnea, is called Cheyne-Stokes breathing, after the physicians who first described it. The mechanism that produces the Cheyne-Stokes ventilation pattern is still argued, but it may entail unstable feedback regulation of breathing. Similar swings in ventilation sometimes occur in persons with heart failure or with central nervous system disease.

In addition, ventilation during sleep may intermittently fall to low levels or cease entirely because of partial or complete blockage of the upper airways. In some individuals, this intermittent obstruction occurs repeatedly during the night, leading to severe drops in the levels of blood oxygenation. The condition, termed sleep apnea syndrome, occurs most commonly in the elderly, in the newborn, in males, and in the obese. Because arousal is often associated with the termination of episodes of obstruction, sleep is of poor quality, and complaints of excessive daytime drowsiness are common. Snoring and disturbed behaviour during sleep may also occur.

In some persons with sleep apnea syndrome, portions of the larynx and pharynx may be narrowed by fat deposits or by enlarged tonsils and adenoids, which increase the likelihood of obstruction. Others, however, have normal upper airway anatomy, and obstruction may occur because of disordinated activity of upper airway and chest wall muscles. Many of the upper airway muscles, like the tongue and laryngeal adductors, undergo phasic changes in their electrical activity synchronous with respiration, and the reduced activity of these muscles during sleep may lead to upper airway closure. (N.S.C.)

THE MECHANICS OF BREATHING

Air moves in and out of the lungs in response to differences in pressure. When the air pressure within the alveolar spaces falls below atmospheric pressure, air enters the lungs (inspiration), provided the larynx is open; when the air pressure within the alveoli exceeds atmospheric pressure, air is blown from the lungs (expiration). The flow of air is rapid or slow in proportion to the magnitude of the pressure difference. Because atmospheric pressure remains relatively constant, flow is determined by how much above or below atmospheric pressure the pressure within the lungs rises or falls.

Alveolar pressure fluctuations are caused by expansion and contraction of the lungs resulting from tensing and relaxing of the muscles of the chest and abdomen. Each small increment of expansion transiently increases the space enclosing lung air. There is, therefore, less air per unit of volume in the lungs and pressure falls. A difference in air pressure between atmosphere and lungs is created, and air flows in until equilibrium with atmospheric pressure is restored at a higher lung volume. When the muscles of inspiration relax, the volume of chest and lungs decreases, lung air becomes transiently compressed, its pressure rises above atmospheric pressure, and flow into the atmosphere results until pressure equilibrium is reached at the original lung volume. This, then, is the sequence of events during each normal respiratory cycle: lung volume change leading to pressure difference, resulting in flow of air into or out of the lung and establishment of a new lung volume.

The lung-chest system. The forces that normally cause changes in volume of the chest and lungs stem not only from muscle contraction but from the elastic properties of both the lung and the chest. A lung is similar to a balloon in that it resists stretch, tending to collapse almost totally unless held inflated by a pressure difference between its inside and outside. This tendency of the lung to collapse or pull away from the chest is measurable by carefully placing a blunt needle between the outside of the lung and the inside of the chest wall, thereby allowing the lung to separate from the chest at this particular spot. The

pressure measured in the small pleural space so created is substantially below atmospheric pressure at a time when the pressure within the lung itself equals atmospheric pressure. This negative (below-atmospheric) pressure is a measure, therefore, of the force required to keep the lung distended. The force increases (pleural pressure becomes more negative) as the lung is stretched and its volume increases during inspiration. The force also increases in proportion to the rapidity with which air is drawn into the lung and decreases in proportion to the force with which air is expelled from the lungs. In summary, the pleural pressure reflects primarily two forces: (1) the force required to keep the lung inflated against its elastic recoil and (2) the force required to cause airflow in and out of the lung. Because the pleural pressure is below atmospheric pressure, air is sucked into the chest and the lung collapses (pneumothorax) when the chest wall is perforated, as by a wound or by a surgical incision.

The force required to maintain inflation of the lung and to cause airflow is provided by the chest and diaphragm (the muscular partition between chest and abdomen), which are in turn stretched inward by the pull of the lungs. The lung-chest system thus acts as two opposed coiled springs, the length of each of which is affected by the other. Were it not for the outward traction of the chest on the lungs, these would collapse; and were it not for the inward traction of the lungs on the chest and diaphragm, the chest would expand to a larger size and the diaphragm would fall from its dome-shaped position within the chest.

The role of muscles. The respiratory muscles displace the equilibrium of elastic forces in the lung and chest in one direction or the other by adding muscular contraction. During inspiration, muscle contraction is added to the outward elastic force of the chest to increase the traction on the lung required for its additional stretch. When these muscles relax, the additional retraction of lung returns the system to its equilibrium position.

Contraction of the abdominal muscles displaces the equilibrium in the opposite direction by adding increased abdominal pressure to the retraction of lungs, thereby further raising the diaphragm and causing forceful expiration. This additional muscular force is removed on relaxation and the original lung volume is restored. During ordinary breathing, muscular contraction occurs only on inspiration, expiration being accomplished "passively" by elastic recoil of the lung.

At total relaxation of the muscles of inspiration and expiration, the lung is distended to a volume—called the functional residual capacity—of about 40 percent of its maximum volume at the end of full inspiration. Further reduction of the lung volume results from maximal contraction of the expiratory muscles of chest and abdomen. The volume in these circumstances is known as the residual volume; it is about 20 percent of the volume at the end of full inspiration (known as the total lung capacity). Additional collapse of the lung to its "minimal air" can be accomplished only by opening the chest wall and creating a pneumothorax.

The membranes of the surface of the lung (visceral pleura) and on the inside of the chest (parietal pleura) are normally kept in close proximity (despite the pull of lung and chest in opposite directions) by surface tension of the thin layer of fluid covering these surfaces. The strength of this bond can be appreciated by the attempt to pull apart two smooth surfaces, such as pieces of glass, separated by a film of water.

The respiratory pump and its performance. The energy expended on breathing is used primarily in stretching the lung-chest system and thus causing airflow. It normally amounts to 1 percent of the basal energy requirements of the body but rises substantially during exercise or illness. The respiratory pump is versatile, capable of increasing its output 25 times, from a normal resting level of about six litres (366 cubic inches) per minute to 150 litres per minute in adults. Pressures within the lungs can be raised to 130 centimetres of water (about 1.8 pounds per square inch) by the so-called Valsalva maneuver—i.e., a forceful contraction of the chest and abdominal muscles against a closed glottis (i.e., with no space between the vocal

apnea
syndrome

Functional
residual
capacity

Elastic
properties
of lung

Airflow
velocity

cords). Airflow velocity, normally reaching 30 litres per minute in quiet breathing, can be raised voluntarily to 400 litres per minute. Cough is accomplished by suddenly opening the larynx during a brief Valsalva maneuver. The resultant high-speed jet of air is an effective means of clearing the airways of excessive secretions or foreign particles. The beating of cilia (hairline projections) from cells lining the airways normally maintains a steady flow of secretions toward the nose, cough resulting only when this action cannot keep pace with the rate at which secretions are produced.

An infant takes 33 breaths per minute with a tidal volume (the amount of air breathed in and out in one cycle) of 15 millilitres, totaling about 0.5 litre—approximately one pint—per minute as compared to adult values of 14 breaths, 500 millilitres, and seven litres, respectively.

If the force of surface tension is responsible for the adherence of parietal and visceral pleurae, it is reasonable to question what keeps the lungs' alveolar walls (also fluid-covered) from sticking together and thus eliminating alveolar airspaces. In fact, such adherence occasionally does occur and is one of the dreaded complications of premature births. Normal lungs, however, contain a substance—a phospholipid surfactant—that reduces surface tension and keeps alveolar walls separated. (A.A.S.)

GAS EXCHANGE

Respiratory gases—oxygen and carbon dioxide—move between the air and the blood across the respiratory exchange surfaces in the lungs. The structure of the human lung provides an immense internal surface that facilitates gas exchange between the alveoli and the blood in the pulmonary capillaries. The area of the alveolar surface in the adult human is about 100 square metres. Gas exchange across the membranous barrier between the alveoli and capillaries is enhanced by the thin nature of the membrane, about 0.5 micrometre, or $\frac{1}{100}$ of the diameter of a human hair.

Convection
and
diffusion

Respiratory gases move between the environment and the respiring tissues by two principal mechanisms, convection and diffusion. Convection, or mass flow, is responsible for movement of air from the environment into the lungs and for movement of blood between the lungs and the tissues. Respiratory gases also move by diffusion across tissue barriers such as membranes. Diffusion is the primary mode of transport of gases between air and blood in the lungs and between blood and respiring tissues in the body. The process of diffusion is driven by the difference in partial pressures of a gas between two locales. In a mixture of gases, the partial pressure of each gas is directly proportional to its concentration. The partial pressure of a gas in fluid is a measure of its tendency to leave the fluid when exposed to a gas or fluid that does not contain that gas. A gas will diffuse from an area of greater partial pressure to an area of lower partial pressure regardless of the distribution of the partial pressures of other gases. There are large changes in the partial pressures of oxygen and carbon dioxide as these gases move between air and the respiring tissues. The partial pressure of carbon dioxide in this pathway is lower than the partial pressure of oxygen, due to differing modes of transport in the blood, but almost equal quantities of the two gases are involved in metabolism and gas exchange.

Oxygen and carbon dioxide are transported between tissue cells and the lungs by the blood. The quantity transported is determined both by the rapidity with which the blood circulates and the concentrations of gases in blood. The rapidity of circulation is determined by the output of the heart, which in turn is responsive to overall body requirements. Local flows can be increased selectively, as occurs, for example, in the flow through skeletal muscles during exercise. The performance of the heart and circulatory regulation are, therefore, important determinants of gas transport.

Oxygen and carbon dioxide are too poorly soluble in blood to be adequately transported in solution. Specialized systems for each gas have evolved to increase the quantities of those gases that can be transported in blood. These systems are present mainly in the red cells, which

make up 40 to 50 percent of the blood volume in most mammals. Plasma, the cell-free, liquid portion of blood, plays little role in oxygen exchange but is essential to carbon dioxide exchange.

Transport of oxygen. Oxygen is poorly soluble in plasma, so that less than 2 percent of oxygen is transported dissolved in plasma. The vast majority of oxygen is bound to hemoglobin, a protein contained within red cells. Hemoglobin is composed of four iron-containing ring structures (hemes) chemically bonded to a large protein (globin). Each iron atom can bind and then release an oxygen molecule. Enough hemoglobin is present in normal human blood to permit transport of about 0.2 millilitre of oxygen per millilitre of blood. The quantity of oxygen bound to hemoglobin is dependent on the partial pressure of oxygen in the lung to which blood is exposed. The curve representing the content of oxygen in blood at various partial pressures of oxygen, called the oxygen-dissociation curve (Figure 15), is a characteristic S-shape because binding of oxygen to one iron atom influences the ability of oxygen to bind to other iron sites. In alveoli at sea level, the partial pressure of oxygen is sufficient to bind oxygen to essentially all available iron sites on the hemoglobin molecule.

Hemo-
globin
and oxygen

Figure 15: The oxygen-dissociation curve, which shows the relationship between the oxygen content of blood (ml O₂/ml blood) and the partial pressure of oxygen. An increase in the temperature or in the concentrations of 2,3-diphosphoglycerate (2,3-DPG), carbon dioxide (CO₂), or hydrogen ions will decrease the affinity of hemoglobin for oxygen and shift the curve to the right. Conversely, a decrease in the above variables will result in increased affinity and therefore shift the curve to the left.

Not all of the oxygen transported in the blood is transferred to the tissue cells. The amount of oxygen extracted by the cells depends on their rate of energy expenditure. At rest, venous blood returning to the lungs still contains 70 to 75 percent of the oxygen that was present in arterial blood; this reserve is available to meet increased oxygen demands. During extreme exercise the quantity of oxygen remaining in venous blood decreases to 10 to 25 percent. At the steepest part of the oxygen-dissociation curve (the portion between 10 and 40 millimetres of mercury partial pressure), a relatively small decline in the partial pressure of oxygen in the blood is associated with a relatively large release of bound oxygen.

Hemoglobin binds not only to oxygen but to other substances such as hydrogen ions (which determine the acidity, or pH, of the blood), carbon dioxide, and 2,3-diphosphoglycerate (2,3-DPG; a salt in the red blood cells that plays a role in liberating oxygen from hemoglobin in the peripheral circulation). These substances do not bind to hemoglobin at the oxygen-binding sites; however, with the binding of oxygen, changes in the structure of the hemoglobin molecule occur that affect its ability to bind other gases or substances. Conversely, binding of these substances to hemoglobin affects the affinity of hemoglobin for oxygen. (Affinity denotes the tendency of molecules of different species to bind to one another.) Increases in hydrogen ions, carbon dioxide, or 2,3-DPG decrease the affinity of hemoglobin for oxygen, and the oxygen-disso-

Hemo-
globin
and other
substances

ciation curve shifts to the right. Because of this decreased affinity, an increased partial pressure of oxygen is required to bind a given amount of oxygen to hemoglobin. A rightward shift of the curve is thought to be of benefit in releasing oxygen to the tissues when needs are great in relation to oxygen delivery, as occurs with anemia or extreme exercise. Reductions in normal concentrations of hydrogen ions, carbon dioxide, and 2,3-DPG result in an increased affinity of hemoglobin for oxygen, and the curve is shifted to the left. This displacement increases oxygen binding to hemoglobin at any given partial pressure of oxygen and is thought to be beneficial if the availability of oxygen is reduced, as occurs at extreme altitude.

Effect of
tempera-
ture

Temperature changes affect the oxygen-dissociation curve similarly. An increase in temperature shifts the curve to the right (decreased affinity; enhanced release of oxygen); a decrease in temperature shifts the curve to the left (increased affinity). The range of body temperature usually encountered in humans is relatively narrow, so that temperature-associated changes in oxygen affinity have little physiological importance.

Transport of carbon dioxide. Transport of carbon dioxide in the blood is considerably more complex. A small portion of carbon dioxide, about 5 percent, remains unchanged and is transported dissolved in blood. The remainder is found in reversible chemical combinations in red blood cells or plasma. Some carbon dioxide binds to blood proteins, principally hemoglobin, to form a compound known as carbamate. About 88 percent of carbon dioxide in the blood is in the form of bicarbonate ion. The distribution of these chemical species between the interior of the red blood cell and the surrounding plasma varies greatly, with the red blood cells containing considerably less bicarbonate and more carbamate than the plasma.

Less than 10 percent of the total quantity of carbon dioxide carried in the blood is eliminated during passage through the lungs. Complete elimination would lead to large changes in acidity between arterial and venous blood. Furthermore, blood normally remains in the pulmonary capillaries less than a second, an insufficient time to eliminate all carbon dioxide.

Buffering
effect of
hemo-
globin

Carbon dioxide enters blood in the tissues because its local partial pressure is greater than its partial pressure in blood flowing through the tissues. As carbon dioxide enters the blood, it combines with water to form carbonic acid (H_2CO_3), a relatively weak acid, which dissociates into hydrogen ions (H^+) and bicarbonate ions (HCO_3^-). Blood acidity is minimally affected by the released hydrogen ions because blood proteins, especially hemoglobin, are effective buffering agents. (A buffer solution resists change in acidity by combining with added hydrogen ions and, essentially, inactivating them.) The natural conversion of carbon dioxide to carbonic acid is a relatively slow process; however, carbonic anhydrase, a protein enzyme present inside the red blood cell, catalyzes this reaction with sufficient rapidity that it is accomplished in only a fraction of a second. Because the enzyme is present only inside the red blood cell, bicarbonate accumulates to a much greater extent within the red cell than in the plasma. The capacity of blood to carry carbon dioxide as bicarbonate is enhanced by an ion transport system inside the red blood cell membrane that simultaneously moves a bicarbonate ion out of the cell and into the plasma in exchange for a chloride ion. The simultaneous exchange of these two ions, known as the chloride shift, permits the plasma to be used as a storage site for bicarbonate without changing the electrical charge of either the plasma or the red blood cell. Only 26 percent of the total carbon dioxide content of blood exists as bicarbonate inside the red blood cell, while 62 percent exists as bicarbonate in plasma; however, the bulk of bicarbonate ions is first produced inside the cell, then transported to the plasma. A reverse sequence of reactions occurs when blood reaches the lung, where the partial pressure of carbon dioxide is lower than in the blood.

Chloride
shift

Hemoglobin acts in another way to facilitate the transport of carbon dioxide. Amino groups of the hemoglobin molecule react reversibly with carbon dioxide in solution to yield carbamates. A few amino sites on hemoglobin

are oxylabile, that is, their ability to bind carbon dioxide depends on the state of oxygenation of the hemoglobin molecule. The change in molecular configuration of hemoglobin that accompanies the release of oxygen leads to increased binding of carbon dioxide to oxylabile amino groups. Thus, release of oxygen in body tissues enhances binding of carbon dioxide as carbamate. Oxygenation of hemoglobin in the lungs has the reverse effect and leads to carbon dioxide elimination.

Only 5 percent of carbon dioxide in the blood is transported free in physical solution without chemical change or binding, yet this pool is important, because only free carbon dioxide easily crosses biologic membranes. Virtually every molecule of carbon dioxide produced by metabolism must exist in the free form as it enters blood in the tissues and leaves capillaries in the lung. Between these two events, most carbon dioxide is transported as bicarbonate or carbamate.

Gas exchange in the lung. The introduction of air into the alveoli allows the removal of carbon dioxide and the addition of oxygen to venous blood. Because ventilation is a cyclic phenomenon that occurs through a system of conducting airways, not all inspired air participates in gas exchange. A portion of the inspired breath remains in the conducting airways and does not reach the alveoli where gas exchange occurs. This portion is approximately one-third of each breath at rest but decreases to as little as 10 percent during exercise, due to the increased size of inspired breaths.

Cyclic
nature of
ventilation

In contrast to the cyclic nature of ventilation, blood flow through the lung is continuous, and almost all blood entering the lungs participates in gas exchange. The efficiency of gas exchange is critically dependent on the uniform distribution of blood flow and inspired air throughout the lungs. In health, ventilation and blood flow are extremely well matched in each exchange unit throughout the lungs. The lower parts of the lung receive slightly more blood flow than ventilation because gravity has a greater effect on the distribution of blood than on the distribution of inspired air. Under ideal circumstances, partial pressures of oxygen and carbon dioxide in alveolar gas and arterial blood are identical. Normally there is a small difference between oxygen tensions in alveolar gas and arterial blood because of the effect of gravity on matching and the addition of a small amount of venous drainage to the bloodstream after it has left the lungs. These events have no measurable effect on carbon dioxide partial pressures because the difference between arterial and venous blood is so small.

Abnormal gas exchange. Lung disease can lead to severe abnormalities in blood gas composition. Because of the differences in oxygen and carbon dioxide transport, impaired oxygen exchange is far more common than impaired carbon dioxide exchange. Mechanisms of abnormal gas exchange are grouped into four categories—hypoventilation, shunting, ventilation–blood flow imbalance, and limitations of diffusion.

If the quantity of inspired air entering the lungs is less than is needed to maintain normal exchange—a condition known as hypoventilation—the alveolar partial pressure of carbon dioxide rises and the partial pressure of oxygen falls almost reciprocally. Similar changes occur in arterial blood partial pressures because the composition of alveolar gas determines gas partial pressures in blood perfusing the lungs. This abnormality leads to parallel changes in both gas and blood and is the only abnormality in gas exchange that does not cause an increase in the normally small difference between arterial and alveolar partial pressures of oxygen.

In shunting, venous blood enters the bloodstream without passing through functioning lung tissue. Shunting of blood may result from abnormal vascular (blood vessel) communications or from blood flowing through unventilated portions of the lung (*e.g.*, alveoli filled with fluid or inflammatory material). A reduction in arterial blood oxygenation is seen with shunting, but the level of carbon dioxide in arterial blood is not elevated even though the shunted blood contains more carbon dioxide than arterial blood.

Shunting

The differing effects of shunting on oxygen and carbon dioxide partial pressures are the result of the different configurations of the blood-dissociation curves of the two gases. As noted above, the oxygen-dissociation curve is S-shaped and plateaus near the normal alveolar oxygen partial pressure, but the carbon dioxide-dissociation curve is steeper and does not plateau as the partial pressure of carbon dioxide increases. In the example in Figure 16, blood perfusing the collapsed, unventilated area of the lung, labeled A, leaves the lung without exchanging oxygen or carbon dioxide. The content of carbon dioxide, indicated by the letter A next to the carbon dioxide-dissociation curve, is greater than the normal carbon dioxide content, indicated by the square. The remaining healthy portion of the lung, labeled B in the figure, receives both its usual ventilation and the ventilation that normally would be directed to the abnormal lung. This lowers the partial pressure of carbon dioxide in the alveoli of the normal area of the lung. As a result, blood leaving the healthy portion of the lung, indicated by the letter B next to the carbon dioxide-dissociation curve, has a lower carbon dioxide content than normal. The lower carbon dioxide content in this blood counteracts the addition of blood with a higher carbon dioxide content from the abnormal area, and the composite arterial blood carbon dioxide content remains normal, as indicated by the arrow next to the carbon dioxide-dissociation curve. This compensatory mechanism is less efficient than normal carbon dioxide exchange and requires a modest increase in overall ventilation, which is usually achieved without difficulty. Because the carbon dioxide-dissociation curve is steep and relatively linear, compensation for decreased carbon dioxide exchange in one portion of the lung can be counterbalanced by increased excretion of carbon dioxide in another area of the lung.

In contrast, shunting of venous blood has a substantial effect on arterial blood oxygen content and partial pressure. Blood leaving an unventilated area of the lung has an oxygen content (indicated by the letter A next to the oxygen-dissociation curve) that is less than the normal content (indicated by the square). In the healthy area of the lung, labeled B in the figure, the increase in ventilation above normal raises the partial pressure of oxygen in the alveolar gas and, therefore, in the arterial blood. The oxygen-dissociation curve, however, reaches a plateau at the normal alveolar partial pressure, and an increase in blood partial pressure results in a negligible increase in oxygen content. Mixture of blood from this healthy portion of the lung (with normal oxygen content) and blood from the abnormal area of the lung (with decreased oxygen content) produces a composite arterial oxygen

content that is less than the normal level, indicated by the arrow next to the oxygen-dissociation curve. Thus, an area of healthy lung cannot counterbalance the effect of an abnormal portion of the lung on blood oxygenation because the oxygen-dissociation curve reaches a plateau at a normal alveolar partial pressure of oxygen. This effect on blood oxygenation is seen not only in shunting but in any abnormality that results in a localized reduction in blood oxygen content.

Mismatching of ventilation and blood flow is by far the most common cause of a decrease in partial pressure of oxygen in blood. There are minimal changes in blood carbon dioxide content unless the degree of mismatch is extremely severe. Inspired air and blood flow normally are distributed uniformly, and each alveolus receives approximately equal quantities of both. As matching of inspired air and blood flow deviates from the normal ratio of 1 to 1, alveoli become either overventilated or underventilated in relation to their blood flow. In alveoli that are overventilated, the amount of carbon dioxide eliminated is increased, which counteracts the fact that there is less carbon dioxide eliminated in the alveoli that are relatively underventilated. Overventilated alveoli, however, cannot compensate in terms of greater oxygenation for underventilated alveoli because, as is shown in the oxygen-dissociation curve, a plateau is reached at the alveolar partial pressure of oxygen, and increased ventilation will not increase blood oxygen content. In healthy lungs there is a narrow distribution of the ratio of ventilation to blood flow throughout the lung that is centred around a ratio of 1 to 1. In disease, this distribution can broaden substantially so that individual alveoli can have ratios that markedly deviate from the ratio of 1 to 1. Any deviation from the usual clustering around the ratio of 1 to 1 leads to decreased blood oxygenation—the more disparate the deviation, the greater the reduction in blood oxygenation. Carbon dioxide exchange, on the other hand, is not affected by an abnormal ratio of ventilation and blood flow as long as the increase in ventilation that is required to maintain carbon dioxide excretion in overventilated alveoli can be achieved.

A fourth category of abnormal gas exchange involves limitation of diffusion of gases across the thin membrane separating the alveoli from the pulmonary capillaries. A variety of processes can interfere with this orderly exchange; for oxygen, these include increased thickness of the alveolar-capillary membrane, loss of surface area available for diffusion of oxygen, a reduction in the alveolar partial pressure of oxygen required for diffusion, and decreased time available for exchange due to increased velocity of flow. These factors are usually grouped under the broad description of "diffusion limitation," and any can cause incomplete transfer of oxygen with a resultant reduction in blood oxygen content. There is no diffusion limitation of the exchange of carbon dioxide because this gas is more soluble than oxygen in the alveolar-capillary membrane, which facilitates carbon dioxide exchange. The complex reactions involved in carbon dioxide transport proceed with sufficient rapidity to avoid being a significant limiting factor in exchange. (R.A.KI.)

INTERPLAY OF RESPIRATION, CIRCULATION, AND METABOLISM

The interplay of respiration, circulation, and metabolism is the key to the functioning of the respiratory system as a whole. Cells set the demand for oxygen uptake and carbon dioxide discharge, that is, for gas exchange in the lungs. The circulation of the blood links the sites of oxygen utilization and uptake. The proper functioning of the respiratory system depends on both the ability of the system to make functional adjustments to varying needs and the design features of the sequence of structures involved, which set the limit for respiration.

The main purpose of respiration is to provide oxygen to the cells at a rate adequate to satisfy their metabolic needs. This involves transport of oxygen from the lung to the tissues by means of the circulation of blood. In antiquity and the medieval period, the heart was regarded as a furnace where the "fire of life" kept the blood boiling. Modern

Role of respiration

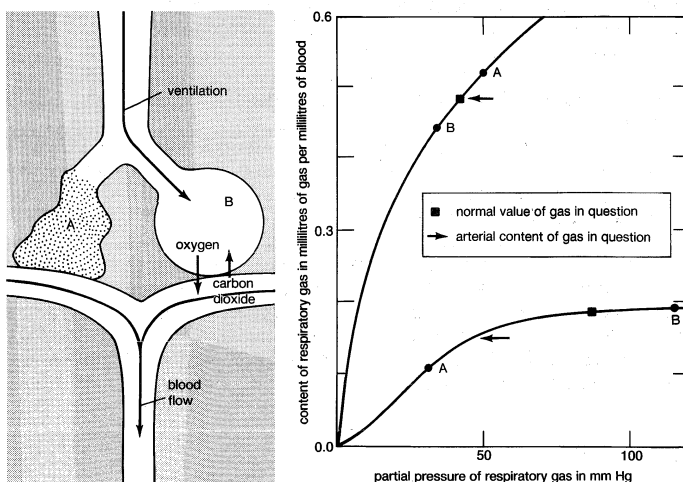

Figure 16: The effect of shunting of blood through nonfunctioning lung tissue on oxygen and carbon dioxide exchange. (Left) Distribution of ventilation and blood flow. (Right) The oxygen- (lower curve) and carbon dioxide- (upper curve) dissociation curves of blood showing the relationships between blood contents and partial pressures of the respiratory gases (see text).

cell biology has unveiled the truth behind the metaphor. Each cell maintains a set of furnaces, the mitochondria, where, through the oxidation of foodstuffs such as glucose, the energetic needs of the cells are supplied. The precise object of respiration therefore is the supply of oxygen to the mitochondria.

Cell metabolism depends on energy derived from high-energy phosphates such as adenosine triphosphate (ATP), whose third phosphate bond can release a quantum of energy to fuel many cell processes, such as the contraction of muscle fibre proteins or the synthesis of protein molecules. In the process, ATP is degraded to adenosine diphosphate (ADP), a molecule with only two phosphate bonds. To recharge the molecule by adding the third phosphate group requires energy derived from the breakdown of foodstuffs, or substrates. Two pathways are available: (1) anaerobic glycolysis, or fermentation, which operates in the absence of oxygen; and (2) aerobic metabolism, which requires oxygen and involves the mitochondria. The anaerobic pathway leads to acid waste products and is wasteful of resources: The breakdown of one molecule of glucose generates only two molecules of ATP. In contrast, aerobic metabolism has a higher yield (36 molecules of ATP per molecule of glucose) and results in "clean wastes"—water and carbon dioxide, which are easily eliminated from the body and are recycled by plants in the process of photosynthesis. For any sustained high-level cell activity, the aerobic metabolic pathway is therefore preferable. Since oxidative phosphorylation occurs only in mitochondria, and since each cell must produce its own ATP (it cannot be imported), the number of mitochondria in a cell reflects its capacity for aerobic metabolism, or its need for oxygen.

The supply of oxygen to the mitochondria at an adequate rate is a critical function of the respiratory system, because the cells maintain only a limited store of high-energy phosphates and of oxygen, whereas they usually have a reasonable supply of substrates in stock. If oxygen supply is interrupted for a few minutes, many cells, or even the organism, will die.

Oxygen is collected from environmental air, transferred to blood in the lungs, and transported by blood flow to the periphery of the cells where it is discharged to reach the mitochondria by diffusion. The transfer of oxygen to the mitochondria involves several structures and different modes of transports. It begins with ventilation of the lung, which is achieved by convection or mass flow of air through an ingeniously branched system of airways; in the most peripheral airways ventilation of alveoli is completed by diffusion of oxygen through the air to the alveolar surface. The transfer of oxygen from alveolar air into the capillary blood occurs by diffusion across the tissue barrier; it is driven by the oxygen partial pressure difference between alveolar air and capillary blood and depends on the thickness (about 0.5 micrometre) and the surface area of the barrier (about 130 square metres in humans). Convective transport by the blood depends on the blood flow rate (cardiac output) and on the oxygen capacity of the blood, which is determined by its content of hemoglobin in the red blood cells. The last step is the diffusive discharge of oxygen from the capillaries into the tissue and cells, which is driven by the oxygen partial pressure difference and depends on the quantity of capillary blood in the tissue. In this process the blood plays a central role and affects all transport steps: oxygen uptake in the lung, transport by blood flow, and discharge to the cells. Blood also serves as carrier for both respiratory gases: oxygen, which is bound to hemoglobin in the red blood cells, and carbon dioxide, which is carried by both plasma and red blood cells and which also serves as a buffer for acid-base balance in blood and tissues.

Metabolism, or, more accurately the metabolic rate of the cells, sets the demand for oxygen. At rest, a human consumes about 250 millilitres of oxygen each minute. With exercise this rate can be increased more than 10-fold in a normal healthy individual, but a highly trained athlete may achieve a more than 20-fold increase. As more and more muscle cells become engaged in doing work, the demand for ATP and oxygen increases linearly with work

rate. This is accompanied by an increased cardiac output, essentially due to a higher heart rate, and by increased ventilation of the lungs; as a consequence, the oxygen partial pressure difference across the air–blood barrier increases and oxygen transfer by diffusion is augmented. These dynamic adjustments to the muscles' needs occur up to a limit that is twice as high in the athlete as in the untrained individual. This range of possible oxidative metabolism from rest to maximal exercise is called the aerobic scope. The upper limit to oxygen consumption is not conferred by the ability of muscles to do work, but rather by the limited ability of the respiratory system to provide or utilize oxygen at a higher rate. Muscle can do more work, but beyond the aerobic scope they must revert to anaerobic metabolism, with the result that waste products, mainly lactic acid, accumulate and limit the duration of work.

The limit to oxidative metabolism is therefore set by some features of the respiratory system, from the lung to the mitochondria. Knowing precisely what sets the limit is important for understanding respiration as a key vital process, but it is not straightforward, because of the complexity of the system. Much has been learned from comparative physiology and morphology, based on observations that oxygen consumption rates differ significantly among species. For example, the athletic species in nature, such as dogs or horses, have an aerobic scope more than twofold greater than that of other animals of the same size; this is called adaptive variation. Then, oxygen consumption per unit body mass increases as animals become smaller, so that a mouse consumes six times as much oxygen per gram of body mass as a cow, a feature called allometric variation. Furthermore, the aerobic scope can be increased by training in an individual, but this induced variation achieves at best a 50 percent difference between the untrained and the trained state, well below interspecies differences.

Within the aerobic scope the adjustments are due to functional variation. For example, cardiac output is augmented by increasing heart rate. Mounting evidence indicates that the limit to oxidative metabolism is related to structural design features of the system. The total amount of mitochondria in skeletal muscle is strictly proportional to maximal oxygen consumption, in all types of variation. In training, the mitochondria increase in proportion to the augmented aerobic scope. Mitochondria set the demand for oxygen, and they seem able to consume up to five millilitres of oxygen per minute and gram of mitochondria. If energy (ATP) needs to be produced at a higher rate, the muscle cells make more mitochondria. It is thus possible that oxygen consumption is limited at the periphery, at the last step of aerobic metabolism. But it is also possible that more central parts of the respiratory system may set the limit to oxygen transport, mainly the heart, whose capacity to pump blood reaches a limit, both in terms of rate and of the size of the ventricles, which determines the volume of blood that can be pumped with each stroke. The issue of peripheral versus central limitation is still under debate. It appears, however, that the lung as a gas-exchanging organ has sufficient redundancy that it does not limit aerobic metabolism at the site of oxygen uptake. But, whereas the mitochondria, the blood, the blood vessels, and the heart can increase in number, rate, or volume to augment their capacity when energy needs increase, such as in training, the lung lacks this capacity to adapt. If this proves true, the lung may well constitute the ultimate limit for the respiratory system, beyond which oxidative metabolism cannot be increased by training.

(E.R.W.)

ADAPTATIONS

High altitudes. Ascent from sea level to high altitude has well-known effects upon respiration. The progressive fall in barometric pressure is accompanied by a fall in the partial pressure of oxygen, both in the ambient air and in the alveolar spaces of the lung; and it is this fall that poses the major respiratory challenge to humans at high altitude. Humans and some mammalian species like cattle adjust to the fall in oxygen pressure through the reversible and

metabolism

Respiratory
acclimati-
zation

non-inheritable process of acclimatization, which, whether undertaken deliberately or not, commences from the time of exposure to high altitudes. Indigenous mountain species like the llama, on the other hand, exhibit an adaptation that is heritable and has a genetic basis.

Respiratory acclimatization in humans is achieved through mechanisms that heighten the partial pressure of oxygen at all stages, from the alveolar spaces in the lung to the mitochondria in the cells, where oxygen is needed for the ultimate biochemical expression of respiration. The decline in the ambient partial pressure of oxygen is offset to some extent by greater ventilation, which takes the form of deeper breathing rather than a faster rate at rest. Diffusion of oxygen across the alveolar walls into the blood is facilitated, and in some experimental animal studies the alveolar walls are thinner at altitude than at sea level. The scarcity of oxygen at high altitudes stimulates increased production of hemoglobin and red blood cells, which increases the amount of oxygen transported to the tissues. The extra oxygen is released by increased levels of inorganic phosphates in the red blood cells, such as 2,3-diphosphoglycerate. With a prolonged stay at altitude, the tissues develop more blood vessels, and, as capillary density is increased, the length of the diffusion path along which gases must pass is decreased—a factor augmenting gas exchange. In addition, the size of muscle fibres decreases, which also shortens the diffusion path of oxygen.

The initial response of respiration to the fall of oxygen partial pressure in the blood on ascent to high altitude occurs in two small nodules, the carotid bodies, attached to the division of the carotid arteries on either side of the neck. As the oxygen deprivation persists, the carotid bodies enlarge but become less sensitive to the lack of oxygen. The low oxygen partial pressure in the lung is associated with thickening of the small blood vessels in pulmonary alveolar walls and a slight increase in pulmonary blood pressure, thought to enhance oxygen perfusion of the lung apices.

Indigenous mountain animals like the llama, alpaca, and vicuña in the Andes or the yak in the Himalayas are adapted rather than acclimatized to the low oxygen partial pressures of high altitude. Their hemoglobin has a high oxygen affinity, so that full saturation of the blood with oxygen occurs at a lower partial pressure of oxygen. In contrast to acclimatized humans, these indigenous, adapted mountain species do not have increased levels of hemoglobin or of organic phosphates in the red cells; they do not develop small muscular blood vessels or an increased blood pressure in the lung; and their carotid bodies remain small.

Native human highlanders are acclimatized rather than genetically adapted to the reduced oxygen pressure. After living many years at high altitude, some highlanders lose this acclimatization and develop chronic mountain sickness, sometimes called Monge's disease, after the Peruvian physician who first described it. This disease is characterized by greater levels of hemoglobin. In Tibet some infants of Han origin never achieve satisfactory acclimatization on ascent to high altitude. A chemodectoma, or benign tumour, of the carotid bodies may develop in native highlanders in response to chronic exposure to low levels of oxygen. (Do.A.H.)

Swimming and diving. Fluid is not a natural medium for sustaining human life after the fetal stage; human respiration requires ventilation with air. Nevertheless, all vertebrates, including humans, exhibit a set of responses that may be called a "diving reflex," which involves cardiovascular and metabolic adaptations to conserve oxygen during diving into water. Other physiological changes are also observed, either artificially induced (as by hyperventilation) or resulting from pressure changes in the environment at the same time that a diver is breathing from an independent gas supply.

Hyperventilation, a form of overbreathing that increases the amount of air entering the pulmonary alveoli, may be used intentionally by swimmers to prolong the time they are able to hold their breath under water. Hyperventilation can be dangerous, and this danger is greatly increased if the swimmer descends to depth, as sometimes

happens in snorkeling. The increased ventilation prolongs the duration of the breath-hold by reducing the carbon dioxide pressure in the blood, but it cannot provide an equivalent increase in oxygen. Thus the carbon dioxide that accumulates with exercise takes longer to reach the threshold at which the swimmer is forced to take another breath, but concurrently the oxygen content of the blood falls to unusually low levels. The increased environmental pressure of the water around the breath-holding diver increases the partial pressures of the pulmonary gases. This allows an adequate oxygen partial pressure to be maintained in the setting of reduced oxygen content, and consciousness remains unimpaired. When the accumulated carbon dioxide at last forces the swimmer to return to the surface, however, the progressively diminishing pressure of the water on his ascent reduces the partial pressure of the remaining oxygen. Unconsciousness may then occur in or under the water.

Divers who breathe from an apparatus that delivers gas at the same pressure as that of the surrounding water need not return to the surface to breathe and can remain at depth for prolonged periods. But this apparent advantage introduces additional hazards, many of them unique in human physiology. Most of the hazards result from the environmental pressure of water. Two factors are involved. At the depth of a diver, the absolute pressure, which is approximately one additional atmosphere for each 10-metre increment of depth, is one factor. The other factor, acting at any depth, is the vertical hydrostatic pressure gradient across the body. The effects of pressure are seen in many processes at the molecular and cellular level and include the physiological effects of the increased partial pressures of the respiratory gases, the increased density of the respiratory gases, the effect of changes of pressure upon the volumes of the gas-containing spaces in the body, and the consequences of the uptake of respiratory gases into, and their subsequent elimination from, the blood and tissues of the diver, often with the formation of bubbles. The multiple effects of submersion upon respiration are not easily separated from one another or clearly distinguishable from related effects of pressure upon other bodily systems.

The increased work of breathing, rather than cardiac or muscular performance, is the limiting factor for hard physical work underwater. Although the increased work of breathing may be largely due to the effects of increased respiratory gas density upon pulmonary function, the use of underwater breathing apparatus adds significant external breathing resistance to the diver's respiratory burden.

Arterial carbon dioxide pressure should remain unchanged during changes of ambient pressure, but the impaired alveolar ventilation at depth leads to some carbon dioxide retention (hypercapnia). This may be compounded by an increased inspiratory content of carbon dioxide, especially if the diver uses closed-circuit and semiclosed-circuit rebreathing equipment or wears an inadequately ventilated helmet. Alveolar oxygen levels can also be disturbed in diving. Hypoxia may result from failure of the gas supply and may occur without warning. More commonly, the levels of inspired oxygen are increased. Oxygen in excess can be a poison; at a partial pressure greater than 1.5 bar ("surface equivalent value" = 150 percent), it may cause the rapid onset of convulsions, and after prolonged exposures at somewhat lower partial pressures it may cause pulmonary oxygen toxicity with reduced vital capacity and later pulmonary edema. In mixed-gas diving, inspired oxygen is therefore maintained at a partial pressure somewhere between 0.2 and 0.5 bar, but at great depths the inhomogeneity of alveolar ventilation and the limitations of gas diffusion appear to require oxygen provision at greater than normal levels.

The maximum breathing capacity and the maximum voluntary ventilation of a diver breathing compressed air diminish rapidly with depth, approximately in proportion to the reciprocal of the square root of the increasing gas density. Thus the practice of using an inert gas such as helium as the oxygen diluent at depths where nitrogen becomes narcotic, like an anesthetic, has the additional advantage of providing a breathing gas of lesser density. The use of hydrogen, which in a mixture with less than

Hazards

pulmonary
function

4 percent oxygen is noncombustible, provides a greater respiratory advantage for deep diving.

At the extreme depths now attainable by humans—some 500 metres in the sea and more than 680 metres in the laboratory—direct effects of pressure upon the respiratory centre may be part of the “high-pressure neurological syndrome” and may account for some of the anomalies of breathlessness (dyspnea) and respiratory control that occur with exercise at depth.

The term carbon dioxide retainer is commonly applied to a diver who fails to eliminate carbon dioxide in the normal manner. An ability to tolerate carbon dioxide may increase the work capacity of a diver at depth but also may predispose him to other consequences that are less desirable. High values of end-tidal carbon dioxide with only moderate exertion may be associated with a diminished tolerance to oxygen neurotoxicity, a condition that, if it occurs underwater, places the diver at great risk. Nitrogen narcosis is enhanced by the presence of excess carbon dioxide, and the physical properties of carbon dioxide facilitate the nucleation and growth of bubbles on decompression.

Independent of the depth of the dive are the effects of the local hydrostatic pressure gradient upon respiration. The supporting effect of the surrounding water pressure upon the soft tissues promotes venous return from vessels no longer solely influenced by gravity; and, whatever the orientation of the diver in the water, this approximates the effects of recumbency upon the cardiovascular and respiratory systems. Also, the uniform distribution of gas pressure within the thorax contrasts with the hydrostatic pressure gradient that exists outside the chest. Intrathoracic pressure may be effectively lower than the pressure of the surrounding water, in which case more blood will be shifted into the thorax, or it may be effectively greater, resulting in less intrathoracic blood volume. The concept of a hydrostatic balance point within the chest, which represents the net effect of the external pressures and the effects of chest buoyancy, has proved useful in designing underwater breathing apparatuses.

Intrapulmonary gas expands exponentially during the steady return of a diver toward the surface. Unless vented, the expanding gas may rupture alveolar septa and escape into interstitial spaces. The extra-alveolar gas may cause a “burst lung” (pneumothorax) or the tracking of gas into the tissues of the chest (mediastinal emphysema), possibly extending into the pericardium or into the neck. More seriously, the escaped alveolar gas may be carried by the blood circulation to the brain (arterial gas embolism). This is a major cause of death among divers. Failure to exhale during ascent causes such accidents and is likely to occur if the diver makes a rapid emergency ascent, even from depths as shallow as two metres. Other possible causes of pulmonary barotrauma include retention of gas by a diseased portion of lung and gas trapping due to dynamic airway collapse during forced expiration at low lung volumes.

Decompression sickness may be defined as the illness, following a reduction of pressure, that is caused by the formation of bubbles from gases that were dissolved in the tissues while the diver was at an increased environmental pressure. The causes are related to the inadequacy of the diver's decompression, perhaps failure to follow a correct decompression protocol, or occasionally a diver's idiosyncratic response to an apparently safe decompression procedure. The pathogenesis begins both with the mechanical effects of bubbles and their expansion in the tissues and blood vessels and with the surface effects of the bubbles upon the various components of the blood at the blood-gas interface. The lung plays a significant role in the pathogenesis and natural history of this illness and may contribute to the clinical picture. Shallow, rapid respiration, often associated with a sharp retrosternal pain on deep inspiration, signals the onset of pulmonary decompression sickness, the “chokes.” Whether occurring alone or as part of a more complex case of decompression sickness, this respiratory pattern constitutes an acute emergency. It usually responds rapidly to treatment by recompression in a compression chamber. (D.H.E.)

Diseases and disorders of respiration

Diseases of the respiratory system may affect any of the structures and organs that have to do with breathing—the nasal cavities, the throat (pharynx), the larynx, the windpipe (trachea), the airways (bronchi), and the lung tissue. In addition, respiration is dependent on normal functioning of the muscles in the chest wall and the diaphragm, which may also be affected by disease. The respiratory tract is the site of an exceptionally large range of disorders for three main reasons: first, it is exposed to the environment and therefore may be affected by dust or gases in the air; second, it possesses a large network of capillaries through which the entire output of the heart has to pass, which means that diseases that affect the small blood vessels are likely to affect the lung; and third, it may be the site of “sensitivity” or allergic phenomena that may profoundly affect function.

SIGNS AND SYMPTOMS

By contrast, the symptoms of lung disease are relatively few. Cough is a particularly important sign of all diseases that affect any part of the bronchial tree. A cough productive of sputum is the most important manifestation of disease of the major airways, of which bronchitis is a common example. In severe bronchitis the mucous glands lining the bronchi enlarge greatly, and up to a cupful of sputum may be produced in a few hours; more commonly, 30 to 60 millilitres of sputum are produced in a 24-hour period, particularly in the first two hours after awakening in the morning. An irritative cough without sputum may be caused by extension of malignant disease to the bronchial tree from nearby organs. The presence of blood in the sputum (hemoptysis) is an important sign that should never be disregarded. Although it may result simply from an exacerbation of an existing infection, it may also indicate the presence of inflammation, capillary damage, or tumour. It is also a classic sign of tuberculosis of the lungs.

The second most important symptom of lung disease is dyspnea, or shortness of breath. This sensation, of complex origin, may arise acutely, as when a foreign body is inhaled into the trachea, or with the onset of a severe attack of asthma. More usually, it is insidious in onset and slowly progressive. What is noted is a slowly progressive difficulty in completing some task, such as walking up a flight of stairs, playing golf, or walking uphill. The shortness of breath may vary in severity, but in diseases such as emphysema (described below), in which there is irreversible lung damage, it is constantly present. It may become so severe as to immobilize the victim, and tasks such as dressing cannot be performed without difficulty. Severe fibrosis of the lung, resulting from occupational lung disease or arising from no identifiable antecedent condition, may also cause severe and unremitting dyspnea. Dyspnea is also an early symptom of congestion of the lung as a result of impaired function of the left ventricle of the heart. When this occurs, if the right ventricle that pumps blood through the lungs is functioning normally, the lung capillaries become engorged, and fluid may accumulate in small airways. It is commonly dyspnea that first causes a patient to seek medical advice, but absence of the symptom does not mean that serious lung disease is not present, since, for example, a small lung cancer that is not obstructing an airway will not produce shortness of breath.

Chest pain may be an early symptom of lung disease, but it is most often associated with an attack of pneumonia, in which case it is due to an inflammation of the pleura that follows the onset of the pneumonic process. This pain is characteristically felt when a deep breath is taken, and it disappears when fluid accumulates in the pleural space, a condition known as a pleural effusion. Acute pleurisy with pain may signal a blockage in a pulmonary vessel, which leads to acute congestion of the affected part, sometimes with a pleurisy over it. Severe chest pain may be occasioned by the spread of malignant disease to involve the pleura, or by a tumour, such as a mesothelioma, arising from the pleura itself. Severe, intractable pain caused by such conditions may require surgery to cut the nerves

supplying the affected segment to give relief. Fortunately, pain of this severity is rare.

To these major symptoms of lung disease—coughing, dyspnea, and chest pain—may be added several of less importance. A wheeziness in the chest may be heard. This is caused by airway obstruction, such as occurs in asthma. Some diseases of the lung are associated with the swelling of the fingertips (and, rarely, of the toes) called “clubbing.” Clubbing may be a feature of bronchiectasis (chronic inflammation and dilation of the major airways), diffuse fibrosis of the lung from any cause, and lung cancer. In the case of lung cancer, this unusual sign may disappear after surgical removal of the tumour. In some lung diseases, the first symptom may be a swelling of the lymph nodes that drain the affected area, particularly the small nodes above the collarbone in the neck; enlargement of the lymph nodes in these regions should always lead to a suspicion of intrathoracic disease. Not infrequently, the presenting symptom of a lung cancer is caused by spread of the tumour to other organs. Thus, a hip fracture from bone metastases, cerebral signs from intracranial metastases, or jaundice from liver involvement may all be the first evidence of a primary lung cancer, as may sensory changes in the legs, since a peripheral neuropathy may also be the presenting evidence of these tumours.

The generally debilitating effect of many lung diseases is well recognized. A person with primary lung tuberculosis or with lung cancer, for example, may be conscious only of a general feeling of malaise, unusual fatigue, or seemingly minor symptoms as the first indication of disease. Loss of appetite and loss of weight, a disinclination for physical activity, general psychological depression, and some symptoms apparently unrelated to the lung such as mild indigestion or headaches, may be diverse indicators of lung disease. Not infrequently, the patient may feel as one does when convalescent after an attack of influenza. Because the symptoms of lung disease, especially in the early stage, are variable and nonspecific, physical and radiographic examination of the chest are an essential part of the evaluation of persons with these complaints.

THE DEFENSES OF THE LUNG

Exposed as it is to the outside environment, the respiratory tract possesses a complicated but comprehensive series of defenses against inhaled material. The cells that form the first line of defense in the smaller radicles of the airway and in the alveoli of the lung are the alveolar macrophage cells. These cells can ingest and destroy bacteria and viruses and can remove small particles. They also secrete chemicals that attract white blood cells to the site, and hence they can initiate an inflammatory response in the lung. Particles picked up by macrophages are removed by them into the lymphatic system of the lung and stored in adjacent lymph glands. Soluble particles are removed into the bloodstream, to be finally excreted by the kidney. This is the route followed by the small lead particles emitted in automobile exhaust, which are inhaled, ingested by macrophages, cleared into the bloodstream, and finally excreted. The half-life of these particles in the lung is about 12 hours.

METHODS OF INVESTIGATION

Physical examination of the chest remains important, as it may reveal the presence of an area of inflammation, a pleural effusion, or an airway obstruction; the first two of these conditions will be visible on chest radiographs, but the third is usually audible only. Examination of the sputum for bacteria allows the identification of many infectious organisms and the institution of specific treatment; sputum examination for malignant cells is occasionally helpful. The conventional radiological examination of the chest has been greatly enhanced by the technique of computerized tomography, which shows small lesions and permits their precise location to be defined. The introduction of the flexible bronchoscope (in place of a rigid instrument) has greatly lessened the discomfort and danger associated with visual inspection of the bronchi and allows small tissue samples to be taken for histological study at the same time.

A number of tests are available to determine the functional status of the lung and the effects of disease on pulmonary function. A simple ventilatory test, the measurement of the velocity of a forced maximal expiration after a full inspiration, allows the degree of airway obstruction to be quantified. Airflow obstruction occurs in asthma and emphysema. A related test, of ventilatory capability, measures the volume that can be forcibly expired in one second after a full inspiration. Ventilatory capability can be simply measured with a spirometer or flow meter, and these devices are widely used in field studies. More complex laboratory equipment is necessary to measure the volumes of gas in the lung; the distribution of ventilation within the lung; airflow resistance; the stiffness of the lung, or the pressure required to inflate it; and the rate of gas transfer across the lung, which is commonly measured by recording the rate of absorption of carbon monoxide—used for this purpose because of the high affinity of hemoglobin for it. Gas transfer is impaired in diseases that destroy the lung or cause severe generalized thickening. Arterial blood gases and pH values indicate the adequacy of oxygenation and ventilation and are routinely measured in intensive care unit patients. Tests of exercise capability, in which work load, total ventilation, and gas exchange are compared before and in response to exercise, are useful in assessing disability.

MORPHOLOGICAL CLASSIFICATION OF RESPIRATORY DISEASE

It is helpful to recall the main divisions of the respiratory system as a basis for the morphological description of respiratory system diseases. The upper airway consists of the nose, nasopharynx, and larynx. Below these structures lies the trachea, or windpipe. Thereafter the airway divides into two major airways, right and left, then into progressively smaller tubes, until finally the terminal bronchioles, which are about one millimetre in diameter, are reached. On average, 16 generations of division occur between the trachea and the terminal bronchioles. Although there is only one airway at the beginning—the trachea—there are about 650,000 terminal bronchioles. The cross-sectional area of the bronchial tree increases with increasing subdivision. The end of each terminal bronchiole opens into an acinus, so called because the structure resembles a cluster of grapes, and from this point onward the gas-exchanging portion of the lung is reached. The alveoli or air sacs, which are divided into groups or lobules by fibrous partitions, or septa, are small hexagonal structures forming a blind end to the acinus. The wall of the acinus consists of blood capillaries, and the remaining structures are extremely thin, only providing supporting tissue for the rich capillary bed that constitutes the parenchyma, or the essential tissue of the lung itself. The parenchyma is the gas-exchanging tissue of the lung and has a surface area roughly comparable to that of a tennis court. Blood is distributed to the lung through the branching pulmonary artery, which subdivides with the bronchial tree and accompanies the smaller bronchioles into the region of the acinus to supply the capillaries of the alveolar wall. Oxygenated blood from the acini is collected into pulmonary veins, which run at some little distance from the bronchioles. An interstitial space exists around the alveoli and around the bronchioles and blood vessels, and this connects the lymph nodes (the small masses of lymphatic tissue that occur along the course of the lymph vessels) situated in the midline of the thoracic cavity and extending in a chain up into the neck and down into the abdomen.

The lung is covered by a protective membrane, the pleura, and the inner lining of the chest wall consists of a similar membrane. The space between these two fibrous coverings, called the intrapleural space, normally contains no air, and only a few millilitres of fluid for lubrication purposes, as during breathing one layer must slide on another. The pleurae may become involved by inflammation or neoplastic disease, in which case an effusion of fluid may occur between the two layers.

From this general description, diseases of the respiratory system may be grouped into the following categories.

Upper airway disease. The nasal sinuses are frequently

phages

the site of both acute and chronic infections. In common with the palate and the nasopharynx, they are also the site of malignant neoplastic changes. Cancer of the larynx is much more common in smokers than in nonsmokers; and cancers of other parts of the upper respiratory tract, some of which may be caused by exposure to dusts and metals, are also more likely to develop in smokers.

The occurrence of upper airway obstruction (particularly common in people who snore) has been documented in sleep laboratory studies. In the sleep apnea syndrome, episodes of obstruction are accompanied by cessation of breathing for up to half a minute and a marked fall in blood oxygen levels, terminating in arousal from sleep. The sleep apnea syndrome is not uncommon. It is not confined to the very obese, although it forms part of the syndrome of severe obesity in which sleep disturbance is common; and it is associated with the daytime somnolence known as the pickwickian syndrome, after Charles Dickens' description of the fat boy in *The Pickwick Papers*. Sleep apnea is caused by relaxation of muscles around the pharynx and obstruction of the airway by the palate. It is related to narrow anatomical dimensions in this area but is also more likely to occur if alcohol is ingested shortly before sleep. Sleep apnea is more than a medical curiosity: it may cause a rise in systemic blood pressure, and the daytime somnolence may occur while the affected person is at work.

Diseases of major bronchi. The major bronchi can become the seat of chronic inflammation, as in chronic bronchitis or bronchiectasis. The latter disease is not uncommonly caused by the familial disease of cystic fibrosis. The major bronchi may also be the site of development of malignant disease.

Diseases of smaller bronchi and bronchioles. It is in the smaller bronchi that major obstruction commonly occurs in asthma, since these bronchioles contain smooth muscle in their walls and the muscle may contract, causing airway obstruction. The small radicles of the bronchial tree, the bronchioles, are commonly involved in infective processes such as viral infections; they are also the primary site of deposition of inhaled dust and particles. Because of the large cross-sectional area of this part of the airway, considerable disease may be present in the bronchioles without affecting the expiratory flow rate. The bronchioles are occasionally the site of a primary noninfective bronchiolitis in persons with rheumatoid arthritis.

The alveolar ducts and alveoli. These structures are the site of primary involvement in many infections, including pneumonia, and it is on the parenchyma of the lung that the main effects of blockage of a pulmonary artery (pulmonary embolus) occur. The capillary bed surrounding the alveoli is subject to damage, and fluid may leak through the alveolar capillaries to accumulate in the lungs (pulmonary edema). The capillary bed is also extensively damaged in the condition known generally as acute respiratory distress syndrome; the exact mechanism of the damage is not yet fully understood. The alveolar walls themselves may undergo diffuse interstitial thickening, a characteristic of diseases grouped under the heading of "diffuse interstitial fibrosis"; interstitial thickening may also occur as a manifestation of collagen diseases such as scleroderma. One of the common forms of emphysema, in which alveolar destruction occurs, entails early loss of tissue at the point where the bronchiole ends in the acinus, resulting in a punched-out lesion in the centriacinar region. It is believed that this form of emphysema is the one that most commonly develops after years of cigarette smoking.

The lung parenchyma is the site of the discrete aggregations of cells, usually giant cells, that form the granulomas characteristic of the generalized disease known as sarcoidosis, and it is in the lung parenchyma that nodules caused by the inhalation of silica particles are found.

The lymphatic system. The system of channels draining the lung may be involved in primary disease of the lungs, but more commonly it is involved in metastatic invasion by distant tumours arising in the breast, stomach, or pancreas.

The pleura. The pleura may be involved in inflamma-

tory or neoplastic processes, either of which may lead to fluid accumulation (pleural effusion) between the two layers.

Although these divisions provide a general outline of the ways in which diseases may affect the lung, they are by no means rigid. It is common for more than one part of the system to be involved in any particular disease process, and disease in one region not infrequently leads to involvement of other parts.

VIRAL INFECTIONS

A wide variety of viruses are responsible for acute respiratory disease. The common cold—frequently of viral origin—can cause inflammation of the trachea and laryngitis, and these processes may extend to involve the lower bronchial tree. After such episodes the ciliary lining of the bronchial tree may be damaged, but the repair process is usually rapid.

Infections with rhinoviruses and adenoviruses are especially important in children, in whom they cause a febrile illness, occasionally with severe bronchiolar involvement. Although recovery is usually rapid, in some infections with respiratory syncytial virus an extensive bronchiolitis develops that may be severe enough to threaten life. In epidemics of these diseases, occasional cases occur in which the course is complicated by inflammation of the pericardium—the membrane enclosing the heart—or by a pleural effusion.

Influenza and parainfluenza viruses are capable of causing severe illness. The influenza virus attacks many systems of the body simultaneously, but the primary site of viral replication appears to be the alveolar cells of the lung. There the virus multiplies many times over within a 24-hour period, and the pulmonary involvement may begin in the parenchyma and cause considerable consolidation and inflammation of lung tissue. It is common for there to be severe tracheitis, bronchitis, and bronchiolitis at the same time. Another form of the disorder is that described as viral pneumonia, in which a distinguishing feature is the presence of patchy areas of atelectasis or partial collapse of lung tissue, without extensive involvement of the bronchial tree. All of these conditions are more dangerous in small children and in the elderly, and the lung that is the seat of a severe attack of influenza may quickly become secondarily infected.

It was secondary bacterial infection that accounted for the high mortality in the influenza epidemic of 1918 and 1919, one of the worst human catastrophes on record. It has been estimated that more than 20,000,000 people around the world died during the epidemic, and of the 20,000,000 people who suffered from the illness in the United States, approximately 850,000 died. It was a characteristic of this epidemic that young people were commonly severely affected. The high mortality resulted from the lack of antibiotics for treating the secondary bacterial infection; widespread malnutrition probably also contributed to the death rate.

There are three immunologically distinct types of influenza virus, designated A, B, and C; parainfluenza viruses are designated by the letter D. Types A, B, and D cause epidemic disease. Within type A there are now known to be at least four distinct strains. The "Asian" strain of type A was responsible for the 1957 influenza epidemic. Epidemic influenza tends to occur in two- or three-year cycles; careful study has allowed predictions to be made of their future occurrence. Although infected individuals develop lasting immunity to a particular strain following an attack of influenza, the immunity is highly specific as to type, and no protection is afforded against even closely related strains. Artificial immunization with high potency vaccines is of value in protecting against previous strains, and the vaccines have been shown to ameliorate the infection in the general population. Their use is particularly indicated in elderly people whose cardiac or lung function is already compromised.

Mycoplasma, identified in 1944 as responsible for a group of pneumonias previously thought to be of viral origin, is a member of a group of organisms known as the pleuropneumonia-like organisms and has also been termed the

Interdependence of respiratory sites

Influenza viruses

Three types of influenza virus

Sleep apnea syndrome

Asthma

"Eaton agent" after the scientist who first described it. *Mycoplasma pneumoniae* is the single most common cause of pneumonia in school-age children and young adults. The infection produces soft patchy shadows on the chest radiograph and relatively few signs on physical examination. A nonproductive cough and fever occur for a few days. Familial spread is common, and disease occurs in epidemic form in young healthy people brought together in clusters, as in military recruit camps and colleges, where a number of outbreaks have been documented. It is not usually a life-threatening disease, but in rare cases it may progress to cause acute respiratory distress syndrome.

Psittacosis and ornithosis, primarily infections of birds, and particularly common among parakeets and parrots, are transmitted to human beings by inhalation of dust particles from the droppings of infected birds. The onset of psittacosis may be quite severe, with headache, insomnia, and even delirium. Gastrointestinal symptoms such as vomiting and pain are frequent, and a cough productive of clear sputum usually develops after a few days. Mild attacks are often unrecognized and dismissed as due to influenza. Recovery is usually complete, but convalescence may be slow. A pandemic of this disease in 1929 was caused by the shipment of 5,000 parrots into Argentina from Brazil for auction. Many of the birds died, and there was considerable human mortality.

Q fever is an infection with *Coxiella burnetii*. The disease was first described in Queensland, Australia; areas in which Q fever is now known to be endemic include Australia, the western United States, Africa, England, and the Mediterranean countries. Animal infection is widespread and involves a large variety of domestic farm animals, particularly cattle and sheep, and some wild animals. Transmission is believed to occur between mammals through ticks and mice. Human disease, which is uncommon, is probably acquired through inhalation of infected material. Laboratory workers and employees in slaughterhouses are particularly at risk. Q fever is usually a mild and self-limited disease, requiring only symptomatic treatment.

The disease chickenpox (varicella), particularly when it occurs in adults, may affect the lung. Acute lesions may occur in the lung parenchyma, leading to a transient but significant fall in arterial oxygen tension (hypoxemia), occasionally necessitating oxygen therapy. Recovery may be slow but is usually complete, although shadows may remain on the radiograph as a result of it.

Whooping
cough

Whooping cough occurs in epidemic form among children and appears to be linked to the later development of the chronic infective process known as bronchiectasis, which occurs as a result of bronchial damage. In western countries, both whooping cough and measles (which causes an acute bronchiolitis) have been controlled by effective vaccines. In developing countries, where these vaccines are not administered, these diseases are still a major cause of mortality in children. Resistance to acute respiratory diseases is reduced when there is malnutrition.

Slow
process of
repair

Lung repair after viral infection. The reparative processes in the lung after any viral attack may be quite slow. Apparent clinical recovery may occur relatively quickly and the radiograph may show no remaining shadows, yet repair and restitution of the alveolar wall may take several additional weeks. There is speculation that the occurrence of a severe viral infection in childhood may impair subsequent development of the lung or even set the stage for chronic respiratory disease in later life, but this has not been proved.

BACTERIAL PNEUMONIA

Before effective antibiotics became available, pneumonia was the respiratory disease responsible for the greatest mortality and consequently was one of the most feared diseases. Because it frequently led to the death of severely disabled, elderly people, it was also known as the "old man's friend." The most common form of the disease is caused by a streptococcus, *Diplococcus pneumoniae*. Infection is followed by an acute illness of sudden onset with high fever, involvement of one or more lobes of the lung with resultant consolidation of the lung tissue, followed by complications such as a lung abscess, pleurisy, or heart

failure; but terminating naturally after about seven days with a high peak of fever and a sudden crisis, followed by a sharp fall in temperature and slow resolution. The classic form of the disease is now rarely seen, since prompt antibiotic therapy controls the acute process within 24 hours. Streptococci cause a diffuse type of bronchopneumonia, and it is this condition that is most likely to occur as a consequence of forced recumbency in elderly people. The infection probably develops in those parts of the lung where airway closure has occurred and where some extravasation of fluid is present. Streptococcal pneumonia may also occur as a complication of an acute attack of influenza, and the much lowered mortality of influenza is to be explained by effective antibiotics against streptococci. Staphylococcal pneumonia occurs as an acute illness in small children and may lead to rapid destruction of lung tissue with abscess formation; however, if the acute state is survived, as it usually is with chemotherapy, the lung recovers fully. This type of pneumonia may also occur as a complication of preexisting lung disease of any kind and may follow aspiration of stomach contents into the lung. The development of antibiotic-resistant staphylococci has meant that this form of pneumonia may be a problem in the hospital environment, complicating other lung disease or occurring postoperatively. Pneumonia due to infection with *Klebsiella pneumoniae* may be difficult to treat and characteristically may occur as a repetitive series of episodes of pneumonia, each running a rather long course with slow resolution. The organism *Hemophilus influenzae* is commonly isolated from the sputum of patients with chronic bronchitis during acute exacerbations of infection, but its exact role as a cause of disease is not well understood.

In all these bacterial pneumonias, the diagnosis may be made from the characteristic radiographic pattern, together with isolation from the sputum of the bacterium primarily responsible.

Legionnaires' disease. In July 1976, an outbreak of severe pneumonia occurred among U.S. veterans attending a convention of the American Legion in Philadelphia. Of the 147 persons admitted to hospitals, 29 died. Identification of the organism responsible (subsequently named *Legionella pneumophila*) constituted a classic medical detective story. The bacterium had evaded detection before because it does not stain with the usual stains used in sputum examination. It is now known that this bacterium may grow in air-conditioning systems or on shower heads, and it has been shown to be responsible for sporadic but severe outbreaks of pneumonia, particularly but not exclusively in older people. Fortunately, the bacterium is sensitive to erythromycin.

Pneumonia of any cause can lead to the development of the serious state known as adult respiratory distress syndrome, which is discussed in detail in a later section.

Pneumonia in immunocompromised persons. For some years prior to 1980, it had been known that if the immune system was compromised by immunosuppressive drugs (given, for example, before organ transplantation to reduce the rate of rejection), the patient was at risk for developing pneumonia from organisms or viruses not normally pathogenic. Patients with AIDS may develop pneumonia from cytomegalovirus or *Pneumocystis* infections, capable of causing invasive pneumonic lesions in the setting of reduced immunity. Such infections are a major cause of illness in these patients, are difficult to treat, and may prove fatal. Infections with fungi such as *Candida* also occur. The diagnosis and management of these cases has become a challenging and time-consuming responsibility for respiratory specialists in cities with large numbers of AIDS cases.

Of all the lung diseases caused by bacteria, pulmonary tuberculosis is historically by far the most important. Particular features of this dreaded condition, to which many writers of the last hundred years have turned for dramatic material, include the severe general debilitation and weakness that it may cause; the insidious nature of the onset of its initial symptoms, which may not be pulmonary in nature; the familial tendency; the long-drawn-out course of the disease and the distressing nature of many of

Legionnaires' disease of 1976

Pulmonary tuberculosis

its manifestations, particularly severe hemorrhage from the lung and from tuberculous involvement of the brain (meningitis), or involvement of the adrenal gland leading to adrenal insufficiency (Addison's disease); and, above all, the general inefficacy of medical treatment before effective antibiotic therapy became available. Antibiotics have greatly reduced the mortality from pulmonary tuberculosis in all developed countries, but the decline in mortality began well before their introduction, and it is clear that improved diet and housing were responsible for this. With antibiotic therapy, however, the bacilli quickly disappear from the sputum and the spread of infection is quickly controlled.

In its classic form, tuberculosis first causes pulmonary inflammation at the apices (upper portions) of the lungs, and it may progress slowly to form a chronic cavity in this region. Secondary infection of the cavity may occur and may be difficult to eradicate. When still active, pulmonary tuberculosis is a constant threat to the patient, because blood-borne spread may occur at any time. Diffuse spread of tuberculosis in the lung (known as miliary tuberculosis) may occur at the onset of the disease. The chest radiograph reveals many small and diffuse shadows. The exact sequence of events that leads to this disseminated form of disease is not understood, but prompt treatment is required to prevent spread to the brain and other organs. Pulmonary tuberculosis remains an important disease.

Treatment
of tubercu-
losis

Streptomycin was the first clinically successful antituberculous drug, and it is still occasionally used. More commonly, rifampin together with isonicotinic hydrazide (isoniazid, or INH) is used first, and ethambutol may be used in addition. INH is never given alone as the tubercle bacilli acquire resistance to it; hence it is often combined with another drug, para-aminosalicylic acid (PAS). It is important to stress that there is no one "best" regimen preferable to all others in every case. Tubercle bacilli can acquire resistance to most of the antituberculous drugs, and skillful treatment consists in combining antibiotics so that resistant bacilli are less likely to be produced. The development of resistance to antibiotics can be delayed by the concomitant use of two or more drugs, by continuous treatment without significant interruption until all bacterial growth has ceased, and by the use of bed rest and resectional surgery in a few selected cases. Surgery may be indicated when a chronic cavity has developed. In most newly diagnosed cases, a year of antibiotic therapy is recommended, although recent observations have suggested that with modern treatment regimens, effective control may be achieved in a shorter period.

The major problem in treating pulmonary tuberculosis is ensuring continued medication and supervision. This may be very difficult in developing countries and in indigent and alcoholic populations of large cities in developed countries. Detection and treatment also pose problems in native communities living in isolated regions, such as the Canadian Eskimos. Although the death rate from respiratory tuberculosis in the Western world has fallen greatly since 1900, it remains a serious and difficult problem in some underprivileged communities, in many tropical countries, and in any population with inadequate medical care and poor diet and hygiene. In addition, pulmonary tuberculosis has reappeared in the West in persons with AIDS, in whom treatment is complicated by diminished immunity.

ALLERGIC LUNG DISEASES

There are at least three reasons why the lungs are particularly liable to be involved in allergic responses to proteins. First, the lungs are exposed to the outside environment, and hence particles of foreign protein—*e.g.*, in pollen—may be deposited directly in the lung; second, the walls of the bronchial tree contain smooth muscle that is very likely to be stimulated to contract if histamine is released by cells affected by the allergic reaction; and third, the lung contains a very large vascular bed, which may be involved in any general inflammatory response. It is therefore not surprising to find that sensitivity phenomena are common and represent an important aspect of pulmonary disease as a whole. The most common and most impor-

tant of these is asthma. This word is loosely applied to all kinds of conditions in which there is airflow obstruction, but it is better reserved for those conditions in which an allergic component of the bronchial obstruction is likely to be present.

Asthma. Spasmodic asthma is characterized by contraction of the smooth muscle of the airways and, in severe attacks, by airway obstruction from mucus that has accumulated in the bronchial tree. This results in a greater or lesser degree of difficulty in breathing. One approach to classifying asthma differentiates cases that occur with an identifiable antigen, in which antigens affect tissue cells sensitized by a specific antibody, and cases that occur without an identifiable antigen or specific antibody. The former condition is known as "extrinsic" asthma and the latter as "intrinsic" asthma. Extrinsic asthma commonly manifests in childhood because the subject inherits an "atopic" characteristic: the serum contains specific antigens to pollens, mold spores, animal proteins of different kinds, and proteins from a variety of insects, particularly cockroaches and mites that occur in house dust. Exacerbation of extrinsic asthma is precipitated by contact with any of the proteins to which sensitization has occurred; airway obstruction is often worse in the early hours of the morning, for reasons not yet entirely elucidated. The other form of asthma, intrinsic, may develop at any age, and there may be no evidence of specific antigens. Persons with intrinsic asthma experience attacks of airway obstruction unrelated to seasonal changes, although it seems likely that the airway obstruction may be triggered by infections, which are assumed to be viral in many cases.

Extrinsic
and intrinsic
forms
of asthma

Asthma acquired as the result of occupational exposure (a special form of intrinsic asthma) is now recognized to be more common than previously suspected. Exposure to solder resin used in the electronics industry, to toluene diisocyanate (used in many processes as a solvent), to the dust of the western red cedar (in which plicatic acid is the responsible agent), and to many other substances can initiate an asthmatic state, with profound airflow obstruction developing when the subject is challenged by the agent.

It is a characteristic of all types of asthma that those with the condition may exhibit airflow obstruction when given aerosols of histamine or acetylcholine (both normally occurring smooth muscle constrictors) at much lower concentrations than provoke airflow obstruction in normal people; affected individuals may also develop airflow obstruction while breathing cold air or during exercise. These characteristics are used in the laboratory setting to study the airway status of patients. As a result of much recent work, it is thought that the diagnosis of asthma of any kind is difficult to sustain in the absence of a general increase in airway reactivity.

The acute asthmatic attack is alarming both for the sufferer and for the onlooker. There is acute difficulty in breathing, and the chest assumes a more and more inspiratory position. Despite the severe respiratory difficulty, the patient remains fully conscious. The most dangerous form of the condition is known as status asthmaticus. The bronchial spasm worsens over several hours or a day or so, the bronchi become plugged with thick mucus, and airflow is progressively more obstructed. The affected person becomes fatigued; the arterial oxygen tension falls still further, carbon dioxide accumulates in the blood (leading to drowsiness), and the acidity of the arterial blood increases to dangerous levels and may lead to cardiac arrest. Prompt treatment with intravenous corticosteroids and bronchodilators is usually sufficient to relieve the attack, but in occasional cases ventilatory assistance is required. In a few cases, death from asthma is remarkably rapid—too rapid for this complete sequence of events to have occurred, although at autopsy the lungs are overinflated. The exact mechanism of death in these cases is not completely understood.

Status
asthma-
ticus

Although the state of the airway is influenced by psychogenic factors, asthma is not correctly regarded as a disease commonly caused by psychological factors. It may interrupt normal activities and schooling to such an extent that it casts a shadow over the development of the personality. More commonly, it tends to diminish in severity

with age, and people who had quite severe asthma in childhood may lead normal lives after the age of 20. It is now known that asthma attacks may be precipitated by food—in small children, possibly by milk; and some adults are extremely sensitive to sulfite compounds in food or wine. A subgroup of asthmatics are so sensitive to aspirin (acetylsalicylic acid) that ingestion of this chemical may lead to a life-threatening attack.

Changes in mortality from asthma in different countries have been closely studied, but the causes are obscure. It is clear, however, that there has been a considerable increase in the rate of hospital admissions for asthma in children and in adults up to the age of 60. Because there is now more effective treatment for asthma than was available previously, it is not clear why this should be occurring. Unless the asthma is complicated by infection (of which that by the fungus *Aspergillus* is common in damp climates), the chest radiograph remains normal. Asthma does not lead to the destructive lesions of emphysema (described below), although the physical appearance of the patient and the sounds of airflow obstruction in the lung may be similar in the two conditions.

Hay fever. Hay fever is a common seasonal condition caused by allergy to grasses and pollens. It is frequently familial, and the sensitivity is often to ragweed pollen. Conjunctival infection and edema of the nasal mucosa lead to attacks of sneezing. Allergic inflammation and the development of polyps in the nasal passages represent a severer form of hay fever that is often associated with asthma.

Hypersensitivity pneumonitis. This is an important group of conditions in which the lung is sensitized by contact with a variety of agents and in which the response consists of an acute pneumonitis, with inflammation of the smaller bronchioles, alveolar wall edema, and a greater or lesser degree of airflow obstruction due to smooth muscle contraction. In more chronic forms of the condition, granulomas, or aggregations of giant cells, may be found in the lung. One of these illnesses is the so-called farmer's lung, caused by the inhalation of spores from moldy hay (thermophilic *Actinomyces*). This causes an acute febrile illness with a characteristically fine opacification in the basal regions of the lung on the chest radiograph. Airflow obstruction in small airways is present, and there may be measurable interference with diffusion of gases across the alveolar wall. If untreated, the condition may become chronic, with shortness of breath persisting after the radiographic changes have disappeared. Farmer's lung is common in Wisconsin, on the eastern seaboard of Canada, in the west of England, and in France. Education of farmers and their families and the wearing of a simple mask can completely prevent the condition.

A similar group of diseases occurs in those with close contact with birds. Various known as pigeon breeder's lung or bird fancier's lung, these represent different kinds of allergic responses to proteins from birds, particularly proteins contained in the excreta of pigeons, budgerigars (parakeets), and canaries. An acute hypersensitivity pneumonitis may also occur in those cultivating mushrooms (particularly where this is done below ground), after exposure to redwood sawdust, or in response to a variety of other agents. An influenza-like illness resulting from exposure to molds growing in humidifier systems in office buildings ("humidifier fever") has been well-documented. It is occasionally attributable to *Aspergillus*, but sometimes the precise agent cannot be identified. The disease may present as an atypical nonbacterial pneumonia and may be labeled a viral pneumonia if careful inquiry about possible contacts with known agents is not made.

BRONCHITIS AND BRONCHIOLITIS

Acute bronchitis. Acute bronchitis most commonly occurs as a consequence of viral infection. It may also be precipitated by acute exposure to irritant gases, such as ammonia, chlorine, or sulfur dioxide. In people with chronic bronchitis—a common condition in cigarette smokers—exacerbations of infection are common. The bronchial tree in acute bronchitis is reddened and congested, and minor blood streaking of the sputum may occur. Most cases of

acute bronchitis resolve over a few days, and the mucosa repairs itself.

Bronchiolitis refers to inflammation of the small airways. Bronchiolitis probably occurs to some extent in acute viral disorders, particularly in children between the ages of one and two years, and particularly in infections with respiratory syncytial virus. In severe cases the inflammation may be severe enough to threaten life, but it normally clears spontaneously, with complete healing in all but a very small percentage of cases. In adults, acute bronchiolitis of this kind is not a well-recognized clinical syndrome, though there is little doubt that in most patients with chronic bronchitis, acute exacerbations of infection are associated with further damage to small airways. In isolated cases, an acute bronchiolitis is followed by a chronic obliterative condition, or this may develop slowly over time. This pattern of occurrence has only recently been recognized. In addition to patients acutely exposed to gases, in whom such a syndrome may follow the acute exposure, patients with rheumatoid arthritis may develop a slowly progressive obliterative bronchiolitis that may prove fatal. An obliterative bronchiolitis may appear after bone marrow replacement for leukemia and may cause shortness of breath and disability.

Exposure to oxides of nitrogen, which may occur from inhaling gas in silos, when welding in enclosed spaces such as boilers, after blasting underground, or in fires involving plastic materials, is characteristically not followed by acute symptoms. These develop some hours later, when the victim develops a short cough and progressive shortness of breath. A chest radiograph shows patchy inflammatory change, and the lesion is an acute bronchiolitis. Symptomatic recovery may mask incomplete resolution of the inflammation.

An inflammation around the small airways, known as a respiratory bronchiolitis, is believed to be the earliest change that occurs in the lung in cigarette smokers, although it does not lead to symptoms of disease at that stage. The inflammation is probably reversible if smoking is discontinued. It is not known whether those who develop this change (after possibly only a few years of smoking) are or are not at special risk of developing the long-term changes of chronic bronchitis and emphysema.

Chronic bronchitis. The chronic cough and sputum production of chronic bronchitis were once dismissed as nothing more than "smoker's cough," without serious implications. But the striking increase in mortality from chronic bronchitis and emphysema that occurred after World War II in all Western countries indicated that the long-term consequences of chronic bronchitis could be serious. This common condition is characteristically produced by cigarette smoking. After about 15 years of smoking, a blob of mucus is coughed up in the morning, owing to an increase in size and number of mucous glands lining the large airways. The increase in mucous cells and the development of chronic bronchitis may be enhanced by breathing polluted air (particularly in areas of uncontrolled coal burning) and by a damp climate. The changes are not confined to large airways, though these produce the dominant symptom of chronic sputum production. Changes in smaller bronchioles lead to obliteration and inflammation around their walls. All of these changes together, if severe enough, can lead to disturbances in the distribution of ventilation and perfusion in the lung, causing a fall in arterial oxygen tension and a rise in carbon dioxide tension. By the time this occurs, the ventilatory ability of the patient, as measured by the velocity of a single forced expiration, is severely compromised; in a cigarette smoker, ventilatory ability has usually been declining rapidly for some years. It is not clear what determines the severity of these changes, since many people can smoke for decades without evidence of significant airway changes, while others may experience severe respiratory compromise after 15 years or less of exposure.

Pulmonary emphysema. This irreversible disease consists of destruction of alveolar walls. It occurs in two forms, centrilobular emphysema, in which the destruction begins at the centre of the lobule, and panlobular (or panacinar) emphysema, in which alveolar destruction

occurs in all alveoli within the lobule simultaneously. In advanced cases of either type, this distinction can be difficult to make. Centrilobular emphysema is the form most commonly seen in cigarette smokers, and some observers believe it is confined to smokers. It is more common in the upper lobes of the lung (for unknown reasons) and probably causes abnormalities in blood gases out of proportion to the area of the lung involved by it. By the time the disease has developed, some impairment of ventilatory ability has probably occurred. Panacinar emphysema may also occur in smokers, but it is the type of emphysema characteristically found in the lower lobes of patients with a deficiency in the antiproteolytic enzyme known as alpha₁-antitrypsin. Like centrilobular emphysema, panacinar emphysema causes ventilatory limitation and eventually blood gas changes. Other types of emphysema, of less importance than the two major varieties, may develop along the dividing walls of the lung (septal emphysema) or in association with scars from other lesions.

A major step forward in understanding the development of emphysema followed the identification, in Sweden, of families with an inherited deficiency of alpha₁-antitrypsin, an enzyme essential for lung integrity. Members of affected families commonly developed panacinar emphysema in the lower lobes, unassociated with chronic bronchitis but leading to ventilatory impairment and disability. Intense investigation of this major clue led to the "protease-antiprotease" theory of emphysema. It is postulated that cigarette smoking either increases the concentration of protease enzymes released in the lung (probably from white blood cells), or impairs the lung's defenses against these enzymes, or both. Although many details of the essential biochemical steps at the cellular level remain to be clarified, this represents a major step forward in understanding a disease whose genesis was once ascribed to overinflation of the lung (like overdistending a bicycle tire).

Chronic bronchitis and emphysema are distinct processes. Both may follow cigarette smoking, however, and they commonly occur together, so determination of the extent of each during life is not easy. In general, significant emphysema is more likely if ventilatory impairment is constant, gas transfer in the lung (usually measured with carbon monoxide) is reduced, and the lung volumes are abnormal. The radiological technique of computerized tomography may improve the accuracy of detection of emphysema. Many people with emphysema suffer severe incapacity before the age of 60; thus, emphysema is not a disease of the elderly only. A reasonably accurate diagnosis can be made from pulmonary function tests, careful radiological examination, and a detailed history. The physical examination of the chest reveals evidence of airflow obstruction and overinflation of the lung, but the extent of lung destruction cannot be reliably gauged from these signs, and therefore laboratory tests are required.

The prime symptom of emphysema, which is always accompanied by a loss of elasticity of the lung, is shortness of breath, initially on exercise only, and associated with loss of normal ventilatory ability. The severity of this loss is a predictor of survival in this condition. But once ventilatory ability is reduced to less than half the normal value, what determines outcome is the severity of the changes in blood gases, chiefly the lowering of arterial blood oxygen tension. The chronic hypoxemia (lowered oxygen tension) is believed to lead to the development of increased blood pressure in the pulmonary circulation, which in turn leads to failure of the right ventricle of the heart. The symptom (subjective evidence perceived by the patient) of right ventricular failure is swelling of the ankles; the signs (objective evidence discovered by the examining physician) are engorgement of the neck veins and enlargement of the liver. These are portents of advanced lung disease in this condition. The hypoxemia may also lead to an increase in total hemoglobin content and in the number of circulating red blood cells, as well as to psychological depression, irritability, loss of appetite, and loss of weight. Thus the advanced syndrome of chronic obstructive lung disease may cause not only such shortness of breath that the afflicted person is unable to dress without assistance, but also numerous other symptoms.

The slight fall in ventilation that normally accompanies sleep may exacerbate the failure of lung function in chronic obstructive lung disease, leading to a further fall in arterial oxygen tension and an increase in pulmonary arterial pressure.
